One study that examined the contribution of diffusion limitation to exercise performance in this patient group showed evidence of a ventilatory impairment that was manifested by a decrease in alveolar oxygen tension.[213] Cardiac impairment such as impaired diastolic filling may occur secondary to pulmonary fibrosis during exercise or restriction of the pleurae and thoracic cavity. Changes in gas exchange during exercise may be the most sensitive indicator of physiological limitation in patients with subclinical evidence of interstitial lung disease.[214,215] However, in terms of prognostic capability, the results of an exercise test for evaluating gas exchange do not appear to augment standard pulmonary function testing.[216]

Individuals after Lung Transplantation

Lung transplantation improves pulmonary function and quality of life in individuals such as those with cystic fibrosis. When exercise responses before and after bilateral lung transplantation are compared, exercise capacity remains low, although improved.[217] This observation has been explained on the basis of poor oxygen extraction.[218] Exercise conditioning is required in these patients postoperatively to maximize their functional capacity. However, maximum oxygen consumption may remain below that of healthy peers matched for age and gender, and anaerobiosis during exercise is achieved earlier. These responses reflect inadequate adaptation of cardiac output in these patients, as well as deconditioning.

Individuals with Asthma

There are several specific aspects to consider when testing and training individuals with exercise-induced asthma.[219] For those who are managed with medication, a low-intensity warm-up before exercise can optimize its therapeutic effect. A longer cool-down may also be beneficial. Individuals with asthma are taught to monitor their unique responses to their medication and its coordination with physical activity and exercise. They also monitor the ambient air (humidity and temperature) to anticipate the potential for bronchoconstriction and respiratory distress. With good knowledge of conditions and medication, individuals with asthma can participate in high-intensity exercise safely.

Individuals with Cystic Fibrosis

General health and wellness have become primary goals for individuals with cystic fibrosis (CF) Twenty years ago, management of people with this condition, primarily children, was based largely on passive removal of excessive secretions by means of postural drainage and vigorous percussion. Now people with cystic fibrosis are living longer, and comprehensive physical therapy management, including a regular program of exercise, is recognized as a central component of promoting general health and airway clearance.[220,221]

Although life expectancy continues to improve in people with CF, end of life usually results from respiratory infection, so exacerbations have to be prevented. With a basis of good health resulting from proper nutrition and exercise, exacerbations may occur less often and last for a shorter time. The exercise program is adjusted during these times and then ramped up afterwards. Medications, including bronchodilators, are coordinated with exercise to produce the best effects both during sessions and over the long term.[222]

Cardiac and Pulmonary Rehabilitation: Common Components

Definition, Purpose, Goals, and Outcomes

Most individuals with heart or lung disease can benefit from the principles of healthful living that underlie the philosophies of conventional cardiac and pulmonary rehabilitation programs. In comparing patients participating in these programs with nonparticipants, cardiovascular deaths are reduced by 20% and sudden death by 37% in the year after infarction.[223] Those who meet the criteria for admission and are within access of a center that offers these programs are evaluated by a multidisciplinary team that establishes the patient's short- and long-term goals and sets up an overall program that includes exercise prescription, a nutritional plan, a smoking cessation program (if required), and life-skills and stress-management instruction. These programs are patient-focused, and the health care team, including the physical therapist, serves largely as health coaches and advisers. Fundamental to that program's success is establishing an individual's readiness to change lifestyle behaviors and participate in a lifelong program of health (see Chapter 1). The

health education component of the program is then targeted to shift the individual to a higher level of readiness or to engage the individual immediately in an active rehabilitation program.

The preadmission workup for cardiac rehabilitation includes a complete history and a questionnaire related to current status and health behaviors and the individual's goals (Figure 24-1). Because of the interdependence of heart and lung function, these questions are relevant to individuals being considered for admission to a pulmonary rehabilitation program, as well as to a cardiac rehabilitation program.

A key component of the assessment on admission to a cardiac or rehabilitation program is an objective assessment of the patient's risk factors, which enables risk-factor-reduction interventions to be specifically targeted and a lifelong health plan designed and implemented.

The relative benefit of structured programs as opposed to community and home-based programs is being debated. Maximizing the potential benefits of the program is key, so the program has to be optimal in terms of the individual's needs, including the setting that will produce the best short- and long-term outcomes. Exercise gains have been demonstrated in healthy middle-aged people when programs are home-based.[224] This evidence supports the idea that individuals with cardiovascular and pulmonary dysfunction who are being managed one-on-one by a physical therapist may also demonstrate benefits when the exercise program is home-based. However, further study is needed to determine the safety and effectiveness of home-based programs for candidates for cardiovascular and pulmonary rehabilitation.

The core components of cardiac and pulmonary rehabilitation programs are shown in Table 24-1; they reflect the skills and expertise of the multidisciplinary team in addressing each individual's needs in a comprehensive manner. These components include awareness of the patient's condition and health education overall, nutrition and weight control, smoking cessation, general physical activity and exercise, and stress management. Psychological support is important with respect to the patient's adjustment to his or her condition; the management of anxiety, anger, hostility, and depression; and the maximization of adherence to recommendations and guidelines related to nutrition, physical activity and exercise, smoking cessation, and a lifelong health plan. Such support is elicited from the individual's family and friends, as well as health care providers.

The exercise program focuses on improving flexibility and strength, as well as aerobic capacity, with the goals of improving the patient's health and capacity to perform the activities of daily living, thus improving quality of life. Psychosocial and end-of-life issues are also an important part of rehabilitation programs and should be addressed, particularly in individuals who are severely ill and their families.

Health education is a major component of cardiac rehabilitation and constitutes a skill in its own right. The patient requires knowledge about health and the incentive to translate this information into his or her own life. Each learner's knowledge deficits are different and learning style is unique; these should be evaluated so that health education can be properly targeted to be the right type, the right level, the right format, and delivered at the right time (see Chapter 28). Knowledge deficits need to be established so that education can be targeted specifically to meet each deficit. For instance, individuals with coronary artery disease typically have little awareness of some of the major risk factors. Generally, their knowledge about cholesterol, use of lipid-lowering medications, and achievement of cholesterol levels consistent with consensus-based guidelines is minimal.[225] Participation in structured cardiac rehabilitation programs improves

Table 24-1 Core Components of Cardiac and Pulmonary Rehabilitation

Assessment	Entrance complaint Height, weight, body mass index Education Occupation/employment Socioeconomic status Family situation Smoking history Alcohol consumption
History	Present illness (medical and surgical details of management to date) Multisystem review (e.g., cardiovascular, peripheral vascular, pulmonary, musculoskeletal, neuromuscular, gastrointestinal, endocrine, renal, liver, immune) Medication status Lab tests and investigations: blood work, ECG, x-rays and scans, exercise test Learning assessment (education level, preferred learning styles, self-efficacy, and behavioral readiness to change.
Goals	Prevention Short term Long term
Interventions	Promotion of empowerment and self-efficacy through teaching Smoking cessation Nutritional counseling (optimal nutrition, lipid management, sodium control, salt control, weight control) Hypertension management Diabetes management Psychosocial management Physical activity counseling Exercise training Work simplification and energy conservation Sleep and rest Vocational rehabilitation Recreational rehabilitation
Outcomes (monitored over the short and long term and consistent with the individual's goals)	Participation Capacity to fulfill unique life roles (e.g., parent, spouse/partner, occupation/profession, worship and spiritual life, recreation and leisure, community activities) Abilities ADLs and task-specific activities related to life roles, including work and home management
Structure and Function	Changes in physiological dependent measures consistent with goal achievements

Modified from Balady GJ, Ades PA, Comoss P, et al: Core components of cardiac rehabilitation/secondary prevention programs, A statement for healthcare professionals from the American Heart Association and the American Association of Cardiovascular and Pulmonary Rehabilitation, Circulation *102:1069-1073, 2000.*

Name:		
Birth Date and Age:		Sex:
Weight: Height:	Body Mass Index:	Waist circumference:
Summary of History	List the dates and types of the medical and surgical procedures you have had over the years.	
Medication	List the medications you are currently taking and the doses and frequencies.	
Family History	Did your father or brothers have heart disease before 55 years of age?	
	Did your mother or sisters have heart disease before 65 years of age?	
Current Status	Do you experience pain (tightness or heaviness) or angina in your chest on exercise?	
	If so, what specifically triggers it? What relieves it? How long does it take to go away?	
	Do you take medication for chest pain/angina?	
	If so, for how long? How much? What is the medication's effect?	
	Do you ever feel short of breath?	
	If so, what triggers it? What relieves it? How long does it take to go away?	
	Do you ever feel short of breath when you lie down?	
	Do you experience pain in your legs when you walk?	
	Have you had this investigated? If so, what was the diagnosis?	
	Do your ankles swell?	
	Do you have high blood pressure?	
	If so, for how long, and how has it been managed?	
	Do you have normal blood pressure now?	
	Do you take medication for high blood pressure? What medication? How much?	

	Is your blood pressure controlled now?	
	Do you have glucose intolerance?	
	Type 2 diabetes?	
	If so, for how long and how is your blood sugar controlled? Is your blood sugar within normal limits now?	
	Do you take insulin? Oral agents? What agents? How much?	
	Do you have thyroid disease?	
	If so, what, and for how long? Do you take medication for your thyroid problem? What is the medication? How much do you take?	
	Is your thyroid controlled now?	
	Do you have anemia?	
	Do you have gastrointestinal complaints?	
	If so, describe them. Are you being medically treated for them?	
	Do you have any musculoskeletal or neurologic problems?	
	If so, describe them. Are you being medically treated for them?	
	Do you have any balance problems?	
	If so, is there an explanation? Are you being medically treated for them?	
	Is your vision normal with or without corrective lenses?	
	Is your hearing normal with or without hearing aids?	
Health Behaviors	Describe your weekly food consumption in terms of whole grains, fruit and vegetables, beans and lentils, meat and fish, saturated and trans fats, refined sugar, and low fiber foods.	
	Do you have high cholesterol?	
	For how long?	
	Have you ever smoked?	
	When, how much, and for how long?	
	Do you smoke now?	
	If so, how much?	

	How much alcohol do you consume? Type, amount, and frequency:	
	What is your regular activity level (describe activity or exercise, intensity of exercise, duration, and frequency each week)?	
	How stressful is your life?	
	Identify life-event stressors.	
	Identify daily-hassle stressors.	
	What are your stress-management strategies?	
	How many hours a night do you sleep on average?	
	How many times do you wake up or get up during the night?	

Fig. 24-1 Preadmission work-up for cardiac rehabilitation.

knowledge related to heart disease, signs and symptoms, and self-management strategies. However, the learning and homework must be evaluated on each visit to determine how well the knowledge has been internalized and put into practice in daily life. Lifestyle recommendations should be suitable for application to daily living. For example, healthy food choices should be described specifically. Energy utilization should be translated into terms that are meaningful for the individual, such as 1000 kilocalories (kcal) of energy per week (although 1500 kcal/week has been identified as the threshold for reducing all-cause mortality risk[226]). People least likely to achieve the latter threshold include women, those with a body mass index of 30 or higher, and those who are 70 years of age or older. Weekly kilocalorie energy expenditure should be a component of the exercise prescription in order to ensure that maximum health benefits are achieved. The physical therapist's capacity to communicate and educate effectively will determine the long-term outcome of the program.

Many outcomes related to a sense of well-being, a health-related quality of life, sickness impact, and life satisfaction are dealt with in conjunction with physiological and clinical outcomes. The former variables are consistent with the International Classification of Function and the impact of disability on the individual, but noncardiac and nonpulmonary outcomes should also be considered.

Chronic disability is often associated with clinical depression, so management of depression alone may improve functional capacity. With respect to pulmonary disease, 45% to 63% of deaths are attributable to advanced lung disease itself.[227] Other factors that explain mortality include nutritional deficits, impaired exercise tolerance, functional performance, and social factors, including marital status. Thus nutrition and exercise are essential elements of cardiovascular and pulmonary rehabilitation. Similar findings have been reported for cardiac disease. A negative emotional state is associated with high long-term mortality. Addressing the individual's psychological status may improve functional status.[228]

Specific rehabilitation goals include the following:

- To serve as a health promotion resource for the individual, community, and health care providers
- To increase aerobic capacity and muscle strength and endurance consistent with overall health and well-being
- To improve capacity to perform the activities of daily living and maintain gainful employment
- To promote self-efficacy in healthy lifestyle behaviors for long-term health and well-being, as well as for secondary prevention
- To shift an individual to a lower risk classification
- To reduce risk for revascularization procedures, medical intervention, and physician and hospital visits
- To promote health and well-being in the patient's family and community
- To reduce direct and indirect health care costs over the short and long term

Setting and Team Members

In addition to the physical therapist, the team consists of physicians, nurses, a psychologist, a social worker, a pharmacist, and in some centers, an exercise physiologist. Typically, the physical therapist is involved with exercise testing and training, program modification and progression, and eventual discharge. Additional roles involve education and risk-factor modification. A physical therapist applies the principles and practices of cardiovascular and pulmonary rehabilitation to any patient in any setting and to patients who have cardiovascular and pulmonary dysfunction or its risk factors as a primary or secondary diagnosis or concern. The guidelines and standards for assessment and exercise testing and training must be adhered to if the best service and the best and safest outcomes are to be achieved.[229]

Components of Physical Therapy

Assessment

Central to comprehensive physical therapy management is focusing on the individual rather than on the condition. Although this chapter emphasizes exercise testing and training in individuals with primary cardiovascular and pulmonary conditions, in reality, people present with comorbidities. Thus individuals with secondary cardiovascular and pulmonary dysfunction (see Chapters 25 and 32) are likely to have a high incidence of primary cardiovascular and pulmonary dysfunction or risk for it (in comparison with the general population). For this reason, underlying risk factors and disease must be examined in all patients, irrespective of their primary presenting diagnoses.

The history, lab tests, and investigations, including scans and ECGs, and the basic assessment of an individual with cardiovascular and pulmonary dysfunction are described in Part Two, but the aspects of the assessment that warrant particular attention in exercise testing and in training individuals with cardiovascular and pulmonary dysfunction are highlighted in this section. Although the cardiovascular and pulmonary systems may be the focus of rehabilitation, a complete review of all systems is necessary to determine limitations imposed by musculoskeletal, neurological, endocrine, hematological, or other conditions. These need to be considered in both testing and training.

The assessment comprises the examination of risk factors, including profiles of the patient's nutrition intake, weight, smoking history, and stress management (including rest and sleep profiles), as well as physical activity and aerobic capacity. Before implementing any intervention, a detailed history, examination, and lab data are accumulated to provide an objective baseline. Within 6 to 8 weeks, elements of the assessment are repeated and outcome measures recorded to determine the degree to which the patient has progressed with respect to achieving short-term goals.

Predictors of long-term survival of myocardial infarction include several factors that need to be identified so that patients can be stratified according to risk. These factors include age, left ventricular ejection fraction, diabetes, hypertension, and elevated resting heart rate.[230] Attention to these factors may help to detect changes in status early and prevent adverse exercise effects by judicious modification of an exercise program. Individuals who develop late-onset heart failure have a tenfold increased risk for mortality. Glucose abnormalities (hyperglycemia and hyperinsulinemia) in those who do not have diabetes are common in individuals with heart failure (43%).[51] Further, these findings are associated with greater functional deterioration than that found in individuals with heart failure *without* glucose abnormalities. Thus knowledge of an individual's glucose tolerance is

essential at baseline and over time within the rehabilitation program.

Well-being extends beyond physical health. Rehabilitation programs record and monitor outcomes related to the subjective sense of well-being, the health-related quality of life, the general quality of life, and life satisfaction. Many scales and questionnaires are available to provide outcomes and fluctuations in these variables over time.

Clinical depression is associated with ischemic heart disease in two ways. First, depression is an independent risk factor for cardiovascular disease and related increased morbidity and mortality.[231] Second, up to 45% of individuals exhibit symptoms of major depression after acute myocardial infarction. Thus individuals referred to cardiac rehabilitation need to be screened for depression, and psychotherapy, counseling, or pharmacotherapy may be indicated. Remediation of depression associated with chronic disease may augment functional capacity independent of physical rehabilitation. Depression and peak aerobic capacity have been reported to be the best independent predictors of patient-reported physical function scores in older individuals with heart disease.[232] These findings suggest a role for depression management that is independent of exercise training but augments functional capacity.

The general assessment must also include an assessment of the individual's learning style (see Chapter 1 and 28). Prochaska's Transtheoretical Model of readiness to change has important implications for rehabilitation programs that are formalized (e.g., cardiac and pulmonary rehabilitation), as well as for individual rehabilitation programs. In addition to the goal of shifting an individual into a lower risk category, another objective is to shift an individual into a higher readiness-to-change category. An individual's readiness to change health-related behavior is assessed, along with his or her intention to engage in the recommended risk-reduction behaviors, including dietary changes, physical activity and exercise, smoking cessation, and relaxation. Readiness to change may differ for each behavior. Barriers include time management, psychological adaptation, and laziness.[233] Another component of the education is the assessment of the individual's knowledge deficits regarding his or her condition.

Interventions

In addition to the exercise program, the patient may also be in a smoking-cessation program and/or a weight-loss program. During the course of management, medications may change. Detailed records of the progress of the patient in these various programs warrant monitoring so that the perceived outcome of exercise can be explained in a valid manner. Other factors such as weight loss, smoking reduction (cessation), or change in medication could explain, in whole or in part, the apparent effect of exercise.

Education

Education is the central component of cardiovascular and pulmonary rehabilitation. The patient is taught the basics of anatomy and the physiology of heart and lung health, basic nutrition, physical activity and exercise, analysis of lab tests, effects of smoking, effects of medications, and so on. In this way, the patient is empowered and, it is hoped, well motivated to be an agent of change in his or her own life. Lifestyle recommendations need to be reinforced regardless of phase of the program. One report estimated that after a coronary event, 50% of smokers resume smoking on discharge from the hospital.[234] With respect to modifying dietary habits, participants in rehabilitation programs may not understand the distinction between the benefits of eating a healthy diet versus simply cutting out certain types of foods from their diets, even after standard instruction about the role of healthy eating to their overall health.[235] Thus tailoring health education information to the needs of program participants is essential if true behavior change is to be effected over the long term.

Like exercise, education can be tailor-made to suit the learning needs of each person (see Chapter 28). Individualization of the education considers age, literacy, preferred learning style, ethnic and cultural issues, and readiness to change. Smoking cessation is the most important intervention for patients with heart disease and pulmonary disease.[236,237]

Promoting self-efficacy and perceived control are central to education strategies developed by physical therapists. Follow-up is needed, however, to ensure self-treatment is sustained over time.[238] Inadequate self-treatment behavior at follow-up suggests that new teaching and learning strategies should be developed to ensure that the quality of self-treatment is maintained.

Exercise Program

A reduction in respiratory rate in patients with chronic heart failure improves pulmonary gas exchange, reduces dyspnea, and increases exercise performance. Such improvement was reported in one study in which respiratory training in these patients involved 1 month of training to breathe at a rate of 6 breaths per minute.[239] Slowing breathing rate may have some application for patients with chronic heart failure who have impaired gas exchange and breathlessness during exercise as well as at rest.

Goals: Short Term

A distinction is made between short- and long-term goals. Short-term goals are aimed at developing and learning strategies for healthier living and reducing cardiovascular and pulmonary risk factors, particularly those that are most life-threatening. Long-term strategies are an extension of short-term goals and address the sustainability of health and fitness consistent with patients' needs, wants, and capabilities for the rest of their lives. These goals include sustained healthy diet and weight control, sustained high daily physical activity level, and aerobic exercise three times a week. In addition, if an individual is receiving medication that relates to cardiovascular dysfunction, a physical therapy outcome is to minimize, reduce, or eliminate the need for medication in the short term and long term.

Goals: Long Term

Long-term goals and outcomes are as important as the short-term physical therapy goals and outcomes. Intervention (drugs and surgery) has short-term benefits, as is evidenced by the apparently high number of repeated revascularization procedures performed, compared with the lifestyle behavioral

changes inherent in physical therapy management, including education, smoking cessation, optimal nutrition, and exercise. At the point of entry into physical therapy (acute, subacute, or chronic, with cardiovascular dysfunction as a primary or secondary diagnosis), a long-term plan with goals, outcomes, and follow-ups is integral to the management plan overall (Table 24-2).

Cardiac Rehabilitation: Specific Components

Phases

Patients are referred to cardiac rehabilitation for management and secondary prevention of myocardial insufficiency and after revascularization procedures, including cardiac surgery.[240] People can also benefit if they have significant risk for disease but are asymptomatic.

The phases of cardiac rehabilitation appear in Table 24-3 (with the exception of phase I, inpatient management, which is described in Chapter 29). Phase I refers to inpatient care (medical and surgical) and the predischarge exercise test.

Phase II refers to a supervised exercise program lasting 3 to 6 months. Phase II usually takes place in a community center where the patients can be monitored during exercise and education by the rehabilitation professions can be ongoing. However, a trial of home-based phase II programs for high-risk patients after cardiac surgery produced the same results as were found in the control group, which received general guidelines to increase activity levels.[241] Further study is needed on the short- and long-term effectiveness of home-based phase II programs as opposed to center-based programs with respect to symptom recurrence, indications for revascularization procedures, and risk-factor reduction.

Phase III refers to the maintenance phase, during which the patient is responsible for exercising mostly at home. This phase lasts from 6 to 12 months.

Phase IV refers to an unsupervised community program. The patient is usually ready for this phase within 9 to 12 months. Patients may be referred to cardiac rehabilitation

Table 24-2 Comprehensive Physical Therapy Management and Lifelong Health Plan

Patient's entry point to physical therapy	A primary diagnosis of cardiovascular or pulmonary dysfunction A secondary diagnosis of cardiovascular or pulmonary dysfunction A diagnosis of cardiovascular or pulmonary dysfunction secondary to dysfunction of systems other than primary oxygen transport dysfunction (i.e., the heart, circulation, or lungs) (Chapters 6, 25, and 32)
Assessment	Readiness to change (precontemplative, contemplative, preparation, action, maintenance) Demographics, including literacy, culture, and education Learning needs and style Preventive goals and outcomes Long-term goals and outcomes Short-term goals and outcomes
Follow-up	Physical evaluation Sustained adherence to behavioral-change programs Visits to physician, clinic, hospital (details of when, why, and, if admitted to hospital, for how long) Medication changes (what, when, why, and dose or discontinued) or new medications (what, when, why, dose)

Table 24-3 Rehabilitation Phases of Cardiac and Pulmonary Rehabilitation

Phase	Cardiac Rehabilitation	Pulmonary Rehabilitation
I*		
II Under supervision in hospital, center, or community-based program or one-on-one session	6 weeks post acute episode or discharge, to 6 months Exercise retest Review of risk factors; lifestyle behaviors and changes Revision of lifestyle recommendations	≤6 weeks post acute episode or discharge, to 6 months Exercise retest Review of risk factors and lifestyle behaviors and changes Revision of lifestyle recommendations
III Under supervision in hospital, center, or community-based program or one-on-one session	6 to 12 months Exercise retest Review of risk factors and lifestyle behaviors and changes Revision of lifestyle recommendations Exit retest for recommendations for self-management phase IV	6 to 12 months Exercise retest Review of risk factors and lifestyle behaviors and changes Revision of lifestyle recommendations Exit retest for recommendations for self-management phase IV
IV Self-management	>12 months Provision for follow-up	>12 months Provision for follow-up

*Phase I is described in Chapter 29, the management of Individuals with Acute Medical Conditions.

when they are stable and not in conjunction with an acute event.

Smoking Cessation

The risk for myocardial infarction is three times higher in patients who continue to smoke after a cardiac event.[242] When patients quit, the risk for reinfarction is reduced to that of nonsmokers prior to the first infarction.

Nutrition and Weight Control

Optimal nutrition and weight control are priorities. Individuals with cardiovascular dysfunction are at risk for fluid and electrolyte imbalances and related ECG irregularities, so these aspects of nutrition need to be included. In addition, patients with chronic heart failure have some special considerations. These patients rely more on fat substrate during exercise than on carbohydrates, which may contribute to increased catecholamines and free fatty-acid levels.[243] These changes may compensate to protect muscle glycogen stores. However, given that fat metabolism is not energy-efficient, this shift may contribute to exercise intolerance.

Psychosocial Issues

Stress management and life-skills training are fundamental to rehabilitation programs in minimizing undue sympathetic arousal and impact on the cardiovascular and pulmonary systems. If indicated, help with depression control and anger and hostility management are provided by the appropriate professionals. Remediation of depression alone can enhance functional status.

Risk Reduction

Prevention and rehabilitation programs aim to reduce an individual's cardiac risk factor category. Figure 24-2 shows an example of a scale for assessing cardiac risk and identifying an individual's category of risk. Using such a scale provides

Step 1: Find your points based on your Age, Blood Pressure, LDL and HDL Cholesterol, and whether you Smoke or have Diabetes.

AGE

Age	M	F
30-34	-1	-9
35-39	0	-4
40-44	1	0
45-49	2	3
50-54	3	6
55-59	4	7
60-64	5	8
65-69	6	8
70-74	7	9

DO YOU HAVE DIABETES?

	M	F
YES	2	4
NO	0	0

CHOLESTEROL

LDL Cholesterol

	M	F
<100	-3	-2
100-129	0	0
130-159	0	0
160-189	1	2
>189	2	2

HDL Cholesterol

	M	F
<35	2	5
35-44	1	2
45-49	0	1
50-59	0	0
>59	-1	-3

DO YOU SMOKE?

	M	F

140-159/ 90-99	2	2
>159/>99	3	3

Fig. 24-2 Cardiac Risk Analysis: Estimate Your Risk for Developing Heart Disease in the Next 10 Years. *(Modified from The Framingham Heart Study, www.nhlbi.nih.gov/about/Framingham/index.html; and Wilson PW, D'Agostino RB, Levy D, et al: Prediction of coronary heart disease using risk factor categories, Circulation 97:1837–1847, 1998.)*

Step 2: Add up your points for Age, LDL-Cholesterol, HDL-Cholesterol, Blood Pressure, Smoking & Diabetes.

Age	
LDL-Cholesterol	
HDL-Cholesterol	
Blood Pressure	
Diabetes	
Smoking	
TOTAL POINTS	

Step 3: Find Your Risk Level Based on Your Point Total.

Total Points	**<–2**	**–2**	**–1**	**0**	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**	**13**	**14**	**15**	**16**	**≥17**
% Risk Male	1	2	2	3	4	4	5	7	8	10	13	17	21	26	32	38	46	54	54	54	54
% Risk Female	1	1	2	2	2	3	3	4	5	6	7	8	9	11	12	14	16	20	22	25	30

Your **Framingham Risk** for developing Heart Disease including a Heart Attack over the next 10 years is denoted by the **%RISK Male or Female** corresponding to your **Total Points Score.**

Step 4: Compare Your Risk to Others. For comparison purposes, **Low Risk** is the risk of developing heart disease within the next 10 years for a Man or Woman of the same age with normal blood pressure and cholesterol who does not smoke or have diabetes.

COMPARATIVE RISK

MALES		
AGE	**AVERAGE RISK**	**LOW RISK**
30-34	3%	2%
35-39	5%	3%
40-44	7%	4%
45-49	11%	4%
50-54	14%	6%
55-59	16%	7%
60-64	21%	9%
65-69	25%	11%
70-74	30%	14%

FEMALES		
AGE	**AVERAGE RISK**	**LOW RISK**
30-34	<1%	<1%
35-39	1%	<1%
40-44	2%	2%
45-49	5%	3%
50-54	8%	5%
55-59	12%	7%
60-64	12%	8%
65-69	13%	8%
70-74	14%	8%

Note that there is no risk estimate for patients < 30 or older than 74 because this analysis is based on real data collected from Framingham

Fig. 24-2, cont'd

Table 24-4 Risk Stratification

Low risk	After uncomplicated myocardial infarction or bypass surgery Functional capacity below 8 METs on 3-week exercise test Asymptomatic at rest, with exercise adequate for most vocational and recreational activities No ECG evidence of ischemia, left ventricular dysfunction, or complex dysrhythmias
Intermediate risk	Functional capacity below 8 METs on 3-week exercise test Shock or congestive heart failure during recent myocardial infarction (<6 months) Inability to self-monitor heart rate Failure to adhere to exercise prescription
High risk	Severely depressed left ventricular function (ejection fraction <30%) Resting complex ventricular dysrhythmias (low-grade IV or V) Premature ventricular contractions appearing or increasing with exercise Exertional hypotension (≥15 mm Hg) Recent myocardial infarction (<6 months) complicated by serious ventricular dysrhythmias Exercise-induced ischemia of more than 2 mm ST depression Survivors of cardiac arrest

MET, Metabolic equivalents (1 MET = 3.5 mL O_2/kg of body weight/minute, which is the metabolic rate at rest).
Modified from American College of Sports Medicine: ACSM's guidelines for exercise testing and prescription*, ed 8, Philadelphia, 2010, Lippincott Williams & Wilkins.*

objective markers for risk factor modification, and evaluating the degree of risk reduction with health behavior change, an important physical therapy outcome. Table 24-4 shows the distinctions among low, intermediate, and high risk for cardiac disease.[244]

After angioplasty, bypass surgery, and medical therapy for fixed obstructions, individuals remain at risk, as judged by the proportion of patients who require further pharmacological and surgical management. Risk-reduction interventions are priorities in this cohort of individuals; they can extend survival, improve quality of life, reduce the need for further invasive procedures such as angioplasty and bypass surgery, and reduce the incidence of myocardial infarction.[245] Secondary risk reduction is as important as primary risk reduction, and it should be a routine component of both medical and surgical management.

Physical Activity and Exercise: Special Considerations

The principles and practice of exercise prescription are described in detail in Chapter 19. However, special considerations for individuals with chronic heart conditions with respect to monitoring, exercise testing, and exercise training are detailed here.

Monitoring

Assessment and monitoring considerations for the individual with heart disease are described in Part Two and Chapter 31. At the onset of the program, a baseline assessment is made of the patient's subjective sense of well-being, including health-related quality of life, impact of sickness and disability, quality of life, and life satisfaction. Related assessments are made throughout the program to observe the program's effects on these outcomes and to assess the impact of the program at its completion.

An individual with primary cardiovascular dysfunction or its risk factors requires particular attention to his or her hemodynamic status. Risk factors, however, do not necessarily predict complications during supervised exercise.[246] Serial lipid profiles, blood pressure, resting heart rate, and body weight are monitored regularly, and interventions are modified accordingly.[247] Blood pressure, however, can be abnormal in individuals with exercise-induced left ventricular systolic dysfunction, which leads to unstable hemodynamic status.[248] Blood pressure may not be a valid measure of exercise stress in such individuals. Further study is needed before exercise risk stratification guidelines can be used with any assurance to monitor supervised rehabilitation programs.

The absolute and relative changes in heart rate, blood pressure, rate pressure product, arterial saturation, and perceived exertion are particularly important. ECGs may be performed intermittently throughout exercise or continuously, as indicated. Recent evidence has questioned the conventional guideline of an ST-segment depression of greater than 1 mm in favor of a more conservative guideline, greater than 0.5 mm during or after exercise.[249] This value is associated with risk for myocardial infarction, requiring bypass surgery, and risk for cardiac mortality.

Exercise-induced silent myocardial ischemia is an important indicator of increased risk for cardiovascular disease (3.5-fold) and stroke (2.2-fold) in men when they are compared with those without silent ischemia. Other risk factors include smoking, hypercholesterolemia, hypertension, and being overweight.[250]

Recovery data are important components of the exercise testing assessment and interpretation. Delayed heart rate recovery is a predictor of mortality,[184] irrespective of angiographic evidence of disease severity.[251] Heart rate recovery is calculated as the difference in heart rate from peak exercise to that recorded at 1, 2, and 3 minutes after exercise. Women have been reported to be more susceptible to postexercise hypotension than men; an active cool-down period may offset postexercise hypotension.[252] Signs and symptoms of overexertion must be monitored (Box 24-2).

Each individual is taught to monitor his or her baseline, exercise, and recovery responses in a logbook at each visit, after the parameters have been prescribed and it is considered safe for the patient to self-monitor in the supervised setting.

Box 24-2 Signs and Symptoms of Overexertion of Particular Importance in an Individual with a Heart Condition

Signs and Symptoms During or Immediately After Exercise

- Chest pain (angina)
- Lightheadedness or confusion
- Nausea and vomiting
- Intermittent claudication
- Prolonged dyspnea (> several minutes)
- Dysrhythmia
- Inappropriate breathlessness
- Inappropriate bradycardia or tachycardia
- Inappropriate hypotension or hypertension

Delayed Effects

- Prolonged fatigue (24 hours or more)
- Insomnia
- Weight gain due to fluid retention
- Persistent ECG irregularities (e.g., PVCs and tachycardia)

PVC, Premature ventricular contraction.

Commonly, the individual is taught to record heart rate and a rating of perceived exertion. In addition, data sheets are logged with respect to stretching and warm-up, the parameters used for each day's exercise (including the aerobic exercise prescription), and the cool-down and recovery periods. Also, completion of the resistance muscle training prescription is logged.

Exercise Testing

Exercise testing is used for diagnosis, assessment of functional work capacity, assessment of the outcome of one or more interventions, including a training program, and prognosis. A poor response to exercise after percutaneous transluminal coronary angioplasty can identify restenosis.[253] The graded exercise test, or maximal stress test, is usually a short (8 to 12 minutes, ideally), progressively ramped, symptom-limited exercise test conducted on a treadmill or cycle ergometer. Several established cardiac stress test protocols, such as the Bruce and the Balke, are available. In some situations, a submaximal test is preferred because a maximal test may be risky or difficult to conduct in a valid manner because of a secondary problem. Recently, the prognostic superiority of a two-step exercise test that combines a low-intensity, steady-work-rate phase and a maximal exercise phase has been reported.[114] An exercise test may answer questions about an individual's status and thus obviate or reduce the need for more invasive and costly testing.[254]

The exercise testing protocol is designed to stress the patient's oxygen transport system—ventilation, heart, circulation, and muscles—progressively and in an integrated manner. Exercise is the single best way to assess the integrated function of these systems and their capacity for oxygen transport. For detailed evaluation and prognosis of a patient with advanced heart failure, assessment of $\dot{V}O_{2peak}$ is preferable to the use of submaximal exercise tests such as the 6-minute walk test.[113] Walking on a treadmill has been reported to have greater diagnostic sensitivity than cycling in asymptomatic men with coronary artery disease.[255]

Valid testing of functional capacity in individuals with cardiac failure is necessary because of the discordance of the results of various tests in the same individual.[256] The 6-minute walk test distance has been reported to be highly reproducible in patients with heart failure.[257] Distance walked is somewhat correlated to the New York Heart Association functional classification and quality of life, and this correlation is stronger for individuals with mild and moderate disease severity (New York Heart Association classifications II and III).[256] Compared with more sophisticated and more invasive testing, the 6-minute walk test can serve to stratify individuals in terms of functional status, which is of therapeutic and prognostic importance.

Chapter 19 describes indications for conducting an exercise test, as well as the relative and absolute contraindications to the test. That chapter also notes the importance of maximizing test validity and reliability by adhering to strict standards for pretest conditions in the patient, including medications, testing standards, and monitoring recovery data. In addition, the chapter describes basic and advanced measures that can be taken, depending on the needs of the patient and the specific purpose of the test. In most individuals with cardiac dysfunction, an ECG is monitored continuously, along with heart rate. Blood pressure and ratings of perceived exertion and dyspnea (PE) are monitored intermittently. Additional measures are taken as indicated. For example, a patient may be limited by arthritic pain, so it is important to monitor discomfort and pain using a standardized scale (see Chapters 15 and 19). Medications must be reviewed and the time at which they were last taken must be noted in order to determine their impact on responses during the exercise test and to establish which measures will be most valid in terms of assessment of exercise response.

Potential complications that could occur during exercise in patients with heart failure must be anticipated and appropriate monitoring instituted to maximize the safety of exercise testing and training. Adverse responses include dysrhythmias and hypotension.[258]

Individuals with unexplained dyspnea are at risk for ischemia and cardiac events. Exercise echocardiography provides independently derived information that identifies patients at risk.[259] Dyspnea requires investigation in individuals with suspected or known heart disease.

Exercise testing has a role in predicting surgical outcomes. $\dot{V}O_{2peak}$ and exercise duration are good parameters for evaluating functional class and postoperative status in people who have undergone valve repairs or valvuloplasty.[116] Patients who have a $\dot{V}O_{2peak}$ of at least 19 mL/kg/min preoperatively achieve a higher functional class 1 year after surgery.

Of particular importance is identifying and recording why the test was stopped—for instance, a predetermined sign or symptom in the patient was reached, or the patient wished to discontinue. Even if the test is being conducted to determine oxygen transport capacity, the cause for termination may be a comorbidity, such as musculoskeletal strain, muscle weakness, or pain or discomfort of musculoskeletal origin.

Exercise Training

The parameters of exercise training are based on the assessment and on the short- and long-term objectives of the exercise program, and these differ for each individual. The training

session begins with a warm-up defined by a work rate intermediate between the target training zone and rest. Warm-up exercise has a protective effect against left ventricular dysfunction in individuals with angina.[260] In a repeat test 30 minutes after the first test, the threshold for angina and ST-segment depression has been reported to increase along with the rate pressure product. No threshold intensity has been identified for aerobic training in individuals with cardiac disease.[261] Even though a lower limit of 45% of $\dot{V}O_2$ reserve is commonly reported in the literature, intensities below this level cannot be ruled out, particularly in extremely deconditioned people. The absence of such a limit supports the need to consider individual differences and to prescribe exercise on an individual basis (Table 24-5).

Many types of exercise can be considered in the exercise prescription. Improvement in walking tolerance and distance is a primary goal because it is a hallmark of independence and mobility, particularly with advancing age, and it is coupled with the upright position and its associated gravitational stress. Walking has multiple physiological benefits in individuals with coronary artery disease[262] as well as in healthy people. Decisions are made based on the specificity principle. If the goal is to improve the patient's functional needs, activities that are closest to those needs are chosen. If improving aerobic fitness and maximum functional capacity is the goal, exercise that involves more limbs would be the best choice.

The use of hydrotherapy and aquacise have been prominent in Europe. Another application that has been reported to have beneficial effects on the exercise responses of individuals with chronic heart failure is thermal hydrotherapy, which involves the passive application of heat and cold.[6] A 6-week program of home-based hydrotherapy was reported to improve resting and submaximal heart rates, in addition to reducing symptoms and improving quality of life. These effects were attributed to physiological adaptations to alternating hot and cold body stimulation. Further study of this application and its mechanisms is necessary; its indications may prove to be positive in individuals challenged by even minimal amounts of exercise.

Conventionally, the exercise intensity for patients with heart disease is set at a proportion of oxygen uptake reserve or heart rate reserve, which suggests a critical threshold for training effects. However, no intensity threshold for aerobic training has been identified, so intensities below the accepted standard probably provide training stimulus, particularly for patients with low functional capacity.[261]

It has been suggested that interval training leads to more marked improvement in hemodynamics in individuals with heart failure than does steady-rate work.[263] Another suggestion is that steady-rate aerobic exercise contributes to greater well-being and quality of life. Further study is needed to examine the effects of various parameters in training protocols in this cohort.

Peak functional capacity depends on muscle strength and endurance in individuals with chronic heart failure.[264] Improvement in subjective symptoms reported in daily activities, especially dyspnea on exertion, however, depends largely on muscle endurance.

Resistance muscle training has an important role in cardiac rehabilitation programs; it allows a patient to regain lost strength, and it facilitates avocational activities and return to work soon after a cardiac event.[265] Resistance muscle training in the form of circuit weight training can be integrated into the cardiac rehabilitation program. Muscle training can be safe and therapeutic even at relatively high workloads in properly selected individuals, including older adults.[266] The hemodynamic response depends on the isometric and postural stabilization component, in addition to the load or resistance used, the muscle mass activated, the number of repetitions in the set, and the duration of each contraction, as well as the

Table 24-5 Guidelines for Exercise Prescription for Individuals with Heart Conditions

Type	Area of Focus	Intensity	Duration	Frequency
Aerobic exercise (walking, ergometry, rowing, running)	Large muscle groups	Percentage of functional capacity ($\dot{V}O_2$) based on HR, RPE, or METs 50% to 85% of HR reserve RPE 3 to 6 (0-10 scale) or 12 to 16 (18-20 scale) METs (40%-85% peak METs)	20 to 40 min continuous Three 10-min sessions per day	Less than 2 to 3 METs, short sessions several times daily 3-5 METs once daily 5-8 METs 3-5 times weekly
Resistance muscle training,* (elastic bands, cuff/hand weights, dumbbells, free weights, pulleys, weight machines)	Peripheral muscle groups	Progressively increasing loads 10% to 50% of maximum	1 to 3 sets of 8 to 15 repetitions maximum** for each muscle group	2-3 days/week

HR, Heart rate; MET, metabolic equivalent; RPE, rating of perceived exertion.

*According to American Association of Cardiovascular Pulmonary Rehabilitation (AACVPR) Guidelines for Pulmonary Rehabilitation Programs (ed 4), "to prevent soreness and minimize the risk of injury, the initial load should allow 12-15 repetitions comfortably. If 1 RM pretest is used, this load would be approximately 30-40% 1 RM for the upper body and 50-60% for hips and legs. Low-risk stratified, well-trained patients may progress to higher loads depending on program goals."

**Repetition maximum is the maximum number of times a load can be lifted before fatigue.

Modified from American College of Sports Medicine: ACSM's guidelines for exercise testing and prescription*, ed 8, Philadelphia, 2010, Lippincott Williams & Wilkins; and AACVPR:* Guidelines for Pulmonary Rehabilitation Programs*, ed 4, Champaign, Ill, 2011, Human Kinetics.*

involvement of the Valsalva maneuver. Upper-body work has been viewed conservatively as an exercise option for individuals with cardiac problems, and it warrants greater emphasis.[267] Despite caveats regarding isometric exercise for individuals with coronary artery disease, one study compared the hemodynamic responses of brief and sustained isometric exercise and dynamic exercise in individuals with heart disease and healthy people.[268] The incidence of myocardial ischemia was reported to be lower during isometric exercise than during dynamic exercise in patients at the same level of perceived exertion. The investigators postulated that isometric exercise generates high perfusion pressure in the coronary arteries and prolongs perfusion, thereby potentially protecting the myocardia from ischemia. Further study is needed to examine this hypothesis.

Lengthening (eccentric) muscle contractions and shortening (concentric) muscle contractions have distinct energetic and metabolic properties that may make one or the other better suited for certain patient populations.[269-271] Eccentric muscle contractions are associated with higher muscle tension and less metabolic demand. For low-risk individuals who have ischemic heart disease without angina, inducible ischemia, or left ventricular dysfunction, eccentric exercise can be recommended; these patients can perform high-load resistance exercise with minimal cardiovascular stress.[272]

Electrical stimulation of the quadriceps has been examined as a form of exercise for individuals with chronic heart failure.[273] Although the improvement in muscle performance and exercise capacity was comparable to that of individuals in an ergometer exercise program, the use of electrical stimulation should be considered in the overall context of the individual's needs. Active exercise has many multisystem benefits that electrical stimulation does not provide. In addition, electrical stimulation is a more passive modality than active exercise, which may be counter to the goal of self-efficacy that cardiac rehabilitation promotes.

Hydrotherapy in a home-based program has shown some interesting applications to individuals with chronic heart failure.[6] In a study of individuals with mild heart failure, an intensive 6-week program of home-based repeated brief cold stimuli appeared to improve peripheral circulation and, in turn, to improve heart-failure symptoms, heart rate response to exercise, and quality of life.

Long-Term Plan

Long-term planning, in which regular physical activity and a structured program of exercise are components, is detailed in Chapter 31 for individuals with chronic, primary cardiovascular, and pulmonary conditions.

Pulmonary Rehabilitation: Specific Components

Phases

The phases of pulmonary rehabilitation can generally be considered comparable to those of cardiac rehabilitation, although they are less well defined in terms of a formal inpatient phase after an acute episode followed by progressively less closely supervised phases (see Table 24-3). A patient with chronic lung disease is more likely to be referred when stable than in conjunction with an acute event. The first graded exercise test may be in the supervised program rather than in the hospital before discharge after an admission for acute symptoms.

Smoking Cessation

Smoking cessation is essential for the health and well-being of all people, in particular those with pulmonary disease. The physical therapist has a responsibility to address this modifiable risk as a priority of management (see Chapters 1 and 31).

Nutrition and Weight Control

The connection between nutrition and lung health has become a focus of research interest, and that research supports the role of good nutrition (in particular, the consumption of fruits, vegetables, and fish) in optimal lung health.[274,275] Diet may be an important cofactor in the development of COPD. Whether good nutrition improves damaged lungs has not been substantiated, but good nutrition improves general health and thus should be a primary recommendation when managing these patients.

Psychosocial Issues

Patients with chronic conditions have higher incidences of depression and poorer psychosocial adjustment than do individuals in the general population. Although chronically poor blood gases can affect psychological and cognitive function, the remediation of any source of depression can independently improve function. Thus depression and other psychological issues must be assessed and managed independently.

Risk Reduction

Lifestyle modification and risk factor modification are fundamental components of the pulmonary rehabilitation program; these modifications include smoking cessation, nutrition and weight control, and stress management, in conjunction with physical activity and exercise. Optimal nutrition is encouraged as a lifelong change in patients with COPD, whose nutritional status is often suboptimal.[276] Carbohydrate-rich foods, known to increase carbon dioxide production, have been targeted as a food group that should be limited in patients with COPD. Small changes in the carbohydrate constituents of diet have been reported to have a major effect on $\dot{V}_{CO_2}$, exercise tolerance, and breathlessness.[277] Smoking cessation is essential to limit further lung damage and has the potential to reverse impaired pulmonary function, improve oxygen transport capacity, and reduce or reverse smoking-related risk factors as the period of nonsmoking lengthens. Reduction of pulmonary and cardiac risk factors in an individual with primary lung dysfunction is essential.

Physical Activity and Exercise: Special Considerations

The principles and practice of exercise prescription are described in detail in Chapter 19. However, special considerations for this patient group, with respect to monitoring, testing, and training, are detailed here.

Monitoring

The objective and subjective measures used to monitor patients with pulmonary dysfunction during exercise are comparable to those used in patients with cardiac dysfunction, because the heart and lung are interdependent. However, ventilatory parameters, such as breathing pattern, arterial saturation as gauged by pulse oximetry, and subjective sense of breathlessness, are particularly important, as are heart rate, blood pressure, and ECG readings.

Exercise Testing

The indications for and contraindications to testing are established (see Chapter 19). The goals of an exercise test are determined beforehand for each given individual. The exercise test may be selected to evaluate aerobic capacity or the strength and endurance of peripheral or respiratory muscles. The demands of upper-body work may compete with breathing demands in some patients, so upper-body work is integrated into the overall program judiciously and monitored accordingly. Upper-body strength tends to be lower than lower-body strength in patients with chronic obstructive lung conditions. Upper-body strengthening can reduce rating of perceived exertion and breathlessness and thus warrants being assessed and trained.[278]

The exercise test to assess cardiovascular and pulmonary conditioning may be maximal or submaximal and may involve a modality such as a treadmill or ergometer, depending on the device's suitability for the patient and on the best means of maximizing the test's validity and reliability. Depending on the purpose of the test, a decision is made beforehand about the patient's medications and when they are taken in relation to the timing of the test. Some patients may be tested with oxygen or purposely without oxygen, or with or without bronchodilators, depending on whether the effect of such interventions is being evaluated. It is essential to monitor dyspnea in these patients and to correlate the dyspnea rating with objective measures. Some patients may have invasive blood work done before, during, and after the test to monitor serial arterial blood gases. Pulse oximetry is routinely monitored along with heart rate and blood pressure. Some patients may require ECG monitoring. Invasive procedures such as arterial blood gas measurement are done as indicated. Respiratory muscle testing and training are based on similar principles. (Detailed descriptions appear in Chapter 26.)

Oxygen consumption studies provide a metabolic and ventilatory profile of the patient's response to progressive exercise and recovery. Submaximal and peak levels of $\dot{V}_{O_2}$ can be examined, along with their physiological and clinical correlates. The ventilatory efficiency can be determined on the basis of the ventilatory equivalent of CO_2 (minute ventilation [$\dot{V}_E$] divided by CO_2 production [$\dot{V}_{CO_2}$]). The limitation of oxygen consumption studies is the difficulty of ensuring a valid and reliable test. The test requires that a face mask or mouthpiece be worn, either of which can distort the patient's breathing. The patient may feel anxious when wearing such devices or may alter his or her breathing pattern because of the increased dead space in the expiratory hose.

Exercise testing can be used to diagnose exercise-limiting factors. For example, exercise testing in a patient with pulmonary fibrosis can distinguish cardiovascular and pulmonary limitations. Exercise-induced hypoxemia in this cohort has been closely related to survival.[279]

Choice of exercise testing and training modalities is determined by the indications for the test and for training. Patients with COPD show different responses to walking and to cycling.[280] Aerobic capacity in walking is less than in cycling and is associated with excessive ventilatory demand during peak exercise supported by increased ventilatory dead space, reduced ventilatory efficiency, and arterial hypoxemia. Arm ergometry is associated with greater dyssynchronous breathing than is leg work, so it may be an inappropriate modality for patients with severe disease.[281]

Low-flow oxygen is a common intervention for hypoxemia in patients with severe COPD. Although long-term oxygen therapy improves survival,[282,283] there remain many unanswered questions regarding the use of the modality and its efficacy during exercise training.[284] Further study is needed to establish its efficacy in improving exercise capacity in patients with hypoxemia, as well as without hypoxemia, and to establish the characteristics of responders versus nonresponders, which will allow for the refinement of exercise prescription in this patient cohort. A study of patients with cystic fibrosis showed that supplemental oxygen speeded recovery after a short bout of maximal exercise and preserved subsequent exercise performance.[285]

In individuals with COPD and mild exercise hypoxemia, relief of breathlessness with supplemental oxygen has been explained by a commensurate reduction in ventilatory demand and reduced blood lactate levels.[286] Short-term use of oxygen before or after exercise has not been supported.[287]

As with exercise testing of any patient, it is essential to record why an exercise test was terminated—whether it was a sign or symptom predetermined by the tester or a symptom of the patient. If it was a symptom reported by the patient, was it shortness of breath or another or unrelated cause, such as dizziness, muscle strain, plantar fasciitis, arthritic discomfort or pain, or imbalance?

Exercise Training

Training involves flexibility and strengthening, as well as aerobic exercise. Although patients learn to self-monitor and pace their exercise based on their responses, many have had long-term physical therapy and instruction in breathing control because of continued altered breathing pattern, even during ADL.[288,289] Walking in conjunction with breathing control is particularly useful for patients with pulmonary dysfunction. Pulse oximetry may have to be used to guide the training session.

Lengthening (eccentric) muscle contractions are associated with reduced energy cost, so such exercise has important therapeutic implications for individuals with poor aerobic capacity.[270] However, eccentric muscle work in the form of downhill walking or cycling on a negative-work ergometer alters breathing patterns toward a tendency to breathe rapidly and shallowly.[269,271] Thus patients require stringent monitoring when performing this type of energy-efficient exercise.

Although resistance muscle training has been receiving some attention for individuals with chronic lung disease, the prescriptive parameters for optimal benefit have yet to be defined. These parameters should become clear when the role of deconditioning as opposed to a disease-specific myopathy

is better understood with respect to the reduced strength observed in these individuals.

Cardiac and Pulmonary Rehabilitation: Future Directions

The effects of cardiac and pulmonary rehabilitation have been well established on the basis of the highest levels of evidence. However, the lack of adequate access to people who would most benefit from primary prevention of heart and lung disease and from management and secondary prevention has limited the impact of these known effects for at-risk or affected individuals or for the health of the community. Health policies must be structured to enable individuals to take advantage of the resources of such programs. Physical therapists need to be well trained in the principles and practice of cardiac and pulmonary rehabilitation so that these can be applied on a one-on-one basis across areas of specialty practice. This is essential because most individuals under the care of a physical therapist have one or more risk factors. These risk factors need to be addressed, irrespective of whether the individual is presenting with cardiac or pulmonary risk factors or with a diagnosis that is primary or secondary. This knowledge is essential to ensure that physical therapy interventions are modified accordingly in patients with these conditions or their risk factors.

Based on epidemiological indicators, behavioral strategies have the greatest potential for long-term improvement in the abilities and participation of individuals with lung conditions (see Chapters 1 and 5). When effectively administered and adhered to, these interventions are not associated with the risks of invasive management, which must be minimized as much as possible commensurate with the individual's functional improvements. On the contrary, these noninvasive interventions help to ensure reduced long-term morbidity and increased health overall, thus reducing health care needs and potentially increasing individual longevity.

Finally, research is needed to establish how best to structure the principles of cardiac and pulmonary rehabilitation on an individual basis to maximize sustainable benefits for life. Some have argued for inclusion and exclusion criteria to maximize the success of the program.[290] Identifying and reducing barriers to access and participation and maximizing adherence through motivational interviewing and cognitive therapeutic interventions may maximize the impact of these services on society.

Summary

Based on state-of-the-art literature, this chapter extends the general exercise testing and training principles described in Chapter 19 to specific considerations in relation to the principles of best physical therapy practice in cardiac and pulmonary rehabilitation programs, regardless of whether delivered in a structured group format or in one-on-one sessions. Structured formal programs are often available only in large urban areas and thus have low access rates. The same principles, however, are fundamental to physical therapy practice overall and can be readily applied in a one-on-one setting in private practice or in a health care facility. These principles should be applied not only to patients with primary heart and lung conditions but also in the physical therapy management of patients being treated for musculoskeletal and neuromuscular conditions who have secondary diagnoses of chronic heart and lung conditions or who have associated risk factors. In these cases, the physical therapy program must be adapted to the requirements of these underlying conditions (or these conditions may need to be managed independently if they have not been previously identified as a priority). In this way, the patient's more serious underlying cardiovascular and pulmonary problem is addressed and the interventions, including exercise prescribed for the musculoskeletal or neuromuscular problems, are modified according to the more serious life-threatening condition. Exercise testing and training are only part of the management of individuals with chronic, primary cardiovascular and pulmonary dysfunction; the comprehensive approach to management is described in Chapter 31.

The common components of cardiac and pulmonary rehabilitation are described and then differentiated based on their distinct underlying pathophysiology and impacts on individuals. Lifelong health behavior change and reduced need for invasive care in the short term and long term are primary outcomes.

The goal of the physical therapist, who is uniquely qualified as an applied clinical exercise physiologist and health coach, is to ensure that the proper components, in particular exercise, are prescribed to meet the specific needs and comorbidities of each individual. One criticism of structured cardiac and pulmonary rehabilitation programs has been that they are overly regimented and insufficiently individualized, putting these programs at odds with contemporary principles of exercise prescription to produce optimal results. Regardless of the program type, physical therapists must prescribe exercise testing and training that will best fit the needs of each individual patient, based on a detailed multisystem assessment, and then evaluate each patient's progress accordingly.

The principles of exercise testing and training in individuals with cardiovascular and pulmonary dysfunction secondary to conditions other than primary cardiovascular and pulmonary dysfunction are described in the following chapter, Chapter 25.

Review Questions

1. Describe how the principles and practices of cardiac and pulmonary rehabilitation are included within the fundamental principles and practices of physical therapy.
2. Describe how the principles and practices of physical therapy, which include cardiac and pulmonary rehabilitation programs, can be applied in a one-on-one setting as well as in a formally structured program.
3. Describe how the goals of physical therapy management in these programs are consistent with the philosophy and framework of the WHO International Classification of Function.
4. Describe the rationale for assessing an individual's readiness to change with respect to participating in a rehabilitation program; discuss its clinical implications. Consider the limitations of this construct.
5. Describe how individuals with chronic cardiovascular conditions can adapt physiologically and psychologically to exercise.

6. Describe how individuals with chronic pulmonary conditions can adapt physiologically and psychologically to exercise.
7. Contrast and compare measurements and outcomes used for individuals with chronic cardiac conditions as opposed to those with chronic pulmonary conditions.
8. Describe the rationale for goal setting with patients at three levels: prevention, short term, and long term.
9. You have been requested to serve on a team to develop a cardiac rehabilitation program in your area. Describe how, as a physical therapist, you will contribute to this program. In particular, consider the competencies you will offer.
10. You have been requested to serve on a team to develop a pulmonary rehabilitation program in your area. Describe how, as a physical therapist, you will contribute to this program. In particular, consider the competencies you will offer.

Summary 416

Review Questions 417

References 417

This chapter extends the general principles of exercise testing and training presented in Chapter 19 and describes special considerations concerning exercise testing and training for individuals with secondary cardiovascular and pulmonary dysfunction. These special considerations are also important when managing an individual with primary cardiovascular and pulmonary dysfunction who, in addition, has cardiovascular and pulmonary dysfunction secondary to other conditions. In that case, management is modified based on the combination of comorbidities. Individuals with progressive degenerative conditions are often older and debilitated; thus the combination of problems is common. Exercise testing and training is one component of the comprehensive physical therapy management of individuals with chronic, secondary cardiovascular and pulmonary dysfunction, which is described in Chapter 32.

Secondary cardiovascular and pulmonary dysfunction refers to dysfunction of the cardiovascular and pulmonary system that is a consequence of pathology other than primary chronic heart and lung disease. Examples of such secondary conditions are described in Chapter 6. These conditions include dysfunction of the musculoskeletal, connective tissue, neurological, gastrointestinal, hepatic, renal, hematological, endocrine, and immunological systems, or some combination thereof. Nutritional disorders, specifically obesity and starvation (anorexia nervosa), also have cardiovascular and pulmonary manifestations. Conditions leading to secondary cardiovascular and pulmonary dysfunction affect one or more steps in the oxygen transport pathway in such a way that the capacity for oxygen delivery is reduced, oxygen consumption is increased, or both.[1] Often oxygen delivery is further compromised by restricted mobility. Oxygen transport limitations resulting from secondary cardiovascular and pulmonary

dysfunction can present subtly, yet have significant clinical implications. Exercise has a primary role in the management of these conditions, along with the elements of comprehensive multidisciplinary prevention and long-term rehabilitation programs.

Contemporary approaches to the rehabilitation of individuals with stroke serve as a prime example of conventional practice aligning with contemporary exercise physiology principles. Over the past 20 years, stroke rehabilitation has shifted from a focus on Bobath and Brunnstrom interventions to structured exercise training. Exercise training in the management of stroke has the potential for driving brain reorganization and exploiting the property of neuroplasticity to maximize functional capacity.[2] Exercise can take advantage of the potential for neural reorganization, optimize functional capacity, and address deconditioning. A focus on endurance and strengthening exercise, task-specific training, and treadmill walking in the rehabilitation of individuals with stroke, in addition to the conventional focus on cognitive engagement, sensorimotor integration, skill acquisition, and social readjustment has been an exciting advance in the rehabilitation of people with strokes.

Another prime example of exercise testing and training being prescribed for noncardiovascular and pulmonary conditions is their inclusion as a component of prehabilitation in preparation for surgery for a range of conditions. Before orthopedic surgical procedures, for example, improvements in functional capacity have been advocated to reduce perioperative complications and speed recovery.[3] Such programs include warm-up, aerobic training, resistance training, flexibility, and daily functional activities.

As a handy reference for clinicians, key points in the assessment, evaluation, and exercise testing and prescription of patients with secondary cardiovascular and pulmonary conditions are summarized in Appendix D.

Assessment and Goals

Assessment

Knowledge of the cardiovascular and pulmonary consequences of conditions other than those of the cardiovascular and pulmonary systems enables the physical therapist to assess oxygen transport status, limitations, and risk factors in these individuals, in addition to ensuring their safety when undergoing physical activity and exercise. Such knowledge enables the physical therapist to prescribe exercise to optimize oxygen transport, maximize functional capacity and life participation, and maintain optimal long-term health.

Goals: Prevention

Many individuals with systemic conditions (see Chapter 6), the focus of this chapter, have manifestations of oxygen transport limitations or one or more risk factors. The risk factors must be identified and considered in a preventive management plan that includes exercise prescription to exploit the preventive effects of activity described in Chapters 18 and 19. Preventive goals for individuals with chronic, secondary cardiovascular and pulmonary conditions include optimizing central and peripheral adaptations to exercise, reducing biomechanical stress and strain (hence minimizing oxygen cost of exercise at submaximal work rates), optimizing fluid dynamics and hemodynamics, and optimizing lung health (e.g., alveolar ventilation, flow rates, mucociliary transport, and lymphatic drainage).

Another consideration with respect to prevention is the fact that many chronic conditions lead to deterioration over time, and this may be exacerbated further with aging and unhealthy lifestyles. Exercise training is modified over time to accommodate each individual's needs and to help offset further deterioration and associated disability. Furthermore, optimal training effects will benefit the individual's health overall and help prevent contracting illnesses whose effects may be more devastating than in the healthy population.

Mobility aids and devices may be indicated for people with progressive functional deterioration. These adjuncts are titrated to the individual's needs to avoid their overuse. Overuse can lead to loss of remaining musculoskeletal function, which must be preserved as much as possible. Thus an individual can use these adjuncts to optimize functional performance throughout the day (e.g., use a wheelchair for activities in which symptoms are anticipated, or use an ankle foot orthosis in the afternoon when the tibial anterior muscle tends to be fatigued and needs support).

Goals: Short Term

When oxygen transport limitations occur, a regimen of physical activity and exercise can be prescribed to elicit the acute effects of exercise (see Chapter 18). Prescription of exercise to elicit its acute effects has a primary role in the management of individuals during acute episodes of illness and setbacks.

Goals: Long Term

When an individual has recovered from an acute episode, or an individual requires subacute and long-term management, a regimen of physical activity and exercise can be prescribed to elicit the long-term effects of exercise described in Chapter 18. The capacity of each individual to respond to an exercise stimulus and the individual's oxygen transport reserve capacity are both assessed in detail. Knowledge of the reserve capacity is essential for optimal exercise prescription.

Individuals with Musculoskeletal Conditions

Exercise is prescribed for a broad range of conditions affecting the musculoskeletal system, with favorable outcomes and no documented deleterious effects. With increased understanding of exercise pathophysiology, physical therapists can prescribe therapeutic exercise that has the greatest benefit in terms of improved activities of daily living and life satisfaction with the least risk. Individuals with mitochondrial myopathies and nonmetabolic myopathies experience typical aerobic responses to low intensity training (i.e., improved aerobic capacity and reduced submaximal heart rate and blood lactate).[4] The extent of these training effects, however, is less in individuals with nonmetabolic myopathies compared with those who have mitochondrial myopathies. Improved aerobic capacity is associated with improved self-reported functional status and quality of life in both groups.

Osteoporosis

Exercise is central to the prevention and management of osteopenia and osteoporosis. In addition to weight-bearing exercise, relatively intense exercise promotes bone density as well as a high volume of activity.[5] Muscle stress across joints appears to be a critical component for osteogenesis; thus torsion around joints such as in racket sports is favorable provided risk for falling is minimized. Practicing tai chi may reduce bone loss in postmenopausal women and may have some role in the management of osteoporosis.[6]

Osteoarthritis

Osteoarthritis has an indirect impact on cardiovascular and pulmonary conditioning because of its effect on mobility. Aerobic exercise can improve functional aerobic capacity in individuals with osteoarthritis, but this effect is less pronounced with hydrotherapy programs.[7] In response to a fitness walking program for obese people with osteoarthritis of the knee, self-efficacy tended to improve commensurate with improved functional capacity.[8] When prescribing an increase in physical activity and exercise, the physical therapist needs to consider the person's weight (not only in terms of the general health benefits of weight loss, but also in relation to the specific need to reduce weight bearing in obese patients). Given the fact that the majority of patients undergoing lower extremity joint replacement are overweight or obese,[9] weight loss in conjunction with exercise is fundamental in the perioperative course of these patients with the expectation that some patients may avoid the need for surgery entirely. Even small amounts of weight gain have profound effects on joints and joint mechanics (hence, increased pain with exercise). In addition, most patients do not lose weight after their joint replacement surgery, so lifestyle changes need to be approached aggressively before, as well as after, surgery.[10]

Scoliosis

Individuals with idiopathic scoliosis and associated restrictive ventilatory disorder can improve pulmonary function with exercise.[11] Selected exercise can improve both vital capacity and chest wall expansion by almost 20%. The role of exercise for remediation of restrictive lung dysfunction associated with other spinal and chest wall deformities warrants further investigation. Correction of spinal defects in individuals with muscular dystrophy, for example, does not improve cardiac or pulmonary function and thus may not result in appreciably improved response to exercise.[12]

Individuals with Neuromuscular Conditions

Stroke

Because the pathoetiology of stroke involves atherosclerosis and hypertension, individuals with stroke need to be managed comparably to individuals with systemic atherosclerosis and circulatory dysfunction. Appropriate precautions must be taken when exercising these individuals or conducting other physical therapy interventions. Within weeks after a stroke, cardiorespiratory deconditioning complicates the clinical picture, along with muscle weakness, spasticity, incoordination, and abnormal gait.[13] In the subacute stage of stroke, individuals who undergo aerobic training can improve aerobic and functional abilities;[14] however, these benefits may not be reflected in the long-term by indexes such as the Frenchay Activities Index.[15,16] Although research is necessary to refine exercise testing and training procedures for individuals with stroke,[17] there is no reason to believe that these patients would not respond to aerobic conditioning to counter the deconditioning that occurs after stroke or that this intervention would not augment gait reeducation and sensorimotor integration. Evidence supports that the application of a modified treadmill training protocol, based on exercise physiology principles, can be superior to conventional approaches to the rehabilitation of people with strokes.[18]

Although individuals with physical impairment secondary to stroke present methodological challenges during exercise testing and training, submaximal oxygen consumption ($\dot{V}O_2$) has good agreement with maximum $\dot{V}O_2$ ($\dot{V}O_{2max}$) when the test is tightly standardized.[19] The high degree of reliability of these tests supports their use as outcome measures in this population. Metabolic assessment during short, submaximal tests, such as a five-minute walk, can provide supplemental information for evaluating gait in individuals with stroke.[20] Individuals with mild-to-moderate impairment from chronic stroke who require hand rail support on the treadmill also have been reported to have good reliability with respect to heart rate and oxygen pulse in peak-effort treadmill testing.[21] However, hand rail support is an important variable that can increase or decrease work intensity and thus must be described and recorded to facilitate comparison of exercise results across tests. Hand rail support can be described on the data sheet with respect to side or front support, one or two hands, finger support or grasp support, and heavy or light support.

Treadmill training has proven to be a useful means of improving fitness and offsetting deconditioning in individuals with stroke. Individuals with impaired gait can improve their oxygen transport reserve capacity with a regular program of treadmill walking.[22] Peak $\dot{V}O_2$ and walking workload are increased, and the energy cost associated with abnormal gait is reduced. For individuals with stroke, these changes may help to enhance functional capacity comparable to those achieved in individuals with other neurological deficits.

Treadmill training and weight support with a body harness for walking after stroke are showing promise in terms of conditioning strategy and gait reeducation.[23] Patients with severe impairments after stroke who retrain their gait with a portion of their body weight (up to 40%) supported during exercise have better outcomes after training than those who carry their full weight.[24] Older individuals and those with the most impairment show the greatest benefits. These individuals walk more symmetrically on a treadmill compared with ground walking, and they walk with less spasticity and improved movement economy.[25] Furthermore, improvement in treadmill walking speed in these individuals generalizes to balance, trunk control, functional activities, and ground locomotion.[24,26] Training at speeds comparable to an individual's normal velocity over ground is more effective than training at speeds above or below that velocity.[27] Also, when different treadmill walking protocols are compared, structured speed-dependent treadmill training, as performed in sports training,

improves walking ability more than either modified progressive treadmill training or conventional gait training.[18]

Despite the compelling results of studies on partial body weight support in the rehabilitation of individuals with stroke, these and related studies often fail to address the principles of physical therapy for management of individuals with systemic atherosclerosis, which include hemodynamic monitoring and possibly electrocardiogram (ECG) screening. One exception was a study by Eng et al (2002)[28] that recommended that actual exertion (defined as a physiology measure; specifically, rate pressure product or heart rate) be measured in conjunction with walking distance in functional walk tests when testing people with stroke. When performance on several functional walk tests was compared, performance was associated with level of impairment rather than perceived exertion or intensity as measured by rate pressure product or heart rate. Thus debility may limit aerobic training capacity.

Aerobic exercise may have a preventive effect for stroke mediated by endothelium-dependent vasodilation in the cerebral arterioles.[29] Several risk factors are associated with impairment of this mechanism. Exercise stimulates the expression of endothelial nitric oxide synthase, which promotes vascular dilation and thereby exercise's potential protective and preventive effect.

Community ambulation is a meaningful outcome for people with stroke.[30] A discrepancy exists, however, between mobility outcomes on standardized measures of community-based individuals and the extent to which they actually get out in the community. Gait velocity is an important variable in determining community ambulation capacity.

Resistance muscle training has been of interest as a component of physical therapy management of individuals with stroke. Strength training augments the benefits of aerobic exercise with respect to functional strength[31] without reinforcing abnormal movement patterns.[32] One study, however, reported no difference between leg exercise training programs with and without resistance.[33] Inadequate exercise prescription to explain the absence of an effect of resistance training cannot be ruled out.

When prescribing exercise for individuals with stroke, it must be remembered that stroke results from a hemodynamic insult—usually high blood pressure. Aerobic exercise and resistance muscle training elicit unique hemodynamic responses; thus the hemodynamic status of individuals with stroke must be assessed in the initial baseline review, considered carefully in the exercise prescription, and assessed in the outcomes of these programs. If blood pressure is being pharmacologically managed, then an objective of exercise will be to augment oxygen transport efficiency and normalize blood pressure. Medications must be followed so that these can be reduced or withdrawn in response to an overall effect of a comprehensive exercise and management program.

Spinal Cord Injury

Spinal cord injury (SCI) can afflict anyone at any age and is certainly a risk in older adults because of the higher probability of falls. Most often, however, SCI results from trauma incurred in young adulthood, and it is more prevalent in men. Depending on the level of the injury, individuals with SCI have altered hemodynamic response to exercise and positional stress. Life expectancy has increased in recent decades for these individuals, which correspondingly has increased their incidence of cardiac risk factors and disease.[34] An active lifestyle and regular exercise are imperative to ensure that these risk factors and related cardiac morbidity are reduced. Heart rate is highly correlated with respiratory minute volume, $\dot{V}O_2$, and workload, which enables exercise to be prescribed in a predictable manner for this group. Exercise capacity is a function of the capacity of the patient to increase heart rate.[35] Significant aerobic gains in peak $\dot{V}O_2$ and work rate peak result from aerobic exercise in combination with functional electrical stimulation of the lower extremity muscles performed, on average, twice a week. Recovery times also improve with training.

Individuals with SCI have a higher heart rate and lower stroke volume during exercise compared with individuals without SCI.[36] Cardiac output is lower at rest. Peak exercise responses are greater for those without SCI with the exception of heart rate. Despite higher heart rates for a given workload, stroke volume and cardiac output are lower. An intact autonomic nervous system is necessary for a large increase in cardiac output and blood flow to working muscles. Thus, depending on the level of the lesion, the heart and peripheral circulation and their capacity to respond to increased work demand are affected.[37] Assessment of autonomic nervous system status is key in exercise testing and training individuals with SCI.[38]

Arm ergometry can be used to test the aerobic capacity of individuals with SCI. Because of the small muscle mass of the arms compared with the legs, the pressure of contracting upper extremity muscles over blood vessels, and the need for postural stabilization, hemodynamic responses are disproportionately elevated compared with the same work intensity performed by the legs. With training, $\dot{V}O_2$ on-off kinetics, but not heart rate, is accelerated in individuals with SCI.[39] Cardiac output during exercise also tends to be lower for these individuals. Thus $\dot{V}O_2$ kinetics may be a prime limiter of exercise capacity in people with SCI, which could contribute to their lower anaerobic threshold with deconditioning.

Wheelchair athletes with SCI show cardiovascular adaptation to exercise. Echocardiographic evidence shows an increase in left ventricular volume compared with individuals without SCI, but this adaptation is less than in healthy runners.[40] Both long-term arm and leg exercise produce morphometric changes in cardiac mass and volume; however, these changes are less pronounced in wheelchair athletes compared with runners. Also, submaximal heart rates are greater for the wheelchair athletes than for runners.

Movement economy varies depending on how a specific activity is performed mechanically. Wheelchair propulsion is more mechanically and energetically efficient, using a pumping motion rather than the traditional semicircular motion.[41] This has implications for energy conservation and minimization of upper extremity overload in individuals with SCI and for optimizing energy-efficient wheelchair design.

Movement economy (i.e., energy cost in relation to workload) is a concern in managing individuals with physical deformity related to musculoskeletal impairments because of the increased energy cost associated with physical activity of tasks and exercise in general. The degree to which spasticity contributes to increased energy cost is unclear. In

individuals with acquired brain injury, for example, $\dot{V}O_2$ increases with exercise in a predictable, linear manner, although energy cost does not increase disproportionately with spasticity.[42]

Finally, unlike able-bodied individuals, those with SCI do not show comparable cardiac adaptation. The typical left ventricular enlargement is not observed,[43] suggesting that peripheral factors are responsible for conditioning with training in this cohort.

Chronic Effects of Poliomyelitis

The last poliomyelitis epidemic in the United States occurred in the 1950s. Individuals who had poliomyelitis as children at that time are now older adults. The delayed effects of having lived for years with poliomyelitis and its associating limitations may begin to manifest with or without postpolio syndrome (PPS). The chronic effects of poliomyelitis affect functional capacity, exercise tolerance, and cardiovascular and pulmonary risk. About 50% of individuals who had poliomyelitis develop PPS. The principles for prescribing exercise are distinct for those survivors of poliomyelitis, with or without PPS.[44,45]

PPS is hallmarked by new fatigue, muscle weakness, and pain.[46] In addition, survivors of poliomyelitis with PPS may experience exercise intolerance, choking and swallowing dysfunction, temperature sensitivity, and psychological problems. Patients who did not have ventilatory involvement at onset, as well as those who had bulbar involvement at disease onset, may have impaired pulmonary function with PPS. During exercise, ventilatory involvement may be evidenced by impaired blood gases that are not apparent at rest.[47] This has been proposed as a mechanism for delaying diaphragmatic fatigue. In addition to the chronic effects of poliomyelitis, survivors of poliomyelitis are also afflicted with the same health challenges faced by their peers who have no history of poliomyelitis. This clinical picture may be further superimposed with weight gain and reduced activity, hence, deconditioning, which is associated with aging in Western cultures.

Overuse abuse has been proposed as a mechanism of the delayed-onset effects of poliomyelitis.[48] Injudicious prescription of strengthening or aerobic exercise can be deleterious to the patient because it contributes to the overuse abuse of affected, as well as unaffected, muscle.[45] A reduced motor unit pool has less capacity to recover with prolonged demands, and this pool is further reduced with advancing years. With a prescribed program of rest and activity that augments muscle and endurance capacity without contributing to the patient's symptoms, an individual can show improved tolerance to activities of daily living.[44]

Because of the overuse abuse phenomenon associated with PPS, an injudicious exercise program (aerobic or muscle strengthening) can lead to further overuse and progressive deterioration.[49] Thus reserve capacity for exercise is assessed based on a detailed assessment so that overuse is not worsened.

An exercise test can be used to assess conditioning and movement economy, which are distinct entities.[46] Modified aerobic training can be prescribed within the limits of subjective complaints of fatigue and discomfort/pain rather than with conventional indexes of exercise intensity (i.e., heart rate and blood pressure). Although conventional submaximal indexes of conditioning may not be apparent after several weeks of training, walking tolerance at subthreshold levels (measured by walking duration) may improve, along with movement economy.[46] Thus some patients with a history of poliomyelitis can respond favorably to a modified walking program.

Individuals with postural malalignment experience biomechanical stress over joints during ambulation, which in turn can contribute to increased energy cost.[50] An individual's overall energy cost must be considered when prescribing exercise. Activities normally associated with low energy cost for an individual with normal posture and muscle strength can have significantly higher metabolic demand in an individual with postural deformity, limb length discrepancy, and strength asymmetry. Because fatigue and pain are symptoms associated with PPS, these subjective parameters must be monitored before, during, and between exercise sessions to monitor immediate and delayed effects and capacity to recover after exercise. In this way deleterious exercise workloads may be minimized. Overall, objective measures of walking performance are reported to be associated with subjective reports of functional capacity.[51]

New muscle weakness is a marker of PPS. Modified strengthening programs may benefit individuals whose muscles are weak from overuse whereas conventional muscle strengthening programs are indicated for muscles weakened by deconditioning.[45] This distinction, that is, muscles that are weak and fatigued from overuse vs. muscles weak from deconditioning, is critical in the physical therapy management of this population. Stronger muscles may help improve peripheral extraction of oxygen at the peripheral level and thus contribute to an aerobic training effect and improved endurance.

Down Syndrome

Down syndrome is an example of a condition marked by mental as well as physical challenges. People with the syndrome vary widely with respect to the severity of the condition and their functional capacity, which ranges from living totally independently and being gainfully employed to being somewhat dependent in these domains. Many individuals with the syndrome benefit from physical therapy that includes a lifelong exercise program, usually commencing in childhood during growth and development. Longevity has improved as a result of improved detection and management of heart defects and prevention of respiratory complications. With greater life expectancy, individuals with the syndrome encounter many of the same acute and chronic conditions that individuals without the syndrome encounter over their lifetime, such as the diseases associated with higher civilization. Cardiac defects and sleep apnea are more common in persons with Down syndrome than in the general population.[52] These conditions may affect exercise capacity; thus exercise and monitoring must be individualized to each person's unique needs. Obesity and deconditioning can further complicate the clinical presentation. Communication style must be adapted with respect to the exercise prescription and health maintenance program. Optimal health is necessary to maximize function

and long-term self-care. A caregiver may need to be involved to promote a sustained program of regular physical activity and exercise.

Individuals with Connective Tissue Conditions

The exercise limitations of individuals with connective tissue conditions result in part from the restrictive component of lung dysfunction associated with these conditions. These individuals may have normal chest x-ray and conventional pulmonary function yet have histochemical abnormalities of their lungs (e.g., shrinking lung associated with scleroderma).

Resting data are limited in predicting responses to activities of daily living and exercise. Thus exercise testing is a primary tool to assess pulmonary function dynamically and thereby unmask abnormalities that can compromise daily function.[53] Women with systemic lupus erythematosus (SLE) have a several-fold increase in incidence of heart disease over other women, corresponding to an increased number of cardiac risk factors.[54] In addition, hypertension and diabetes are also more prevalent in this group.

Individuals with Rheumatoid Conditions

Individuals with rheumatoid arthritis (RA) have a higher incidence of cardiovascular disease and related mortality. Despite normal left ventricular systolic function, left ventricular diastolic function is impaired without clinical evidence of cardiovascular disease, which may place this group at risk.[55] At maximal exercise, heart rate, systolic blood pressure, and peak $\dot{V}O_2$ are comparable for individuals with RA and healthy people.

Contemporary approaches to the management of people with RA include exercise prescription for strength, endurance, and emotional well-being.[56] Joint inflammation may be reduced with judiciously prescribed exercise.

Individuals with Gastrointestinal Conditions

Conditions such as irritable bowel syndrome and Crohn's disease are characterized by disturbed homeostasis related to gut motility and function. Because these conditions are chronic and medical care is noncurative, physical deconditioning and debility are common. Few studies have examined the acute or chronic effects of exercise in this population, so specific guidelines for testing and training are lacking. One study examined the effects of moderately intense exercise (60% of $\dot{V}O_{2max}$ for 1 hour) on gastrointestinal function in individuals with Crohn's disease who were in remission.[57] The conventional measures of gastrointestinal function were unchanged. It may be necessary to observe caution because of oxygen metabolite production and potential zinc deficiency. Individuals with gastrointestinal conditions have nutritional deficits that must be considered when placing increased metabolic demands on energy substrate stores. The capacity of these individuals to respond to exercise appropriately will fluctuate with exacerbations and remissions of their conditions. It is hoped that with improved health and functional capacity, the duration between exacerbations will be increased, the severity of exacerbations will be reduced, and speed of recovery will be increased.

Individuals with Hepatic Conditions

The exercise responses of individuals with hepatopulmonary syndrome (HPS) are not well understood, which has hampered attempts to define guidelines for mobilization and exercise testing and training. One study, however, has shown that individuals with HPS have markedly reduced aerobic capacity and exercise-induced hypoxemia that exceeds the limitations of patients with liver disease but without the syndrome.[58] Hypoxemia and increased ventilatory dead space at peak exercise support impairment in the pulmonary circulation.

Exercise capacity and maximum oxygen consumption are impaired by cirrhosis. This can be explained by an associated cirrhotic cardiomyopathy. Myocardial thickening and ventricular stiffness lead to decreased diastolic function and inotropic and chronotropic incompetence when the oxygen transport system is stressed during exercise.[59]

Individuals with Renal Conditions

Limitation of mitochondrial oxidative capacity has been ruled out as a limiter of exercise capacity in patients with chronic renal failure.[60] Muscle oxygen conductance, however, is low.

Exercise has a role in the management of individuals undergoing hemodialysis. One study examined the role that normalizing hemoglobin has on exercise response of these individuals.[61] Although both young and old subjects showed evidence of improved oxygen transport and exercise tolerance, exercise responses were not normalized completely. Further, impaired potassium regulation appeared related to hemoglobin concentration and was thought to contribute to exercise limitation.

Patients with end-stage renal disease can also benefit from exercise. Minimally, deconditioning may be prevented, but alternatively, functional status will be improved. An ideal exercise program should have both aerobic exercise and resistance muscle training components, and the prescription for both should be designed to minimize cardiovascular and musculoskeletal risks. Exercise is initiated at a low level to ensure the exercise responses are normal and the patient responds favorably before progression of the prescription. With respect to exercising patients who are severely ill, the consequences of not exercising must be considered.[62] Regular physical activity, particularly when the patient is relatively stable and well, must be encouraged. This ensures that the patient is as well as possible when a change in his or her condition occurs, which in turn speeds recovery and minimizes associated challenges to aerobic and strength status.

Erythropoietin therapy in the management of patients with chronic renal failure fails to augment peak $\dot{V}O_2$ as much as might be predicted from a corresponding increase in hemoglobin.[63] Lactate differences may explain abnormal muscle oxygen transport and reduced exercise tolerance in these patients. Erythropoietin-mediated increases in hemoglobin,

however, reduce the respiratory exchange ratio at submaximal exercise (comparable to activities of daily living), reflecting a decrease in anaerobic metabolism and reduced exercise stress.[64]

Chronic renal insufficiency is strongly associated with exercise-induced ischemia in individuals with atherosclerosis. The greater the severity of atherosclerosis in these individuals with chronic renal insufficiency, the greater their cardiovascular risk.[65]

Frequent exercise for patients with renal disease has been proposed as a means of maximizing effective use of their anemia-imposed reduced oxygen delivery capacity.[66]

Individuals with Hematological Conditions

Sickle cell anemia is a common hematological condition in the United States with a high prevalence in the African American population. Patients with sickle cell disease have reduced hemoglobin and oxygen transport capacity. On maximal exercise testing and endurance testing, they have lower exercise tolerance; however, their responses relative to deconditioned individuals without sickle cell anemia are generally comparable.[67] Thus exercise performance of these individuals must be interpreted in this context.

Individuals with Endocrine Conditions

Individuals with diabetes warrant special consideration with respect to exercise testing and training. Exercise imposes demands on energy substrates and their utilization. Blood glucose abnormalities associated with diabetes necessitate monitoring blood glucose fluctuations before, during, and after exercise. The physical therapist must ensure that the individual eats appropriate foods and at appropriate times in relation to physical activity and exercise. Obesity management is fundamental to the goals of an exercise program as well as normalizing blood glucose metabolism.

Autonomic neuropathies, myopathies, and angiopathies contribute to abnormal exercise responses. Acute exercise responses (e.g., heart rate and blood pressure) may be blunted, as may subjective response to exercise. People with diabetes have a higher incidence of silent ischemia. Heart rate and blood pressure may be less valid indexes of workload. Peripheral vascular disease may result from the direct effect of diabetes, as well as vascular occlusive disease, which is accelerated in individuals with diabetes compared with those who do not have this condition. Altered glucose transfer may also interfere with normal exercise responses. Weight control and nutrition are important to optimize training responses. The capacity to exhibit an optimal training response depends on disease severity, management of the disease, and complications (HbA_{1c} provides an index of potential complications). Limb perfusion and skin perfusion are monitored before and after exercise. Well fitting, smooth, clean socks must be worn at all times.

Special considerations include monitoring blood glucose before, during, and after exercise (immediate and delayed), at least initially when prescribing exercise for a person with diabetes. Exercise is postponed if blood glucose is extremely high and in the presence of ketone bodies. Daily regular exercise is recommended to maintain health and optimal blood glucose regulation. Intensity should be mild to moderate for a given individual.[68] Exercise is judiciously timed with the intake of both foods of optimal glycemic index for the person's needs and insulin or oral agents, as indicated. With improved glucose tolerance and insulin sensitivity and a long-term aerobic exercise program, the need for insulin or oral agents will be affected. The need for these will be eliminated, ideally, or at least reduced.

Individuals with thyroid disease warrant close monitoring. Those who are hypothyroid will be more easily fatigued. Their medical management requires close monitoring to ensure that their condition is normalized as much as possible. If it is, these individuals should have generally normal exercise responses. Those with hyperthyroidism will have high resting heart rates and blood pressure and exaggerated exercise responses.

Individuals with Immunodeficiency Conditions

The pharmaceutical drugs that have been developed to improve the survival of individuals with human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS) (e.g., highly active antiretroviral therapy [HAART]) can impair oxygen transport, hence reducing functional capacity. At peak exercise, heart rate has been reported to be lower and stroke volume higher in individuals with HIV taking HAART when compared with individuals with HIV not taking the drug.[69] The a-vO_2 difference was lower at peak exercise for those on the drug. HAART is a primary contributor to decreased muscle oxygen extraction-utilization in individuals infected with HIV. The physical therapist must be highly knowledgeable about the combined response of exercise and the potent medications used to control the disease in these individuals. This is important in order to build on an individual's exercise reserve capacity when health is best, as well as to maintain health and social participation. It is hoped that with improved health and conditioning, morbidity and its severity are reduced.

Immunodeficiency has been implicated in chronic fatigue syndrome (CFS). This syndrome, currently of unknown etiology, appears to run its course over time. Guidelines for exercise testing, particularly maximal testing and training, have been uncertain. In one study individuals with CFS were exercise-tested to the maximal extent. Exercise responses were comparable to individuals with reduced conditioning without CFS, supporting the theory that the physiological responses of individuals with CFS were not abnormal and that exercise testing resulted in no harmful or deleterious effects.[70]

Individuals with Cancer

The physical capacity of cancer survivors and their capacity to respond to exercise conditioning vary depending on the primary type of cancer, the presence of metastases, chemotherapy and radiation therapy and their schedule of administration, and other morbidity.[71] Mind-body considerations, including the psychological, cognitive, and physiological (immune) interface of the patient's presentation and related outcomes, are emphasized. Given that cancer is a leading cause

of morbidity and premature mortality and that many cancer survivors can expect to die with the condition rather than *from* it as a result of advances in cancer management, the role of exercise has been a focus of attention over the past decade or so. The goals have been to improve health and conditioning, potentially augment remission and reduce progression through immunity stimulation, and reduce the negative effects of the potent treatments that are often administered. Muscle weakness and fatigue are primary complaints of patients with cancer. These complaints are likely related to the body's attempt to heal itself and in response to the potent treatments, as well as the overall deconditioning associated with illness.[72,73]

General guidelines for exercise testing and prescription include resistance training in conjunction with aerobic exercise.[71] Exercise provides both psychological and physical benefits in enabling an individual to thrive when living with cancer. The parameters of the exercise program may vary depending on a patient's response to potent radiation and chemotherapy (i.e., reducing the intensity and frequency or temporarily discontinuing the program). The role of exercise in improving the health and well-being of people with cancer and in attenuating the negative effects of potent treatments has been a hotbed of research in recent years. Significant advances can be expected in refining exercise testing and training parameters in the near future.

Individuals with Nutrition-Related Conditions

Obesity

In preparation for exercise prescription, the individual who is obese requires a comprehensive multisystem assessment to establish all factors that may limit exercise tolerance. These individuals require high volumes of physical activity and exercise (see the physical activity and exercise pyramid in Chapter 1) in conjunction with a nutritious dietary program. Introducing more exercise, however, must be done gradually so that it is as enjoyable as possible and also less likely to cause musculoskeletal strain and injury. Biomechanics change with weight loss, and exercise becomes biomechanically less stressful and better tolerated.

Prescriptive parameters for optimal weight loss remain a matter of debate with respect to prolonged, low-intensity aerobic exercise versus short, high-intensity exercise. Moderate intensities of effort, however, have been reported to be more effective at mobilizing fat, whereas heavy exercise promotes energy expenditure after exercise.[2] The critical factor is the number of calories expended, and burning calories is best achieved with a regularly active lifestyle supplemented with additional formal exercise sessions. Lower-intensity exercise may be favored to avoid musculoskeletal strain or for psychological and motivational reasons. Aerobic training increases lipid oxidation during exercise in fasting conditions.[74] Such a regimen maintains glucose homeostasis and facilitates fat oxidation. Additional benefits of endurance training for individuals who are obese include reduced cholesterol and insulin concentrations in the blood.

Some individuals may benefit from a structured program (see Chapter 32) and the social support of others in the program.

Anorexia Nervosa

The malnutrition and weight loss due to catabolism associated with anorexia nervosa predisposes individuals with the condition to deconditioning and impaired oxygen transport reserve capacity. Such capacity is vital to optimally respond and adapt to exercise and the physical demands of daily life in the short and the long term.[75] Fluid and electrolyte imbalance can complicate the clinical picture and is the primary cause of death in extreme cases. Although quantitatively abnormal, responses to exercise may be appropriate in the absence of abnormal myocardial performance. Exercise is prescribed in conjunction with an optimal nutritional plan so that further catabolism is not precipitated.

Summary

This chapter extends the general exercise testing and training principles covered in Chapter 19 and describes special considerations for exercise testing and training individuals with cardiovascular and pulmonary dysfunction secondary to conditions other than primary chronic heart and lung disease. Exercise testing and training is one component of a comprehensive physical therapy management program that is described in Chapter 32.

Conditions that can lead to secondary cardiovascular and pulmonary dysfunction include dysfunction of the musculoskeletal, connective tissue, neurological, gastrointestinal, hepatic, renal, hematological, endocrine, and immunological systems, or some combination thereof. Nutritional disorders, specifically obesity and starvation (anorexia nervosa), also have cardiovascular and pulmonary manifestations. Exercise has a primary role in the management of these conditions, along with the elements of a comprehensive multidisciplinary prevention and rehabilitation program. Knowledge of the potential cardiovascular and pulmonary consequences of conditions other than primary cardiovascular and pulmonary disease is essential to prescribe mobilization and exercise safely and therapeutically for individuals with these conditions to maintain their health and well-being (capacity for activity and participation in life with least physiological risk). Individuals with these conditions are often managed by physical therapists. Thus the cardiovascular and pulmonary manifestations must be considered with respect to physical activity recommendations and the prescription of optimal and safe exercise programs.

Individuals with the potential for cardiovascular and pulmonary dysfunction secondary to noncardiovascular and pulmonary conditions are at significant health risk. Even minor illnesses can have a major impact on their functional capacity. Further, many of these conditions have a progressive degenerative component. This, coupled with aging, can result in what may seem to be a sudden functional decline. Thus oxygen transport of these individuals can benefit from the general health benefits of a lifelong program that includes an exercise program modified based on changes in their condition. Finally, individuals with chronic, secondary cardiovascular and pulmonary conditions likely have underlying risk factors for primary cardiovascular and pulmonary conditions comparable to the general population, if not to a greater extent. Thus both types of pathoetiology must be considered when

evaluating limitations in life participation and related activities and their remediation, as well as when evaluating preventive measures for lifelong health and well-being.

Review Questions

1. Describe how chronic, secondary cardiovascular and pulmonary dysfunction associated with the following conditions can limit a person's participation in life and associated activities in the absence of chronic, primary cardiovascular and pulmonary conditions.
    1. Musculoskeletal (osteoporosis and osteoarthritis)
    2. Connective tissue (systemic lupus erythematosus, scleroderma) and autoimmune conditions (rheumatoid arthritis)
    3. Neurological (stroke, spinal cord injury, chronic effects of poliomyelitis)
    4. Gastrointestinal
    5. Hepatic
    6. Renal
    7. Hematological
    8. Endocrine
    9. Immunological
    10. Obesity
    11. Anorexia nervosa
2. Describe special considerations for exercise testing and training of individuals with the conditions listed in question 1.

The capacity of the respiratory muscle pump is vital for the movement of air to the level of gas exchange in the respiratory system. Impairment of the respiratory pump compromises ventilation, gas exchange, and tissue respiration. The respiratory muscles drive ventilation. In conditions where the load on the respiratory muscles is increased or the capacity of the respiratory muscles is decreased, muscle weakness can occur. Breathing pattern (i.e., rapid shallow breathing) adapts, however, to help counter respiratory muscle fatigue.[1] Although this adaptation decreases the effectiveness of gas exchange, a breathing pattern with a lower tidal volume and higher breathing rate helps minimize respiratory muscle fatigue.

Although the adaptation in breathing pattern affects the effectiveness of gas exchange, prevention of muscle fatigue and respiratory arrest requires modification of the breathing pattern (i.e., there is a decrease in tidal volume and an increase in breathing rate). Figure 26-1 illustrates this adaptation in patients at risk for respiratory failure. Respiratory muscle weakness increases the relative load for breathing (inspiratory pressure/maximum inspiratory pressure [PI/PI_{max}] ratio, see Figure 26-1), and this can lead to clinical consequences such as dyspnea, impaired exercise performance, ineffective coughing, respiratory insufficiency, weaning failure, and death. Dysfunction of the respiratory muscles is observed in several conditions such as chronic obstructive pulmonary disease, asthma, cystic fibrosis, neuromuscular disease including spinal cord injury, congestive heart failure, and critical illness. This chapter describes the clinical relevance of respiratory muscle weakness, the assessment and testing of respiratory muscle function, and the application and effectiveness of respiratory muscle training for the conditions above and its role in weaning some patients from mechanical ventilation.

Respiratory Muscle Assessment

Respiratory Muscle Strength Testing

Clinically, respiratory muscle strength is measured as PI_{max} and maximum expiratory pressure (PE_{max}). These pressures are measured using a small cylinder that fits in the patient's mouth with a circular mouthpiece (Figure 26-2). A small leak in the cylinder (2 mm diameter and 15 mm length) prevents high pressures that could be caused by the contraction of the cheek muscles.[2] Standardizing the lung volume at which the pressures are measured is crucial.[3] To prevent chest wall and lung recoil pressures from contributing to the pressure generated by the inspiratory muscles, measurements are recorded at functional residual capacity (FRC). This lung volume, however, is difficult to standardize. In clinical practice, PI_{max} is measured from residual volume, whereas PE_{max} is measured at total lung capacity (TLC). At least five repetitions should be performed. Respiratory muscle testing is described in detail in the American Thoracic Society/European Respiratory Society position statement (2002).[4]

Several groups of investigators have published norms for PI_{max} and PE_{max} (Table 26-1).[2,7,8] Regardless of the norms used,

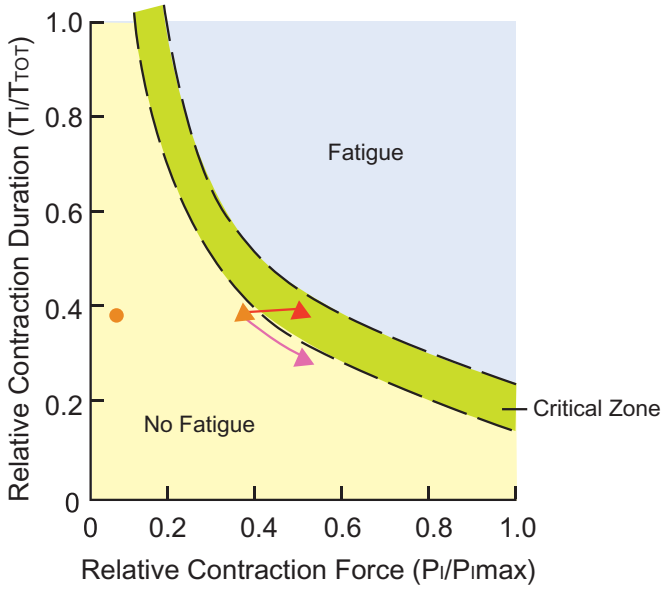

Fig. 26-1 The relationship between relative contraction force (PI/PI_{max}) and relative contraction duration (TI/T_{TOT}) in a healthy subject (d) and a patient with COPD (m). The hatched area represents the critical zone in which fatigue develops. With progressive mechanical loading (e.g., exercise and acute exacerbation), the patient with COPD needs to increase PI and, therefore, might fall into the fatiguing zone (*dashed arrow*). This is generally avoided by a concomitant reduction in the duration of inspiration, TI/T_{TOT} (*solid arrow*). This results in a decrease in tidal volume and a consequent increase in respiratory rate to maintain constant minute ventilation. Interventions aimed at reducing the load on the inspiratory muscles (PI) or increasing the maximum capacity of the inspiratory muscles (PI_{max}) reduce the relative contraction force of the inspiratory muscles. This prevents muscle fatigue and, thus, respiratory insufficiency. *(Modified from Bellemare F, Grassino A: Effect of pressure and timing of contraction on human diaphragm fatigue,* J Applied Physiol *53:1190-1195, 1982).*

Fig. 26-2 Assessment of respiratory muscle strength with measurement of mouth pressure.

the standard deviation is typically large. Therefore weakness is not easy to define.[11] Inspiratory weakness is defined as a PI_{max} lower than 50% of predicted[12] in the presence of clinical signs (e.g., dyspnea, impaired cough, and orthopnea) consistent with reduced respiratory muscle strength. Other methods, such as the sniff maneuver, have been developed as tools to quantify global respiratory muscle function.[13] The results of the sniff maneuver have been reported to be highly reliable in children with neuromuscular disease. More invasive methods such as electric or magnetic diaphragm stimulation can provide more accurate and detailed information on diaphragmatic function[14] and are useful in the diagnosis of diaphragmatic paresis. For most clinical applications, however, the assessment of inspiratory and expiratory mouth pressures is sufficient.

Respiratory Muscle Endurance Testing

Several tests for assessing respiratory muscle endurance capacity have been described. Most commonly the patient breathes against a submaximal inspiratory load (60% to 75% PI_{max}) for as long as possible.[15,16] This test can detect changes in inspiratory muscle endurance after training. Incremental threshold loading, breathing against an incremental load (approximately 5 cm H_2O) every 2 minutes, is also reproducible.[17] The highest load that can be sustained for two minutes is termed the *sustainable pressure* and is expressed as a percentage of the maximal load.[17,18] Healthy people can usually sustain 70% of the PI_{max} for 2 minutes.[18] Johnson and colleagues[17]

reported large intra-individual variations in this percentage, which tends to decrease with age. The sustainable pressure has been shown to be less than the maximal inspiratory and expiratory pressures in individuals with chronic obstructive pulmonary disease (COPD).[19] A third method[20-22] is a repetitive maximal inspiratory or expiratory maneuver performed against an occluded airway with a well-defined contraction duration (10 seconds) and relaxation time (5 seconds). The relative decline in maximal pressure after 18 contractions is a measure of the endurance capacity of the respiratory muscles.

Respiratory Muscle Training Methods

Comparable to muscle training of the peripheral skeletal muscles, training of the respiratory muscles aims to improve specific characteristics of inspiratory or expiratory muscle contraction force, endurance, or velocity (Table 26-2).[23-25]

Inspiratory Muscle Training

Because the inspiratory muscles are mainly involved in repetitive contractions with low intensity, training strategies emphasize enhancing inspiratory muscle endurance. Two types of training (i.e. threshold loading [Figure 26-3] and normocapnic hyperpnea [NCH] [Figure 26-4]) are currently practiced. During NCH, the patient is asked to breathe at a high proportion (>60%) of the maximal voluntary ventilation for 15 to 20 minutes.[23,26] In the past, the equipment used for this type of training was complicated, but recently a simpler, partial rebreathing system has been developed.[27]

During inspiratory resistive breathing the patient inhales through a mouthpiece with an adapter fitted with an adjustable diameter. This resistance is flow-dependent. Adequate training intensity is achieved only with feedback of the target pressure if flow and pressure are tightly coupled.[28] Recently, a flow-independent resistance has been developed, the so-called threshold loading valve, a valve that opens at a critical pressure.[29,30] Training intensity varies across studies, from as high as maximal sustained inspiratory (Müller) maneuvers[31] to 50% to 80% PI_{max}[16,32-34] to a low intensity of 30% PI_{max}.[34-37] All these studies carefully controlled the target pressure or the threshold loading during training.[30] Threshold loading has the advantage of being independent of inspiratory flow rate[30] but requires a build-up of negative pressure before flow is initiated; hence it is inertive in nature. The fact that threshold loading enhances velocity of inspiratory muscle shortening[38]

Table 26-2 **Training Modalities for Inspiratory Muscle Resistive Training (IMT) and Respiratory Muscle Endurance Training (RMET)**

	IMT	RMET (Voluntary Isocapnic Hyperpnea)
Type	Strength	Endurance
Duration	15 minutes, twice daily,	30 minutes, 6-12 weeks
Frequency	5-7x per week	5x per week
Intensity	30-50%PImax with individual incremental load, weekly control of load/technique	V_E = 50-60% MVV, breathing frequency 50-60/min

could provide additional benefit because this shortens inspiratory time and increases time for exhalation and relaxation. Increased relaxation time may prevent the development of muscle fatigue in patients who are at risk. In addition, shortening inspiratory time will increase expiratory time, thus reducing dynamic hyperinflation, which is an important advantage in patients with COPD.

Expiratory Muscle Training

Explosive expiratory maneuvers and low-intensity contractions of the abdominal muscles are similar to those involved in coughing, the Valsalva maneuver, and exercise. Consequently, training parameters for expiratory muscle training can be either high-intensity strength training or moderate- to low-intensity endurance training. An example of the parameters for endurance expiratory muscle training is 30 minutes of continuous training at 15% to 45% of PE_{max}.[39] An example of strength training parameters is 15 Valsalva maneuvers at 60% of PE_{max}.[40] Both training programs can be implemented using expiratory resistance at the mouth, such as threshold loading.[40,41]

Respiratory Muscle Training in Health

Diaphragm fatigue can occur during sustained high-intensity exercise.[42,43] Several studies have shown that unloading respiratory muscles (by using low-density gas mixtures or mechanical ventilation) can lead to an increase in exercise performance.[44,45] In athletes, heavy (but not moderate) respiratory muscle work has an impact on whole body exercise performance by affecting limb blood flow and limb muscle fatigue during heavy exercise.[46,47] One mechanism to explain these improvements in exercise performance is the "respiratory muscle metaboreflex" (Figure 26-5).[47] Therefore a rational basis exists for improving the strength and endurance of the respiratory muscles in order to improve exercise performance. In 14 competitive rowers, inspiratory muscle training (IMT) significantly improved PI_{max} and performance on a 5000-meter trial compared with a placebo control group.[48] A small but significant decrease in swimming time needed to cover 100 meters and 200 meters was observed after 6 weeks of IMT compared with a placebo control group.[49] After following 5 weeks of respiratory muscle endurance training (RMET), nine competitive cyclists had a 25 seconds (+2%) improvement on an 8-km trial. No differences were founded in peak work rate or maximal exercise capacity ($\dot{V}O_{2max}$).[50] Leddy and colleagues (2007)[51] reported a 4% decrease in time on a 4-mile run after 4 weeks of RMET. All these small improvements in exercise performance are also practical and relevant since small differences in athletes' performance can be the difference between winning and losing a race. On the other hand, several studies in endurance athletes observed no differences in maximal exercise capacity, other than an increase in respiratory muscle strength and endurance.[52,53]

An overview of the literature shows important methodological limitations of the available studies, such as a low number of study participants, no comparison with a (randomized) control group, and exercise performance outcomes that are less sensitive (maximal exercise capacity instead of a

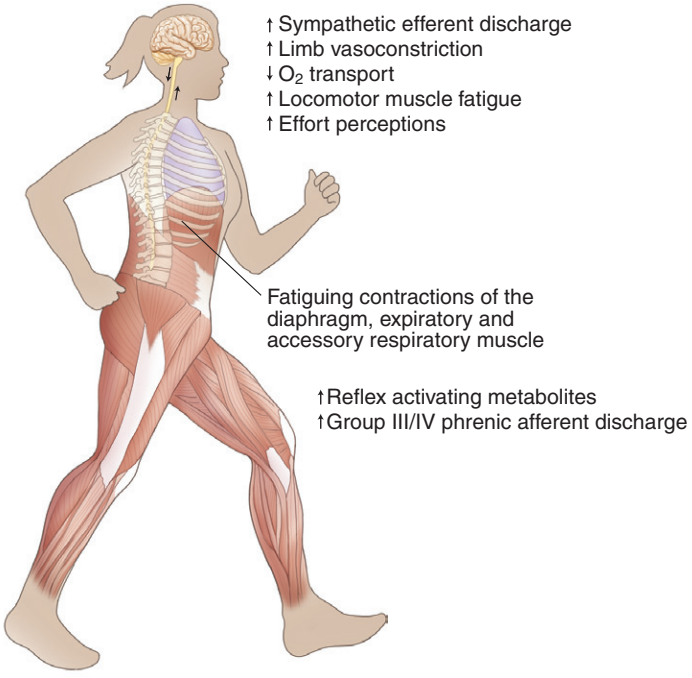

Fig. 26-5 Effects of high respiratory muscle work of breathing on exercise performance. (Qlimb = limb muscle perfusion). *(From Romer LM, Polkey MI: Exercise-induced respiratory muscle fatigue: Implications for performance,* J Appl Physiol *104:879-888, 2008.)*

time trial). Based on our current understanding and available studies, we conclude that the capacity to meet high ventilatory demands improves with respiratory muscle training in healthy people and this can be associated with an improvement in exercise performance. Future studies are needed to confirm the beneficial effects of respiratory muscle training on exercise performance in health.

Respiratory Muscle Training in Disease

Chronic Obstructive Pulmonary Disease

Respiratory muscle weakness is often observed in patients with chronic obstructive pulmonary disease (COPD).[54-58] Adaptation of the diaphragm results in greater fatigue resistance and improved muscle function.[59,60] The diaphragm is remodeled in part by the transformation of fast fiber types to slow fiber types.[61,62] Despite these adaptations, both functional inspiratory muscle strength[55] and endurance[56] remain compromised in patients with COPD and contribute to hypercapnia,[63] dyspnea,[64,65] nocturnal oxygen desaturation,[33] and reduced walking distance.[66] During exercise, patients with COPD use a larger proportion of their maximal inspiratory pressure than healthy people.[67] This pattern of breathing is closely related to dyspnea during exercise[67] and may induce respiratory muscle fatigue and probably limits exercise capacity.

Another mechanism involved in the potential role of respiratory muscles in exercise limitation is the respiratory muscle metaboreflex (see Figure 26-5). Inspiratory muscles should become more fatigue-resistant by increasing their work capacity and should consume a smaller fraction of the total cardiac output during exercise, which in turn, should be available for the working muscles during exercise. In patients with COPD, diaphragmatic fatigue after exercise has been observed in only a small number of patients.[11,68] However, this might be related to the insufficient length of the exercise protocols and the absence of inspiratory muscle weakness in the subjects evaluated. Improved limb muscle blood flow after IMT has been observed in patients with chronic heart failure[69-71] but has not yet been studied in patients with COPD. Reductions in dynamic hyperinflation and dyspnea during exercise after IMT have also been proposed as mechanisms linking inspiratory muscle capacity to whole body endurance capacity; thus further study is needed.[72]

Compelling evidence suggests that breathing against an inspiratory load increases both maximal inspiratory pressure[16,28,32-37,73] and endurance of the inspiratory muscles.[28,33,34,73] Respiratory muscle training has been reported to produce hypertrophy of predominantly type I and IIA fibers in the diaphragms of hamsters.[74,75] The proportion of type I fibers and size of type II fibers in the external intercostals after IMT has been recently reported to increase in a study of patients with COPD.[76] Dyspnea[36,37,77] and nocturnal desaturation time[33] also decreased, while exercise performance tended to improve (Table 26-3).[78,79] In addition to exercise training, IMT can improve exercise capacity more than exercise training alone.[16,32,35,37] Based on systematic reviews with meta-analyses, IMT can improve inspiratory muscle strength and endurance, functional exercise capacity, and quality of life while also decreasing dyspnea.[78,79] The addition of IMT to a general exercise training program improved PI_{max} and tended to improve the exercise performance of patients with inspiratory muscle weakness (PI_{max} < 60 cm H_2O).[78,79] Long-term effects were shown for exercise performance and dyspnea in patients with COPD who continued performing their training program three times per week at high training intensity (60% PI_{max}).[80] NCH was applied in one randomized controlled trial and resulted in enhanced respiratory muscle endurance and exercise capacity as well as quality of life in patients with COPD.[26] Inspiratory muscle endurance training was shown to be less effective than respiratory muscle strength training.[79]

In conclusion, well-controlled inspiratory muscle training for people with inspiratory muscle weakness secondary to COPD can improve inspiratory muscle function, and it can lead to further improvement in exercise capacity, as well as decreased dyspnea and nocturnal desaturation time. Training intensity, however, should be at least 30% of the maximal inspiratory pressure and training duration for 30 minutes per day.

Table 26-3 Effect Size of Inspiratory Muscle Training Based on Meta-Analysis (n = 32)

	Effect size	P value
PI_{max} (cm H_2O)	13	.001
Endurance (s)	261	.001
Endurance (cm H_2O)	13	.001
6MWD (m)	32	.001
MVV (L)	3	.37
$\dot{V}o_{2max}$ (mL/kg/min)	1,3	.06
CRDQ score (points)	3,8	.007
Dyspnea (Borg)	−0.9	.001
Dyspnea (TDI)	+2.8	.001

PI_{max}, Maximal inspiratory pressure; 6MWD, 6-minute walk distance; MVV, maximal voluntary ventilation; $\dot{V}o_{2max}$, maximal oxygen uptake capacity; CRDQ, chronic respiratory disease questionnaire; Borg, scale of breathlessness; TDI, total dyspnea index.

From Gosselink R, De Vos J, van den Heuvel SP, et al: Impact of inspiratory muscle training in patients with COPD: What is the evidence? Eur Respir J *2011;37:416-425, 2011.*

Asthma

Respiratory muscle weakness is not frequently observed in patients with asthma.[80-82] Although some studies report a moderate reduction in inspiratory muscle strength,[81] other studies have not found inspiratory muscle strength to be affected.[20,56] Inspiratory muscle endurance has been shown to be increased in people with asthma[20] but reduced in those who are steroid dependent.[56] In patients with asthma, dyspnea has been observed to be greater in women than in men, resulting in their greater need for beta-2 agonists. This may reflect sex differences in inspiratory muscle strength.[80] IMT has been studied in people with asthma, and evidence from randomized trials supports that, in addition to improvements in inspiratory muscle strength, dyspnea and beta-2 agonist use was

reduced in those with high dyspnea and high use of beta-2 agonists,[83] especially among women.[80] A Cochrane review, however, concluded that the evidence supporting a role for IMT for people with asthma was inconclusive.[84]

Cystic Fibrosis

Reports on the inspiratory muscle strength in people with cystic fibrosis (CF) have also been contradictory. Some have shown that inspiratory muscle strength is decreased,[85-88] whereas others have shown that it is normal[89,90] and others have shown it is supranormal.[91-93] The discrepancy across studies can be attributed to methodological inconsistencies such as age, degree of pulmonary dysfunction, nutritional status, and the assessment of PI_{max}. Severity of disease, nutritional depletion, and systemic inflammation have been considered contributors to respiratory muscle weakness in people with CF.[94] On the other hand, normal or supranormal PI_{max} in the CF population can be explained by the chronic increase of respiratory workload due to the combination of progressive airflow obstruction, hyperinflation, and airway resistance, which could produce a training effect.[89,95-97]

Given the similarities in abnormal lung mechanics for people with CF and with COPD, the rationale to indicate IMT for patients with CF is based on the benefits observed with this intervention in patients with COPD. There are few reports on IMT in patients with CF.[91,95,96,98,99] The modalities of IMT used in these patients are similar to those described for other patients with chronic obstructive diseases such as COPD and asthma. Early studies described the use of the NCH[98] and inspiratory resistive training[91] modalities. Recent studies, however, have used threshold loading.[95,96,99] As yet, there is no consensus by experts regarding the optimal training intensity for patients with CF. Even though training at low intensity (40% PI_{max}) improves inspiratory endurance,[95] high-intensity training (80% PI_{max}) can further augment inspiratory muscle function, pulmonary function, and exercise capacity.[96]

Recently, two meta-analyses have been published about the effects of inspiratory muscle training in patients with CF.[100,101] Both systematic reviews point out a scarcity of randomized controlled trials and a huge difference among inspiratory muscle training protocols. Therefore evidence is weak supporting IMT as a means of improving inspiratory muscle function in children, adolescents, and adults with CF. In addition, the benefit of IMT on dyspnea, exercise capacity, and quality of life for these populations remains unclear.

Quadriplegia

Several studies have reported that inspiratory or expiratory muscle training is a means of enhancing inspiratory or expiratory muscle function in individuals with quadriplegia, reducing dyspnea, and improving exercise performance.[102-105] In one systematic review, the investigators concluded that respiratory muscle training (RMT) tended to improve expiratory muscle strength, vital capacity, and residual volume. Insufficient data were available to make conclusions concerning the effects of RMT on inspiratory muscle strength, respiratory muscle endurance, quality of life, exercise performance, and respiratory complications.[105] A randomized controlled trial showed that NCH training in patients with spinal cord injury improved respiratory muscle strength and endurance. Further, respiratory complications occurred less frequently after training.[105]

Neurological and Neuromuscular Disease

Independent of the site of the pathology (e.g., the central nervous system, peripheral nerves, neuromuscular junction, and/or muscles themselves), respiratory muscle weakness associated with other factors (e.g., pulmonary dysfunction and immobility) plays a role in increasing the risk for ventilatory failure and respiratory complications, hence, morbidity and mortality.

The mechanisms underlying respiratory muscle dysfunction in patients with neuromuscular disease (NMD) are complex and dependent on the particular disease and its stage. In patients with amyotrophic lateral sclerosis (ALS), involvement of inspiratory muscle weakness is prominent and underlies ventilatory insufficiency and symptoms, while expiratory muscle weakness is mainly present in symptomatic patients and affects cough.[106] Progressive respiratory muscle weakness has been described in Duchenne muscular dystrophy (DMD). A recent study has confirmed a progressive impairment of the diaphragm compensated by an increase in the contribution of the ribcage to tidal volume.[107] Patients with Parkinson syndrome can exhibit respiratory muscle weakness even if the severity is mild, but the syndrome is less associated with dyspnea.[108] The weakness is associated with impaired exercise performance while quality of life and daily living activities appear unaffected.[109] Respiratory muscle function is affected in patients with acute ischemic stroke but it is not related to dyspnea.[110] Diaphragm contractility is affected on the contralateral side, which may be related to an increased incidence of pneumonia.[111] In addition, acute ischemic stroke has been related to expiratory muscle weakness and reduced peak flow rate, which may determine cough inefficiency.[112] Besides diminished respiratory strength and endurance, patients with generalized myasthenia gravis are more dyspneic than are control subjects.[113]

The indications for IMT in NMD are based on the benefits of strengthening the respiratory muscles, which may delay pulmonary complications and the onset of respiratory failure.[114] Studies have reported improved respiratory muscle function after IMT in various types of NMD.[115-117] Inspiratory muscle training (60% of sniff nasal inspiratory pressure, for 10 minutes, 3 times a day, 7 days a week, for 12 weeks) resulted in strengthening of the inspiratory muscles and also delayed the decline in respiratory function in patients with ALS.[118] Because of controversy about the benefits of respiratory muscle training in patients with DMD, either improvement or insignificant changes in respiratory muscle function, a recent statement of American Thoracic Society does not completely recommend this intervention for these patients.[4]

In studies that reported improvement in respiratory muscle function, the inspiratory resistance adjustments varied from 30%[117] to 70%-80% PI_{max}[119] and the period of training from 6 weeks to 24 months. An additional benefit was reduced perception of respiratory load, which could translate into reduced dyspnea.[117] In patients with Parkinson syndrome, IMT increased both strength and endurance of the respiratory muscles and reduced the perception of dyspnea.[120] One study has described the benefits of expiratory muscle training for

patients with Parkinson disease.[121] An improvement in voluntary cough and swallowing was observed after training the expiratory muscles, which consisted of five sets of five breaths against 75% PE_{max} for 4 weeks. However, whether these benefits can prevent aspiration in these patients remains unclear. In patients with subacute stroke, IMT improved respiratory muscle function, exercise capacity, and quality of life.[122] In summary, the protocol consisted of two 15-minute sessions, starting with a load of 40% PI_{max} and going up to 60% PI_{max} (threshold loading) for six times a week for 6 weeks. Patients with myasthenia gravis have showed improvement in respiratory muscle function and also in dyspnea symptoms after inspiratory[123,124] and inspiratory plus expiratory muscle training.[125] For patients with multiple sclerosis, IMT has been recommended by Klefbeck and colleagues (2003)[126] as an additional intervention to physical training. In that study, patients breathed daily for 30 times through an inspiratory resistance of 40%-60% PI_{max} imposed by the threshold loading over a 10-week period. Although inspiratory muscle function is commonly affected in neuromuscular diseases, expiratory muscle strength is preferentially impaired in patients with multiple sclerosis[40] and it is inversely related to their disability status;[127] thus EMT has been shown to be beneficial for patients with multiple sclerosis.[40,128]

An association exists between training intensity and improvement of respiratory muscle capacity.[116] Patients with NMD who have more than 25% of predicted pulmonary function can respond to training.[31,117] Patients with severe impairment of ventilatory function, however, may show less improvement in respiratory strength because they are less able to achieve the critical training intensity, respiratory muscle weakness may predispose their muscle to damage rather than benefit from training, and their muscle mass may be insufficient. In the long term, the progression of most neuromuscular diseases affecting muscle probably impedes an optimal training effect.

Inspiratory and expiratory training enhances the respiratory muscle performance in patients with NMD. The transfer of these gains to increased cough effectiveness, reduced respiratory infection, and delayed ventilatory failure warrant detailed study.

Chronic Heart Failure

Although impairment of cardiac function is the principal factor associated with reduced functional capacity in people with chronic heart failure (CHF), abnormal respiratory muscle function plays an important role in premature exercise termination and contributes to sensory consequences, especially breathlessness on exertion. Exertional dyspnea can result from respiratory muscle weakness, increased respiratory muscles activity, or both.[64]

Reduced respiratory muscle strength in patients with CHF has been shown both with volitional[129-131] and nonvolitional (twitch transdiaphragmatic pressure)[132] measurements. Changes in pulmonary function secondary to ventricular dysfunction, increased left ventricular size, chronic pulmonary congestion, reduced lung compliance, and increased airway resistance[133] result in an altered breathing pattern in which patients breathe near residual volume at rest and experience limitations related to expiratory flow with minimal exercise.[134] Therefore the ventilatory muscles are subjected to increased work of breathing (WOB),[133,135] which may lead to respiratory muscle fatigue. As a positive consequence of the high WOB in people with heart failure, however, the diaphragm exhibits a predominance of slow myosin heavy chain isoforms with an increase in oxidative enzymes and a decrease in glycolytic capacity.[136] These adaptations are similar to those observed after endurance training of the limb muscles in healthy people. These observations are consistent with the well-preserved endurance of the inspiratory muscles when expressed as a function of endurance time, as well as the inspiratory muscle load-to-capacity ratio in patients with CHF.[137]

The effects of inspiratory muscle training in patients with CHF have been well documented.[44,70,138-144] No consensus exists in the literature related to types of training, intensity, and duration of IMT, which may explain the range in responses of patients with CHF to IMT. Based on the literature, the usual intensity is at least 30% of PI_{max},[44,70,138,142,144] but an intensity of 60% of PI_{max}[143] has also been used. Although some studies used IMT three times per week,[138,139,141,143] others trained the patients either six[140] or seven times per week.[70,144] The duration of each session varied between 10 and 30 minutes, and sessions were performed over 6 to 12 weeks.

IMT for people who have CHF increases inspiratory strength[44,70,138-140,142-144] and endurance,[138,140-143] increases maximal exercise capacity as reflected by improved exercise duration[141] or oxygen consumption,[70,142,143] increases submaximal exercise capacity evaluated by the 12-minute walking test[140] and 6-minute walking distance,[70,138,140-143] and improves both dyspnea[139-143] and quality of life.[70,143] Recently, IMT has been reported to improve oxygen uptake efficiency in patients with CHF and inspiratory muscle weakness (PI_{max} < 70% of predicted).[145] In addition, 4 weeks of IMT led to an improvement of limb blood flow during exercise.[69] It has been speculated that IMT reduces inspiratory muscle overload and, in turn, peripheral muscle vasoconstriction, a contributor to exercise limitation in these patients.[146]

Based on its capacity to improve respiratory muscle performance and exercise capacity, IMT can be considered an additional tool that is safe and effective in the comprehensive management of respiratory muscle dysfunction in patients with CHF.

Weaning Failure

The majority (75% to 80%) of patients who are mechanically ventilated can be weaned to breathe spontaneously without difficulty.[147] Patients who experience difficulty weaning have poorer prognoses, including increased mortality and prolonged intensive care unit (ICU) stay and rehabilitation. Several factors contribute to weaning failure, such as the underlying disease, age, muscle weakness, malnutrition, hypoxemia and hypercapnia, and medications (e.g., corticosteroids and muscle relaxants). The method of weaning affects the outcome.[147] Current expert opinion supports that familiarity and skill are the most important determinants of the choice of weaning. The specific method seems less important. Weaning based on bedside assessment and the use of standardized protocols is effective. Daily screening of respiratory function and trials of spontaneous breathing result in shortening of the period of mechanical ventilation, thus reducing the complications and costs associated with an ICU stay.[148-152]

A spontaneous breathing trial can be used to assess readiness for extubation with the performance of serial measures such as tidal volume, respiratory rate, maximal inspiratory airway pressure, and the rapid shallow breathing index.[153] Early detection of worsening clinical signs such as distress, airway obstruction, and paradoxical chest wall motion, ensures that serious problems are prevented. Airway patency and protection (i.e., an effective cough mechanism) should be assessed before the commencement of weaning. Peak cough flow is a useful parameter to predict successful weaning in patients with neuromuscular disease or spinal cord injury when extubation is anticipated.[154] A rating of "airway care score" has been developed based on the quality of the patient's cough during airway suctioning, the absence of excessive secretions, and the frequency of airway suctioning.[150] These therapist-driven protocols are action plans based on consensus and expert opinion. Physical therapists contribute to the assessment and treatment of patients who have difficulty being weaned from mechanical ventilation. Noninvasive ventilation can facilitate weaning,[155] prevent postextubation failure in patients at risk,[156] and reduce ICU costs.[157] In addition, there is accumulating evidence that weaning problems are associated with failure of the respiratory muscles to resume ventilation.[158] Inspiratory muscle training might be beneficial in patients who fail to wean. Uncontrolled trials of inspiratory muscle training (IMT, threshold loading; see Figure 26-3) observed an improvement in inspiratory muscle function and a reduction in duration of mechanical ventilation and weaning time.[159-162] Interim analysis of a randomized controlled trial comparing inspiratory muscle training at moderate intensity (≈50% PI_{max}) with sham training in patients with weaning failure showed that a larger proportion of the training group (76%) could be weaned compared with the sham group (35%).[163] The addition of IMT in the management of acute critically ill patients from the beginning of mechanical ventilation neither reduced weaning time nor the reintubation rate.[164]

Biofeedback of the pattern of breathing to the patient can also enhance the weaning process of patients receiving long-term mechanical ventilation.[165] Voice and touch may be used to augment weaning success either by stimulation to improve ventilatory drive or by reducing anxiety.[166] Environmental influences, such as ambulating with a portable ventilator, have been shown to benefit attitudes and outlooks in long-term ventilator-dependent patients.[167]

Summary

Respiratory muscle weakness and fatigue have been identified in a variety of conditions and associated with clinically important symptoms such as dyspnea, impaired cough, exercise impairment, respiratory insufficiency, and weaning failure; and survival. Respiratory muscle training is a treatment option for weak respiratory muscles seen in a range of conditions. However, its indications, contraindications, and the specific criteria that determine the type of testing and training, intensity of training, and potential side effects warrant elucidation. Regardless, tools have emerged that are enabling physical therapists to identify and assess the severity of respiratory muscle weakness and thereby intervene in a timely and effective manner.

Review Questions

1. Define respiratory muscle weakness and explain how it is measured. How does it clinically manifest?
2. Distinguish respiratory muscle weakness from respiratory muscle fatigue.
3. How are respiratory muscle strength and endurance related to exercise capacity, and how is exercise capacity related to respiratory muscle strength and endurance?
4. Describe current concepts and principles related to respiratory muscle strength testing.
5. Describe how respiratory muscle endurance testing differs from respiratory muscle strength training. What are the training implications?
6. Distinguish between inspiratory and expiratory muscle training, how they are assessed, and how their different training programs are prescribed.
7. Explain what the differences in inspiratory and expiratory muscle strength and endurance indicate about individuals with each of the following conditions: asthma, cystic fibrosis, quadriplegia, and chronic heart failure.
8. How might respiratory muscle training augment weaning? How would the indications be established?
9. What remains to be elucidated in the area of respiratory muscle testing and training?

What does the literature say about a possible role for complementary and alternative therapies in helping to achieve common therapeutic goals for patients with cardiac, pulmonary, and/or vascular pathology? Believe it or not, there is a wealth of literature available, with some articles reflecting greater scientific rigor than others. Cardiovascular and pulmonary pathology is highly correlated with increased stress, and many complementary therapies are designed specifically to help people modify stress-related behaviors.

What Are Complementary Therapies?

Complementary therapies are often viewed as holistic, mind/body, or energy-based therapies, and they are categorized and referred to in a variety of different ways. Some other common names include alternative therapies, alternative medicine, and integrative therapies. Complementary therapies are used by physical therapists to complement (usually not to replace) traditional therapies from the allopathic model of health care and are considered energy-based therapies that stress the importance of vibration or energy flow, both in the application of the intervention and in the response by the patient.

The goal of most of these therapies is to "unblock" obstructed body energy so that the body can heal itself.[1] It is hypothesized that homeostasis, balance, and self-regulation (the highly advanced ability of the body/mind to supply optimum conditions for metabolism, such as proper pH, body temperature, etc.) result from the unrestricted flow of body energy, along with molecules from breathing, fluid, and nutrition.[2,3] A system out of balance becomes vulnerable to early mortality. A system in balance becomes resistant to inflammation. Some suggest that inflammation is the foundation of all diseases and disorders.[4] Two large studies, one in men and one in women, demonstrated that higher levels of C-reactive protein correlate with a higher risk for heart attack and stroke and treatments that reduce C-reactive protein level reduce heart disease risk.[5,6] Therefore complementary therapies are used to facilitate the flow of body energy (or chi) and thus help the body restore balance and return to a healthier state.

Examples of Complementary and Alternative Therapies

The following are examples of complementary and alternative therapies that have been found to be useful in health care. A list and brief description of these therapies can be found in Appendix E.

Manual Therapies

Manual therapies, also known as body work, include myofascial release, craniosacral therapy, Rosen method, Rolfing, Hellerwork, soma, neuromuscular therapy, massage, and osteopathic and chiropractic medicine. The manual therapies involve the use of hands on the body/mind surface to stimulate bioelectromagnetic force. How this occurs remains a mystery. Research by Hunt and others is currently being conducted to measure energy flow from the body.[7-9] Perhaps both mechanical and energetic forces stimulate response from the tissue in several ways. It has been hypothesized that mechanical force may be transformed into a chemical response within the collagen of the myofascia, causing a flow of the polyglycoid layer of the collagen by way of a piezoelectric effect.[10] For patients with cardiovascular and pulmonary pathology, the manual therapies can assist in opening up the ribcage and vertebral spine to allow increased ventilation and better posture, thereby supporting cardiorespiratory health.

Mind/Body Interventions

Mind/body intervention include psychotherapies, support groups, meditation, imagery, hypnosis, dance and music therapy, art therapy, prayer, neurolinguistic psychology, biofeedback, yoga, Pilates, and tai chi. These interventions are examples of how movement and verbal and nonverbal communication with the mind/body can open up new pathways for thought and thereby unblock potentially blocked energy flow or chi. Likewise, with the new understandings of epigenetics (see discussion below), the energy (or vibration) of one's perception or belief drives DNA function, either for means of growth or for means of protection/survival.[2,3] These interventions are quite prevalent in the treatment of cardiorespiratory and pulmonary disorders. Stress is positively affected when the person is aware of thoughts and habits that affect the mind/body in a negative way. These interventions put the patient back in control of negative behaviors, and focusing on the breath is often an integral part of furthering relaxation.

Movement Awareness Interventions

Movement awareness interventions include Feldenkrais method, the Alexander technique, and the Trager approach. It is postulated that movement awareness interventions help people bring to consciousness the way in which they tend to move habitually so that they can practice new ways of moving and holding themselves posturally, thus freeing up blocked energy that gets trapped in fascia and soft tissue as a result of maintaining habitual postures. Those people who walk with protracted scapulae and forward heads are revealing fascial restrictions around the thoracic inlet, lungs, and mediastinum. It is hypothesized that tight fascia, revealed in extremes of posture, restricts blood flow and nerve conduction critical to the maintenance of healthy heart tissue.

Energy Work

TRADITIONAL CHINESE MEDICINE

Traditional Chinese medicine includes acupuncture, acupressure, reflexology, and qi gong. These approaches within the system of traditional Chinese medicine focus on enhancing the flow of chi along body pathways or meridians, but the concept of meridians and energy flow is just one part of this complex, centuries-old system of health care. The acupuncture or acupressure or reflexology point is a specific point where access to the flow of chi on a meridian is most available. One analogy is that an acupuncture point is to a flow of chi as a subway entrance is to the train tracks below the surface.

BIOELECTROMAGNETICS

Bioelectromagnetics include thermal applications of magnets and nonionizing radiation such as radiofrequency hyperthermia laser and pulsed electromagnetic field therapy. Credible research exists on the effects of electromagnetic energy for wound healing and bone repair. *Biomicroelectromagnetics* is the term applied to the energy that seems to emanate from the hands of people who have been accepted as healers.[8] Ultrasound and diathermy have been used in physical therapy for decades as deep heat mechanisms, and although there is not a clear understanding of the mechanism of action, it undoubtedly involves a stimulation of energy flow; therefore this therapeutic approach falls in the bioelectromagnetic category. The use of magnets in physical therapy is quite controversial, but there are some very compelling results from case studies that make it important to include in this category.

PERSONAL TRANSMISSION OF HEALING ENERGY

Methods of personal transmission of healing energy include Reiki, noncontact therapeutic touch, and distant healing prayer. The practitioner goes through a period of training in order to learn how to focus attention and intention on transmitting the universal life force for healing and well-being, either through touch (Reiki), manipulation of bioenergy fields (noncontact therapeutic touch), or focusing the mind for distant healing effects (intercessory prayer and Reiki).

Herbal Approaches

Naturopathy and homeopathy represent the use of plants and animal substances to fight off disease and the use of wise nutrition to combat illness. Naturopathy, like osteopathic medicine, represents an entire system of health care that uses homeopathy, osteopathy, proper nutrition, and other means to bring about healing. Naturopathic physicians complete 4 years of medical school. Homeopathy involves the use of minute chemicals in diluted solution to resolve chemical imbalances in the body. Proper nutrition has long been associated with cardiac and pulmonary health, especially in Dean Ornish's plan for healing from cardiac pathology.[11]

Mind/Body Link

Mind/body health care has brought about a way of linking the traditional linear research methods with the more contemporary, complementary, and alternative health care practices. The influence of the mind on the body was first introduced in the Western hemisphere by Herbert Benson, a well-known Harvard cardiologist, through his research on Tibetan monks who were able to control their autonomic nervous system to the extent that they could lower their body temperatures and respiration rates and enter a wakeful, hypometabolic physiological state by will.[12] This information shocked the Western world, and Benson presented his data most dramatically by videotaping the actual sessions of the monks taking control of their bodies with their minds.

The proof that the mind and body are inextricably linked has since been well documented in various studies. Indeed, there is a basic science devoted to the study of the effect of the mind on the body: *psychoneuroimmunology*, a term that Ader and Cohen are credited with creating. Studies have shown that the mind affects the immune system by way of the autonomic nervous system and by way of the "fluid" nervous system, or the nonadrenergic and noncholinergic nervous system.[13]

Candice Pert has clearly articulated the physiological functioning of the fluid nervous system, which manifests by way of the effects of thought on the neurotransmitters, the neuropeptides, and the steroids of the body.[14] The neurotransmitters and the neuropeptides communicate with most of the cells of the body. This science has been termed *psychoneuroendocrinology*. It is no longer correct to assume that the mind resides only in the cranium or the brain. In truth, the mind has been shown to reside in every cell in the body. According to Pert and others, the science clearly reveals that all cells have memory.[14] The biochemistry of psychoneuroendocrinology reflects a flow that is different from that of microelectropotentials or the exchange of energy from the hands of the therapist, but which illustrates, nonetheless, that the mind and the body are inseparable and the mind communicates with every cell of the body.

Complementary and alternative therapies are energy-based therapies that require an understanding that there is such a phenomenon as vital flow of energy in the body and that the natural state of the body is to be healthy.[15] Cells are constantly in a state of flux, with old cells dying off and new cells being created continuously. But the body/mind persists in continuously working toward fighting off disease and healing cells whose loss would threaten the thriving of the entire system. With this awareness, illness is understood as an aberration set up by an imbalance caused by restriction in flows. The body has many energies, or vibrations, and the ways that we can observe energy at work in the body are varied. For example, electrocardiograms, electroencephalograms, and electromyograms all measure the energy output from various body organs. The piezoelectric effect, another energy phenomenon, enables osteoblastic activity, which keeps our bones strong. Mechanical energy in gravity is transformed to chemical energy to allow the osteoblasts to deposit calcium appropriately in our skeleton. But now we understand that perhaps the most powerful of the many vibrations our cellular receptors respond to is the vibration of perception.

The science of epigenetics posits that the genes in our cells respond to vibrational signals. For the cells to function, receptors on the surface of the cell wall must respond to the vibration to which they are attuned, resulting in a cascade of actions that lead to the DNA ordering the appropriate protein chain linkage to result in the needed function.[2,14] Basic to the understanding of the mind and body being inseparably linked is the fact that one of the most powerful vibrations that cells respond to is the vibration of perception or belief.[2,14] The more a person perceives threat, stress, or danger, the more there is a resulting vibration to which cells respond with an autonomic fight or flight response—the hypothalamic-pituitary-adrenal (HPA) axis.[16] It has been long understood that chronic stress contributes to pathology in the cardiovascular and pulmonary systems. The DNA of cells is responding in a "digital" (on-or-off) way either to signals vibrating for growth needs or signals vibrating for protection needs. When protection needs take over, blood is shunted to life-sustaining viscera and to the extremities for flight or fight. Thus some organs are not being nourished in a health-producing manner. Over time, immune system function is also diminished and this can lead to inflammation and disease of the heart and lungs.[17] A system out of balance becomes vulnerable to early mortality. A system in balance becomes resistant to inflammation. As stated previously, some suggest that inflammation is the foundation of all diseases and disorders.[4]

Biomicroelectro-potentials, or the subtle energies in electromagnetic fields that emanate from the hands of "healers," are currently being researched.[8,18] It is believed that complementary and alternative therapies have an effect on patients by way of the energy that emanates from the healer's hands. This energy is of a frequency of 0.3 to 30 Hz, which is usually centered around 8 to 10 Hz.[19,20]

As we move into this new century, many researchers and practitioners in health care are seriously exploring and publishing studies that reveal new ways of viewing reality. What we know about quantum physics and systems theory, combined with what we have observed and experienced in terms of the inadequacies of traditional allopathic medicine in overcoming chronic illness and autoimmune disease and the growing tendency of patients and clients to seek out complementary and alternative therapies, situates us well into a paradigm shift, a revolution in the linear and materialistic view of reality. A common perspective is that current medicine falls short because it is designed on the infectious disease model, or mechanistic model, in which it is hoped that a single drug or intervention will be able to cure and save lives.

Most current diseases, especially the chronic diseases that affect people, do not lend themselves to single-purpose cures. Chronic illness is most adequately addressed when the patient is involved in the healing process as an active partner, when the patient is willing to make certain lifestyle changes to eliminate choices that interfere with wellness, and when illness is perceived by patients and practitioners not as a simple biophysiological event but as a system or contextual event. We are all consciously and unconsciously influenced by a variety of systems that we are embedded within and that mandate our reactions to inflammation and illness. No two people react to illness in the exact same way, and no two people heal from illness in the exact same way. Practically any physical therapist or health care professional will admit that how a person thinks or perceives has an enormous amount to do with how he or she responds to health and illness. A vast range of systems affect all of us at any given time—just a few examples are our

birth order, our identity, how we feel about ourselves and our family members, how well we enjoy our work and our recreation, how meaningful our relationships are, what the weather is like, who won the Super Bowl, and what we ate for breakfast.[21]

Traditional Therapies Applied from a Holistic Approach—Intention

Patients with cardiovascular and pulmonary complications often present with comorbidities of acute and chronic diseases that challenge our available interventions. The application of energy medicine or holistic approaches in treating these patients is becoming more commonplace. Indeed, many traditional therapies can be applied from a holistic approach. For instance, in working with patients with cardiovascular and pulmonary pathology, treatments such as massage, exercise, and relaxation can be approached by a therapist in a traditional manner in which the intention is a mechanical, linear effect, or it can be approached in a holistic or mind/body manner in which the intention is to attempt to influence the flow of vital energy. When massage and exercise are offered as treatments from a holistic perspective, the idea is to enhance the flow of body energy and bring about homeostasis.

Researchers confirm the importance of hope and faith in one's physician and practitioners, including physical therapists.[22] It has been established that a patient's belief that the practitioner has hope for the patient's recovery seems to help, but exactly how this facilitates healing remains unclear. It seems to be related to the concept of intention and the effects of consciousness and nonlocal mind.[22]

To ignore the positive effect of therapeutic presence is to neglect a powerful intervention. How practitioners interact with their patients, not just what they *do*, is vitally important.[1] Time and again, patients mention that a critical factor in their healing response was the positive effect of being truly listened to by their care provider. Now research is finally documenting the effects of positive intention and the therapeutic exchange of energy.[22]

The Problem of Scientific Evidence

Should physical therapists use complementary therapies that have shown good clinical results but have not been proven scientifically to be efficacious? The answer is yes, but not a simple yes. At the foundation of this issue are two ethical questions. What right do we, as professionals, have to subject patients to treatments that have not been proven to be efficacious by way of scientific evidence? Conversely, what right do we have to deny patients holistic treatments that have been shown for centuries to benefit patients and have a negligible chance of causing harm? Physical therapy has a long history of using therapeutic agents for the good of patients without any science to explain efficacy or mechanism of action. And now that we are finally doing this important research on ultrasound, heat, exercise, and electrical modalities, we can apply this knowledge to complementary therapies such as tai chi, yoga, transcendental meditation, and craniosacral therapy.

Some contradictions inevitably arise when we attempt to apply traditional scientific principles to the study of complementary therapies. Reductionist science tries to show evidence of cause and effect by reducing the experimental variables (ideally, to just one) and by reducing all possible outcomes in order to eliminate the effects of chance (or other causes) on the evidence that is collected. However, unlike single cells or molecules, human beings and their illnesses do not lend themselves to being reduced in such a manner. People are whole systems of interacting needs and functions (physical, intellectual, emotional, spiritual, and social) that cannot be fully understood by separation from one another or by reduction. Systems theory, from the life sciences, is foundational to holistic or complementary therapies and states that the whole can never be fully understood by reducing it to its parts, because the whole is always more than the sum of the parts. How the parts interact with one another is critical to understanding the whole. Reductionism tries to control for this confounding variable.

Complementary therapies such as tai chi, acupuncture, biofeedback, meditation, cognitive behavioral therapy, music therapy, hypnosis, electrical stimulation, prayer and distant healing efforts, yoga, and qi gong have been shown to be effective in the relief of pain and anxiety and in the improvement of balance by way of the randomized controlled trial (RCT).[23] Literature reviews of mind/body therapies in the treatment of musculoskeletal disorders with implications for older adults have been conducted.[24,25] Still, the fact remains that many complementary therapies, especially those manual therapies designed to assist in the release of fascial restrictions in order to restore the flow of the body's self-regulating energy, do not lend themselves to study by the RCT because energy itself cannot be measured or seen. Only the results of energy can be measured (heat, work, movement, etc.), and we cannot yet validate what results occur from what intervention, except by way of anecdote and measuring the effects of treatment on impairments and function. However, scientists such as Valerie Hunt, James Oschman, Gary Schwartz, Linda Russek, Candace Pert, and others are busy working out the biochemical, quantum physics, and systems theories that postulate physiological and biochemical mechanisms of action, which will allow us to hypothesize basic cellular energy theory.[10,26-28] This basic cellular energetic theory can then be tested to describe the evidence that we need. If we can hypothesize a basic mechanism of action of myofascial release, for example, then we can examine whether that action does indeed take place in the way that the theory postulates. However, we will never be able to *see* energy, any more, for instance, than we can see velocity.

Demonstration of efficacy and safety is paramount to professional care. But is this goal actually achievable to the satisfaction of the scientific community? Not as long as reductionism remains the gold standard in the search for reality. In 1997, the Council on Scientific Affairs of the American Medical Association suggested that "physicians should evaluate the scientific perspectives of unconventional theories for treatment and practice, looking particularly at potential utility, safety and efficacy of these [holistic] modalities."[23]

Holistic approaches should not be exempt from careful study. In addition to randomized trials, complementary therapies must be researched by way of case studies, single case designs, and other methods of systematic examination of intervention and results. And as we build the body of evidence justifying the positive benefits of the restored flow of healing

energy that help the body/mind self-regulate and heal itself, we may just come to realize that complementary therapies have done more to restore healing to health care than had been anticipated. What follows is a review of the evidence of how complementary therapies influence normal cardiovascular and pulmonary responses and the effect that they have on patients with cardiovascular and pulmonary conditions.

Use of Specific Complementary Therapy Interventions in Cardiovascular and Pulmonary Conditions

As described throughout Part III of this book, the goal of physical therapy intervention is to improve the efficiency of the oxygen transport and gas exchange systems. The decision to use a specific complementary therapy and integrate it into more traditional cardiovascular and pulmonary treatments is often dependent on the practitioner's familiarity with the intervention. Rehabilitation practitioners without specialized training in a complementary therapeutic intervention frequently do not realize that they are already incorporating components of complementary therapies in established, traditional therapeutic interventions. Patient education, including behavioral and biofeedback techniques used to alter breathing patterns and reduce sympathetic nervous system stimulation, are forms of mind/body therapies. These interventions have been studied extensively, reported in the literature, and are widely used and accepted in clinical practice.[29-31]

Physical therapy practitioners with expertise in a specific complementary intervention may decide to focus their treatment on cardiovascular and pulmonary impairments. Tai chi and yoga are mind/body therapies that emphasize coordinated breathing with movement. These interventions may be used as the primary approach to treat the impairment, or they may complement traditional physical therapy. The body of evidence addressing the usefulness of these interventions in improving oxygen transport has expanded in both quantity and quality in recent years.[32-36]

Other interventions that have not been subjected to rigorous, scientific study may still be worthy of clinical application. For example, the Alexander technique, which emphasizes posture and movement, intuitively suggests an improvement in oxygen transport. An improvement in posture optimizes muscle function, thoracic cage efficiency, and hence oxygen transport; however, there is limited research published on this technique in relation to the cardiovascular and pulmonary systems.[37]

The increasing consumer demand for complementary and alternative medical (CAM) therapies has occurred despite the lack of rigorous or acceptable scientific investigation into many of them. In an attempt to protect the general public from unethical and unsafe practices, the National Heart, Lung, and Blood Institute and the National Center for Complementary and Alternative Medicine (NCCAM) have proposed that large-scale clinical trials be performed to determine standards of practice and safety standards.[38] NCCAM proposed initiatives to support research and the development of specialized centers to study cardiovascular disease and also reported a 96% increase in funding for these initiatives in 2005.[39,40] It is important for all health care practitioners to become familiar with some of the more popular CAM therapies, recognize that our patients are using them, and be especially aware of the effects of these therapies on the cardiovascular and pulmonary systems.

The following section reviews the normal cardiovascular and pulmonary responses to various CAM interventions in healthy individuals. A presentation of the evidence for using specific complementary and alternative medicine therapies to treat major cardiovascular and cardiovascular and pulmonary pathologies follows. A discussion of naturopathic and homeopathic therapies is outside the scope of this chapter. Breathing exercises will be discussed in relation to a specific CAM therapy. Traditional breathing exercises (e.g. diaphragmatic, pursed-lip, etc.) are addressed elsewhere in this book.

Cardiovascular and Pulmonary Responses to Complementary and Alternative Medical Therapies

Tai Chi

Tai chi is one of the most well-studied mind/body therapies. During sessions of the many forms of tai chi (see Appendix E), cardiovascular responses have been documented in novices as well as in master practitioners. In several of these studies, responses have been compared to cardiovascular and pulmonary responses observed in other forms of exercise (e.g. bicycle ergometry and treadmill ambulation). Most investigations are small and have methodological shortcomings. A brief sampling of the results of several studies addressing the cardiovascular and pulmonary responses found during tai chi practice can be found in Table 27-1. In general, in these studies of healthy individuals, gender and experience level do not seem to influence the responses. It is reasonable to conclude that tai chi is a low- to moderate-intensity exercise that emphasizes the oxygen transport system. Investigators generally conclude that tai chi is a safe activity for healthy individuals. Prescreening for mind/body interventions is recommended, however, just as would be expected for any other exercise intervention.[37]

Several authors have investigated the cardiovascular and pulmonary benefits of a prolonged program of tai chi. In contrast to the studies reported in Table 27-1, several others demonstrate that experienced tai chi chuan practitioners achieve significantly higher maximum oxygen consumption ($\dot{V}O_{2max}$) levels than do sedentary subjects.[46-52] These authors conclude that tai chi is a form of aerobic exercise, it has benefits for health-related fitness, and it may slow the decline in cardiorespiratory fitness in older, healthy individuals.

In a small study (n = 32), Wang and colleagues (2002)[34] studied endothelium-dependent dilation in skin vasculature in healthy, older (69.9 ± 1.5 years), male tai chi practitioners and a control group. Their results demonstrate that when compared with older sedentary men (67.0 ± 1.0 years), long-time, experienced practitioners of tai chi have more favorable arterial and venous hemodynamics. In some cases these vascular findings were comparable to a group of younger, healthy, sedentary men (23.5 ± 0.68 years).

Young and colleagues (1999)[53] compared the effects of aerobic exercise and tai chi on blood pressure responses in

Table 27-1 Cardiovascular and Pulmonary Responses Found During Continuous Tai Chi Exercise

Study Authors	Tai Chi Form	Sample Characteristics and Methods	Cardiovascular and Pulmonary Responses
Schneider, 1991[41]	Wing chun (WG) Tai chi chuan (TCC)	Experienced practitioners $\dot{V}O_{2max}$ measured on treadmill	TCC: 36.4% $\dot{V}O_{2max}$, 59.8% HR_{max}, $\dot{V}_E/\dot{V}O_2$ 21.7 WG: 52.4% $\dot{V}O_{2max}$, 70.5% HR_{max}, $\dot{V}_E/\dot{V}O_2$ 24.2
Lan, 2001[42]	Yang tai chi chuan	15 men Age 26-56 years Experienced practitioners (>1 year) $\dot{V}O_2$ measured on cycle ergometer	TCC: 58% HR_{max} (max on cycle was 186 ± 8), 55% $\dot{V}O_{2max}$ (max on cycle was 39.1 ± 7.7)
Brown, 1989[43]	Tai chi chuan (long form Yang style, Cloud H)	6 men Experienced practitioners $\dot{V}O_2$ measured on cycle ergometer	TCC: Vf 11.3, $\dot{V}_E/\dot{V}O_2$ 23.47, V_D/V_T 20% Cycle: Vf 15.7, $\dot{V}_E/\dot{V}O_2$ 27.41, V_D/V_T 27% Cardiac output, stroke volume, and HR were not significantly different between TCC and ergometry at the same $\dot{V}O_2$
Fontana, 2000[44]	Tai chi in slow and fast movements in sitting and standing	26 healthy adults Age 21-50 years Convenience sample Novice and experienced practitioners	METs: Sitting 1.5 ± 0 .2, Slow standing 2.3 ± 0.3, Fast standing 2.6 ± 0.5, Breathing exercises 3-3.6, 43%-49% predicted HR_{max}
Chao, 2002[45]	Tai-chi/qi-gong (54 motions divided into 3 sets)	47 adults Age 32-76 years Experienced practitioners (mean 3.6 ± 2.6 years)	50% $\dot{V}O_{2max}$ in older adults (≥65 years) 60% $\dot{V}O_{2max}$ in women Each motion ± 3 METs

$\dot{V}O_{2max}$, Maximum oxygen uptake (in L/min or mL/kg/min); $\dot{V}_E/\dot{V}O_2$, ventilatory equivalent for oxygen; *Vf,* ventilatory frequency in breaths per minute; V_D/V_T, ratio of dead space ventilation to tidal volume; *METs,* metabolic equivalents (1 MET = 3.5 mL of oxygen/kilogram/weight).

older individuals (79% women). In this RCT of 62 sedentary older adults (66.7 ± 5.2 years), subjects participated in 12 weeks of either aerobic exercise or tai chi. Baseline systolic blood pressure (BP) was 130 to 159 mm Hg. Subjects were not on antihypertensive medication, and results indicated similar statistically significant reductions in systolic BP occurred in both intervention groups. Of note, the aerobic exercise group demonstrated a significant increase in predicted $\dot{V}O_{2max}$, whereas the tai chi group did not. The authors concluded that both light- and moderate-intensity exercise programs can have an important effect on systolic blood pressure. Thornton and colleagues (2004)[54] found similar reductions in BP in normotensive sedentary women, ages 33 to 55 years. In contrast, Chen and colleagues (2006)[55] found no reduction in BP in older adult residents of long-term care facilities when they participated in a 6-month simplified tai chi program. Their program was customized for deconditioned subjects, and the authors concluded that the lack of significant changes in BP was due to the very low intensity of the exercise.

Yoga

Another popular mind/body intervention is yoga. The cardiovascular responses to several types of yoga in healthy children and adults have been investigated.[56-59] General conclusions are difficult to make, given the weaknesses of the studies and the different characteristics of the types of yoga studied. Table 27-2 lists cardiovascular and pulmonary responses before and after a single yoga session or a period of yoga practice. Overall it appears that those forms of yoga that primarily involve meditation show minimal changes in cardiovascular and pulmonary parameters when compared with those forms that include stimulation phases.

Other Mind/Body Therapies

Although social support is not typically considered a mind/body therapy, part of the success of many of the CAM interventions has been attributed to group interactions or those interactions between subject and practitioner. In a review of 81 studies, Uchino and colleagues (1996)[66] investigated the benefits of social support on the cardiovascular, endocrine, and immune systems. Social support includes individual, family, or group interactions. There is strong evidence correlating a decrease in cardiovascular reactivity in healthy individuals when social support is increased.

Manual Therapies/Body Work Therapies

There is a paucity of literature addressing cardiovascular and pulmonary responses to body work interventions in healthy individuals. One study of therapeutic massage demonstrated statistically significant reductions in cardiovascular parameters after a 3-day intervention of slow-stroke back massage on individuals in a rehabilitation setting.[67] Twenty-four adults (age range 52 to 88 years) underwent daily intervention. Statistically significant decreases in systolic and diastolic BP were noted each day; this was true for heart rate (HR) and respiratory rate (RR) only on days 1 and 3. Subjects also reported improved perception and less anxiety.

Cottingham and colleagues (1988b)[68] investigated the effects of the Rolf method of soft tissue mobilization on parasympathetic nervous system (PNS) tone in 32 young, healthy men. This RCT compared a group that performed 45 minutes of Rolfing with pelvic mobilization (pelvic lift) with a control group that received a 45-minute durational touch without Rolfing (pelvic lift intervention). At baseline all subjects had

Table 27-2 **Cardiovascular and Pulmonary Responses to Yoga Practices in Healthy Individuals**

Study Authors	Type of Yoga	Sample Characteristics and Methods	Cardiovascular and Pulmonary Responses
Telles, 1993[60]	Brahmakumaris Raja yoga meditation	18 males Age 20-52 years (34.1 ± 8.1) Experienced practitioners Subjects served as own control in sessions of random thinking	Yoga: HR increased compared with baseline and control Yoga and control: no difference in measures of autonomic function
Schell, 1994[61]	Hatha yoga	Experienced practitioners Control group volunteers	Yoga: HR decreased during practice compared with controls Yoga and control: no difference in BP or endocrine measures
Ray, 2001[62]	Hatha yoga	40 men Age 19-23 years $\dot{V}O_{2max}$ measured on cycle ergometer Both yoga and conventional physical exercise groups performed 1 hour of activity every morning for 6 months	Yoga: $\dot{V}O_{2max}$ increased from baseline; perception of exertion decreased from baseline Conventional physical exercise: $\dot{V}O_2$ increased from baseline; no change in perception of exertion (no information was given regarding differences between group outcomes)
Telles, 2000[63]	Cyclic meditation (calming and stimulating) Shavasana (calming)	40 male volunteers Age 27 ± 5.7 years Experienced practitioners Measurements taken before and after yoga session	CM: $\dot{V}O_2$ decreased 32.1%, RR rate decreased 18%, TV decreased 28.8% SH: $\dot{V}O_2$ decreased 10.1%, RR decreased 15.2%, TV decreased 15.9% Results were significantly different from baseline and decreases were significantly greater in CM than SH
Knowles, 2003[64]	Asanas (yoga poses) Pranayama (breathing exercises)	Single case study Age 42 years Healthy male Performed 6 days per week for 10 weeks 5 poses and 2 breathing exercises	Vital capacity: increased 9% Chest circumference measures: increased in all regions Chest flexibility measures: increased in forward bending
Haggins, 2007[65]	Hatha yoga	20 practitioners with <1 year yoga experience Age 31 ± 8.3 years 18 females 30 min sitting, 56 min beginner yoga, 10 min TM walking at 2-3 mph	Measurements taken at rest and after yoga, 2 mph TM and 3 mph TM Measures included $\dot{V}O_2$, HR, %MHR, METs, kcal/min Metabolic cost of yoga comparable to TM walking at 2 mph

$\dot{V}O_2$, Oxygen consumption (mL/min); *RR,* respiratory rate (breath rate); *TV,* tidal volume (breath volume), *CM,* cyclic meditation; *SH,* shavasana; *TM,* treadmill; *HR,* heart rate; *%MHR,* percent maximum heart rate.

an anterior pelvic tilt. PNS tone was measured before, immediately after, and 24 hours after intervention. Results demonstrated a significant increase in PNS tone and decreased standing pelvic tilt angle in the intervention group. Earlier, Cottingham and colleagues (1988a)[69] demonstrated an increase in PNS tone with the pelvic lift technique unrelated to the durational touch used simultaneously in the technique. The authors concluded that this intervention of soft tissue pelvic manipulation (i.e., durational touch plus pelvic lift) can help individuals with muscle dysfunction and conditions associated with reduced PNS activity and increased sympathetic nervous system activity. Reduced PNS and increased SNS can be representative of deconditioning.

In a small study of 12 children and adults, investigators attempted to examine the reliability of craniosacral intervention interpretation among three expert practitioners of craniosacral therapy.[70] They also investigated the relationship of the craniosacral rate to HR and BP of subject and practitioner. Results demonstrated no interrater reliability among the three practitioners. Results also demonstrated no relationship between HR and BP and the craniosacral rates. Although this study did not attempt to report on the effects of craniosacral therapy on cardiovascular parameters, the results do shed light on potential considerations for future study design.

Green and colleagues (2004)[71] conducted a rigorous review of the evidence for using craniosacral therapy. Nine of the 34 studies reviewed looked at whether movement of cranial bones was possible, and 10 of the 34 studies looked at whether cerebrospinal fluid moves rhythmically. The authors concluded that evidence supports the belief that there is a cranial "pulse" or rhythm that is separate from the cardiac or respiratory rhythms.

Energy Work Interventions

A few studies addressing the cardiovascular and pulmonary responses to energy work in healthy subjects have been conducted. Some of these are summarized in Table 27-3. In most cases, methodological weaknesses limit generalizations about the results. Studies of Reiki demonstrate trends toward increased relaxation and improved immune system markers.[74-76] In a study of qi-training, the authors provide a

Table 27-3 Cardiovascular and Pulmonary Responses to Energy Work in Healthy Individuals

Study Authors	Energy Work	Sample Characteristics and Methods	Cardiovascular and Pulmonary Responses
Hinman, 2002[72]	Magnets Negative polarity Positive polarity	Double-blind RCT 75 adults, 25 in each group Age 21-57 years Measurements at rest, 1, 5, 10, 15 minutes on magnet mattress and 5 min after exposure	BP and HR responses were not significantly different between positive polarity, negative polarity, and control groups
Martel, 2002[73]	Magnets	Prospective RCT 20 healthy men Age 25 ± 2 years Magnets worn for 30 min on 2 separate occasions Measurements at 10, 20, 30 min	Forearm blood flow responses were not significantly different from placebo
Wardell, 2001[74]	Reiki	Convenience sample 23 healthy subjects Age 29-55 years Treatment consisted of 30 min of Reiki by expert practitioner Measurements before, during, and after session	Pretreatment to posttreatment: significant decrease in anxiety, BP; trend to decrease in EMG (muscle tension) and salivary cortisol; significant increase in salivary IgA; trend to increase galvanic skin temperature, indicating relaxation
Wetzel, 1989[75]	Reiki	48 healthy individuals (plus 10 controls) Monitored over 24 hours	Pretreatment to posttreatment: significant improvement in hemoglobin and hematocrit
Olson, 2003[76]	Reiki	24 subjects with cancer pain Treated 1.5 hours with Reiki or 1.5 hours of rest for 4 consecutive days	Significant decrease in HR, DBP, on day 1 Significant decrease in pain on days 1 and 3 Trend to decrease in DBP on day 3 Significant increase in psychological quality of life from day 1 to day 7 No change in SBP or RR days 1-4
Lee, 2000[77]	Qi-training (3 stages): Sound 10 min Motion 10 min Meditation 10 min	12 healthy volunteers Age 19-37 years 1 hour per day, 6 times per week 1.3 ± 0.2 years of training	After 10 min: significant decrease in SBP and RPP, trend in decrease HR, RR After 60 min: significant decrease in HR, SBP, RR, and RPP from baseline

RCT, Randomized control trial; *DBP*, diastolic BP; *SBP*, systolic BP; *RPP*, rate-pressure product.

detailed description of the intervention facilitating replication of the study with a larger sample.[77] The two studies investigating responses to magnets demonstrate no significant differences from control.[72,73] Of interest, in a study investigating the safety of prosthetic mini-magnets in individuals with cardiac pacemakers, the authors found no electrocardiographic changes in 9 of 12 subjects. When the magnets were moved at least 1 cm away from the pacemaker implant, the changes in the other 3 subjects no longer existed.[78]

In a well-written and well-designed paper, investigators reported on the effects of acupuncture on autonomic nervous system (ANS) function.[79] Twelve healthy volunteers, six men and six women, ages 23 to 48 years, underwent randomized needle insertion into three distinct acupuncture sites. Measures of ANS function were monitored during the 25-minute intervention period and for the 60 minutes after intervention at each insertion site. An interesting combination of results was found, depending on the needle insertion site. Stimulation of the ear site resulted in increased PNS activity during both the needle insertion and the poststimulation periods. Stimulation of the skin over the left thenar muscle resulted in increased sympathetic nervous system (SNS) and PNS activity during both measurement periods. Stimulation of the right thenar muscle resulted in an increase in SNS and PNS activity during the poststimulation period, but no changes were seen during the needle insertion period. These results begin to shed light on which acupuncture interventions may be cardiosuppressive and possibly account for the calmness and relaxation often reported after treatment. Delayed responses may have a therapeutic effect as well.

In a controversial study by Rosa and colleagues (1998),[80] the investigators failed to demonstrate that those practitioners of noncontact therapeutic touch were able to perceive a "human energy field." Significant limitations to the study have been noted, including experimenter bias, inconsistent conclusions, and incomplete statistical analysis.[81] Although this study does not address cardiovascular and pulmonary responses to therapeutic touch, it does provoke discussion about the difficulties of conducting research on this intervention.

A study by Haas and colleagues (1986)[82] is worthy of mention in this discussion of energy interventions. These authors were able to demonstrate the ability of musical rhythm to "pace" respirations. In a sample of 20 healthy volunteers (half of whom were musically trained), breathing rhythms were correlated with metronome and tapping rhythms. This ability of musical rhythms to entrain respiration may have potential benefits in managing stress-induced respiratory patterns.

Risk Factors for Coronary Artery Disease

Numerous complementary therapies have been studied and shown efficacious in the management of known risk factors for coronary artery disease (CAD).[83-85] Specifically, interventions addressing psychological stress and hypertension have been extensively examined.

Stress Reduction

First studied in the late 1970s and early 1980s, the benefits of meditation and the "relaxation response" have been recognized by Benson and colleagues (1977).[86] They postulated that when properly applied, these interventions facilitated downregulation of the SNS and upregulation of the PNS.

During 15 to 30 minutes of practicing the relaxation response, changes in cardiovascular and pulmonary parameters have been noted. These include a decrease in RR and oxygen consumption ($\dot{V}O_2$) and an increase in cardiac output (CO) without a concurrent increase in BP, reflecting a reduction in peripheral vascular resistance. In addition, skilled practitioners of the relaxation response demonstrate a decrease in $\dot{V}O_2$ at a constant workload during treadmill activity.[87]

In an important paper addressing the impact of psychological factors on the development of cardiovascular disease, researchers related CAD to depression, anxiety, personality factors and character traits, social isolation, and chronic life stress.[88] Several authors have addressed behavioral interventions effective in the management of these psychosocial stresses.

In a comprehensive metaanalysis of 70 articles, the treatment of trait anxiety with transcendental meditation (TM), progressive relaxation, relaxation response, and electromyographic (EMG) biofeedback were reviewed. Sources for the reviewed articles included journals, dissertations, and books. All interventions had a positive effect on self-reports or physiological measures of anxiety. Transcendental meditation had the strongest effect of the four interventions studied. In general, subjects who received more frequent interventions initially and who were followed the longest received the most benefit. It was recommended that future studies measure performance outcomes and that subjects be closely followed in an attempt to reduce loss due to attrition.[89]

Miller and colleagues (1995)[90] reported on 22 subjects with anxiety disorders who participated in a noncontrolled clinical trial. Subjects were trained in mindfulness meditation, participated in a once-a-week group program for 8 weeks, and were followed-up for 3 years. Significant reductions in medications and counseling requirements were noted. The authors concluded that "mindfulness training … may be able to provide medical patients suffering from anxiety with a set of tools for achieving effective long-term non-pharmacological self-regulation … and be used as a complement to more conventional medical interventions."[90] Conversely, Astin (2003)[30] reported an increase in anxiety levels in 17% to 31% of subjects practicing relaxation interventions and an increase in anxiety levels in up to 53.8% of subjects practicing TM. No negative medical consequences were reported as a result of the increased anxiety levels. Several causes for this negative response were postulated, including subjects' fear of losing control, general restlessness, intrusive thoughts, and feelings of vulnerability.

Several small, noncontrolled clinical studies examining the effects of TM on blood levels related to cardiovascular disease have been reported. Infante and colleagues (2001)[91] measured plasma catecholamine levels (epinephrine, norepinephrine, and dopamine) in 19 skilled practitioners of TM. Resting values were compared with catecholamine levels in nonmatched controls. Results demonstrated lower values in the skilled practitioners when compared with the controls. The authors concluded TM may have been responsible for the lower catecholamine levels and consequent downregulation of the SNS. Similarly, Schneider and colleagues (1998)[92] concluded that TM may have been responsible for lower serum lipid peroxide levels found in 18 practitioners of TM compared with higher levels found in 23 nonmatched, nonpracticing control subjects. Lipid peroxide has been implicated in the pathophysiology of atherosclerosis.

Cognitive approaches to the reduction of stress have been subjected to clinical study. McCrone and colleagues (2001)[93] compared the effectiveness of psychoeducational interventions on 33 male subjects with risk factors for CAD. In addition to nutrition counseling and exercise training, educational sessions addressing cardiovascular disease, risk factors, and stress reduction were offered to 25 participants. These subjects were also trained to use specific skills to improve their responses to stress and were given audiotapes to practice progressive muscle relaxation. Eight subjects in the nonrandomized control group received weight management counseling and health education only and did not participate in any discussions related to stress management. All subjects, ranging in age from 57 to 79 years, participated in the interventions for 6 months. Although both groups showed improvements in risk factor profiles, improvement was greater in the group trained in stress management interventions. Significant improvements were noted in BP, lipid profile, obesity indices, and fitness level.

In spite of a positive theoretical basis for the use of CAM therapies in stress management, many interventions have not been subjected to systematic investigation. Table 27-4 summarizes the effects of tai chi, Feldenkrais method, yoga, and therapeutic massage in stress management. Although these four studies have significant methodological weaknesses, the number of subjects participating in each study is formidable. These initial attempts at providing efficacy of the respective intervention help suggest a launching ground for future study.

Hypertension

There is a significant body of literature that addresses the benefits of CAM interventions in the management of hypertension (HTN). The majority of the larger studies address mind/body interventions, with most demonstrating positive effects on BP. In 1999 the Canadian Hypertension Society and the Heart and Stroke Foundation of Canada published guidelines recommending "individualized cognitive behavior modification to reduce the negative effects of stress."[98]

Eisenberg and colleagues (1993)[99] performed a metaanalysis addressing the effectiveness of cognitive behavioral therapies on HTN. Interventions accepted in this review were biofeedback, meditation, the relaxation response, progressive relaxation techniques, and stress management interventions such as imagery. They collected more than 800 published papers; however, because of methodological problems in the majority

Table 27-4 **Effect of Selected CAM Therapies in Stress Management in Healthy Individuals**

Study Authors	CAM Therapy	Sample Characteristics and Methods	Outcomes
Jin, 1992[94]	Tai chi	48 male and 48 female Experienced practitioners Subjected to mental stress before intervention Randomized to 4 groups (tai chi, brisk walking, meditation, neutral reading) Measurements before and after intervention	Pretreatment to posttreatment: significant decrease in salivary cortisol levels; improved mood states; reduction in HR, BP, for tai chi were similar to walking at 6 km/h
Kolt, 2000[95]	Feldenkrais	54 volunteers College age Followed-up for 2 weeks Randomized to 3 groups Reduction maintained 1 day later (Feldenkrais, relaxation, or control) Measurements taken 4 times (baseline, before fourth session, after fourth session, 1 day after fourth session)	Feldenkrais and relaxation groups: significantly reduced anxiety scores in females after fourth session when compared with anxiety scores before fourth session and to controls
Hanley, 2003[96]	Therapeutic massage	69 subjects Randomized to 3 groups (6 sessions of therapeutic massage, 6 sessions of relaxation tape used in surgery, relaxation tape to use at home)	Pretreatment to posttreatment: significant improvements in sleep scale and index of well-being scores in all 3 groups; strong patient preference for therapeutic massage
Kalayil, 1989[97]	Yoga meditation and progressive relaxation	80 middle-grade students Randomly assigned to 4 groups (YM, PR, reading control, and catnap)	At baseline all 4 groups were similar in HR and state anxiety Results included: YM and PR decreased state anxiety, headaches, and general tension; YM decreased HR; catnap decreased headache when compared with reading control

YM, Yoga meditation; *PR*, progressive relaxation.

of papers, their limited inclusion criteria of adult subjects with diastolic BP of 90 to 114 mm Hg, lack of randomized control design, weak description of the study, and poor reporting of BP values, only 26 studies were entered for detail review. Results of this comprehensive analysis of 1264 patients indicated superior outcomes in the group receiving cognitive intervention techniques when compared with controls. No one intervention demonstrated more favorable outcomes than any other. In addition, when control groups were subjected to a placebo intervention (i.e., sham biofeedback), no significant differences in outcomes were noted. This is consistent with the belief that an intervention effect is inherent in the concept of placebo.[31]

In two RCTs of African American subjects, investigators examined the effects of stress reduction approaches on HTN. In one study, 111 males and females with mean BP of 147/92 mm Hg and mean age of 67 years were randomized to a 3-month trial of TM and progressive muscle relaxation (PMR) or a lifestyle modification education control program.[100] Results demonstrated that TM had a greater effect at lowering both systolic and diastolic BP than did PMR and that both intervention groups demonstrated a significantly greater impact on BP reduction than did the control group. In a small but well-designed study, Barnes and colleagues (2001)[101] recruited 34 African American adolescents (ages 15 to 18 years) with high-normal BP (>85th and <95th percentile for age and sex, respectively. After randomization, 17 subjects participated in 2 months of daily, 15-minutes sessions of TM. The control group attended seven weekly, 1-hour lessons on health education. Measures of cardiovascular function were collected at rest and during performance of a stressful activity (at baseline and again at the end of the intervention period). Although no significant changes were noted in resting values, results indicated that individuals in the TM group responded more favorably to stressor activities. Blood pressure increased appropriately during the activity in both groups; however, the degree of elevation was reduced in the TM group when compared with controls.

Reduction in antihypertensive medication requirements has been reported when mind/body therapies are added to the management regimen of HTN. In an RCT, Shapiro and colleagues (1997)[102] studied 39 individuals with medically treated HTN. Subjects trained in cognitive behavior therapies (i.e. PMR, biofeedback, deep diaphragmatic breathing, and imagery) showed a 73% reduction of BP medication requirements during the study follow-up period compared with a 35% reduction in the control group. In addition, 55% of subjects in the intervention group were completely free of medication compared with only 30% of subjects in the control group. The reduction in BP levels was consistent across clinical, ambulatory, and home settings.

Yucha and colleagues (2004)[103] reviewed 20 RCTs investigating the effects of biofeedback on HTN. Several forms of biofeedback, including thermal, EMG, and electrodermal, resulted in reductions in blood pressure when the intervention was combined with related cognitive therapy and relaxation training. When biofeedback was the sole intervention, significant reductions in BP were not demonstrated. Wang and colleagues (2004)[104] performed a systematic review of the effects of tai chi on chronic conditions, including HTN. They reported

on four moderate-sized studies: two randomized controlled trials and two nonrandomized controlled trials. Outcomes of all four studies indicated significant reduction in BP in older individuals and in those recovering from acute MI.

In addition to the mind/body therapies discussed above, several additional studies investigating the effects of select CAM therapies in individuals with HTN are summarized in Table 27-5. Although the evidence presented in these studies is weak, these investigations provide valuable insights to consider when structuring future research protocols. Several review articles addressing effects of other interventions are summarized in Table 27-6. In general, the results of these investigations assist in providing evidence for the benefit of the intervention in the management of HTN. In one review, Levin and Vanderpool (1989)[110] consider the beneficial effects of religious commitment and affiliation in the management of HTN. Possible explanations offered for lower blood pressure in individuals with HTN include the psychosocial effects of membership in an organized religious community, the inherent health promotion behaviors and preferences often supported by religious traditions, and the psychodynamics of religious rites, faith, and belief systems.

In the review articles of the effects of qi gong in HTN, authors acknowledge significant methodological weaknesses in many of the studies reviewed.[111,112] Some of the reported weaknesses include selection biases, lack of randomization, noncompliance with the intervention, concerns regarding BP measurement reliability, and the differences among the many styles of qi gong , which were not typically considered. Two review articles on the effects of tai chi on HTN are included in Table 27-6. Significant improvement in BP was reported in the eight studies reviewed by Yeh and colleagues (2008).[113] Lee and colleagues (2010)[114] found conflicting results in their review; they attributed their inconsistent outcomes to inadequate baseline BP testing in all four of the studies reviewed (one study was common to both of these reviews). Finally, Kim and colleagues (2010)[115] presented a thorough review of 20 articles on the effects of acupuncture on HTN. They acknowledged that 17 of the 20 studies were poor quality and concluded that further "rigorously designed studies" are needed.[115] Of note, no significant adverse reactions were documented in any of the tai chi or acupuncture articles reviewed.

Cardiovascular Conditions

Much of the pathophysiological basis for applying CAM therapies to cardiovascular conditions rests in the relationship between the cardiovascular system and the ANS.[116] Stimulation of the ANS, specifically the SNS, can cause both an increase in circulating levels of catecholamines and damage to endothelial cells lining arterial walls. Often triggered by psychological factors, the resulting increase in metabolic and myocardial oxygen demand has a negative impact on the oxygen transport system.[88] Interventions that can reduce or reverse these responses to SNS stimulation have a potential positive effect on cardiovascular conditions. Recently, a

Table 27-5 Effect of Selected CAM Therapies in the Management of HTN

Study Authors	CAM Therapy	Sample Characteristics and Methods	Outcomes
Paran, 1996[105]	Biofeedback	38 patients (15 white-coat HTN; 23 essential HTN) Random assignment Biofeedback given 1 time per week for 4 weeks	Pretreatment to posttreatment: both groups had statistically significant reductions in BP in the clinic; white-coat HTN had significantly lower SBP and DBP at home than essential HTN
Patel, 1975[106]	Yoga (and biofeedback), "psychophysical relaxation exercise"	40 patients with HTN Followed-up for 9-12 months 20 received intervention; 20 remained as controls	Statistically significant reductions in BP and anti-HTN medication requirements in intervention group
Brownstein, 1989[107]	Yoga relaxation	Case report Age 46 years Male History of mild essential HTN 6-week program	Discontinuation of anti-HTN medications; normalization of DBP; return to full flight status (aviator in U.S. Air Force)
Zucker, 1997[108]	Qi gong (breathing, meditation, movement)	22 patients with HTN (15 in intervention group, 7 control) Intervention classes 2 times per week for 8 weeks	Pretreatment to posttreatment: significant decreases in SBP, DBP, MAP, RR in intervention group; significant increases in QOL in intervention group
McCraty 2003[109]	Stress reduction (Inner Quality Management) Biofeedback	32 information technology employees with HTN Mean age 46, 9 females; Intervention (I): three sessions totaling 16 hours over 2 weeks followed by home program with optional review session at 2 months and follow-up measures at 3 months	Both control (C) and I reduced BP; reduction in I was significantly greater than C; 3 in I were able to reduce or terminate BP medications Compared with C, I showed significant increase in well-being and work satisfaction, and decrease in stress symptoms, depression, phobic anxiety Reduced BP was correlated with reduced stress symptoms

MAP, Mean arterial blood pressure; *QOL*, quality of life.

Table 27-6 Select CAM Therapies and their Effects on HTN: Summary of Review Papers

Study Authors	CAM Therapy	Number of Articles Reviewed	Outcome Variables	Outcome
Levin, 1989[110]	Religion*: RC, RA	20	SBP, DPB, HTN, heart disease mortality, HTN-related mortality, history of HTN	RC: 19 studies demonstrate intervention is associated with lower BP or lower rates of HTN; 5 studies demonstrate protective effects of intervention RA: significantly lower rates of HTN-related morbidity and mortality in highly devout, behaviorally strict groups (e.g., Mormons, Buddhists, Seventh-Day Adventists, clergy)
Sancier, 1999[111]; Mayer, 1999[112]	Qi gong	30	BP, measures of blood flow, CHF, acute MI, stroke, total mortality rate	Decreased stroke and mortality; decreased anti-HTN medication requirements
Yeh 2008[113]	Tai chi	8	SBP, DBP, compliance, medications	Tai chi groups demonstrated significant reductions in BP, higher compliance with home program, and more effective BP control
Lee 2010[114]	Tai chi, >60 years old	4	BP	Two reviews reported significant reduction in BP in tai chi group when compared with control or wellness education program Two reviews reported no reduction in BP compared with resistance training, usual activity or aerobic exercise
Kim 2010[115]	Acupuncture, traditional meridian needle insertion points	20	BP	Significant reductions in BP in both high- and low-quality studies; duration of reduction in BP was variable amongst studies; magnitude of BP reduction was greater when acupuncture, rather than sham treatment, was used in conjunction with anti-HTN medications

RC, Religious commitment; *RA*, religious affiliation.

*Measures of religion include religious attendance, church membership, religious affiliation, ethnic traditions within Judaism, monastic orders, clergy status, religious education, and subjective religiosity.

number of authors have looked at the impact of various CAM interventions on heart rate variability (HRV).[117-121] The variability in R-R intervals between normal sinus rhythm cardiac cycles reflects the balance of SNS and PNS cardiac control. Low HRV has been associated with disease, whereas high HRV tends to indicate cardiovascular health and improved prognosis. In addition, *patterns* of HRV appear to reflect alterations in emotions and have been used to further demonstrate cardiovascular physiological responses to CAM interventions.[122]

Coronary Artery Disease

Beneficial effects of CAM interventions in the use of CAD management are documented throughout the published literature.[29,30,32,123-125] Although significant methodological problems are apparent in many papers, numerous large, well-designed studies can be found. Much of the evidence supporting the use of these interventions in individuals with CAD demonstrates improvement in exercise tolerance, reduction of ischemia, and reduction of anxiety and depression. Mind/body techniques, including cognitive behavioral interventions, yoga, tai chi, guided imagery, and music therapy, have been successfully used in patients with CAD. The benefits of energy work, including distant healing prayer and qi gong, in patients with CAD have been reported.

In 1959, Friedman and Rosenman[126] first documented the relationship between certain emotional behaviors and the prevalence of CAD.[127] They defined the type A behavior pattern as "an emotional syndrome characterized by a continuously harrying sense of time urgency and easily aroused free-floating hostility."[127] In subsequent decades, the study of interventions aimed at modifying the behavior of individuals with type A behavior pattern and CAD was undertaken.

In a large study of post-myocardial infarction (MI) patients with type A behavior, 1013 subjects were randomized into three groups.[127] Of the total, 270 subjects received group cardiac counseling, 592 subjects received both cardiac counseling and type A behavioral counseling, and the remaining 151 individuals did not receive any counseling. Subjects were followed for 4½ years to determine the impact of type A behavior counseling on recurrent coronary events (both nonfatal infarctions and cardiac deaths). Cardiac counseling sessions consisted of 90-minute group meetings during which diet, exercise, medications, cardiovascular pathophysiology, and possible surgical procedures were discussed. Type A behavioral counseling sessions included progressive muscle

relaxation, as well as specific psychotherapeutic interventions. Results indicated statistically significant reductions in recurrence rates of cardiac events in both intervention groups, with a greater reduction in the rate of recurrent events in those subjects who received both forms of counseling.

In a landmark study of 48 patients with known CAD, Ornish and colleagues (1990)[11] analyzed the number of coronary artery lesions detected at angiography before and after a year-long lifestyle intervention. In addition to a low-fat vegetarian diet, smoking cessation, and a moderate exercise program, subjects participated in a stress management training program of guided imagery. At the end of the year, the 28 subjects in the intervention group demonstrated statistically significant fewer coronary lesions than the 20 subjects in the usual-care control group. The regression in coronary atherosclerosis was attributed to the comprehensive lifestyle changes, brought about without the assistance of lipid-lowering medications. Clinical reports of angina were reduced as well.

Upon recognition of the impact of emotions on the recurrence rate of cardiac events in individuals with CAD, behavioral interventions became routine therapies in cardiac care.[33] Dusseldorp and colleagues (1999)[128] published a metaanalysis of the results of 37 studies investigating the effects of psychoeducational programs on patients with known CAD. All studies were conducted between 1974 and 1997 and were categorized according to stress management (SM) and health education (HE) interventions. Interventions used included various combinations of education, cognitive-behavioral therapies, relaxation, imaging, and emotional support. A number of studies included SM and HE interventions in combination with standard exercise training programs typically found in traditional cardiac rehabilitation programs. Results from studies administering either SM or HE intervention suggested a 34% reduction in fatal cardiac events and a 29% reduction in recurrent MI. The authors concluded that although psychoeducational therapies should be encouraged in cardiac rehabilitation programs, future research focusing on specific SM or HE interventions is warranted. In another metaanalysis addressing the effects of psychosocial interventions in subjects with CAD, Linden and colleagues (1996)[129] reviewed 23 studies of 2024 patients and 1156 control subjects. In addition to the typical education component of cardiac rehabilitation programs, almost half of the studies included in this analysis involved some form of CAM treatment as an intervention. These included relaxation, breathing relaxation, and music therapy. Just as in the aforementioned metaanalysis, the benefits of adding a psychosocial component to these cardiac rehabilitation programs significantly reduced morbidity and mortality and psychological distress.

In 2000, in a scientific statement presented by the American Heart Association and the American Association of Cardiovascular and Pulmonary Rehabilitation, psychosocial management was identified as a "core component of cardiac rehabilitation/secondary prevention programs."[130] Suggested interventions included "individual and/or small group education and counseling regarding adjustment to coronary heart disease, stress management, and health-related lifestyle change … supportive rehabilitation environment and community resources to enhance patient's and family's level of social support."[130]

The relationship between mental stress and myocardial ischemia in men with CAD has been well studied. Investigators have found an increased likelihood of having mental–stress-induced ischemia in individuals who experience daily life ischemia.[131] Individuals with chronic anxiety and depression also exhibit more episodes of myocardial ischemia than those without documented anxiety and depression.[132] In a 5-year, nonrandomized controlled study of 94 men with documented mental–stress-induced ischemia, researchers reported on the usefulness of a stress management program.[133,134] In addition to educational classes, the intervention group received instruction aimed at reducing the physiological effects of stress. This included instruction in progressive muscle relaxation and individual sessions of EMG biofeedback. Outcomes of recurrent cardiac events were significantly reduced in the stress management group when compared with the control group at 1-, 2-, and 5-year follow-up. Overall reductions in hostility and clinical depression were also reported as statistically and clinically significant. The 5-year financial burden, including hospitalization and physician costs, was also significantly less in the stress management group. Similar results were reported by Zamarra and colleagues (1996)[135] in a small, nonrandomized controlled study of the effects of an 8-month trial of TM. At follow-up bicycle exercise testing, participants demonstrated increases in exercise duration and maximal workload achieved and a delay in the onset of ST depression. In an early paper, Benson and colleagues (1975)[136] reported on the beneficial effects of the relaxation response in reducing the number of premature ventricular contractions (PVC) in individuals with stable CAD. Subjects in this report practiced the relaxation response for 20 minutes, twice a day. Frequency of PVCs was documented by Holter monitor at baseline and again after 4 weeks.

In a thorough review Villagomeza (2006)[137] explored the impact of spirituality in patients with heart disease. Twenty-six studies were discussed and included patients with acute MI, coronary artery bypass graft surgery, congestive heart failure, and heart transplant. Definitions of spirituality were listed for all articles reviewed. Most studies were descriptive or observational, and most measurement instruments were interview- and questionnaire-based; several studies used physiological and performance-based measurements. The author did not focus any conclusions on the effects of "spirituality" on heart disease but rather addressed a framework from which spirituality could be more easily studied. Irrespective of the definition of spirituality used in the 26 reviewed papers, the impact on outcomes appeared favorable.

Several studies have demonstrated no or limited improvements in cardiovascular outcomes with the intervention of specific behavioral therapies. In a large (n = 2328) RCT of early post-MI intervention, investigators reported limited benefit of psychological counseling.[138] In this 2-year follow-up study, patients with acute MI returned within 28 days of the acute event to participate in 7 weeks of outpatient counseling, including PMR and skills to reduce stress. Subjects in the intervention group experienced significantly fewer episodes of angina; however, mortality, clinical complications, and clinical sequelae of CAD did not differ between groups. The authors concluded that the intervention was conducted too soon after the cardiac event, possibly accounting for the reduced treatment effect. In a study of patients participating in a phase II cardiac rehabilitation program, progressive muscle relaxation and guided imagery interventions failed to result in beneficial outcomes.[139] Although there were methodological limitations

Table 27-7 Effect of Selected Mind/Body Therapies in CAD

Study Authors	MBT Therapy	Sample Characteristics and Methods	Outcomes
Manchanda, 2000[140]	Yoga	Prospective RCCT 42 men with CAD 2 groups Intervention: yoga, RF control, diet control, moderate exercise Control: RF control, AHA step 1 diet control	Yoga group: (compared with controls) significant decrease in number of anginal episodes per week; improved exercise capacity; decreased body weight, total cholesterol, LDL cholesterol, triglycerides; fewer revascularization procedures; more lesion regression and less lesion progression (angiographic findings); improved functional class, symptomatic status, and RF profile
Friedlander, 1986[141]	Religion (Orthodox Jewish)	Had first MI: 454 men (51% secular) 85 women (50% secular) Healthy, no CAD: 295 men (21% secular) 391 women (16% secular)	Higher risk for first MI if: older, smoker, less education; European born; secular, men and women; results persisted 2-3 months after acute event
Strawbridge, 1997[142]	Religion	5286 survey respondents Followed-up for 28 years Analyzed for association between attendance at religious services and mortality	Frequent attenders compared with infrequent attenders: lower mortality rates; results were stronger for females; improved health practices (stop smoking, increase exercising, increase social contacts, stay married)
Chang, 2010[143]	Tai Chi	54 patients with CAD; 22 did 90 min tai chi 1x/week for 6 months 32 patients usual care Modified Bruce TM at baseline and 6 months	Improved RPP and RPP reserve in tai chi group compared with usual care
Park, 2010[144]	Tai Chi	85 adults with CAD (50 males); 53-75 years (mean 66 years); measures at baseline and 6 months 33 received tai chi (1x/week for 60 min) and education nutrition (1 hr /month) stress management (1 hr/month) 19 received tai chi only 33 received usual care	Tai chi is safe for population Tai chi with education significantly improved cardiovascular risk factors (BP, lipids), QOL, BMI when compared with tai chi–only group

MBT, Mind/body therapy; *RCCT*, randomized control clinical trial; *RF*, risk factors; *AHA*, American Heart Association; TM, treadmill; *RPP*, rate-pressure product; *QOL*, quality of life; *BMI*, body mass index.

in this paper, the authors similarly concluded the timing of the interventions may have contributed to the absence of benefit.

Results of the effects of selected mind/body therapies in CAD are summarized in Table 27-7. Manchanda and colleagues (2000)[140] investigated the effects of yoga on numerous cardiovascular measures. Although improved outcomes were documented in the intervention group when compared with controls, the demonstrated benefits may be due to the moderate exercise component of the intervention and not necessarily the yoga component.

Tai chi practice has been recommended as a therapeutic intervention in balance disorders and fall prevention in older adults.[25,145,146] Its potential benefits as replacement for or as an adjunct therapy in cardiac rehabilitation programs have been suggested as well.[143,144,147] In an interesting commentary in 1992, Ng stated that tai chi "has many similarities with … walking exercise—the most recommended aerobic exercise for coronary artery disease."[148] Further clinical study is warranted to provide evidence of the benefit of tai chi in the population with CAD.

Two papers addressed the use of several mind/body and manual therapies to assist with anxiety reduction in patients undergoing cardiac catheterization. McCaffrey and colleagues (2005)[149] reported on the use of music therapy, massage, guided imagery, and therapeutic touch. These interventions were performed within the hour before the diagnostic procedure. Outcomes demonstrated reduction in BP, HR, and worry, along with improved mood, in the intervention group when compared with the control group. In another study, using a visual analogue scale, authors demonstrated that "PalmTherapy" was effective in reducing anxiety levels before the procedure. PalmTherapy is an intervention that uses continuous pressure on various points in the hand.[150]

There is minimal evidence available investigating the effects of energy work on patients with CAD. Several studies compared acupuncture to sham acupuncture in individuals with angina.[151] Although no significant differences were noted in the number of anginal episodes or nitroglycerin use, the use of sham acupuncture has been questioned. As noted earlier, not all practitioners agree on proper needle location; hence what one practitioner thinks is an active acupuncture site may

be considered a sham site to another practitioner. An interesting review of the effects of acupuncture on cardiac dysrhythmias was recently published.[152] The authors considered the ineffectiveness of antiarrhythmic drugs in managing certain dysrhythmias and aimed to examine the impact of acupuncture on reducing these abnormal cardiac rhythms. They reported on eight studies; seven were case studies or case series, and one was a randomized controlled trial. A total of 150 subjects participated in the eight studies, and the mean age was 54 years. Male and female participants were included, and dysrhythmias, although diverse, were primarily supraventricular tachycardia, sinus bradycardia, and ventricular extrasystoles. All participants received antiarrhythmic medications in addition to acupuncture. Treatments ranged between 1 day and 6 months, and between 1 and 50 sessions; each session lasted an average of 20 minutes. The primary outcome measured in all studies was the frequency of dysrhythmia presentation or conversion to normal sinus rhythm. Between 87% and 100% of participants demonstrated improvement; no dropouts or adverse effects were reported. There were significant methodological weaknesses in many of the studies, which led the authors to conclude that future large, rigorous trials are warranted.

Another role for CAM therapies that address stress reduction in patients with CAD is based on the relationship between chronic stress and reduced immune system function. Individuals with depressed immune systems are more vulnerable to inflammatory processes, the latter recently implicated in CAD.[153-155]

Cardiac Surgery

The Complementary Care Center (CCC) at Columbia-Presbyterian Medical Center is a "multifaceted program dedicated to evaluating and researching the effects of new modalities in health care."[156] Since 1995, practitioners at this center have been evaluating and researching the effects of various types of CAM therapies. One area of intervention involves patients having cardiac surgery. Upon initial evaluation, these patients are offered several options to help with recovery and healing. Some of these modalities include meditation, music therapy, yoga, massage, and therapeutic touch. Audiotapes can be used at various times in the perioperative period, including 5 to 10 days preoperatively, intraoperatively, immediately postoperatively, and during the recuperation phase. Therapeutic touch has been offered on the day of surgery and on postoperative days 2 and 3. Group yoga classes are offered to those patients who are medically stable as early as the third postoperative day. In addition, patients are encouraged to contact a religious leader of their choice. Continuation of these therapies is offered to the patient after hospital discharge. Patients can choose to attend sessions at the center or at a more convenient site.

The innovative approach used at the CCC resonates with the philosophy of increasing the patient's participation in his or her health and healing. Liu and colleagues (2000)[157] have reported on the use of CAM therapies in 376 consecutive patients undergoing cardiac surgery. Patients were surveyed before surgery, and 75% reported using CAM therapies. When prayer and vitamins were excluded, 44% reported using CAM therapies. Seventy-two percent of subjects were male, 76% were white, and 59% were well educated. No differences in overall CAM use were found among sex, age, race, or education level. The authors did offer an important recommendation. They noted that only 17% of patients had discussed their use of CAM therapies with their physicians, and 48% of patients did not want to discuss the topic at all. Since the frequency of CAM use found in this sample was consistent with the frequency of CAM use reported in the general population, the authors reinforced the importance of questioning patients about their use of CAM therapies.[158]

Evidence supporting the use of selected CAM therapies perioperatively is found in Table 27-8. Although methods were not always comprehensive in these studies, all demonstrated improvement in cardiovascular outcomes. In the study by Barnason and colleagues (1995)[160] the authors concluded that effects of the music therapy on outcomes were consistent with a relaxation response, and in the study by Garbossa (2009),[162] authors concluded that education and instruction in hospital routine significantly reduced preoperative anxiety when compared with control subjects.

In another small but clinically important study, Miller and Perry (1990)[163] examined the benefit of a deep-breathing relaxation technique on pain tolerance in patients undergoing cardiac surgery. On the evening before surgery, 15 subjects were taught a slow, rhythmic, deep-breathing relaxation technique in addition to traditional preoperative instruction. The remaining 14 subjects only received the traditional preoperative instruction. All subjects were visited by the investigators on the day of surgery and on postoperative day 1 for conversation; however, only subjects in the intervention group were encouraged to perform the relaxation technique. Patients in the relaxation group had significant decreases in systolic and diastolic BP, HR, RR, and self-report of pain (on visual descriptor scale) when compared with controls. The authors concluded that "relaxation techniques may interrupt the pain-anxiety cycle" and that, although there were methodological problems with their study, this "may be an effective nonnarcotic, noninvasive pain-relieving modality after" cardiac surgery. Additional study of the relaxation response has demonstrated a reduction in postoperative arrhythmias, as well as reduced tension and anger in patients undergoing cardiac surgery.[32]

Congestive Heart Failure

There are a limited number of published investigations on the effects of CAM therapies in patients with congestive heart failure (CHF). Results of several papers are summarized in Table 27-9. It is of interest that two of these papers used several interventions to achieve improved outcomes. This may be of value, given the multiplicity of systems affected in CHF. Unfortunately, the degree of ventricular impairment was not documented in these studies. In addition, care must be taken when interpreting results of single case studies of patients with cardiac disease. The placebo effect evoked by the investigator's enthusiasm and expectation of success has been well studied in this population.[169,170] Symptomatic and objective improvements have been documented in angina outcomes related to pharmacological interventions and after sham cardiac surgical procedures.

Two studies listed in Table 27-9 discuss the impact of tai chi on patients with CHF.[167,168] The authors of both studies concluded that tai chi is a safe and effective adjunct in the usual

Table 27-8 Effects of Selected CAM Therapies on Outcomes of Cardiovascular Surgery

Study Authors	CAM Therapy	Sample Characteristics and Method	Outcome
Lan, 1999[159]	Tai chi	Prospective, 1-year program, 20 patients >3 months since CABG Age 53-64 years All males Tai chi group: 20 min w/up, 24 min tai chi, 10 min c/d; daily program Control group: walking program 10 min w/up, 30 min walking, 10 min c/d; 3 times per week $\dot{V}O_{2max}$ measured on cycle ergometer	Tai chi: increased $\dot{V}O_{2max}$; increased compliance with attendance
Barnason, 1995[160]	Music therapy	Prospective, random, repeated measures 96 subjects underwent elective CABG Age 37-84 years 65% male Three groups (music therapy, music-video therapy, rest group) 30-minute intervention on postoperative days 2 and 3 (inpatient)	Music therapy: improved mood; decreased heart rate; decreased SBP or DBP
Oxman, 1995[161]	Social support Religion	232 patients 21 deaths within 6 months of elective open heart surgery	Predictors of mortality: history of previous cardiac surgery; greater impairment in presurgery ADL; older age; lack of participation in social or community groups; absence of strength and comfort from religion
Garbossa, 2009[162]	Cognitive	51 patients undergoing CABG were randomized; 24 educated on CABG procedure preoperatively regarding what to expect; 27 received usual care	Preoperative anxiety was reduced in educated group compared with usual care No effect on length of stay in hospital

CABG, Coronary artery bypass graft surgery; *w/up*, warm-up; *c/d*, cool down; *ADL,* activities of daily living.

management of patients with CHF. Authors suggest large randomized controlled trials are warranted for this population. Finally, a pilot study involving the impact of "HeartMath" on patients with CHF was reported.[117] HeartMath includes a psychoeducational intervention that addresses "positive emotion refocusing and emotional restructuring."[109] Authors acknowledged that this intervention warrants further exploration; however, they concluded that improvements in emotional well-being carry over to improvements in functional capacity in patients with CHF.

Patients in the Coronary Care Unit

In two interesting, detailed, and well-designed studies, investigators examined the effects of intercessory prayer (praying for others) on outcomes of patients admitted to a coronary care unit.[171,172] With only slight differences in design, Harris and colleagues attempted to replicate the results that Byrd demonstrated a decade earlier. Both studies were large, randomized, controlled, blinded trials (Byrd with 393 subjects, Harris with 990 subjects). Patients were admitted to the coronary care unit (CCU) with a wide variety of diagnoses in both studies. In addition to common cardiac diagnoses, patients had conditions such as pneumonia, chronic obstructive lung disease, diabetes mellitus, renal failure, sepsis, liver disease, and gastrointestinal bleeding. Patients were monitored for new problems, new diagnoses, and new therapeutic interventions that occurred after hospital admission through discharge. This information contributed to the scoring systems used by investigators to determine distinctions between recovery rates and severity of complications during hospitalization. Intercessors in the Byrd study were "born again" Christian individuals, while intercessors in the Harris study represented a variety of Christian traditions, including 35% nondenominational, 27% Episcopalian, and Protestant or Roman Catholic observers. In the original study, Byrd assigned three to seven intercessors to each patient in the intervention group. Intercessors were asked to pray daily (until hospital discharge) for the individual's rapid recovery and prevention of complications, as well as contribute other prayers they believed would be beneficial to the patient. They were provided the patient's first name, diagnosis, general condition, and pertinent updated information. Harris and colleagues randomly assigned a five-member team to pray for each patient. Intercessors were not given any information about the patient. They were asked to pray daily for 28 days for a "speedy recovery with no complications" and anything else the intercessor believed appropriate. Results from both studies demonstrated statistically significant better outcomes in patients who were prayed for when compared with those not prayed for. Although in both studies the length of hospital stay was not significantly different between control and intervention groups, the CCU course severity scores were significantly different between control and intervention groups. Control subjects in the Byrd study required more frequent ventilatory assistance, antibiotics, and diuretics than subjects in the intervention group. Control subjects in the study by Harris and colleagues received higher scores on a scale quantifying severity of clinical outcomes from excellent to catastrophic than did subjects in the intervention group.

Table 27-9 Effects of Selected CAM Therapies in CHF

Study Authors	CAM Therapy	Sample Method and Characteristics	Outcome
Moser, 1997[164]	Skin-temperature biofeedback Relaxation Guided imagery	40 patients with advanced CHF Randomized to intervention (BFR) or control (C) BFR included 1 session of skin-temperature biofeedback, guided imagery of hand warmth, and progressive muscle relaxation C group underwent measurement session but no intervention	Baseline: comparable measurements between groups When comparing BFR with C, BFR showed: increased skin temperature in finger and foot; increased cardiac output; decreased systemic vascular resistance; decreased RR No changes in oxygen consumption or catecholamines were found in either group
Bernardi, 1998[165]	Complete yoga breathing	15 patients with CHF; 11 healthy volunteer controls (C) CHF patients were randomized to intervention (YB) or rest (R) YB included reduction of RR through controlled breathing (CB) and altered breathing pattern within each breath to include diaphragm, lower chest, then upper chest in inspiration and expiration, 1 hour per day for 1 month Measurements at baseline, end of 1 month and 1 month after completion Maximum symptom-limited cycle ergometer exercise test	Baseline: Sa_{O_2} was lower during spontaneous breathing (SB) in CHF compared with C; Sa_{O_2} instability was higher during SB in CHF compared with C At 1 month: Sa_{O_2} decreased during SB in YB compared with R, and approximated C during CB R results compared with YB: decreased sensation of dyspnea; decreased SB rate 13.4 ± 1.5 to 7.6 ± 1.9 bpm; Sa_{O_2} (%) increased 92.5 ± 0.3 to 93.2 ± 0.4; $\dot{V}o_{2max}$ increased 13.9 to 15.9 ± 0.8; maximum cycle workload increased 92 ± 6 to 100 ± 4 watts
Shinnick, 2002[166]	Meditation Acupuncture Qi gong	Case report 97-year-old terminally ill male Utilized interventions PRN	Qi gong used to increase body temperature Acupuncture to help sleep and improve appetite Meditation increased peacefulness, lucidity, and ability to control breathing
Luskin 2002[117]	Psychoeducational biofeedback (HeartMath, HM)	Pilot study; 33 patients, NYHA Class 1-3; mean age 66 years 8-week intervention (HM) or control (C) HM received 10 hours training over 10 weeks and home program ≥5x/day	When compared with C, HM decreased 22% perceived stress (C increased 7%) and decreased 34% depression (C increased 13%); HM significantly improved mental health and vitality on SF 36; HM increased 14% on 6 MWT (C decreased 2%)
Yeh G 2004[167]	Tai Chi	30 patients; NHYA Class 1-4; EF <40% (mean 23% ± 7%); mean age 64; 19 males Tai chi (TC) group received 1 hour tai chi 2x/week and usual care for 12 weeks, control (C) group received usual care Measurements were taken at baseline and at 12 weeks	Compared with C, TC group improved QOL, increased distance on 6MWT, decreased serum BNP; there was a trend to increase $\dot{V}o_{2peak}$
Barrow 2007[168]	Tai Chi Chuan and Chi Kung	52 patients; NYHA 2-3; mean age 68.9; 42 males Patients were randomized to receive 55 minutes of tai chi (TC) 2x/week or standard care (C), for 16 weeks	No difference was found in the Incremental Shuttle Walk Test between groups; significant improvement was found in TC group in symptom scores and reduction in depression scores

Sa_{O_2}, Oxygen saturation; *bpm*, breaths per minute; *PRN*, whenever needed; *6MWT*, 6 minute walk test; *$\dot{V}o_{2peak}$*, peak oxygen uptake; *QOL*, quality of life; *BNP*, brain naturietic peptide

The basis of this therapeutic effect of distance healing remained unexplained by the authors. The outcomes provided by these two randomized controlled clinical trials, however, warrant continued exploration into the possible benefits of intercessory prayer in medical outcomes. McCullough and colleagues (2000)[173] reported data from 42 publications in a metaanalysis examining the association of religious involvement to all-cause mortality. Their results resonate with those of the Byrd and Harris studies, and they concluded, from sampling more than 126,000 participants, that religious involvement was significantly associated with lower mortality rates. Similarly, they recommend that "elucidating the nature of this robust but poorly understood association could be a fruitful topic for future research at the interface of psychology and health."[173]

Music has been used as a method to induce relaxation in patients in the CCU. Bolwerk (1990)[174] presented 17 patients (11 males) with music therapy within the first 48 hours of CCU admission after experiencing an acute MI. Eighteen control patients (16 males) were given usual care. Anxiety levels were monitored in both groups within 48 hours of hospital admission and again 3 days later. Both groups were similar at baseline. Those patients in the intervention group received 3 consecutive days of 22 minutes of "relaxing, calming" music. At repeat testing, significantly greater reductions in anxiety scores were found in those individuals who

received music therapy compared with the control group. Although there were significant limitations in the design of the study, the authors concluded that the repetitive nature of music can reduce anxiety in patients experiencing an acute MI.

Pulmonary Conditions

The basis for using CAM therapies in the management of individuals with cardiovascular and pulmonary disease is twofold. In addition to focusing treatment goals on the reduction of SNS stimulation and metabolic demands, CAM therapies also alter the mechanics of the musculoskeletal pump of the thorax. As addressed earlier in Part III of this book, improvements in thoracic mobility and movement efficiency contribute to reduced metabolic demands and improved oxygen transport.

Asthma

Numerous factors have been implicated as causative agents of asthma. In addition to respiratory infection and allergens, emotional stress has been identified as a trigger. Generalized panic symptoms have been found to be both a cause of asthma as well as a response to an exacerbation of asthma. Panic and anxiety states correlate with hyperventilation, a symptom closely related to a hyperactive respiratory drive. A heightened respiratory drive is not always favorable in individuals with known asthma because it can further challenge airways that are already bronchoconstricted.[81] Hyperventilation itself may exacerbate asthma because the rapid movement of cooler and dryer air into the airways can trigger further bronchoconstriction.

Repressive coping styles have also been associated with asthma morbidity.[81] Individuals with this behavior pattern typically ignore their symptoms, including dyspnea, and fail to seek timely health care. These individuals tend to have relatively high levels of endogenous opioids, neurochemicals that can depress unpleasant sensations. Consequently, these substances may limit an individual's ability to recognize early signs of bronchoconstriction. Additional evidence suggests that reduced immune system responsiveness in the setting of chronic emotional stress heightens inflammatory and infective processes, both of which are implicated in asthma exacerbation.

Numerous CAM therapies have been studied in attempts to reverse a number of these factors associated with asthma morbidity. Many of these studies have methodological shortcomings; however, several are well designed and provide insights into possible mechanisms of intervention efficacy. It is reported that between 4% and 79% of adults with asthma and between 33% and 89% of children with asthma use CAM therapies as part of their disease management regimen.[175] Relaxation therapy has been widely investigated; however, the results are inconsistent.[176,177] In a metaanalysis of six studies on the effects of relaxation training in children with emotionally triggered asthma, McQuaid and Nassau (1999)[178] concluded that "relaxation training is probably a most efficacious intervention" in this population. They noted concern regarding methods used in the articles reviewed and noted that only three of the studies reviewed in this analysis used appropriate controls, and only one examined maintenance of posttreatment effect. Although statistical significance was achieved in these investigations, the reduction of symptoms was less than 10% of baseline values, leading the authors to believe that the changes would not be clinically significant. Lehrer (1998)[81] also concluded that relaxation therapy may only be effective with specific asthma patients. His results indicate significant improvement in asthma exacerbation in individuals with emotionally triggered events when relaxation interventions are used. He noted worsening of symptoms when they were acute, however, and concluded that "relaxation training may provide protection from emotionally induced asthma"[81] when symptoms are chronic. Some theories regarding the failure of relaxation therapy to benefit individuals with asthma relate to its effect on the ANS. Evidence demonstrates that relaxation therapy downregulates the beta receptors of the SNS and thus reduces bronchodilation, an unfavorable outcome for individuals with asthma.

In a metaanalysis of 31 studies published between 1972 and 1993, Devine reported on the effects of psychoeducational care on adults with asthma. Psychoeducational interventions were defined as "education, behavioral skill development, cognitive therapy, and/or nonbehavioral support/counseling."[179] The author concluded that, despite methodological flaws primarily due to small numbers of subjects, education and relaxation-based behavioral interventions demonstrated improvement in clinical measures of pulmonary function. These measures included peak expiratory flow rate (PEFR), functional status, regimen compliance, use of medications, psychological well-being, and ability to use an inhaler properly. Similarly, a review of 12 well-designed studies investigating the effects of limited asthma education (information only) demonstrated a significant improvement in perceived asthma symptoms and reduced visits to the emergency department in adults with asthma.[180] In a controlled study of 35 children ages 5 to 6 years, researchers investigated the effects of a 6-month psychoeducational program that included guided imagery on several clinical and immunological outcomes associated with asthma control.[181] In addition to education classes and workshops for parents, daily instruction was given to the children to imagine visual images of unobstructed airways, mast cells, and immunoglobulin E (IgE) suppression. The results demonstrated significant reductions in the number of asthmatic episodes requiring medical attention and reduced bronchodilator requirements in the intervention group when compared with the control group. Spirometric values, specifically forced expiratory volume in 1 second (FEV_1), improved in the intervention group despite reduction in bronchodilator use. In addition, markers associated with immune system function (specific IgE levels, leukocyte surface markers, B cells) demonstrated improved efficiency. Conversely, a review of eight clinical trials investigating the effects of a limited asthma education program on more than 1400 children with asthma failed to demonstrate any reduction in emergency department visits or hospital admissions.[182] It appears that the addition of a guided imagery program to an asthma education program improves outcomes in children.

In a well-designed RCT of the effects of guided imagery on a group of adult patients with asthma, outcome measures failed to reveal statistically significant differences between intervention and control groups.[183] Measures of FEV_1, anxiety, depression, quality-of-life scales, and the number of visits to the emergency department were not different between groups.

Those subjects who practiced mental imagery, however, demonstrated statistically significant decreases in medication usage and reported feeling more power and control in their ability to change the course of their disease. Authors stressed the pilot nature of this study and concluded that if a larger sample was studied, more significant outcomes may have been achieved because there were trends favoring the mental imagery group in all outcome measures.

Preliminary study of the effects of the Alexander technique on measures of pulmonary function warrants further investigation.[184-186] To date, no controlled studies investigating the effects of this technique on individuals with asthma have been published. Although performing artists (musicians, singers, actors) with or without asthma reportedly benefit from this intervention, systematic study is lacking. Austin and Ausubel (1992)[184] documented improved pulmonary function measures in 10 healthy adults after 20 private sessions of therapy with the Alexander technique. No such improvement was found in 10 healthy adults in an untreated matched control group. Significant increases were demonstrated in PEFR, maximum voluntary ventilation (MVV), maximal inspiratory pressure (MIP), and maximal expiratory mouth pressure (MEP).

Both EMG and thermal biofeedback interventions have been studied in the management of asthma. Several of these interventions have been aimed at increasing HR. It has been postulated that by increasing HR, the accompanying increase in beta SNS activity produces increased bronchodilation. The few studies investigating this intervention have not been able to validate this theory due to design flaws.[81] Other trials of biofeedback have focused on general muscle relaxation and facial muscle relaxation. In a comprehensive review, McQuaid and Nassau (1999)[178] concluded that studies investigating biofeedback with general muscle relaxation demonstrate similar results as those trials using relaxation without biofeedback. These results are inconclusive and conflicting in individuals with asthma. Similarly, Ritz and colleagues (2004)[187] recently concluded in their review that studies addressing the use of biofeedback in the treatment of asthma were of poor quality and limited their ability to recommend this intervention. There is, however, strong evidence supporting the use of EMG biofeedback on the frontalis muscle of children with asthma.[178,188] Tension in this muscle has been correlated with increased airway resistance, presumably a consequence of a trigeminal-vagal reflex. Well-designed, carefully detailed studies examining reduced tension in facial muscles have demonstrated improvements in clinical measures of pulmonary function, including PEFR and asthma severity.[188]

The effects of yoga on asthma have been investigated by several authors. A summary of selected studies is found in Table 27-10. Results of these studies are still insufficient to draw sound conclusions. These initial trials, however, provide reasonable evidence supporting the use of yoga as complementary in the management of asthma. Although a discussion of breathing techniques is outside the scope of this chapter, there is evidence suggesting the value of certain interventions in asthma management.[193] Yoga breathing overlaps with some of these breathing exercises (e.g. slow, deep breathing mimics pranayama yoga exercise). In addition, Wronski (2008)[194] offered a preliminary discussion of the benefits of Pilates breathing in children with asthma.

Writing about emotionally traumatic events has been shown to have physical and psychological benefits. Smyth and colleagues (1999)[195] studied 58 adults with asthma (mean age 41 years). Subjects were randomized to an intervention group that was instructed to write about the most stressful event in their lives, while the control group wrote about an emotionally neutral event. Subjects were instructed to write for 20

Table 27-10 Effect of Yoga on Asthma

Study Authors	Type of Yoga	Sample Characteristics and Method	Outcomes
Tandon, 1978[189]	Yogic breathing exercises and posture	22 patients with severe chronic airway obstruction Matching groups of 11 subjects Yoga group (YG) and control group (CG) followed-up monthly for 9 months; CG received physiotherapy breathing	Compared with CG, the YG showed: significant increase in maximum work by 60.55 kpm; symptomatic improvement
Jain, 1991[190]	Yoga	46 young individuals with asthma Age 11-18 years All had history of childhood asthma Subjects acted as their own controls	Compared with baseline, significant increase in pulmonary function and exercise capacity At 2-year follow-up, reduced symptoms and drug requirements
Vedanthan, 1998[191]	Slow breathing (pranayama) Postures (asanas) Meditation	Adults with asthma Age 19-52 years 17 volunteers randomly divided into yoga (YG) and nonyoga groups (NYG) YG practiced 3 times per week for 16 weeks Both groups maintained daily symptom and medication diaries; AM and PM PEFR; weekly spirometry and questionnaires	Compared with NYG, the YG showed: significant degree of relaxation and positive attitude; better yoga exercise tolerance; trend towards decreased use of beta adrenergic inhalers; no difference in pulmonary function measures
Sodhi, 2009[192]	Yoga breathing	128 patients with mostly mild asthma randomized into 2 groups, 8 weeks of yoga training (YT) or control (C); PFT performed at baseline, 4 and 8 weeks	YT group increased % predicted PEFR, FEV_1, FVC, FEF_{25-75}, FEV_1/FVC when compared with C

minutes, on three consecutive days. At a 2-week follow-up, mean FEV_1 in the intervention group increased significantly from 63.9% of predicted values to 76.3% of predicted values. These statistically significant improvements were maintained at 2- and 4-month follow-up testing. No changes in FEV_1 were noted in the control group. Although the results of this study are complicated by the inclusion of subjects with rheumatoid arthritis, the authors offer strong preliminary evidence for the value of this writing intervention.

Most of the CAM therapies discussed thus far in the management of asthma have been mind/body techniques. Although there is a paucity of publications addressing the effects of body work on asthma, the effects of manual therapy on asthma have been reviewed.[196,197] In general, the methodological differences between all studies and the shortcomings of each individual study preclude any strong recommendation supporting the use of manual therapy in the treatment of asthma. Two of the studies reported on chiropractic manipulation as compared with sham maneuvers, and a third compared massage therapy with a relaxation control group. Significant improvement in measures of lung function was found in the massage therapy study. Two studies found no differences between intervention and control groups when chest physiotherapy was compared with placebo and when footzone (reflexology) therapy was compared with a no-treatment control group.

Acupuncture, a form of energy work, has been discussed extensively in the management of asthma. Several review studies and metaanalyses have been published addressing the effects of acupuncture on various outcomes related to asthma.[198-201] Inclusion criteria for an article to be reviewed in one of these publications consisted of randomized control design and measurement of objective pulmonary function outcomes, most often FEV_1. Significant disagreement exists among investigators regarding details of acupuncture interventions, including proper location of needles, depth of needle penetration, and frequency and duration of treatment.[202-205] There is general agreement, however, that strong evidence exists to support the *process* of inserting acupuncture needles into individuals with asthma. Medici and colleagues[204] have demonstrated that whether or not the actual point of needle insertion is considered proper is unessential. They successfully demonstrated that regardless of the site of needle insertion, certain physiological responses occur with acupuncture that improve pulmonary function in patients with asthma. They offer several possible rationales for the improvement—a direct physiological release of substances in response to the invasiveness of inserting the needles into the body, a physiological response triggered by the interaction between practitioner and subject (including the intention of the practitioner to heal the subject), or some other unknown, as yet undefined, factor. Hence most investigators conclude that more research is necessary to understand the complexities of acupuncture as an intervention and how it can best be prescribed in the treatment of asthma. It is important to note here that although very rare, there have been a few reports of pneumothorax and cardiac tamponade occurring consequent to needle insertion in the thorax.[206]

Preliminary evidence exists that qi gong may be an effective adjunct to medical management of asthma.[111] When pharmacological intervention is combined with qi gong, reported benefits include symptom reduction, improved immune system function, decreased sick leave and hospitalization days, decreased emergency department visits, and decreased antibiotic requirements for bronchial infections. These effects could result in a reduction in asthma-related morbidity and a substantial cost savings.

Chronic Obstructive Pulmonary Diseases

Pulmonary rehabilitation programs have been traditionally used as adjuncts to pharmacological management of chronic obstructive pulmonary disease (COPD). These programs generally consist of exercise training and a variety of educational and supportive interventions. Strong evidence has been shown to support pulmonary rehabilitation interventions in improving outcomes in patients with COPD.[207-211] These outcomes include reduced perception of dyspnea, increased work tolerance, and increased physical conditioning. Results, however, are inconsistent with regard to improvements in pulmonary function measures.

Devine and Pearcy (1996)[179] performed a metaanalysis of 65 studies investigating the effects of psychoeducational therapies in adults with COPD. For purposes of their analysis, they included education, exercise, and/or psychosocial support as psychoeducational therapies. Most of the articles were found in journals (66%) and dissertations (29%) and were published between 1954 and 1994. Of the studies, 34% were RCTs, 54% included a control group, and 15% had a placebo-type control. Data were included on 3642 individuals, with 72% reported as having COPD, 25% reported as having COPD or asthma, and 3% as having COPD, asthma, or other chronic pulmonary disease. Subjects ranged in age between 43 and 70 years, 81% of the studies had more men than women, and 19% had men only. Almost half of the studies were conducted in an outpatient setting, and about one-fourth were conducted in the inpatient hospital setting. The remaining studies involved various settings, including home.

Although the results of Devine and Pearcy's analysis revealed significant benefits of various interventions, the authors noted methodological weaknesses in many of the studies, including no mention of the duration of intervention in almost half of them. Statistically significant benefits of the various interventions are listed in Table 27-11. In general, education-only interventions were of benefit in improving the subject's knowledge of psychomotor skills. Relaxation-type interventions were effective in improving dyspnea and psychological well-being. An overwhelming benefit of pulmonary rehabilitation interventions was demonstrated in many studies. All of the pulmonary rehabilitation programs included in this analysis had education and large-muscle exercise components; 75% had breathing retraining; 57% had relaxation training; 54% had physical therapy; 43% had psychosocial support; 40% had occupational therapy; 29% had nutritional education; and 18% had vocational counseling. Although the results of this analysis begin to shed light on the benefits of individual interventions, more research is warranted. Recognition of the contribution of each of the specific CAM therapies offered within the umbrella of pulmonary rehabilitation may be difficult. This is consistent with Devine and Pearcy's conclusion that further research efforts to break down interventions within pulmonary rehabilitation may not be clinically wise, given the complex needs of these patients.

In a recent review of psychological interventions for individuals with cystic fibrosis (CF), Glasscoe and Quittner

Table 27-11 **Effect of Various Psychoeducational Interventions on Outcomes in Individuals with COPD**

Outcome Variable and Measurement	Number of Studies	Statistically Significant Beneficial Interventions	Nonstatistically Beneficial Interventions
Psychological well-being (e.g., anxiety, mood questionnaires)	26	Relaxation-type therapy Pulmonary rehabilitation	Education only
Endurance (e.g., time/distance able to exercise)	16	Pulmonary rehabilitation	Education
Oxygen uptake ($\dot{V}o_{2max}$)	8	Vigorous exercise (e.g., 60 minutes of supervised exercise 3 times per week for 9 weeks)	Mild exercise (e.g., 10 minutes of exercise 3 times per day)*
Functional status (e.g., sickness impact profile)	—	Pulmonary rehabilitation Breathing exercise and large muscle exercises	Education only
Dyspnea (visual analogue scales)	—	Pulmonary rehabilitation Progressive muscle relaxation	Guided imagery
Pulmonary function (static volumes and FEV_1)	—	Static volumes improved Pulmonary rehabilitation	FEV_1 no change Education only relaxation/imagery Pulmonary rehabilitation
Knowledge of psychomotor skills (e.g., accurate inhaler use)	—	Education only	
Adherence (self-reports, provider assessed compliance)	—	Pulmonary rehabilitation	Education only
Utilization of health care (e.g., ED visits, hospitalizations and LOS)	—	Pulmonary rehabilitation	Education only

ED, Emergency department; *LOS*, length of stay.

*Significant negative effect.

Based on data from Devine EC, Pearcy J: Meta-analysis of the effects of psychoeducational care in adults with chronic obstructive pulmonary disease, Patient Education and Counseling *29:167–178, 1996.*

(2009)[212] found 13 randomized controlled trials studying 529 pooled participants. Interventions were primarily behavioral or educational and focused on promoting improved quality of life and knowledge for effective disease management. Patients and family members demonstrated improvement in emotional and knowledge-based outcomes; no consistent lung function measurement outcomes were noted.

Intuitively, yoga would seem a beneficial adjunct to the medical management of COPD. Components of yoga include slow breathing, or pranayama, and body positions, or asanas. At times meditation is included as well. Unfortunately, investigation of the effects of yoga on COPD is in its infancy and is still mostly anecdotal.[213] The reports include improved perceptions of dyspnea and decreased anxiety.

Similarly, singing therapy would appear to benefit individuals with breathing impairments. Irons (2010a; 2010b)[214,215] performed two appropriate literature reviews to study this: one to determine the effects of singing therapy on individuals with bronchiectasis, and one on individuals with CF. No studies were found for either population. Alternatively, music therapy, used primarily for relaxation, has been found effective as a complement to chest physical therapy in toddlers with CF[216] and in adults with infectious lung diseases.[217] In a recent review, Huth (2005)[218] reported on the benefits of massage therapy in the same populations. Individuals with CF and those with chronic lung disease demonstrated reduction in anxiety and improved measures of pulmonary function after 2 to 4 weeks of a 20-minute intervention. Further research is needed because these studies were small and had numerous methodological limitations.

Lung Cancer

Two large and thorough reviews recently reported on noninvasive interventions used for patients with lung cancer.[219,220] Only randomized controlled trials were included, and several of the studies analyzed were common to both reviews. Sola (2009)[220] categorized studies into six groups according to intervention, including the use of treatments for breathlessness, structured nursing support programs, nutritional intervention, psychotherapeutic interventions, exercise, and reflexology. Primary outcome measures were well-being and quality of life. Measures of pulmonary function were not reported; measures of functional activity were reported in two studies. All studies reported significant improvement in well-being or in quality of life in the intervention groups when compared with controls. When breathlessness was the primary outcome measure, all studies also reported significant improvement in the intervention group when compared with controls.[219] Interventions for breathlessness included individualized counseling and psychosocial support, breathing control training, relaxation and anxiety management, and activity pacing. The authors of both reviews recommended caregiver training for this population given the many components of intervention required to effectively tailor a noninvasive program for each individual. They also

suggested large, well-designed, higher-quality studies in the future.

Summary

This chapter has several purposes: (1) to introduce the reader to complementary therapies in general, (2) to define several of the common complementary therapies found in rehabilitation and then examine the literature on the effects of these therapies on the normal cardiovascular and pulmonary systems, and (3) to discuss the efficacy of the use of these complementary therapies with patients with cardiovascular and pulmonary pathologies. The quality of evidence found in the literature is inconsistent, with designs representing the entire research spectrum, from individual case studies to large and well-designed RCTs. The most sophisticated studies found were those investigating the efficacy of tai chi, yoga, acupuncture, intercessory prayer, and psychoeducational group work on various cardiovascular and pulmonary conditions, including CAD, CHF, cardiac surgery, COPD, asthma, and HTN.

Given the widespread presence of cardiovascular and pulmonary illness in our society and the fact that people are using complementary therapies, it is essential that therapists be adequately prepared to understand, administer, and correctly interpret responses to these interventions and that they strive to conduct and publish the required research to establish efficacy.

Review Questions

1. Describe the cardiovascular and pulmonary responses to mind/body therapies in healthy individuals and discuss how these responses may be helpful or harmful to patients with cardiac or pulmonary diseases.
2. Identify three CAM therapies that include components of traditional physical therapy (e.g., yoga, tai chi, biofeedback, massage, Alexander method) and compare and contrast goals of the CAM therapies with goals of traditional physical therapy relative to the cardiovascular and pulmonary systems.
3. Choose three forms of energy work therapies and discuss their (possible) effects on the cardiovascular and pulmonary systems.
4. Design a study investigating the effects of one energy work intervention and one manual therapy/body work intervention on cardiovascular and pulmonary responses in individuals with cardiac or pulmonary disease.
5. Choose a cardiovascular and pulmonary diagnosis and describe how you would plan a program using CAM therapies to help treat a patient with the diagnosis.

According to the *Guide to Physical Therapist Practice,* patient/client-related instruction is one of the three major components of physical therapist intervention.[1] In cardiovascular and pulmonary physical therapy, choosing an effective procedural intervention is based on the physiological evaluation of the patient. Similarly, choosing effective patient instruction or education methods is based on the learning needs assessment of the patient.[2] The overall goal of patient education is for the patient to practice health behaviors that promote health, well-being, and independence in self-care. Cardiovascular and pulmonary patient education can pose a significant challenge to the physical therapist. Patient education interventions can range from teaching a hospitalized patient about cardiac risk factor modification to designing a series of community-based exercise classes for children with asthma. Meeting this challenge is important because the benefits of patient education include reduced health-care costs, reduced disability, enhanced patient decision making, improved patient knowledge, and increased quality of life. In addition, physical therapists share with other health-care providers the responsibility of ensuring that patients have the opportunity to make informed choices in their care. Unless effective patient education is implemented, this opportunity will be lost.

The overall objective of this chapter is to provide the clinician with an understanding of the principles and practice of effective patient education. To meet this objective, patient education is defined and pertinent learning theories are presented, supported by examples of how they relate to cardiovascular and pulmonary patient education. The learning needs assessment of the patient is explained, followed by a description of patient education methods and materials. Because the effectiveness of patient education efforts is important to evaluate, methods to determine effectiveness are addressed. Finally, interprofessional considerations and educational resources are discussed.

Defining Patient Education

Physical therapists believe that patient education is an important part of patient care.[3] The teaching role of the physical therapist has been reported as highly valued by patients as

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

well.[4] According to the Consumer and Patient Health Information Section of the Medical Library Association (1996),[5] patient education is "a planned activity, initiated by a health professional, whose aim is to impart knowledge, attitudes and skills with the specific goal of changing behavior, increasing compliance with therapy and, thereby, improving health."[5]

Several factors make patient education unique when compared with other types of teaching. The patient may have limited or no access to teaching because of financial and/or geographical barriers to health care. The learner may lack a sense of well-being because of signs and symptoms of an acute illness, making learning more difficult. The relationship between the teacher and the learner in patient education may be perceived as hierarchical—a medical authority figure instructing a lay person. The learner's emotional status may be fearful or anxious, depending on the medical situation. Superimposed time constraints, such as length of hospital stay or length of clinic appointment, may have a direct impact on patient education. The physical therapist and the patient may be from different cultures. Furthermore, the learner may have limited health literacy. Any of these factors may pose barriers to learning. In addition, the patient's family dynamics may be altered as family members try to cope with the patient's illness or disability. The physical therapist's responsibility extends to determining readiness and ability to learn and including the family in the education process.

Objectives

The overall objective of patient education is to effect a durable cognitive improvement that results in a positive change in an individual's or group's health behavior. In most cases the physical therapist must embark on a process to meet this objective in the course of procedural interventions. The education process consists of assessing the learning needs of the patient, identifying measurable, realistic objectives, planning and implementing the patient education program, and finally, evaluating its effectiveness. Specific examples of patient education learning objectives are listed in Box 28-1.

Achieving these objectives will lead to the achievement of a host of documented benefits of patient education. These include reduced length of hospital stay,[6] reduced patient anxiety,[7] improved health-related knowledge,[8] increased quality of life,[9] and improved response and adherence to medical treatment.[10] Patient education has also been shown to empower patients to take more active roles in their health care.[11] Patients who are educated partners in their care are able to be smart consumers in the health-care system and adapt more readily to the changes in their lifestyles that result from illness. Educated patients learn and understand the health consequences of their behaviors and choices.

Box 28-1 Patient Education Objectives

1. Enhanced patient-clinician rapport
2. Increased knowledge of health disorder/condition
3. Increased adherence to physical therapy treatment plan
4. Decreased health-care costs
5. Increased self-efficacy
6. Increased ability to make informed health-care choices
7. Improved patient outcomes (such as quality of life, mobility, etc.)

Learning Theory: Concepts Pertinent to Cardiopulmonary Patient Education

Behavioral scientists of the 20th century developed a variety of learning theories and models that attempt to explain the complexities of human behavior. Subsequent models have emerged that specifically address health behavior. Although a comprehensive discussion of these models is beyond the scope of this chapter, a list of references for further reading may be found at the end of this chapter (see Bibliography). The discussion of the three theoretical concepts that follows is designed to provide the clinician with a rationale for patient education practice in terms of its basis in learning theory. The concepts are social-cognitive theory, the health-belief model, and the behavior-modification approach.

The social-cognitive theory as developed by Bandura (1986)[12] posits that human behavior can be explained and predicted using the following key regulators: incentives, outcome expectations, and efficacy expectations. For example, a myocardial infarction patient perceives value in following the exercise program (incentive). Patients with this incentive will attempt to exercise if they believe that their current sedentary lifestyle poses a threat to health. These patients also believe exercise will reduce that threat (outcome expectation) and that they are personally capable of performing the exercise program (efficacy expectation). Outcome and efficacy expectations directly relate to patients' beliefs about their capabilities and the relationship of their behaviors to successful outcomes. In essence, then, behavior is influenced by perceptions that create expectations for similar outcomes over time.

To function competently in a given environment requires a belief in one's ability to attain a certain level of performance. Bandura terms this self-efficacy.[13] He argues that perceived self-efficacy influences all aspects of behavior, including learning new skills and inhibiting or stopping current behaviors. Self-efficacy has the following four primary determinants:

1. Performance accomplishments, which is the strongest determinant and refers to "acting out" the desired behavior and mastering the task, resulting in increased self-efficacy
2. Vicarious experience, which involves learning through observing the actions of others, especially actions with clear, rewarding outcomes
3. Verbal persuasion
4. One's physiological state as it relates to the perceived ability to perform a given task

For example, a pulmonary rehabilitation program increases a patient's self-efficacy when the patient successfully completes multiple exercise sessions (performance accomplishments), learns how to deal with dyspnea by consulting fellow program graduates (vicarious experience), receives counseling on energy conservation techniques from the staff (verbal persuasion), and notes that oxygen saturation measured 95% before exercising (physiological state).

The health-belief model, developed in the early 1950s, theorizes that patients are likely to take a health action in the following situations: they believe they are at risk for illness; they believe that the disease poses a serious threat to their lives should they contract it; they desire to avoid illness and believe

that certain actions will prevent or reduce the severity of the illness; and they believe that taking the health action is less threatening than the illness itself.[14] This model was originally developed in an attempt to understand why large numbers of people failed to accept preventative care or screening tests for early disease detection. Subsequent studies have used the model to analyze compliance with regimes for hypertension, asthma, and diabetes.[15] The health-belief model conveys that in the context of health behavior some stimulus or "cue to action" is necessary to initiate the decision-making process. These cues can be internal (i.e., a productive cough) or external (i.e., instructional video on pulmonary hygiene techniques). Once the behavior commences, it is understood that many demographic, structural, personal, and social elements are capable of influencing the behavior. In addition, perceived barriers (i.e., unpleasant side effects) may limit or prevent undertaking the recommended behavior.

The behavior-modification approach has its roots in operant-learning theory and consists of techniques that manipulate environmental rewards and punishments in relationship to a specified behavior.[16] The theme of this approach is that an individual's behavior can gradually be shaped to meet a set objective. According to Becker (1990),[17] the behavior-modification approach frequently follows a general plan: "identify the problem; describe the problem in behavioral terms; select a target behavior that is measurable; identify the antecedents and consequences of the behavior; set behavioral objectives; devise and implement a behavior change program; and evaluate the program."[17] This plan is similar to the patient/client management model[1] that physical therapists use to achieve optimal patient care outcomes. The physical therapist examines the patient, describes the problem(s) in functional terms (evaluation and diagnosis), sets short-term and long-term functional goals, designs a plan of care to meet those goals (prognosis), implements the plan (intervention), and reevaluates the patient. These similarities may facilitate the use of the behavioral-modification approach by physical therapists.

Health-care contracts can be useful in implementing the behavior-modification approach. An example of such a contract may be seen in Box 28-2. The contract should be realistic, measurable, and renewable.[18] Specific goals, time frames, behaviors, and contingencies are written in the contract. The clinician and patient discuss and then sign the contract. Positive and negative reinforcements are used to facilitate the desired behaviors in the patient. Ideally, once the contract expires, the patient feels competent and is able to continue the desired behaviors without the external reinforcements.

Box 28-2 Health Care Contract

Date:

Contract goal: [specific outcome to be attained]

I, [Client's Name], agree to [Detailed description of required behaviors, time, and frequency limitations] in return for [Positive reinforcements contingent on completion of required behaviors; timing and mode of delivery of reinforcements].

I, [Provider's Name], agree to [Detailed description of required behaviors, time, and frequency limitations].

(Optional) I, [Significant Other's Name], agree to [Detailed description of required behaviors, time, and frequency limitations].

(Optional) Aversive consequences: [Negative reinforcements for failure to meet minimum contract requirements].

We will review the terms of this agreement and will make desired modifications, on [date]. We hereby agree to abide by the terms of the contract describe above.

Signed: [Client]

Signed: [Significant Other, if relevant]

Signed: [Provider]

Contract effective from [Date] to [Date].

Needs-Based Approach to Patient Education

The most important aspect of planning for patient education is assessing the learner. The process of patient education requires assessment of the total patient and family, including an understanding of the psychosocial, socioeconomic, educational, vocational, and cultural qualities of the patient and family unit.[19] Assessing educational needs of the patient allows the physical therapist to determine what the patient needs to know to meet the desired cognitive and behavioral teaching objectives. This assessment also increases patient-teacher rapport and allows the physical therapist to individualize the learning experience.

Learning Needs Assessment

Tools

The American Physical Therapy Association's Commission on Accreditation of Physical Therapy Education in their Normative Model of Physical Therapist Professional Education: Version 2004[20] requires that the graduate physical therapist be able to "effectively educate others using culturally appropriate teaching methods that are commensurate with the needs of the learner."[20] Learning needs can be assessed in a variety of ways. These include patient and family interviews, questionnaires and surveys, written tests, and observation of patient performance.[21] Interviews allow the physical therapist to ask questions directed at determining the patient's view of the illness, including associated beliefs and attitudes. Questionnaires and surveys can be used in conjunction with the interview to document the patient's responses to specific questions about his or her condition. Open-ended questions such as "What are the major problems your illness has caused for you and your family?" elicit more information than a multiple-choice format. Written tests can be helpful in determining what patients already know when the tests are given, before any teaching. These tests can also identify problems with reading, comprehension skill, and health literacy. Observing patients as they perform a skill, such as diaphragmatic breathing, reveals whether the patient can demonstrate the correct technique. The physical therapist can also pose questions to the patient during the demonstration to determine whether the patient knows the rationale for the exercise.

Areas to Assess

The learning needs assessment encompasses the following five major areas: perceptual, cognitive, motor, affective, and environmental (Box 28-3). By addressing these five areas, the physical therapist will obtain an accurate picture of the patient's learning abilities, knowledge level, performance skills, attitudes, and cultural influences.

The perceptual area encompasses the learner's ability to receive information via the senses. If the learner's sight, hearing, or sense of touch is impaired, the instructor may need to make modifications so that the information can be received by the learner. The comprehension of symbols, such as numbers, words, or pictures, also needs to be assessed in the perceptual area. The instructor needs to know what meaning the learner attributes to the symbols that will be used in the education program to ensure clarity.

The cognitive area addresses the learner's knowledge and problem-solving skills. The instructor needs to know how much the learner already knows and what needs to be learned. The instructor also needs to know if the learner has any problems with memory. Short- or long-term memory deficits may require that the instructor integrate a prompting system into the education plan.

The patient's fine- and gross-motor skills and functional mobility are covered in the motor area. The instructor needs to be aware of the physiological changes in the patient that affect abilities to perform activities necessary for a given education program. For example, if patients who are wheelchair users are interested in attending a support group, the physical therapist would ensure that it is being held in a room that is wheelchair accessible.

The affective area comprises the learner's attitudes, beliefs, and readiness to learn. Identifying the learner's value-belief system will assist the instructor in determining what is important to the learner and facilitating motivation. The patient's perception of wellness may vary from the absence of disease to an enhanced healthy state. What the instructor feels is important to learn may not be what the patient feels is important to learn. Identifying what the patient values early on will prevent instructor (and patient) frustration later.

Cultural influences and personal and societal resources are included in the environmental area. It is important for the instructor to be aware of the patient's lifestyle, religion, traditions, roles, and primary language in order to individualize the patient's learning experience. Presence or absence of the patient's resources may affect consistency in, and access to, patient education.

All five of these areas can be addressed with the use of a learning needs assessment survey (Box 28-4). By using a survey in combination with the physical therapy patient evaluation, the therapist can gather all the necessary information to create an optimal patient education experience. The survey in Box 28-4 consists of three parts, which can be adapted to any patient care setting. In the pediatric setting, some of the questions could be asked of the parent(s) or rephrased to address school-age children. Part I primarily assesses the patient's perception of the illness or disability and its impact on the patient's life. Part II lists a wide variety of teaching methods and asks the patient to indicate which methods he or she personally feels are most useful. Part III identifies specific topics about which the patient would like to know more. This part is also helpful in alerting the therapist that referrals to other members of the interprofessional health-care team may be required. For example, if the patient selects "I would like to know more about what I should eat," the therapist would make a referral to the dietitian. Patients' answers provide clues to learning style preferences that work best for them and can often provide clues to health literacy issues.

Box 28-3 Learning Needs Assessment Areas

Perceptual
- Ability to receive input (vision, hearing, and touch)
- Comprehension of symbols (figures, numbers, words, and pictures)

Cognitive
- Knowledge and analytical skills
- Memory

Motor
- Fine- and gross-motor skills
- Physical adaptations and responses to illness or stimuli

Affective
Attitudes
Value-belief system
Motivation (readiness to learn)
Perception of overall wellness

Environmental
Personal and societal resources
Amount of instructor contact and setting
Cultural influences (language, traditions, roles, religion, and lifestyle)

Health Literacy

Certain barriers, such as limited health literacy, can alter the effectiveness of patient education and rehabilitation interventions, such as promoting lifestyle behavior changes.[22,23] Health literacy can be described as a person's ability to comprehend health information and use that information to make informed decisions about his or her health and medical care.[24] Specifically, the patient needs these skills when reading consent forms, prescription drug information, food labels, rehabilitation instructions, and appointment slips or when filling out a health insurance form or reviewing a health care bill.[25-27] Health literacy is required to read a peak flow meter, to understand body mass index (BMI), and to recognize whethera blood pressure reading is considered high.[28] Signs of limited health literacy can be found in Box 28-5. Limited health literacy increases the risk for hospitalization, the overall cost of health care, and mortality rates. Studies have shown that patients with limited health literacy are more likely to report difficulties with activities of daily living (ADLs) and instrumental activities of daily living (IADLs) as a result of poor or diminished physical health and pain that interferes with normal work activities.[29] Those with limited health literacy also have higher rates of diabetes, hypertension, obesity, depressive symptoms, and physical limitations. Older adults with limited health literacy also may demonstrate a higher incidence of heart failure, arthritis, and multiple health conditions, and they tend to have a greater need for complex medical

Box 28-4 Learning Needs Assessment Survey

Your physical therapist would like to help you learn what you need to know to function as independently as possible and manage your illness/disability. Please answer the following questions.

Part I

Name:

Please describe your illness and/or disability here:

1. Do you have any problems seeing or hearing?
2. Do you have any body areas that are numb (can't feel)?
3. How long have you had this illness/disability?
4. What problems has it caused you?
5. Are you able to care for yourself at home?
6. Are you responsible for the care of any others at home?
7. Do you have someone at home to help you? If so, whom?
8. What questions or concerns do you have?
9. Do you practice a religion? If so, which?
10. What language(s) do you understand best?
11. How much education/schooling have you had?
12. What is your occupation?

Part II

There are many different ways to learn. Please read the list of ways to learn below and circle the ones that help you learn best.

- Reading
- Listening to lectures
- Watching demonstrations
- Using interactive videos or computer programs
- Attending seminars
- Practicing a skill or doing a simulation
- Taking written tests
- Group discussion
- Reflecting by myself
- Playing games
- Role playing
- Computer/Internet activities
- Other

Part III

I would like to know more about (check all that apply to you):

___ How to clear mucus from my lungs
___ What causes heart disease
___ How to avoid shortness of breath
___ What I should eat
___ Exercise
___ My medications
___ Monitoring myself
___ Planning my social life and/or work life
___ What to do if I have chest pain
___ Planning for sexual intimacy
___ What causes lung disease
___ Coping with my feelings
___ How to stay well
___ How to quit smoking
___ How to sleep better
___ How to access community resources

Other things I would like to know:

The three most important things I need to know are:

Box 28-5 Signs of Limited Health Literacy

- Incompletely or inaccurately completed registration or intake forms
- Frequently missed appointment times
- Inability to name medications or explain purpose of medications or difficulty in taking medications correctly
- Lack of follow-through with referrals to other health-care providers
- Lack of follow-through with home exercise programs or illness/disease management strategies

From Weiss BD: Health literacy and patient safety: Help patients understand. Manual for clinicians, ed 2, Chicago, Ill, 2007, American Medical Association and AMA Foundation. Available at: http://www.amaassn.org/ama1/pub/upload/mm/367/healthlitclinicians.pdf

management.[29,30] Patients with limited health literacy have less knowledge about hypertension, diabetes, and asthma.[25] Inadequate health literacy skills are key factors in the exacerbation of heart failure.[31]

Health literacy is also linked to improved compliance with a physical therapy plan of care and ultimately leads to better health and medical care outcomes.[32] Current cardiovascular and pulmonary research demonstrates that patients with adequate health literacy are more likely to keep records of their blood glucose test results[33] and demonstrate improved medication compliance with a diagnosis of cardiovascular disease.[34] Patients with chronic obstructive pulmonary disease (COPD) who receive and understand self-management education have decreased hospital admissions.[35] Although outside the scope of this chapter, certain formal assessment tools can be used to determine an adult patient's health literacy level (Table 28-1).

Interpretation of Findings

The next important step after gathering information with the learning needs assessment survey is to interpret the findings. The physical therapist looks at the answer to each item on the survey and uses that information in the process of designing the content and method for teaching that patient. Primary and secondary prevention can be integrated into the content to promote overall wellness. Interpretation of the survey findings means applying the patient's current health concerns, learning abilities, and knowledge deficits to future learning activities. By identifying the patient's needs, the physical therapist is able to make informed choices in the planning and implementation of each patient's education experience.

Formulation and Prioritization of Goals

As physical therapists set intervention goals for their patients, they should include educational goals. Intervention goals usually describe functional outcomes (e.g., "The patient will perform a stand-and-pivot transfer from bed to chair, independently"), and they are written in behavioral terms. Educational goals should also be written in behavioral terms. For example, "Mr. J will safely perform percussion and postural drainage to Mrs. J's right lower lobe." The stated behavior

Table 28-1 Health Literacy Screening and Assessment Tools

Test	Characteristics	Advantages	Disadvantages
Rapid Estimate of Adult Literacy in Medicine (REALM)	Consists of 66 items Used to measure how well patients read words frequently encountered in medical settings Score divides health literacy skills into four categories of grade-equivalent reading levels	Takes 3-4 minutes to administer	Inability of the test to distinguish reading levels beyond ninth grade Test does not measure understanding of the words Test is only available in English
Test of Functional Health Literacy in Adults (TOFHLA)	"Gold standard" of health literacy testing Consists of a 50-item reading comprehension section and 17-item numeric ability test Scores patients in three different categories consisting of adequate, marginal, or inadequate health literacy	Available in English and Spanish and 14-point font Measures a wide range of reading levels and measures comprehension skills	Takes 22 minutes to administer
Test of Functional Health Literacy in Adults, short version (S-TOFHLA)	Shortened version of TOFHLA Consists of two prose passages to assess reading comprehension Scores patients in three different categories: adequate, marginal, or inadequate health literacy Useful in identifying patients with very limited reading ability	Takes 7 minutes to administer Available in English and Spanish and 14-point font	Measures only reading comprehension
Short Assessment of Health Literacy for Spanish-Speaking Adults (SAHLSA)	Based on the REALM Measures health literacy in patients who speak Spanish Consists of 50 words, each with a correct and incorrect meaning A score between 0 and 37 indicates inadequate health literacy	Takes 5 minutes to administer	
Newest Vital Sign (NVS)	A six-question assessment based on an ice cream nutrition label Assesses literacy and numeracy	Takes 3-5 minutes to administer Available in English and Spanish Has high sensitivity for detecting limited health literacy	
Single-Item Literacy Screener (SILS)	Question asks, "How often do you need to have someone help you when you read instructions, pamphlets, or other written material?" Respondents choose one of these responses: 1-Never, 2-Rarely, 3-Sometimes, 4-Often, or 5-Always A score of 2 or greater is considered positive	Takes less than 1 minute to administer	

From Cutilli CC: Do your patients understand? OrthopNurs *24(5):372–377, 2005; Davis TC, Long SW, Jackson RH, et al: Rapid estimate of adult literacy in medicine: A shortened screening instrument, Fam Med 25(6):391–395, 1993; Mancuso JM: Assessment and measurement of health literacy: An integrative review of the literature,* Nurs Health Sci *11:77–89, 2009; Parker RM, Baker DW, Williams MV, et al: The test of functional health literacy in adults: Anew instrument for measuring patients' literacy skills,* J Gen Int Med *10(10):537–541, 1995; Baker DW, Williams MV, Parker RM, et al: Development of a brief test to measure functional health literacy,* Patient Educ Couns *38(1):33–42, 1999; Lee SY, Bender DE, Ruiz RE, et al: Development of an easy-to-use Spanish health literacy test,* Health Serv Res *41(4 Pt 1):1392–1412, 2006; Weiss BD, Mays MZ, Martz W, et al: Quick assessment of literacy in primary care: The newest vital sign,* Ann Fam Med *3:514–522, 2005; Pfizer: The newest vital sign: Anew health literacy assessment tool for health care providers. must be observable and measurable. Motor skills can be observed, knowledge skills can be tested, and safety can be documented.

Prioritizing the patient's educational goals in conjunction with other intervention goals enhances the therapist's efficiency. Referring again to the learning needs assessment survey (see Box 28-4) to determine what knowledge is important to the patient will guide the therapist in creating the most appropriate prioritization of goals. Simplicity is usually best. Overwhelming patients with a huge list of items to be accomplished may discourage them before they even start. If the patient's learning needs are great, start by breaking down the list of goals into smaller groups. Choose the most important goals and try to accomplish those first. If you run into a series of failures, tackle the next group. Build on each success the patient experiences.

Educational Methods

Method Selection

In addition to considering the level of health literacy of the patient and the caregiver, using the learning needs assessment survey (see Box 28-4) will allow the clinician to choose education methods that will facilitate optimal learning in a given patient or group. The patient(s) can self-select the available learning methods that have the greatest learning potential. A combination of methods may be necessary to achieve the educational goals that have been set. If a patient is not sure which methods to indicate, the therapist can base the choice on the other information provided in the survey (e.g., sensory deficits, health literacy level, or type of information desired).

One way to determine learning styles without completing a survey is to ask patients (or their caregiver) about any hobbies and how they became proficient with the hobby. For example, did they read about it, watch a video, or take a class to learn about the hobby?[32] Surveys generally require regular updates to ensure that all of the offered methods are listed and that any discontinued methods are removed from the list. In addition, the physical therapist should assess potential learning materials for readability, age-appropriateness, accuracy of content, intended audience, and clarity.[19] Recently, even the American Diabetes Association (ADA) and the American Heart Association (AHA) had their written materials reviewed for things such as reading level, word usage, clear and specific behavioral recommendations, etc.[36] Please see Box 28-6 for guidelines for creating patient education materials, as well as Box 28-7 for resources for developing and assessing readability of printed patient education materials.

Box 28-6 Guidelines for Creating Printed Patient Education Materials

- Avoid using unfamiliar words. Use plain language. Use only monosyllabic or disyllabic words in short sentences.
- Keep line length between 40 and 50 characters.
- Use large fonts (at least 14 points). Avoid using italics, all capital letters, or fancy script text.
- Use layouts with substantial amounts of white (blank) space.
- Focus materials on desired behaviors rather than on medical facts.
- Avoid using blue, green, or lavender because older adults may have more difficulty differentiating these colors.
- Use more than one form of communication to clarify written concepts, such as pictures that are culturally sensitive and personally relevant.

Advantages and Disadvantages

Each education method has its own advantages and disadvantages. Table 28-2 lists the key advantages and disadvantages of 13 education methods. The table is designed to assist the physical therapist in determining the settings and populations in which the methods will be most useful. However, this is not a comprehensive list. In fact, some health education challenges require truly innovative approaches.

In Boston, Massachusetts, for example, community healthcare providers were faced with a dilemma. The incidence of acquired immune deficiency syndrome (AIDS) among women of color was increasing. Latino, African-American, and Haitian women were not receiving vital information about how to prevent the transmission of the human immunodeficiency virus (HIV). These communities were largely distrustful of the healthcare establishment and were not mobilized to stop the spread of HIV. How could they be reached? The Boston Women's AIDS Information Project (BWAIP) trained lay women to educate other women in the places where they congregate, such as beauty salons. Informational brochures, condoms, and posters were distributed in a number of beauty salons in communities where women were at highest risk for contracting HIV. Lay and professional educators gave presentations, showed videos, and answered questions from the staff and patrons of these establishments, thus empowering them to disarm myths about AIDS, to encourage other women to make appropriate behavior changes, and to make referrals to neighborhood health centers for testing and evaluation.

Another area of education that may require a unique approach is teaching young children about their bodies and health. In 1993, members of the interdisciplinary team caring for children with cystic fibrosis (CF) at Texas Children's Hospital in Houston held a CF Education Day for the children and their parents. The children ranged in age from 7 to 11 years. To teach them about anatomy, a special anatomy apron was fabricated. The apron had life-sized removable organs made of stuffed fabric. The children took turns wearing the apron

Table 28-2 **Comparison Chart for Education Methods (Adults and Children Unless Otherwise Noted)**

Type	Advantages	Disadvantages
Reading	Patient can refer back to material. Low effort for instructor.	Requires instructor follow-up for comprehension.
Lecture	Time-efficient for instructor. Cost-efficient.	Low interaction. May pacify rather than engage.
Demonstration	Adds sensory data to learning. Allows for problem solving and modification.	Instructor needs proficiency in the skill being taught.
Video	Access to restricted areas. Portrays events that are infrequent, costly, and difficult to reproduce. Portable.	Noninteractive. May pacify rather than engage. Requires costly electronic equipment. Difficult to control quality.
Audiotape	Portable. Useful for sight-impaired learner.	Requires electronic equipment.
Group discussion	Effective use of instructor time. Enlarges pool of real-life experiences. Nonthreatening to some learners. Mutual support possible.	Not as much individual attention given. Group may be hard to control (e.g., too talkative, shy, hostile). Strong facilitator skills needed.
Clubs, camps, and retreats	Draws on community and individual resources. Needs less professional input and time.	Same as above. Some risk for perpetuating myths and false information.
Individual instruction	Instructor can tailor learning to student's needs and desires. More one-on-one time.	Inefficient use of instructor time. Limited pool of experience on which to draw.
Games and directed activities	Helpful for children. Reduces anxiety. Uses repetition. Fun. Unexpected experiences can lead to new understandings or insights.	May be difficult to schedule space and find participants.
Computer programs	Interactive, self-paced. Large information capacity. Time-efficient for instructor.	Expensive. Special equipment and space needed. May require expert help.
Seminars and workshops	Diversity of instructors and formats. Pool of experts and community resources. Can tailor content broadly or narrowly.	Expensive. May cause scheduling and space problems.
Role-playing	Allows trial runs, problem-solving, simulated experiences.	Threatening to some. Can be time-consuming. Instructor needs to be skilled in techniques and in dealing with effects on participants.
Oral and written tests	Can provide instructor with evidence of what learner needs to be taught and what has been learned.	Literacy and supplies required, if written. May be time-consuming.

and learned to identify and locate the organs by removing and replacing the apron's heart, lungs, intestines, and pancreas.

By evaluating the advantages and disadvantages of available education methods, the physical therapist can choose the methods that are most effective and use them to his or her best advantage. Consideration must be given to cost, equipment, scheduling, labor, time, site, flexibility, and reusability. For example, digitally recorded or videotaped presentations may be easy for the instructor to schedule, present, and reuse, but they can be costly to purchase and they require expensive equipment for viewing.

Content

The specific content of patient education materials and programs should be determined by the needs of the individual or group being taught. There are, however, topics common to many cardiovascular and pulmonary education efforts. These topics are listed in Box 28-8. The physical therapist can use these topics as a checklist to explore the content covered (or to be covered) in a given cardiopulmonary education experience. Although physical therapists may not be responsible for teaching on all these topics, they should be familiar with all the topics taught by the healthcare team. Educational materials on all of these topics have already been developed by a variety of healthcare providers, educators, and organizations and may be available for use by physical therapists (see Interprofessional Considerations and Resources, later in this chapter).

Determination of Effectiveness

Determining the effectiveness of patient education efforts involves evaluating what the patient learned, as well as how the teacher taught. Sometimes patients learn in spite of educational efforts. Physical therapists need to examine their effectiveness at teaching and strive to improve their teaching skills just as they strive to improve their other clinical skills. Being able to communicate ideas and receive meaningful feedback from patients from diverse racial, ethnic, vocational, religious, and generational backgrounds is crucial for physical therapists. Formal or informal surveys of patients and families who have participated in education efforts can provide the physical therapist with information on teaching effectiveness from the patient and family perspective.

Physical therapists are responsible for evaluating and documenting the results of their patients' education activities.

Box 28-8 Cardiovascular and Pulmonary Patient Education Content

- Health promotion/wellness
- Smoking cessation
- Infection control
- Risk-factor awareness and modification
- Benefits and effects of pleasurable activity
- Resumption of sexual activity
- Normal cardiovascular and pulmonary anatomy and physiology, oxygen transport
- Cardiovascular and pulmonary disease process
- Airway clearance techniques and suctioning
- Energy conservation and pacing techniques
- Stress management: awareness of anxiety and depression and relaxation training
- Resumption of school activities (children)
- Instructions geared for parents of children with cardiovascular and pulmonary conditions
- Cardiopulmonary resuscitation (CPR), basic life support
- Heart rate, blood pressure, and dyspnea self-monitoring
- Nutrition
- Medications (schedules, actions, and side effects)
- Use of oxygen and other respiratory equipment
- Medical procedures (cardiac catheterization, bronchoscopy, cardiopulmonary transplantation)
- Community resources
- Emergency procedures
- Problem-solving techniques
- Sleep management skills

From Kunik ME, Veazey C, Cully JA, et al: COPD Education and cognitive behavioral therapy group treatment for clinically significant symptoms of depression and anxiety in COPD patients: A randomized controlled trial, Psychol Med *38, 385–396, 2008.*

Observing a patient or caregiver perform a skill (such as paced breathing) will give the physical therapist the opportunity to determine whether the patient or caregiver has learned and properly performed the skill. Once the physical therapist has observed the skill being properly performed or when the patient or caregiver has "taught back" the skill, the therapist can document it as such in the medical record. The amount of supervision and equipment required, if any, should also be included in the documentation.

Presenting information in visual form, for example, using pictorial aids and videos, has been recommended[37] for patients diagnosed with COPD who are identified as having limited health literacy. For patients undergoing cardiac catheterization, an interactive, computer-based information program is suggested.[38] Patient education for patients with coronary heart disease should be "multi-faceted and interprofessional."[39]

Teacher-Learner Relationship

According to Locke (1986),[40] the primary step to understanding others is an awareness of one's self. Acknowledging one's own personal values, interests, and biases will significantly increase one's sensitivity toward others. The skilled teacher is aware of his or her own communication style and its limitations and can convey the desire to help despite those limitations.

The teacher-learner relationship that develops between physical therapist and patient is largely the result of communication between the two in the context of culture. Communication is a two-way process consisting of verbal and nonverbal messages. The interpretation of these messages depends on the cultural cues operating in the educational setting. Fairchild (1970)[41] defines culture as all social behavior, such as customs, techniques, beliefs, organizations, and regard for material objects, including behaviors transmitted by way of symbols. According to Locke (1992), "the primary mode of transmission of culture is language, which enables people to learn, experience, and share their traditions and customs."[42] In addition, culture can be expressed or experienced via economic and political practices, art, and religion. Health care and medicine have their own cultures. To meet the needs of culturally diverse populations and engage in positive, productive relationships, physical therapists must operate from a framework of cross-cultural understanding. This understanding and knowledge can then be reflected in patient education efforts.

For example, in a large, urban, acute care hospital, two physical therapy staff members were working together to treat an older adult Jewish woman who was critically ill. The clinicians worked carefully to reposition the woman without disturbing the many tubes and lines that were present. Later the woman expressed that she did not want to have two physical therapy clinicians working with her at the same time. She confided to the nurse that it felt it was too much like the Jewish ritual washing of the body after death, which is traditionally performed by two people. This interpretation of the therapy surprised the physical therapy staff members who had treated the woman, because although they were also Jewish, this thought never occurred to them. The next time the clinicians went to see the woman, they explained why it was necessary for both of them to be present during the treatment. They also encouraged the woman to have other supportive people present and to play her favorite recorded music during the therapy session.

Communication

Patients with cardiovascular and pulmonary diseases, such as congestive heart failure, are not always comfortable communicating with health-care professionals or questioning the physician's decisions. In *Circulation* (2009),[43] the American Heart Association's publication, health-care professionals are encouraged to avoid using medical jargon and phrases (such as "echo," "stress test," and "ECG"), because these terms may confuse patients. Instead, health care providers should explain in plain terms the action steps they want a patient to take.[43] In 2011, the Heart Failure Society of America described a five-step process for clinicians working with patients who have heart failure,[44] culminating in encouraging patients' use of the "Ask Me 3" questions:[45]

1. What is my main problem?
2. What do I need to do?
3. Why is it important for me to do this?

Physical therapists can use the communication strategies outlined in Box 28-9 to create an effective educational experience to fit the individual learner's needs. These guidelines can

Box 28-9 Communication Strategies

- Avoid talking down to the patient.
- Use active listening; ask open-ended questions.
- Avoid jargon; minimize information about anatomy and physiology.
- Use simple sentence structure and plain language.
- Speak slowly; use analogies.
- Introduce no more than four main messages per session.
- Stress concrete, specific action steps the patient should take.
- Create an environment conducive to patients asking questions.
- Ensure understanding of information through regular review, patient demonstration, and repetition. Use the "teach back" method and have patients restate the information in their own words.
- Give directed feedback to correct errors until full understanding is achieved.

be tailored to a variety of patient populations with differing levels of health literacy.

Patient Adherence

The effectiveness of physical therapy treatment, or of any medical treatment, depends on the patient following the health-care provider's recommendations (adherence). Unfortunately, there is often a gap between what the patient is asked to do and what the patient actually does. This gap, or nonadherence, has an incidence rate estimated to be between 18% and 35%.[46,47] Factors affecting patient adherence include knowledge about the illness and its expected course, complexity of the recommendations, convenience, availability of support system, financial resources, the patient's beliefs, and the effectiveness of patient education, especially for pulmonary patients.[48]

Patient education can improve adherence when the information explains what behaviors are expected, when they should be performed, and what to do if problems arise. Plans for patient education sessions should strive to avoid or remove barriers to patient adherence. These efforts include simplifying and individualizing treatment regimens, fostering collaborative teacher-learner relationships, enlisting family support, making use of interdisciplinary and community resources, and providing continuity of care.[49] By using an approach that integrates these efforts, the physical therapist can optimize patient adherence to the prescribed physical therapy program.

Interprofessional Considerations and Resources

The interprofessional health-care team has evolved as the complexity and number of available medical treatments has grown. Physical therapists are trained to function as part of an interprofessional team and are responsible for learning the areas of responsibility and expertise covered by each member of their team. The team concerned with cardiovascular and pulmonary care consists of licensed and nonlicensed health-care providers and may include any or all of the following:

- Physician
- Nurse
- Physical therapist
- Occupational therapist
- Exercise physiologist
- Dietitian
- Laboratory technologist
- Pharmacist
- Social worker
- Chaplain or pastoral care associate
- Clinical psychologist
- Speech/language pathologist
- Vocational rehabilitation counselor
- Home-care personnel
- Respiratory therapist
- Equipment vendors
- Insurance company representative

All of the above providers may not be present on every team, but their services should be available for patients who need them. By understanding what services and patient education materials are provided by each discipline, the physical therapist can reinforce previously presented concepts and avoid giving conflicting information. This also allows the physical therapist to make referrals to the appropriate discipline when other knowledge deficits are identified.

Interprofessional team members can also provide the physical therapist with important patient feedback and information. Teaching methods found to be successful with a given patient by the nurse, for example, could be communicated to the physical therapist. The therapist can then use similar methods with that patient for physical therapy education objectives. Communication between team members is enhanced by regular team meetings or rounds and by having an electronic medical record to document completed patient education experience.

Health-related organizations can also be rich resources for patient education information. The American Heart Association and the American Lung Association, for example, offer many cardiovascular and pulmonary materials to health-care providers for little or no cost. State public health and local community service agencies may also be sources for printed or audiovisual materials. The U.S. Department of Health and Human Services has numerous divisions and institutes that address health education and research. Cardiovascular and pulmonary publications can be obtained from the Federal Consumer Information Center, Washington, DC (or at www.hhs.gov).

Community organizations such as YMCA, YWCA, and the American Red Cross offer a wealth of health education materials and classes. Many of these agencies also have catalogs of their educational offerings, which can be obtained by calling

- MedlinePlus

their local offices. Local public, medical, and hospital libraries are also useful for seeking out available health education materials. Many Chambers of Commerce keep lists of local support groups or clubs, such as Breather's Club or Heartbeats. Regional state colleges or universities have departments dedicated to health education and may have cardiovascular and pulmonary materials to share. Please refer to Box 28-10 for a list of trusted online sources of patient information.

Summary

This chapter defines patient education and describes selected learning theories as they relate to cardiovascular and pulmonary patient education. The evaluation of the patient's learning needs is emphasized, and the advantages and disadvantages of a variety of educational methods are discussed. The role of the teacher-learner relationship and patient adherence are explained in reference to the determination of patient education and treatment effectiveness. Finally, interprofessional health-care team interactions and resources for patient education materials are considered.

Review Questions

1. Discuss the benefits of patient education, including the impact on health-care costs and the patient's perception of wellness.
2. Contrast and compare a variety of teaching methods used in patient education.
3. Explain the rationale for patient education using concepts of adult learning theories or models.
4. Describe the aspects of planning for patient education.
5. Discuss the components of a learning needs assessment survey and ways to modify it for specific patient populations.
6. Critique a variety of written patient education materials using criteria specific to patients with cardiovascular and pulmonary conditions.
7. Explain how to determine the effectiveness of patient education activities from both the patient's and the physical therapist's point of view.
8. Discuss the components of a health literacy assessment and ways to modify interventions for those with limited health literacy.

Summary 486
Review Questions 486
References 486

This chapter describes the physical therapy management of individuals with primary, acute dysfunction of the cardiovascular and pulmonary systems. Such dysfunction may limit participation in life and its related activities in the short- or long-term. Further, such dysfunction can constitute life threat in the absence of limitations to life participation and quality of life (e.g., hypertension and dysrhythmias). Management principles for people with several types of common acute medical conditions are described. Although medical conditions are usually classified as either primary pulmonary disease or primary cardiovascular disease, the heart and lungs work synergistically to effect gas exchange and cardiac output and in series with the peripheral vascular circulation to effect tissue perfusion.[1,2] Thus impairment of one organ system invariably has implications for the function of the other. Threat to or impairment of oxygen transport has implications for all other organ systems; thus a multisystem approach is essential for overall management (see Chapters 1 and 5). The primary, acute pulmonary conditions that are presented in this chapter include atelectasis, pneumonia, bronchitis, bronchiolitis, acute exacerbations of chronic airflow limitation, asthma, cystic fibrosis, interstitial pulmonary fibrosis, and tuberculosis. For further epidemiological and pathophysiological detail on these conditions, refer to Mason and colleagues (2010)[3] and West[4] (2007). The primary, acute cardiovascular conditions presented include hypertension, medically stable angina, and uncomplicated myocardial infarction. For further details on these conditions, refer to Sokolow and Cheitlin[5] (2004), Fauci and colleagues[6] (2008), and Woods and colleagues[7] (2009).

The pathophysiology underlying the medical management of each condition extends the pathophysiology content of Chapter 5 and, in turn, provides a basis for each condition's physical therapy management. The management principles presented are not intended to serve as treatment prescriptions for any particular patient. The treatment priorities presented are based on the underlying pathology, as well as the potential complexity of its manifestation for a patient. Without discussion of a specific patient and knowledge of other clinically relevant factors (i.e., the effects of restricted mobility, recumbency, and the effects of extrinsic and intrinsic factors on the patient's presentation including sociocultural context; see Chapter 17); however, the specific parameters of the treatment prescription cannot be completely established. Integration of patient-specific information is essential for treatment to be specific and maximally effective. Chapter 31 extends the principles involved with the management of many of the acute

medical conditions described in this chapter, detailing their subacute and chronic stages.

Cardiovascular Pathology

Hypertension

Pathophysiology and Medical Management

Essential hypertension, the "silent killer" (of unknown etiology), is the most common type of hypertension (90% of all reported cases). Although salt sensitivity has been implicated in hypertension in African Americans and increased rennin production in the Hispanic population,[8] salt consumption is a serious health concern in the North American population. Widespread campaigns are being aimed at reducing salt consumption in the pediatric as well as adult population.[9] Reducing consumption by one-third is estimated to reduce the prevalence of hypertension substantially.

Generally, hypertension is classified as mild, moderate, or severe. It is generally managed pharmacologically with vasodilators (i.e., afterload reducers), diuretics (i.e., volume reducers), and beta-blocking agents (i.e., inotropic agents). Despite a primarily pharmacological orientation to the management of hypertension, a high proportion of individuals with hypertension still have high blood pressure and are at increased risk for its deadly complications. Hypertension is a significant health care concern in that the condition is frequently associated with heart disease, stroke, and renal dysfunction and failure.[10] Thus its consequences can be dire. As described in Chapter 1, hypertension often occurs in the presence of obesity and diabetes, which complicates the clinical picture further.

Pharmacological management may have a role in the control of hypertension, given its serious consequences and the necessity of maintaining blood pressure within acceptable limits. Like all medication, its effects must be monitored closely to ensure that the desired outcomes are being achieved. The following decisions must be made:

1. To what degree does pharmacological intervention appear warranted, given the patient's severity of hypertension and overall clinical picture?
2. To what degree could the hypertension be managed with nonpharmacological interventions?
3. To what degree could pharmacological and nonpharmacological interventions be used concurrently? What type of schedule might be anticipated to wean the patient off medication with time or at least minimize it?

Principles of Physical Therapy Management

Physical therapists treat patients with hypertension as a primary or secondary diagnosis. If it is a secondary diagnosis, it is important that the diagnosis is not overlooked. What the physical therapist can do for the hypertension may be clinically more significant than management of the primary diagnosis for which the patient is referred. As with many other lifestyle-related conditions, antihypertensive medication may be perceived by the patient as addressing the problem, whereas in many instances, it only addresses the effect. Lifestyle changes are necessary to normalize blood pressure with the goal of eliminating the need for blood pressure medication.[11]

Exercise therapy can be an effective intervention for the management of hypertension with the primary goal of eliminating the need for medication.[12] Secondarily, physical therapy with a focus on exercise and health education, including smoking cessation and basic nutritional counseling, is aimed at reducing the need for medication or its potency. The foundation of management in a patient with hypertension is a lifestyle review and recommendations in consultation with the patient. Recommendations include nutrition, weight control, exercise, smoking cessation, and stress management.[13] Medical management may include beta blockers and diuretics to reduce plasma volume or other antihypertensive medication. A prescription of regular aerobic exercise may control hypertension.[14] The prescription is based on a consideration of the patient's coexistent problems and general health status. If obesity is a concurrent problem, an exercise program is prescribed to address both concerns.

More frequently, physical therapists treat patients whose hypertension is a secondary condition. Thus, whether the patient is being treated for osteoarthritis, stroke, or cardiovascular and pulmonary dysfunction, treatment is modified accordingly. An exercise prescription includes generalized aerobic exercise at an intensity that is optimally therapeutic and not associated with any excessive or untoward hemodynamic responses.

Patients with labile hypertension are the most difficult patients for whom to prescribe an exercise program because of the irregularity of their blood pressure responses. The intensity is modified at each session to accommodate these variations. Because beta blockers and other medications blunt heart rate responses to exercise, the exercise prescription parameters are defined on the basis of some other objective hemodynamic response or on subjective responses (e.g., the Borg scale of perceived exertion).

The benefits of a modified aerobic exercise prescription include elimination of medication, reduction of medication, and improved pharmacological control on the same dose of medication. In addition, the patient derives all the other multisystem health benefits of exercise. A program of aerobic exercise should be carried out in conjunction with other lifestyle changes associated with blood pressure control (e.g., nutrition, weight control, stress reduction, and smoking cessation program). Medications should be monitored by the physician during the training program. In addition to exercise having a direct effect on controlling hypertension, the effect of exercise on overall metabolism may alter the absorption and degradation of the medications, which in turn can reduce the prescriptive requirements of that medication. Those types of exercise that are associated with a disproportionate hemodynamic challenge (e.g., static movements and stabilizing postures) are not usually indicated. Rather, aerobic exercise that is rhythmic, involves the large muscles of the legs and possibly the arms, and is performed frequently is indicated. Physical therapy outcomes include reduction or elimination of antihypertensive medication with self-monitoring and optimal lifestyle management.

A patient who is being managed acutely with high blood pressure may benefit from relaxation strategies, breathing control, and stress management. Further, complementary therapies, as described in Chapter 27 may have an important role. For noninvasive physical therapy management of hypertension, see Chapter 31.

Angina

Pathophysiology and Medical Management

Angina refers to pain resulting from ischemia of the myocardium and often precedes myocardial infarction. Coronary artery disease is the primary cause of myocardial infarction and is among the leading causes of death in the Western world. Lifestyle factors, including high-fat diet, stress, and low activity levels, contribute to atherosclerosis and fat deposition within the coronary blood vessels. When these deposits narrow or totally occlude the vessel lumen, blood flow is restricted or totally obstructed. As the heart continues to demand oxygen and nutrients in order to work properly, blood supply must be increased. If one or more of the myocardial blood vessels is stenosed, insufficient blood reaches the working myocardial fibers, and ischemia and pain result. The classic description of anginal pain is retrosternal, vice-like, gripping pain radiating to the left side and down the arm and up into the neck; however, anginal pain may occur bilaterally anywhere above the umbilicus. Furthermore, patients vary considerably with respect to the degree to which the severity of the pain correlates with the degree of myocardial ischemia and infarction. Thus even apparently minimal chest pain may be associated with significant ischemia, and its clinical significance should not be minimized. Approximately 10% to 15% of individuals who have a myocardial infarction do not report chest pain. Chest pain can also be blunted in individuals with diabetes as a result of the autonomic neuropathy.

Principles of Physical Therapy Management

The management of patients with ischemic heart disease who are hemodynamically unstable and require intensive monitoring to assess and to monitor physical therapy treatment is described in Chapter 34. This section addresses management of the patient with a cardiac medical condition who is stable and uncomplicated. Physical therapists must be knowledgeable and proficient in management of the patient with cardiac conditions because these patients are referred with cardiac disease as a primary or secondary problem. With respect to heart disease being a secondary diagnosis, patients often come to the physical therapist for the management of an orthopedic complaint with a history of angina, frank myocardial infarction, or hypertension. The principles for physical therapy in management of patients with acute ischemic heart disease are presented within the principles of phase I cardiac rehabilitation (Table 29-1). Because physical therapy invariably involves physically stressing a patient either with therapeutic exercise or with the application of a therapeutic modality, the physical therapist must address the following questions when managing a patient with ischemic heart disease and its risk factors:

1. Does the patient's cardiac status preclude treatment? Why?
2. Is additional information about the patient necessary before physical therapy assessment and treatment? What information?
3. How should treatment be modified? Why?
4. Is the patient using antianginal medication appropriately? Is the prescription current? Does the patient have the antianginal medication present at all times?
5. Are there other medications that may influence the patient's cardiovascular and pulmonary status and response to treatment? What are they? How might the patient's responses to treatment, particularly exercise, be affected?
6. What physiological parameters should be monitored before, during, and after treatment?
7. What is the patient's knowledge about his or her condition? Can the patient clearly identify what triggers the angina and what makes it worse and better? What lifestyle changes have been made? What should be reinforced and what education is necessary?

A key consideration in the management of any person with cardiovascular dysfunction is minimizing myocardial strain. Thus mobilization and exercise prescription must incorporate appropriate warm-up, steady-rate, cool-down, and recovery phases, and the type of exercise should be rhythmic and involve the legs (i.e., areas of large muscle mass) and possibly the arms as well. Initially, low-intensity activity that restricts the heart rate to no more than 20 beats above resting heart rate may be indicated to minimize the work of the heart without immobilizing the patient completely. Ejection fraction is not necessarily a good indicator of exercise tolerance because these variables are not well correlated. Upper-extremity work alone is more hemodynamically demanding than lower extremity work and thus is prescribed cautiously, if at all, at least in the early stage. Exercise or physical activity involving sustained static postures and isometric muscle contraction are contraindicated. Breathing should be coordinated with activity such that breath holding and straining are avoided.

Table 29-1 Phase I of Cardiac and Pulmonary Rehabilitation (Inpatient, <7 to 10 days)*

Cardiac Rehabilitation	Pulmonary Rehabilitation
After anginal attack, myocardial infarction, operative procedures including bypass surgery and valve surgery	After acute exacerbation or thoracic surgery (e.g., admission lung resection)
Optimize oxygen transport by directing treatment to the underlying limitations of structure and function (impairments)	Optimize oxygen transport by directing treatment to the underlying limitations of structure and function (impairments)

*Phases II, III, and IV are related to subacute and chronic care (see Chapter 31).

Modified from Piotrowicz R, Wolszakiewicz J: Cardiac rehabilitation following myocardial infarction. *Cardiology Journal* 15:481–487, 2008.

An individual with a history of angina, regardless of whether he or she is taking antianginal medications, must be hemodynamically monitored (i.e., heart rate, blood pressure, rate pressure product, and subjective responses; ECG monitoring may also be indicated).

Individuals prone to angina may exhibit symptoms in certain body positions.[15,16] Usually, this reflects an increased workload and increased work of the heart. Recumbent positions increase the mechanical work of the heart by increasing central blood volume.[17] These patients are not encouraged to lie flat. Instead, the head of bed is elevated 10 to 15 degrees. Side-lying positions, particularly left side-lying, increase the work of the heart by compressing the heart and impeding ventricular filling and ejection. Patients with impaired oxygen transport and without prior cardiac disease may exhibit myocardial stress and ischemia in these body positions. Thus patients with impaired or threatened oxygenation must be monitored closely, particularly during turning and activities in which oxygen demand is increased—at these times, oxygen delivery must be increased correspondingly.

The use of medication to minimize the risk for angina and ischemic heart disease warrants review. The need for statins, commonly prescribed lipid-lowering medications, can be reduced through optimal lifestyle choices in many patients. One inherent danger of such a drug, however, in addition to its well documented side effects, is that patients may become complacent, believing that the drug will offset the need to make necessary lifestyle changes. More important, lifestyle changes largely address the cause of the problem, whereas medication such as statins only address an effect. The principles of the physical therapy management of patients with stabilized angina include health education, risk factor reduction, and a long-term health program (see Chapters 24 and 31).

Uncomplicated Myocardial Infarction

Pathophysiology and Medical Management

Myocardial infarction, commonly referred to as a heart attack, refers to insufficient myocardial perfusion resulting in a macroscopic area of damage and necrosis of the heart. Infarction results most frequently from narrowing and occlusion of the coronary blood vessels secondary to atherosclerosis. Other causes include occlusion secondary to a thrombus or embolus, reduced blood pressure, or coronary vasospasm. Angina, or ischemic chest pain, often precedes or accompanies a myocardial infarction. Infarctions vary in severity from being silent (i.e., having no characteristic signs and symptoms and thus going undetected) to being fatal. Most infarctions, when detected, require some hospitalization and monitoring to ensure that the infarction is not evolving further and that the patient is medically stable and in no danger. Chapter 34 describes the management of patients with complicated myocardial dysfunction who are admitted to a coronary care unit. This section focuses on the patient with mild heart disease, the patient with cardiac dysfunction who is discharged from hospital, the patient who has a history of ischemic heart disease, and the patient who is hospitalized for a condition other than heart disease but develops and is being managed for myocardial ischemia. Judicious movement and body positioning are essential elements in the management of the patient with myocardial infarction.[18] Because these interventions can place significant demands on cardiovascular and pulmonary function and oxygen transport, they must be prescribed specifically by physical therapists with considerable knowledge and expertise in the area.

Principles of Physical Therapy Management

Table 29-1 shows the primary components of care in the acute phase of management (phase I of cardiac rehabilitation). Physical therapy constitutes a prime hemodynamic stress secondary to exercise and gravitational stress secondary to mobilization/exercise and body position changes. Thus it is essential to establish the adequacy of the patient's cardiovascular and pulmonary system to effect oxygen transport during and between treatments. The optimal treatment prescription is based on the patient's overall signs and symptoms of coronary insufficiency and hemodynamic instability. The physical therapist must be knowledgeable in detecting inadequate myocardial tissue perfusion and in reducing and preventing myocardial tissue damage. In addition, acute or chronic impaired heart pump function leads to reduced cardiac output and systemic tissue perfusion. Clinical manifestations include reduced mentation, reduced renal function, fatigue, malaise, and moist, cool, and cyanotic skin.

Regardless of whether the patient is being treated in the hospital (in a general ward or in the physical therapy department within the hospital) or in the private physical therapy clinic, the patient must be hemodynamically monitored. Minimally, heart rate and blood pressure must be taken before, during, and after treatment, along with a subjective rating of anginal chest pain. ECG monitoring is usually continuous in the early stages of the infarction. The object of treatment is to have the patient remain below his or her anginal threshold so that anginal pain is avoided. Breathlessness or rating of perceived exertion may also be used. The rate pressure product (RPP) (i.e., the product of heart rate and systolic blood pressure) is highly correlated with myocardial oxygen uptake and work. Previous stress tests will establish the RPP at which angina occurs, and the intensity of the exercise dose should be set at 65% to 80% of this threshold. Patients on beta-blockers have a blunted hemodynamic response to exercise, particularly heart rate responses. In such cases, use of ratings of perceived exertion to define the upper and lower limits of an acceptable mobilization stimulus may be indicated.

In some cases, patients have labile angina (i.e., the onset of angina does not occur reliably at a given RPP). This patient and the patient who reports angina at rest are at higher risk, and appropriate precautions must be taken. First, the patient must be assessed to establish that treatment is not precluded (see pertinent questions to be answered before treating a patient with angina). Second, monitoring is essential and may include ECG monitoring. Third, treatments are prescribed below symptom threshold, which is usually consistent with a low exercise intensity in these patients. Comparable with any patient experiencing low functional work capacity, exercise prescribed on an interval schedule enables the patient to achieve a greater volume of work.

When selecting body positions for the patient with a myocardial infarction, the therapist selects those that will minimize the work of breathing and of the heart.[19] Significant central fluid shifts are minimized by encouraging the upright

position as much as possible to reduce the work of the heart[20] and by raising the head of the bed 10 to 15 degrees when the patient is recumbent. Patients with elevated intracardiac pressures are less susceptible to orthostatism (see Chapter 20).

Similar to the management of the patient who has a history of angina, the therapist should avoid body positions, static postures, activities, and respiratory maneuvers associated with increased hemodynamic strain (e.g., breath holding).

Relaxation is central in the management of the cardiac patient who is prone to being anxious and apprehensive. Furthermore, such patients have a high prevalence of sleep-disordered breathing,[21] so a sleep assessment is warranted. Relaxation interventions that can be suggested include autogenic relaxation, progressive relaxation, Benson's relaxation response procedures, biofeedback, and meditation. Also, the patient needs to identify and minimize stress triggers and effective, individual-specific, nonpharmacological relaxants. Relaxation training with or without pharmacological support can be integrated into treatment.[7] Patients with ischemic heart disease are often apprehensive and anxious about the intensity of physical activity they can undertake. Thus performing physical activity and exercise while monitored and under the supervision of a physical therapist is often reassuring and gives the patient confidence to perform activity when unsupervised.

The quality and quantity of the patient's sleep and a profile of sleep-wake periods should be reviewed to ensure he or she is deriving maximal benefit. Rapid-eye-movement sleep with bursts of sympathetic activity during the early hours of the morning may constitute a period of increased risk for the patient with cardiac dysfunction.

Appropriate safety precautions must be taken in all settings where physical therapists practice, given that most physical therapy interventions physically stress patients and that coronary symptoms can occur regardless of whether the patient has a known underlying ischemic heart disease. In addition, because the overall U.S. population is aging, physical therapists are treating a growing number of older persons who are known to have a higher prevalence of cardiovascular conditions. In addition, young adults are presenting with symptoms and signs of cardiovascular conditions.

Optimal lifestyle habits and a lifelong health plan are central to maximizing recovery and improving an individual's long-term prognosis. Good nutrition and hydration, good sleep habits, stress management, smoking cessation, and regular physical exercise are all salient to comprehensive physical therapy management (see Chapters 24 and 31). As in the management of patients with other lifestyle-related conditions, the physical therapist needs to reinforce public health policy and health promotion guidelines regarding healthy lifestyle choices, including avoidance of inactivity and regular physical activity.[22]

Pulmonary Pathology

Atelectasis

Pathophysiology and Medical Management

Atelectasis refers to partial collapse of lung parenchyma. The pathophysiological mechanisms contributing to atelectasis are multiple (Table 29-2). These mechanisms include physical compression of the lung tissue (e.g., resulting from increased pleural fluid, pus, pneumothorax, compression during thoracic surgery, or adjacent areas of lung collapse) or obstruction of an airway (e.g., due to secretions or tumor) with subsequent reabsorption of oxygen from the trapped air by the pulmonary capillaries resulting in a collapse of the lung tissue distal to the obstruction (i.e., reabsorption atelectasis).

There are two primary types of atelectasis: microatelectasis and segmental and lobar atelectasis. Microatelectasis is characterized by a diffuse area of lung units that are perfused but not ventilated, leading to a right-to-left shunt. Ill and hospitalized patients who are deprived of being regularly upright and moving have reduced lung volumes and are prone to breathing at low lung volumes, which leads to microatelectasis. Thus such patients require prophylactic measures to avoid the effects of atelectasis on oxygen transport and gas exchange. When the conditions for normal lung inflation are removed, alveolar collapse occurs instantly.

Microatelectasis is associated with reduced lung compliance because of reduced lung expansion. Patients who are mechanically ventilated are prone to microatelectasis because the normal mechanics of breathing are violated. This may be explained in part by restricted mobility, recumbency, and reduced arousal, in addition to reduced functional residual capacity (FRC). Positive end-expiratory pressure (PEEP) is routinely added to minimize these effects. High ventilator system pressure is required to counter reduced lung compliance, which indicates that atelectatic lung tissue it not readily re-expandable.

Microatelectasis is not diagnosed readily with chest x-ray but can be established in conjunction with clinical findings. Nonetheless, microatelectasis can be anticipated in every ill and hospitalized patient whose normal respiratory mechanics are disrupted, particularly in recumbent, relatively immobile patients. These effects are further exacerbated in patients who are smokers, older, overweight, sedated, have abdominal masses, spinal deformities, or chest wall asymmetry, or some combination of these factors.

Commensurate with its distribution, atelectasis presents with reduced chest wall movement and reduced breath sounds over the involved area. A chest x-ray shows increased density over the involved areas with a shift of the trachea and mediastinum toward the collapsed lung tissue. The patient may be tachypneic and cyanotic because of shunting. Segmental atelectasis results from progression of microatelectasis and obstruction of airways with reabsorption of gas in the distal lung units of a bronchopulmonary segment or lobe.

The patient who depends on a mechanical ventilator to breathe is predisposed to atelectasis because of an unnatural, monotonous breathing pattern, restricted movement, and abnormal and prolonged recumbent body positions. These factors contribute to reduced mucociliary transport, abnormal distribution of pulmonary mucus, and the accumulation of mucus in the dependent lung fields. Furthermore, production of mucus may be increased as a result of tracheostomy or the presence of an endotracheal tube. Mucociliary clearance is further compromised by reduced ciliary activity resulting from high concentrations of oxygen, medication, and loss of an effective cough due to an artificial airway.

The effect of atelectasis on oxygen transport reflects its type and distribution. Hypoxemia, right-to-left shunt, reduced lung compliance, and increased work of breathing are common

Table 29-2 Pathophysiological Mechanisms Contributing to Atelectasis

Central Mechanisms	Breathing at low lung volumes (e.g., when in pain or after certain medications) Inability to generate adequate inspiratory pressure and volume Central disruption of breathing centers controlling normal periodic and rhythmic breathing pattern
Extramural Mechanisms	Chest wall deformity Asymmetry of intrathoracic structures Respiratory muscle weakness (e.g., neuromuscular disease) Phrenic nerve inhibition (e.g., secondary to upper abdominal or cardiovascular thoracic surgery) Compression of lung parenchyma secondary to pleural fluid accumulation, blood, plasma, and pus Compression of lung parenchyma during surgery Reduced lung expansion secondary to reduced movement Compression of lung parenchyma secondary to static body positioning Compression of lung parenchyma secondary to prolonged static body positioning Mechanical ventilation Increased alveolar surface tension
Mural Mechanisms	Airway narrowing secondary to increased bronchial smooth muscle tone Calcification or altered anatomical integrity of airways Edema of the bronchial wall and epithelium
Intramural Mechanisms	Impaired mucociliary transport Increased pulmonary secretions Inspissated pulmonary secretions Altered distribution of pulmonary secretions Mucus plug
Space-Occupying Lesions	Exudative and transudative fluid in the lung parenchyma Foreign-body aspiration Inflammation
Other Factors	Increased compliance and dynamic airway compression secondary to age-related changes to the lung Increased time constants because of increased airway resistance, reduced compliance, or both Splinting or casting of chest wall restricting normal three-dimensional chest wall movement Pain and altered breathing pattern Medications including narcotics, sedatives, and relaxants Supplemental oxygen

clinical manifestations. An increased temperature reflects inflammation or infection and not atelectasis per se.

Principles of Physical Therapy Management

Because it can develop instantaneously when respiratory mechanics are disrupted, microatelectasis should be anticipated and prevented. Those factors that contribute to atelectasis for a given patient are countered accordingly with aggressive prophylactic management. Many of the causes of atelectasis outlined in Table 29-2 can be readily reversed. The assessment includes a detailed analysis of the underlying cause(s) and mechanism(s) so that these can be addressed directly for a given patient.

Atelectasis is always treated aggressively because it has the potential to worsen, develop into a severe clinical manifestation, and lead to pneumonia. In turn, overwhelming pneumonia can precipitate acute respiratory distress syndrome (Chapter 36), which is associated with considerably poorer outcomes. Based on long-standing physiological evidence, treatment continues to be primarily directed at reversing the underlying contributing mechanisms whenever possible. For example, atelectasis resulting from restricted mobility is remediated with mobilization. Atelectasis resulting from prolonged static positioning and monotonous tidal ventilation is managed with mobilization, manipulating body position to increase alveolar volume of the atelectatic area, manipulating body position to optimize alveolar ventilation, or some combination of these interventions. Atelectasis arising from reduced arousal is managed by minimizing the causative factors contributing to reduced arousal coupled with frequent sessions of mobilization and the upright position to stimulate arousal, promote greater tidal volumes and alveolar ventilation, increase zone 2 (area of optimal ventilation and perfusion matching), increase FRC, and minimize closing volume. Most often in a given patient, atelectasis results from a combination of these factors, thus necessitating a multipronged approach in its management.

Breathing control and coughing maneuvers augment the cardiovascular and pulmonary physiological effects of mobilization and body positioning. Coordinating these interventions distributes ventilation more uniformly rather than directing gas to already open alveoli, which overdistends these units. The distribution of ventilation has long been known to be altered primarily by body positioning rather than deep breathing.[23] Sustained maximal inspiratory efforts may augment alveolar ventilation; however, the parameters necessary for such efforts to be maximally therapeutic remain to be elucidated.

If impaired mucociliary transport or excessive secretions are obstructing airways and contributing to atelectasis, mobilization of pulmonary secretions is the goal. Mobilization and a physiological stir-up regimen[24] are instituted as soon as possible for multiple reasons in patients who are acutely ill to augment oxygen transport and minimize reduction in aerobic capacity (Chapter 18). In the event of excessive secretions,

mobilization may need to be more vigorous to stimulate eucapnic deep breaths and inspiratory efforts and, hence, effective coughs. Stir-up, coined 70 years ago by Dripps and Waters[25] aptly describes the clinical role of physiologically perturbing a patient to reduce risk and improve outcomes.

Pneumonia

Pathophysiology and Medical Management

Pneumonia is a common complication and cause of morbidity and mortality in the hospitalized patient, particularly in the very young and very old. Comparable to other types of infections, pneumonia results when the normal defense mechanisms fail and, in this case, inadequately protect the lungs from infection, particularly where atelectasis has developed. Infiltrates secondary to pneumonia may result from areas of atelectasis as well as contribute to further atelectasis.

As air is inspired through the nasal passages, it is cleansed of particulate matter by filtration (cilia sweep it to the nasopharynx), impaction (irregular contour of the chamber causing particles to rain out), swelling of hygroscopic droplet nuclei (which are either filtered or become impacted), and defense factors located in the mucous blanket, such as immunoglobulins (IgA), lysozymes, polymorphonuclear leukocytes, and specific antibodies. Particles that escape one of these defense mechanisms in the nasopharynx may be prevented from entering the lower airways of the larynx. The mucosa of the larynx is sensitive to chemical irritation or mechanical deformation and responds by eliciting the cough reflex. The high velocities created by the cough are sufficient to clear several branches of the tracheobronchial tree of particulate matter. The cough reflex is frequently absent or depressed in patients who are unconscious from drug overdose, epilepsy, alcohol ingestion, or head injury. Patients with artificial airways are more susceptible to infection because the normal defense mechanisms are bypassed, causing organisms to be deposited directly in the lower airways. In the lower airways, the cough mechanism is rendered ineffective by endotracheal tubes, which prevent approximation of the vocal cords, and by tracheostomy tubes, which cause air to bypass the cords altogether.

The trachea and the tracheobronchial tree to the level of the respiratory bronchioles are protected by the cough reflex, filtration (again by cilia, which transport particles to the pharynx), impaction, and chemical factors (IgA). Below the level of the respiratory bronchioles, the cough reflex is ineffective and filtration and transportation of particles by cilia cannot occur because cilia are absent. The alveolar macrophages play an important role in protecting these airways from particulate matter. Macrophages ingest organisms and transport them to the lymphatic system or higher in the tracheobronchial tree, where cilia can sweep them to the pharynx. This process of phagocytosis can be slowed or stopped by hypoxia, alcohol ingestion, air pollutants, corticosteroids, immunosuppressant agents, starvation, cigarette smoke, and even supplemental oxygen.

Routes of Infection

A patient who has impaired or ineffective defense mechanisms of the respiratory tract becomes susceptible to a variety of organisms. The major routes of infection include airborne organisms, circulation, contiguous infection, and aspiration. In the past 20 years, hospitalized patients whose immunity is compromised are susceptible to superbug infections, which necessitates aggressive medical management and isolation techniques.[26]

Viral Pneumonias

Most respiratory viral infections are contracted by droplets from the respiratory tracts of infected persons. These viruses are responsible for interstitial pneumonias, tracheobronchitis, bronchiolitis, and the common cold. The ciliated cells of the respiratory tract are the most frequent site of infection. They become paralyzed and degenerate, with areas of necrosis and desquamation. The mucociliary blanket becomes interrupted because destruction of the cilia leaves a thin layer of nonciliated basal replacement cells. Inflammatory responses cause exudation of fluid and erythrocytes in both the alveolar septae and the airways. Congestion and edema become predominant with the formation of intraalveolar hyaline membranes. These changes in the normal mucosal structure and cilia increase the susceptibility of the involved lung to superimposed bacterial infections. This is the most common complication associated with viral infections and is usually responsible for the fatalities that occur.

The patient with viral pneumonia presents with fever, dyspnea, loss of appetite, and a persistent, nonproductive cough. On auscultation, normal breath sounds are heard throughout both lung fields with scattered inspiratory crackles. X-ray changes range from minor infiltrates to severe bilateral involvement. Consolidation and pleural effusions occur less frequently. Secondary bacterial infections occur frequently, causing patients to develop productive coughs.

Influenza may lead to viral pneumonia in 1% to 5% of cases. Influenza includes acute viral respiratory tract infection and is characterized by a sudden onset of headache, myalgia, and fever. The route of infection is by inhalation of airborne particles from an infected person. The incubation period is 24 to 72 hours.

Pulmonary lesions include edema of the respiratory epithelium with necrosis and hemorrhage. At the alveolar level, interstitial edema, proliferation of type I cells, hemorrhage, and an increased number of macrophages are seen. In patients with pneumonia, secondary bacterial infections are frequent and are the cause of most fatalities.

Medical management of viral infections is supportive and preventive. Patients should receive vaccines whenever possible to build up antibodies against specific viruses. Once the patient has contracted the organism, treatment becomes supportive, with rest, salicylates, and high fluid intake being the main treatment priorities. Patients who become more acutely ill with viral pneumonia should be on a vigorous preventative program to lessen the possibility of bacterial infection. Recovery also depends on good nutrition, hydration, sleep, rest, and reduced stress.

PRINCIPLES OF PHYSICAL THERAPY MANAGEMENT

Patients may respond to mobilization coordinated with breathing control exercises and positional rotation for enhancing alveolar ventilation, mucociliary transport, and gas

exchange overall.[27] Extreme body positions have long been known to enhance alveolar volume and ventilation as well as ventilation and perfusion matching.[28-31] Vigorous treatment should be initiated at the first sign of a superimposed bacterial infection, which is often accompanied by a productive cough. The appropriate devices should be prescribed at this time (e.g., ultrasonic or medication nebulizers to loosen secretions). Postural drainage may be indicated in addition to mobilization for airway clearance. Treatments, particularly mobilization, must be paced to avoid unduly tiring the patient or increasing oxygen demand beyond the patient's capacity to adequately deliver oxygen. Increasing oxygen demands excessively may compromise the patient's gas exchange. Patient education is also fundamental to the treatment that is to be instituted between treatments (i.e., mobilization and positional rotation coordinated with breathing control and coughing maneuvers).

The goal of cardiovascular and pulmonary physical therapy in the management of viral pneumonia is to augment alveolar ventilation, increase perfusion, increase diffusion, and improve ventilation and perfusion matching, thereby reducing the threat to oxygen transport and gas exchange. Treatments are prescribed to optimize oxygen transport and gas exchange, minimize fatigue and lethargy, and help reduce further infection risk.

Bacterial Pneumonia

Bacterial pneumonia causes the largest number of deaths per year by an infective agent and is a major cause of death, particularly in young patients and older adults. The patient presents with an abrupt onset of a severe illness characterized by fever, tachypnea, dyspnea, hypoxemia, tachycardia, and a cough that produces bloody or purulent sputum. The clinical findings depend on the organism involved and the extent of the pneumonia in the lungs. The infective process may resolve with medications, aerosols, and physical therapy, or it may spread to contiguous areas, causing pleural effusion and empyema.

Bacterial pneumonia can occur as either primary or secondary infections. Primary pneumonias arise in otherwise healthy individuals and are usually pneumococcal in origin. Secondary pneumonias occur when the patient's defense system becomes ineffective.

Pneumococcal pneumonia is caused by pneumococcal bacteria, a gram-positive organism. It occurs most frequently in the winter months in adults, often males, between 15 and 40 years of age. Patients present clinically with abrupt illness characterized by fever, cough, purulent or rust-colored sputum, and pleuritic chest pain over the affected lung field. Physical examination may reveal decreased expansion of the chest over the affected area and muscle splinting. On auscultation, there may be bronchial breath sounds (indicating consolidation), decreased or absent breath sounds, and wheezes or crackles over the affected lung. Chest x-rays may show atelectasis, infiltrates, and consolidation.

There are four stages associated with bacterial infection of lung tissue: engorgement, red hepatization, gray hepatization, and resolution. The engorgement stage occurs within the first few days of infection and is characterized by vascular engorgement, serous exudation, and evidence of bacteria colonization. Red hepatization occurs within 2 to 4 days as a result of diapedesis of the red blood cells. The alveoli are full of polymorphonuclear leukocytes, fibrin, and red blood cells. The organism continues to multiply within the fluid exudate. Areas of consolidation become evident. Gray hepatization occurs within 4 to 8 days and is characterized by evidence of abundant fibrin, decreased polymorphonuclear leukocytes, and dead bacteria. Consolidation continues to be a problem in this stage. Resolution occurs after 8 days as areas of consolidation begin to resolve. Many macrophages are seen, and evidence of enzymatic digestion of exudate is present. The affected tissue becomes softer with large amounts of grayish-red fluid present within the alveoli. This process continues for 2 to 3 weeks with the lung gradually assuming a more normal appearance.

Pleural involvement occurs frequently, with the pleural spaces filling with the same type of fluid seen within the alveoli. Resolution is slower because there are few surfaces available for phagocytosis. Complications that may occur in patients with pneumococcal involvement include empyema, superinfections (occur when large numbers of new organisms invade the lung), abscesses, atelectasis, and delayed resolution (defined as taking more than 4 weeks to resolve).

Treatment of pneumococcal pneumonia includes the use of antibiotics. Thoracentesis is performed when pleural fluid is present. The patient should also receive ultrasonic nebulization and physical therapy. If severe, supplemental oxygen therapy may be indicated.

Staphylococcal pneumonia is caused by a gram-positive organism. It rarely occurs in the healthy adult but is a frequent cause of pneumonia in children, infants, and patients with chronic lung diseases, especially carcinoma, tuberculosis, and cystic fibrosis. Clinically, the patient's manifestations are similar to those seen in the patient with pneumococcal pneumonia. Some differences appear in the chest x-ray (e.g., patchy areas of infiltrate). Consolidation occurs infrequently in this type of pneumonia. Pleural effusions, empyema, abscesses, bronchopleural fistulas, and pneumatoceles (subpleural cyst-like structures) often occur. Treatment includes medication, rest, increased fluid intake, ultrasonic nebulization or medication nebulizers, and aggressive physical therapy.

Streptococcal pneumonia is caused by a gram-positive organism, *Streptococcus pyogenes*. It occurs most frequently in very young, very old, or debilitated patients. The clinical picture is very similar to that of staphylococcal pneumonia. Again, consolidation is rare and chest x-rays usually show one or more areas of patchy infiltrates. Complications are rare, but empyema does occasionally occur. Treatment for this organism is the same as that for pneumococcal pneumonia.

Haemophilus influenzae pneumonia is caused by a gram-negative organism and occurs primarily in children as bronchiolitis and in adults who have chronic bronchitis. The clinical picture is the same as for the other bacterial pneumonias, with numerous areas of infiltration evident on x-ray. On auscultation, breath sounds are generally good, with crackles heard at the end of inspiration. Treatment of this pneumonia includes antibiotics, oxygen, ultrasonic nebulization, and physical therapy.

Other gram-negative organisms causing pneumonia include *Escherichia coli* and *Pseudomonas aeruginosa*. These are seen most frequently in patients with underlying disease, especially pulmonary disease, and in those who are debilitated. These organisms are frequently the cause of superinfections

in individuals who have received massive doses of broad-spectrum antibiotics. Clinically, these patients present with cough, fever, and dyspnea. On auscultation, crackles, bronchial breathing, and diminished or absent breath sounds can be noted. X-ray changes frequently show bibasilar infiltrates, with the amount of involvement being widely variable. As for other bacterial pneumonias, treatment includes medications, ultrasonic nebulization, and physical therapy.

Principles of Physical Therapy Management

The goals of management of bacterial pneumonia include reversing alveolar hypoventilation, increasing perfusion, reducing right-to-left shunt, increasing ventilation and perfusion matching, minimizing the effects of impaired mucociliary transport, minimizing the effects of increased mucous production, and optimizing lymphatic drainage of the lungs. Bacterial pneumonia is frequently associated with increased mucus production. With respect to airway clearance, management focuses on augmenting mucociliary clearance overall, reducing excess mucus accumulation, and reducing mucus stasis. The role of traditional manual physical therapy techniques remains equivocal in the management of adults with pneumonia.[32] Patients are often mobile and should be encouraged to be so to promote lung expansion, augment flow rates, stimulate deep tidal volumes (breaths), and augment mucociliary transport and lymphatic drainage.[27,33,34] The oxygen demands of mobilization and exercise, however, must be within the patient's capacity to delivery oxygen. These interventions are prescribed such that they avoid jeopardizing this balance and unduly fatiguing the patient. Deep breathing and effective coughing are important maneuvers for clearing airways with special attention to the avoidance of airway closure. Prescriptive body positioning can be used to optimize ventilation and perfusion matching,[29,35-37] which may be more uniform in the prone position[38] (see Chapter 20). A secondary goal is offsetting aerobic deconditioning from this episode of acute illness, particularly in older adults or patients who are debilitated with chronic conditions.

Acute Exacerbation of Chronic Bronchitis

Pathophysiology and Medical Management

Chronic bronchitis is a common condition in smokers and is characterized by a cough that produces sputum for at least 3 months overall and recurs for 2 consecutive years. Pathological changes include increased size of the tracheobronchial mucous glands and goblet cell hyperplasia. Mucous cell metaplasia of bronchial epithelium results in a decreased number of cilia. Ciliary dysfunction and disruption of the continuity of the mucous blanket are common. In the peripheral airways, bronchiolitis, bronchiolar narrowing, and increased amounts of mucus are observed.

Chronic bronchitis results from long-term irritation of the tracheobronchial tree. The most common cause of irritation is cigarette smoking. Inhaled smoke stimulates the goblet cells and mucous glands to secrete excessive mucus. Smoke also inhibits ciliary action. The hypersecretion of mucus, ciliary damage, and dyskinesis lead to impaired mucus transport and a chronic productive cough. The fact that smokers secrete an abnormal amount of mucus increases the risk for respiratory infections and increases the length of the recovery time from these infections. Although smoking is the most common cause of chronic bronchitis, other factors that have been implicated are air pollution, certain occupational environments, and recurrent bronchial infections.

Although many patients with chronic bronchitis have a high partial pressure of carbon dioxide on arterial blood ($PaCO_2$), the pH is normalized by renal retention of bicarbonate. Over the long term, the bone marrow produces more red blood cells, leading to polycythemia. The work of the heart is increased as a result of higher blood viscosity. Long-term hypoxemia leads to increased pulmonary artery pressure and right ventricular hypertrophy.

Patients with chronic bronchitis have tenacious, purulent sputum that is difficult to expectorate. In an exacerbation (usually caused by inflammation or infection or both), these patients produce even more sputum, which tends to be retained and to stagnate. Retained secretions obstruct airways, thus air flow, and reduce alveolar volume. The resulting ventilation and perfusion inequality increases hypoxemia, carbon dioxide (CO_2) retention, accessory muscle use, metabolic demand, and breathing rate. Partial arterial oxygen tension (PaO_2) is further reduced, and $PaCO_2$ tends to increase. Hypoxemia and acidemia increase pulmonary vasoconstriction, which increases pulmonary artery pressure and predisposes the patient to right heart dysfunction or failure over time.

A patient with an acute exacerbation of chronic bronchitis tends to have the following characteristics: (1) The patient is often stocky in build and dusky in color. (2) The patient exhibits significant use of accessory muscles of respiration and has audible wheezing or wheezing that is audible on auscultation. (3) Intercostal or sternal retraction of the chest wall may be noted. (4) Edema in the extremities, particularly around the ankles, and neck vein distention reflect decompensated right heart failure. (5) The patient may report that breathing difficulty began with increased amounts of secretions (with a change in their normal color), which is often difficult to expectorate, and increased cough productivity. (6) PaO_2 is reduced, $PaCO_2$ increased, and pH reduced. Pulmonary function tests indicate reduced vital capacity, forced expiratory volume in 1 second (FEV_1), maximum voluntary ventilation, and diffusing capacity, as well as increased FRC and residual volume. Debility and deconditioning contribute to suboptimal health, accentuated symptoms, and compromised function.

Principles of Physical Therapy Management

During an exacerbation requiring hospitalization, patients with chronic bronchitis are usually treated with intravenous fluids, antibiotics, bronchodilators, and low-flow supplemental oxygen. Diuretics and digitalis are often given to treat associated right heart failure. Airway clearance interventions are selected (i.e., mobilization, body positioning, and possibly postural drainage). These interventions are coordinated with breathing control and coughing maneuvers to facilitate secretion removal and optimize coughing and expectoration while minimizing dynamic airway compression and alveolar collapse. During recovery, exercise is increased with supplemental oxygen as needed. These patients need to avoid exposure to

bronchial irritants (e.g., cigarette smoking, second-hand smoke, and air pollutants) and be adequately hydrated to thin secretions to facilitate mucociliary transport and expectoration.

Patients with chronic bronchitis can benefit from a comprehensive rehabilitation program designed for patients with chronic pulmonary disease, and such a program is best initiated within 1 month of an exacerbation.[39] Even modest exercise has long been known to improve walking capacity and subjective well-being.[40] Components of acute management are shown in Table 29-1 and are comparable to cardiac rehabilitation phase I. Specific details of exercise prescription in the management of chronic obstructive pulmonary disease and of a comprehensive pulmonary rehabilitation program are described in Chapters 24 and 31. Maximizing health and risk factor reduction are principal goals to minimize further pulmonary pathological changes and damage including irreversible emphysema. High-priority strategies include targeted education, smoking cessation, and nutritional and exercise counseling. Individuals who do not have access to such formal structured pulmonary programs (the majority of people), can be managed by the physical therapist, who applies the same principles of practice on an individual basis.

Bronchiolitis

Pathophysiology and Medical Management

Bronchiolitis results from peripheral airway inflammation. Although bronchiolitis is more often seen in babies and small children because of the small caliber of their airways (Chapter 37), adults may be afflicted with this condition, often secondary to some other condition. In severe bronchiolitis, the exudate in the peripheral airways becomes organized into a connective tissue plug extending into the peripheral airway. The inflammatory process resembles that in other tissues (i.e., an inflammatory stage followed by a proliferative healing stage). Such inflammation is associated with vascular congestion, increased vascular permeability, formation of exudate, mucus hypersecretion, shedding of the epithelium, and narrowing of the bronchioles. Fluid is exuded out of the circulation onto the alveolar surfaces, replacing the surfactant. This, in turn, increases the surface tension and promotes airway closure. The secretion production associated with airway irritants and inflammation results from the excess mucus production in combination with the inflammatory exudate, consisting of fluid protein and cells of the exudate. The underlying pathophysiological cascade contributes to both a restrictive and an obstructive component of pulmonary limitation. Airway obstruction results if these exudative substances are not removed. The airway epithelium has the capacity to repair and reline the lumen. A rapid turnover of cells may contribute to cell sloughing and further airway obstruction and a thickened basement membrane. The obstruction associated with bronchiolitis leads to ventilation and perfusion abnormalities and diffusion defect. Clinically, the patient presents with a productive cough. Obliterative bronchiolitis has been reported to be the most significant long-term complication of heart-lung transplantation.[3] Medical management is directed at inflammation control with medications, fluid management, and oxygen administration if necessary. Prevention of infection is a priority.

Principles of Physical Therapy Management

The principal pathophysiological deficits of bronchiolitis include ventilation and perfusion inequality and a diffusion defect. These deficits result from secretions produced by inflammation and increased mucus production and from atelectasis of adjacent alveoli. Physical therapy promotes mucociliary transport and the removal of secretions and mucus to central airways, promotes alveolar expansion and ventilation, optimizes ventilation and perfusion matching and gas exchange, and reduces the risk for infection.

Bronchiolitis is common in babies and young children. The effects of inflammation and obstruction in small children are always serious because the anatomical and physiological components of the cardiovascular and pulmonary systems are smaller, respiratory muscle tone is less well developed, the anatomical configuration of the chest wall is cylindrical, breathing is less efficient under 2 years of age, spontaneous movement and body positioning are more restricted (infants in particular spend more time in non-upright positions), and children are at greater risk for infection (see Chapter 37).

Acute Exacerbation of Chronic Airflow Limitation

Pathophysiology and Medical Management

Chronic airflow limitation (chronic obstructive lung disease) is a leading cause of preventable death from smoking. There are two principal types of emphysema: centrilobular and panlobular. Both types can coexist; however, centrilobular emphysema is 20 times more common than panlobular emphysema. Centrilobular emphysema is characterized by destruction of respiratory bronchioles (see Figure 5-1), as well as edema, inflammation, and thickened bronchiolar walls. These changes are more common and more marked in the upper lung fields. This form of emphysema is found more often in men than women, is rare in nonsmokers, and is common among individuals with chronic bronchitis. Panlobular emphysema is characterized by destructive enlargement of the alveoli distal to the terminal bronchioles (see Figure 5-1). This type of emphysema is also found in individuals with alpha$_1$ antitrypsin deficiency. Airway obstruction in these individuals is caused by loss of elastic recoil or radial traction on the bronchioles. When individuals with normal lungs inhale, the airways are stretched open by the enlarging elastic lung, and during exhalation the airways are narrowed as a result of the decreasing stretch of the lung. The lungs of individuals with panlobular emphysema, however, have decreased elasticity because of disruption and destruction of surrounding alveolar walls. In turn, this leaves the bronchioles unsupported and vulnerable to collapse during exhalation. This form of emphysema can be local or diffuse. Lesions are more common in the bases than the apices and tend to be more prevalent in older adults.

Bullae, emphysematous spaces larger than 1 cm in diameter, may be found in patients with emphysema (see Figure 5-2). They appear to develop from an obstruction of the conducting airways that permits the flow of air into the alveoli during inspiration but does not allow air to flow out during expiration. This causes the alveoli to become hyperinflated and eventually leads to destruction of the alveolar walls with a

resultant enlarged air space in the lung parenchyma. These bullae can be more than 10 cm in diameter and, by compression, can compromise the function of the remaining lung tissue (see Figure 5-3). If this happens, surgical intervention to remove the bulla is often necessary. Pneumothorax, a serious complication, can result from the rupture of bullae.

Both types of emphysema can lead to chronic chest wall changes. The loss of elastic recoil of the lung parenchyma disturbs the balance between the normal lung elastic recoil pulling the chest wall in and the natural mechanical tendency of the chest wall to spring out. This balance is essential in maintaining normal FRC (i.e., the air in the lungs at the end of a normal tidal breath). Because the residual volume of the lungs is increased, FRC is correspondingly increased. This increase is not functional, however, because it reflects increased dead space. These patients are still prone to dynamic airway compression and airway closure because of the loss of the normal elastic recoil of the lung parenchyma (i.e., increased compliance). This contributes to uneven distribution of ventilation and decreased diffusing capacity. The pressure volume curve is shifted and ventilation is less efficient.

With loss of elastic recoil and the normal tethering of the alveoli keeping them patent, the chest wall tends to expand outward, thereby contributing to the hyperinflated chest associated with the patient with chronic airflow limitation. The alveolar units are structurally less uniform and the distribution of ventilation becomes even less homogeneous. Inspiratory and expiratory times of the alveolar units also become heterogeneous. The alveoli require long inspiratory filling times (i.e., long time constants). For this reason, the patient with chronic airflow limitation adopts a characteristic breathing pattern in which inspiration and expiration tend to be prolonged. On expiration, the patient may spontaneously adopt a pursed-lip breathing pattern, which is believed to augment alveolar patency and promote collateral ventilation and gas exchange in the lungs by creating positive back pressures. In addition, the patient may expire actively to compensate for the loss of the passive elastic recoil that normally empties the lungs at end tidal volume. Overall, the work of breathing is increased. As the lungs become more chronically hyperinflated, the chest wall becomes increasingly barrel-shaped and rigid. Loss of both the normal shape of the chest wall and the bucket and pump handle motions further compromises efficient respiratory mechanics and breathing.

The most common complaint of the patient with emphysema is dyspnea. Physically, these individuals appear thin and have an increased anteroposterior chest wall diameter. Depending on disease severity, they breathe using the accessory muscles of inspiration (Chapter 5). These patients may be observed leaning forward, resting their forearms on their knees, or sitting with their arms extended at their sides, pushing down against the bed or chair to elevate their shoulders and improve the effectiveness of the accessory muscles of inspiration.

Patients with emphysema have increased respiratory work to maintain relatively normal blood gases. On auscultation, decreased breath sounds can be noted throughout most or all of the lung fields. Radiologically, the emphysema patient has overinflated lungs, flattened hemidiaphragms, and a small, elongated heart (see Figure 5-4). Pulmonary function tests show a decreased vital capacity, FEV_1, maximum voluntary ventilation, and a greatly reduced diffusing capacity. The total lung capacity, the residual volume, and the FRC are increased. Arterial blood gases reflect a mildly or moderately lowered PaO_2, a normal or slightly raised $PaCO_2$, and a normal pH. Patients with emphysema, unlike patients with chronic bronchitis, tend to develop cardiac insufficiency with progression of the condition, leading to failure at the end stage of the disease. At this stage, cardiac hypertrophy may be evident.

Hypoxemia leads to hypoxic pulmonary vasoconstriction, which shunts blood from under-ventilated to better-ventilated areas of the lung. The afterload against which the right heart has to pump is increased. This elevates pulmonary vascular resistance and pulmonary artery blood pressure (i.e., pulmonary hypertension). Over the long term, the right heart hypertrophies to work against this increased resistance and eventually may fail (right ventricular failure). Heart enlargement secondary to any cause alters the electrical conduction pattern, affecting electromechanical coupling and cardiac output. The altered size and heart position within the chest wall can be detected by ECG changes, as well as by echocardiogram.

Treatment of emphysema that requires hospitalization often includes intravenous fluids, antibiotics, and low-flow supplemental oxygen. Some patients require bronchodilators, diuretics, and digitalis. Patients with chronic airflow limitation can adapt to high $PaCO_2$ levels and thus can become dependent on their hypoxic drives to breathe. Therefore low-flow supplemental oxygen is administered to these patients to avoid abolishing their O_2-dependent drive to breathe.

The incidence of emphysema increases with age. It is most often found in patients with chronic bronchitis and is more prevalent in smokers than nonsmokers. There appears to be a hereditary factor. Severe panlobular emphysema can develop in patients with an $alpha_1$ antitrypsin deficiency relatively early in life, even though they never smoked. Repeated lower respiratory tract infections may also play a role in the pathology of emphysema.

Chronic bronchitis and emphysema are marked by a progressive loss of lung function and corresponding cardiac dysfunction. Death rates reported by various studies depend on the methods of selection of patients, types of diagnostic tests, and other criteria. In general, the death rates 5 years after diagnosis are 20% to 55%. The 5-year survival rates based on FEV_1 have been reported to be 80% in patients with a FEV_1 greater than 1.2 L, 60% in patients with an FEV_1 close to 1 L, and 40% for patients with an FEV_1 less than 0.75 L. If these flow rates, however, are found in patients with complications of resting tachycardia, chronic hypercapnia, and a severely impaired diffusing capacity, the survival rates are reduced by 25%. Other factors that have been associated with a poor prognosis are right ventricular failure, weight loss, radiological evidence of emphysema, a dyspneic onset, polycythemia, and Hoover's sign (inward movement of the ribs on inspiration). The most frequent causes of death in patients with airflow limitation are congestive heart failure (secondary to right ventricular failure), respiratory failure, pneumonia, bronchiolitis, and pulmonary embolism.

As emphysema becomes chronic, the hemidiaphragms become more horizontally positioned, placing the muscle fibers at a less efficient position on their length tension curve.[41] When the muscle fibers of respiration are mechanically disadvantaged, the work of breathing is increased, thereby also increasing energy demands and oxygen cost. Respiratory

muscle weakness and fatigue are serious complications of chronic lung disease that predispose the patient to respiratory muscle failure (Chapters 26 and 34).

The net effects of the pathological changes on gas exchange are hypoxemia, hypercapnia, and reduced pH consistent with respiratory acidosis. Long-term respiratory insufficiency leads to chronically impaired oxygen transport and gas exchange. To compensate for hypercapnia, production of bicarbonate is increased to buffer retained CO_2 (i.e., compensated respiratory acidosis). Red blood cell production (i.e., polycythemia) is increased, raising the oxygen-carrying capacity of the blood. The negative effect of polycythemia, however, is increased viscosity of the blood, leading to increased risk for circulatory stasis, thromboses, and increased work of the heart.

Principles of Physical Therapy Management

Standards of practice for chronic obstructive lung disease have been well documented globally.[42,43] Priorities are minimizing exacerbations and reducing overuse of antibiotics.[44] Physical therapy has a primary role in helping to prevent this condition and its sequelae (including premature death), as well as in managing it without drugs and surgery as much as possible.

The patient with emphysema is prone to chronic pulmonary infections and respiratory insufficiency. The clinical picture is hallmarked by alveolar collapse and destruction, ventilation and perfusion mismatch, and diffusion defect. These defects result in impaired or threatened oxygen transport if the physiological compensations are unable to maintain adequate blood gases. Shortness of breath is exacerbated, and breathing is labored. Increased work of breathing reflects airway obstruction and inefficiency of respiratory mechanics and the respiratory muscles. Because of long-term airway disease, mucociliary transport is disrupted. Therefore in the presence of a pulmonary infection and increased production of pulmonary secretions, secretion removal can be a major problem for the patient.

Table 29-1 shows the primary components of care in the acute phase of management, which can be compared with acute cardiac care (phase I of cardiac rehabilitation). Specific treatments are prescribed for the patient based on the specific clinical findings (i.e., the type and severity of the cardiovascular and pulmonary dysfunction and the presence of infection). Therefore treatments include mobilization coordinated with breathing control and coughing maneuvers, which are effective in enhancing alveolar ventilation, mobilizing secretions, and facilitating ventilation and perfusion matching. Body positioning can be prescribed to alter the distribution of ventilation, to aid mucociliary transport, and to remove pulmonary secretions. Although "pure" emphysema is typically dry, postural drainage positions can facilitate the removal of pulmonary secretions from specific bronchopulmonary segments if indicated. In any given body position, alveolar volume is augmented in the uppermost lung fields and alveolar ventilation is augmented in the lowermost lung fields. The type and extent of pathology determine the degree of benefit these physiological effects will have on oxygen transport.

In addition, body positioning is essential to optimize respiratory mechanics and enhance pulmonary gas exchange, thereby reducing the work of breathing and the work of the heart. The assessment defines the parameters of the treatment prescription that will be effective in relieving the work of breathing and the work of the heart. This information is essential not only for prescribing beneficial positions but also for avoiding deleterious positions. A sitting, leaned-forward position will assist ventilation secondary to the gravitational effects of the upright position on cardiovascular and pulmonary function. If the arms are supported, this position stabilizes the upper chest wall and rib cage, thereby facilitating inspiration. Some patients, in respiratory distress and with horizontally positioned hemidiaphragms, benefit from recumbent positions in which the hemidiaphragms are elevated within the chest wall by the viscera falling against the underside of the hemidiaphragms in this position (i.e., viscerodiaphragmatic breathing).[45] The muscle fibers of the diaphragm are mechanically placed in a more favorable position with respect to their length-tension characteristics. This effect may further be augmented in the head-down position in some patients.[46] Other patients, however, cannot tolerate recumbent positions; in fact, respiratory distress may be increased. If optimal treatment outcome has not been achieved with mobilization and body positioning coordinated with breathing control and coughing maneuvers, conventional physical therapy procedures may offer additional benefit in some patients (e.g., postural drainage and manual techniques if a refractory purulent infective process is present).

Because of the tendency toward dynamic airway compression resulting from the highly compliant airways of individuals with emphysema, open-glottis coughing maneuvers are indicated. Specific outcome measures are recorded before, during, and after treatment to assess short- and long-term treatment effects. In addition, between-treatment maneuvers are central to maximizing overall treatment effectiveness. Conveying information effectively and specifically to the patient, nursing staff, and perhaps family members is therefore crucial to achieving a maximal treatment outcome.

As with the individual who has chronic bronchitis, people with chronic airflow limitation due to emphysema should be prescribed a lifelong health program that includes smoking cessation, basic nutritional counseling, and exercise counseling (see Chapters 24 and 31). Based on the assessment, the physical therapist makes a decision with respect to whether professional counseling may augment outcomes (e.g., smoking cessation counselor), whether the patient may benefit from pharmacological support for smoking cessation, and whether the general practitioner needs to be consulted. A decision is also made as to whether a professional nutritionist should be involved. Improved aerobic conditioning can reduce the frequency and severity of subsequent acute exacerbations.[47] Quality of life is associated with fewer clinical signs and symptoms.[48]

Acute Exacerbation of Asthma

Pathophysiology and Medical Management

Asthma is a condition characterized by an increased responsiveness of bronchial smooth muscle to various stimuli and is manifested by widespread narrowing of the airways that changes in severity either spontaneously or as a result of treatment. During an asthma attack, the lumen of the airways is narrowed or occluded by a combination of bronchial smooth muscle spasm, inflammation of the mucosa, and an overproduction of viscous, tenacious mucus.

Asthma that begins in patients under the age of 35 years is usually allergic or extrinsic. These asthma attacks are precipitated when an individual comes into contact with a given substance to which he or she is sensitive, such as pollens or household dust (see Table 29-1). Patients with asthma can be allergic to a number of substances rather than only one or two.

If a patient's first asthma attack occurs after the age of 35, often there is evidence of chronic airway obstruction with intermittent episodes of acute bronchospasm. These individuals, whose attacks are not triggered by specific substances, are referred to as having nonallergic or intrinsic asthma (Table 29-3). Chronic bronchitis is commonly found in this group, and this is the type of asthma most often seen in the hospital setting.

The patient with asthma presents with the following picture during an attack. Lung volumes and expiratory flow rates are reduced, and the distribution of ventilation is less homogeneous.[24] The patient has a rapid rate of breathing and uses the accessory respiratory muscles (see Figure 5-6). The expiratory phase of breathing is prolonged, with audible wheezing. The patient may cough frequently, but unproductively, and may complain of tightness in the chest. Radiologically, the lungs may appear hyperinflated or show small atelectatic areas (reabsorption atelectasis). Early in the attack arterial blood gases reflect slight hypoxemia and a low P_{CO_2} (from hyperventilation). If the attack progresses, the P_{O_2} continues to fall as the P_{CO_2} increases above normal. As obstruction becomes severe, deterioration of the patient is evidenced by a high CO_2, a low P_{O_2}, and a pH of less than 7.3.

Patients who are hospitalized are treated with intravenous fluids, bronchodilators, supplemental oxygen, and corticosteroids. Breathing control in the acute attack relaxes the patient, helps manage the attack more effectively, and provides a means of helping to reduce subsequent attacks. Airway clearance procedures may have a role if the cough becomes productive. Patients should avoid bronchial irritants and substances that worsen or induce significant bronchospasm or an attack.

An asthmatic attack that persists for several hours and is unresponsive to medical management is referred to as status asthmaticus. This condition constitutes a medical emergency, necessitating admission to the intensive care unit (see Chapter 34).

Table 29-3 Factors That Precipitate Asthmatic Symptoms

General Precipitating Factor	Specific Examples of Triggers
Allergic or extrinsic asthma	Pollen (especially ragweed) Animals Feathers Molds Household dust Food
Nonallergic or intrinsic asthma	Inhaled irritants Cigarette smoke Dust Pollution Chemicals
Ambient environment	High humidity Cold air
Respiratory infections	Common cold Bacterial bronchitis
Drugs	Aspirin
Emotions	Stress Excitement
Exercise	Continuous aerobic Continuous aerobic in cool environment

Principles of Physical Therapy Management

The hallmark of an acute exacerbation of asthma is bronchospasm, an increased responsiveness of airway smooth muscle to various stimuli (i.e., reversible airway obstruction). Although bronchospasm can be a feature of chronic bronchitis and emphysema, the primary cause of airway obstruction in these conditions results from anatomical and physiological changes that are not usually reversible.

Table 29-1 shows the primary components of care in the acute phase of management, which are comparable to acute cardiac care (phase I of cardiac rehabilitation). Physical therapy is directed at improving gas exchange without aggravating bronchospasm and other symptoms and reversing these when possible. In one systematic review, the role of breathing exercises for people with acute asthma was not substantiated.[49] Thus relaxing the patient's overbreathing by whatever method works best is recommended. Patients experiencing an acute asthmatic attack may reduce their respiratory rate with a CO_2 rebreathing bag; the benefits may be augmented by reducing a hyperventilatory response with optimal positioning.[50] Overall oxygen demand, including that associated with an increased work of breathing, needs to be reduced during an exacerbation of asthma. This may require reduced activity, body positioning that improves breathing efficiency, judicious rest and sleep periods, altered diet or restricted diet, adequate hydration, maintenance of a thermoneutral environment, rest, reduced arousal, reduced social interaction and excitement, and reduced environmental stimulation. Although general relaxation does not directly relax bronchial smooth muscle, it will assist breathing control, reduce arousal and metabolic demands, and promote more efficient breathing.

Airway narrowing and obstruction is a hallmark of this condition secondary to increased bronchial smooth muscle tone and airway edema. Even small amounts of pulmonary secretions can obstruct the lumen of narrowed airways, which leads to reabsorption atelectasis distal to the site of obstruction, impaired gas exchange, and reduced Pa_{O_2}. Thus mucociliary transport is a priority. Mucous clearance can be further impeded by the addition of serous fluid to pulmonary mucus, resulting from airway irritation and inflammation. Cilia are less effective at clearing mucoserous fluid compared with mucus alone. In addition, sheets of ciliated epithelium are shed into the bronchial lumen, further contributing to the stasis of secretions. Thus optimizing the mobilization of secretions and their removal is a priority even in the presence of scant secretions. Interventions that optimize mucociliary transport are selected to minimize exacerbating bronchospasm and further increases in airway resistance.

The primary goals in the management of asthma include reducing airway narrowing, improving alveolar ventilation, reducing the work and energy cost of breathing, reducing hypoxemia or minimizing its threat, and optimizing lung compliance.

Treatment outcome is assessed with indices of oxygen transport overall and of the function of the individual steps in the pathway.[51] Bedside spirometry, including peak expiratory flow rate, is a sensitive indicator of ensuing compromise in oxygen transport. Some patients use a peak expiratory flow rate meter at home to detect such changes and as an early indicator of the need for medical attention.

Individuals with asthma can often learn to control their condition effectively with optimal health education and an overall lifelong health program (see Chapters 24 and 31).

Acute Exacerbation of Cystic Fibrosis

Pathophysiology and Medical Management

Cystic fibrosis (CF) is a complex multisystem disorder transmitted by an autosomal-recessive gene that affects the exocrine glands. CF involves all of the major organ systems in the body and is characterized by increased electrolyte content of the sweat, chronic airflow limitation, ventilation inhomogeneity, and pancreatic insufficiency. Definitive diagnosis of CF includes positive family history, clinical symptoms of poor digestion, growth or recurrent pulmonary infection, and most important, a positive sweat chloride test. Survival has increased dramatically since 1940 when survival was reported to be approximately 2 years. Thus, although CF is congenital and manifests in childhood, this condition has now become an adult disorder. Adult patients with CF often have an upper lobe infiltrate, with evidence of atelectasis and bronchiectasis, and chronic staphylococcal infections. The beat frequency of the cilia is often slowed to approximately 3 mm per minute, compared with 20 mm per minute in age-matched, healthy, control subjects.[52] Patients can be categorized into three general groups: those with no significant pulmonary signs, those with pulmonary signs and occasional cough and sputum, and those with pulmonary signs and constant cough and sputum. Those patients in the last group tend to have significantly impaired pulmonary function test results, reduced diffusing capacity, and increased hemoptysis, particularly in the presence of an abnormal chest x-ray and hyperinflation. Airway hyperreactivity appears to be variable.

Peripheral airways are often abnormal either anatomically or functionally because of mucus plugging. The lungs of patients with CF may be excessively stiff at maximal lung capacity, with a loss of elastic recoil at low lung volumes. Regional ventilation is nonuniform and contributes to ventilation and perfusion mismatch and hypoxemia.[24]

The chronic pulmonary limitation in CF is related to increased secretion of abnormally viscous mucus, impaired mucociliary transport resulting in airway obstruction, bronchiectasis, hyperinflation, infection, and impaired regional ventilatory function, leading to impaired ventilation and perfusion matching and gas exchange. Radiologically, changes are most pronounced in the upper lobes, especially the right upper lobe.

Principles of Physical Therapy Management

Prophylactic cardiovascular and pulmonary physical therapy, including facilitation of mucociliary transport and maximizing alveolar ventilation, in conjunction with the judicious use of antibiotics, provides effective measures for controlling or slowing the effects of bronchial and bronchiolar obstruction. Involvement of the patient and caregivers in chronic care in the long term is particularly important. Understanding the pathology and course of CF is essential to modify treatment prescription during exacerbations and remissions of the disease.

Table 29-1 shows the primary components of care in the acute phase of management, which can be compared generally with acute cardiac care (phase I of cardiac rehabilitation). The clinical deficits related to oxygen transport include impaired mucociliary transport, increased mucus production, increased difficulty clearing mucus, impaired ventilation and perfusion matching, right-to-left shunt, a diffusion defect, respiratory muscle weakness or fatigue, and reduced cardiovascular and pulmonary conditioning. The increased production of mucus and the difficulty removing mucus increase the risk for bacterial colonization and chronic respiratory infections. These manifestations of CF are worsened with recumbency. Significant postural hypoxemia has been reported in patients with CF when moving from sitting to a supine position.[53] Thus the object of treatment is to optimize oxygen transport and pulmonary gas exchange. Given the pathophysiological deficits in an acute exacerbation of CF, the specific goals are to enhance mucociliary transport, promote airway clearance, optimize alveolar ventilation and therefore gas exchange, maximize the efficiency of oxygen transport overall, and prevent and minimize infection.

Although the degree to which patients with chronic lung conditions, and in particular CF, can respond to aerobic training may be limited, it is essential that their capacity to transport oxygen overall is optimized to compensate for deficits in specific steps of the oxygen transport pathway.[54] Deconditioning severely impairs oxygen transport. Improved aerobic capacity and cardiovascular and pulmonary conditioning are central in the management of patients with CF. Prescriptive aerobic exercise enhances the efficiency of oxygen transport overall by reducing airway resistance by mobilizing secretions, improving the homogeneity of ventilation in the lungs and therefore ventilation and perfusion matching, optimizing oxygen extraction at the tissue level, and increasing respiratory muscle endurance.[55] If optimal conditioning is maintained, oxygen transport is not as compromised during acute exacerbations given the improved efficiency of oxygen transport overall. These effects will be lost, however, as the patient deconditions secondary to restricted mobility and recumbency during the acute episode. Thus it is important that mobility is minimally restricted during an exacerbation (based on the clinical assessment and morbidity) and that exercise conditioning is a mainstay of management between exacerbations. An important additional effect of long-term exercise, which has particular importance for patients with CF, is improved immunity.[56] This may minimize the risk for infection and perhaps minimize the severity of an infection once acquired. Patients with CF can have an abnormal hemodynamic response to exercise and myocardial adaptation; thus appropriate cardiac assessment and monitoring is indicated.[57]

In severe exacerbations the patient is extremely stressed physiologically and has significantly increased oxygen consumption because of the increased work of breathing and for the heart. In addition, the patient is prone to arterial desaturation. Thus minimizing undue oxygen demand and fatigue guides the selection of treatment interventions and their parameters in conjunction with stringent monitoring. These patients become hypoxemic and distressed readily. Treatment interventions are selected based on the assessment and the patient's ability to tolerate the treatment and derive optimal benefit. Gradual, paced, low-intensity mobilization and frequent body positioning enhance mucociliary transport and airway clearance and maximize the efficiency of the steps in the oxygen transport pathway. Postural drainage can offer additional benefit in these patients if further clearance is required. The addition of manual techniques may be indicated; however, stringent monitoring must be carried out given their potential deleterious effects on gas exchange.[58]

Forced coughing and expiratory techniques can contribute to airway closure, whereas huffing and other forms of modified coughing with an open glottis minimize airway closure and can be more effective in removing secretions that have accumulated centrally without compromising ventilation and gas exchange. Forceful coughing, in which the glottis closes, contributes to airway closure and thus should be avoided, particularly in patients with elevated pulmonary artery pressure, because of the concomitant increase in intrathoracic pressure and strain on the heart and lungs. Patients with CF have severe paroxysms of coughing. This significantly increases intrathoracic pressure, which in turn impedes venous return and cardiac output. Although coughing is an essential mechanism for mucociliary clearance in these patients, the untoward cardiac effects must be minimized.

Over the past decade, other interventions aimed at secretion clearance in the treatment of patients with CF have included autogenic drainage, the use of the positive expiratory pressure (PEP) mask, and the Flutter valve.[2,59] One study of patients with CF hospitalized for acute exacerbations compared the short-term efficacy of three regimens: postural drainage (PD), positive expiratory pressure physiotherapy (PEP), and high-frequency chest compression (HFCC) physical therapy.[60] The authors reported no change in lung function or in sputum production when the number of coughs was considered.

Autogenic drainage is based on the theory that the equal pressure point is shifted along the airways by altering the lung volume at which the patient breathes. The patient initially breathes slowly and deliberately at low lung volumes, then at mid and high lung volumes. Breathing at low lung volumes is believed to loosen secretions from the walls of the airways. This is followed by breathing at mid lung volumes, which is believed to help localize and collect the secretions. Finally, breathing at high lung volumes is believed to centralize and facilitate the removal of the secretions with coughing. Thus autogenic drainage may enhance the effectiveness of the patient's cough by manipulating lung volumes and flow rates and controlling coughing to avoid unproductive coughing and wasteful expenditure of energy. The patient is coached by the physical therapist to breathe slowly and deliberately at the volumes set by the therapist, who gauges the patient's ventilatory effort and work by placing his or her hands around the patient's chest. The patient is not encouraged to breathe below end-expiratory volume and is encouraged to suppress coughing until the expelling phase (i.e., the phase during which the patient is breathing at high lung volumes).

Autogenic drainage may be a useful adjunct for facilitating airway clearance in patients with CF. It is a procedure that patients may use independently and can be applied relatively unobtrusively. It helps optimize the patient's coughing efforts and minimizes the potential for airway closure in these patients. This procedure is designed to minimize exhaustive, metabolically costly coughing and preserve energy to expectorate most effectively.[61]

The PEP mask and Flutter® valve device are believed to reduce airway closure in conjunction with exercise, thus optimizing alveolar ventilation and enhancing mucociliary clearance in patients with CF.[62] Individuals with CF can often learn to control their condition effectively with optimal health education and overall lifelong health program (see Chapters 24 and 31).

Acute Exacerbation of Interstitial Pulmonary Fibrosis

Pathophysiology and Medical Management

Interstitial lung disease has been associated with various occupations and the inhalation of inorganic and organic dusts. Conditions associated with the inhalation of inorganic dusts include silicosis, asbestosis, berylliosis, and talc or coal pneumoconiosis. These conditions are most often seen in miners, welders, and construction workers. Workers exposed to organic material, such as fungal spores and plant fibers, may develop a serious pulmonary reaction known as extrinsic allergic alveolitis. Generally, interstitial lung disease is characterized by inflammation of the lung parenchyma, which may resolve completely or progress to fibrosis. Interstitial pulmonary fibrosis results from the deposition of connective tissue after repeated bouts of infection. The pathophysiological deficits are commensurate with morphological changes of interstitial infiltration and fibrosis, intraalveolar exudate, and alveolar replacement (see Figure 5-12). Lung compliance and lung volumes are reduced, expiratory flow at mid lung volume is increased (stiff, inelastic lungs), diffusing capacity is reduced, and hypoxemia can be present in the absence of hypercapnia. The chest x-ray of a patient with interstitial pulmonary fibrosis secondary to sarcoidosis is shown in Figure 5-12. Other changes include increased resting heart rate, pulmonary hypertension, impaired gas exchange, and shortness of breath during exercise, as well as at rest in some cases. Symptoms can be reversed by removing the worker from the exposure through change of employment, modification of the materials handling process, or use of protective clothing and masks. Repeated exposure to these organic dusts may result in irreversible interstitial fibrosis.

Reaction to fumes and gases can also lead to chronic restrictive patterns of lung disease. Individuals exposed to plastics being heated at high temperatures are also exposed to gases that are toxic to the respiratory system. Chronic pathological changes and impaired gas exchange can result.

Medical management is directed at reducing inflammation, reducing pulmonary hypertension, and increasing arterial oxygenation. Pharmacological management may include corticosteroids for inflammation, immunosuppressive agents,

and oxygen therapy. Removing the patient from the work environment contributing to interstitial pulmonary fibrosis is essential in managing the disease and its long-term consequences.

Principles of Physical Therapy Management

The primary clinical manifestations of an acute exacerbation of interstitial pulmonary fibrosis reflect an acute or chronic problem, usually resulting from an inflammatory episode, pulmonary infection, or both. The mechanisms responsible include reduced alveolar ventilation, an inflammatory process and its manifestations, potential airway obstruction, increased work of breathing, and in severe cases, increased work of the heart. These patients are susceptible to desaturation during exercise and thus need to be monitored closely.

Table 29-1 shows the primary components of care in the acute phase of management, which are similar to those of acute cardiac care (phase I of cardiac rehabilitation). In mild cases mobilization increases the homogeneity of ventilation and ventilation and perfusion matching. Between treatments and in the management of the severely affected patient, body positioning is used to reduce the work of breathing and arousal, maximize alveolar ventilation, maximize ventilation and perfusion matching, and optimize coughing.

Patients with moderate-to-severe interstitial lung disease may desaturate during sleep and readily desaturate on physical exertion.[63] Thus they warrant close monitoring during and between treatments. Increased pulmonary vascular resistance secondary to hypoxic vasoconstriction contributes to increased work of the right heart and potential cardiac insufficiency.

General debility and deconditioning warrant an exercise program that can optimize the conditioning and function of all of the steps in the oxygen transport pathway.[64] Individuals with interstitial pulmonary fibrosis require health education and an overall health program to help manage their symptoms (see Chapters 24 and 31).

Tuberculosis

Pathophysiology and Medical Management

Although the incidence of tuberculosis, a lifelong disease, has declined significantly over the past several decades, this disease has been experiencing a resurgence in the industrialized world in recent decades. This may reflect declining sanitation and health standards in some segments of the population and immigration patterns.

Most infections result from inhalation of airborne tubercle bacilli, which triggers an inflammatory response. This response includes flooding of the affected area with fluid leukocytes and later macrophages. The area becomes consolidated; pathologically, the condition is considered a tuberculous pneumonia. The infiltrating macrophages become localized and fused, resulting in the characteristic tubercle. Within 2 to 4 weeks the central part of the lesion necroses. Tuberculosis is associated primarily with pulmonary infection that is comparable with other infectious pneumonias. Tuberculosis, however, is distinct in that it may affect other parts of the body. Symptoms include fatigue, fever, reduced appetite, weight loss, night sweats, hemoptysis, and a cough with small amounts of nonpurulent sputum with pulmonary involvement. The course of the disease is variable. Some lesions heal promptly, whereas other patients experience progression and ensuing death. Other systems that can be involved include brain and meninges, kidney, reproductive, and bone. In some individuals the disease appears to remit, whereas in others tuberculosis progresses to affect other organ systems or previously dormant foci can be reactivated.

The effects of tuberculosis on pulmonary function are variable, depending on the extent and type of lesions. Lesions may involve the lung parenchyma, the bronchi, the pleurae, and chest wall. Parenchymal involvement can reduce lung volumes, leading to hypoventilation of perfused lung units. Significant disease leads to impaired arterial blood gases, whereas areas of unaffected lung may adequately compensate in milder cases. If fibrosis has occurred, lung compliance will be correspondingly reduced. Airflow resistance may be increased from narrowing or distortion of the bronchioles because of fibrosis. Pleural involvement may result in effusions, empyema, pleural fibrosis, and spontaneous pneumothorax. Unlike parenchymal damage, small amounts of pleural restriction can produce significant changes in pulmonary function. Clinically, patients with significant pleural involvement have significant restrictive disease and correspondingly low lung volumes. The work and energy cost of breathing are markedly increased. Shortness of breath is a common complaint. Comparable with an interstitial pulmonary fibrosis patient, the patient adopts a rapid, shallow breathing pattern to reduce the high cost of elastic work of breathing. Thus the dead space tends to be hyperventilated and alveolar hypoventilation results.

In addition to alveolar hypoventilation, lung tissue and pulmonary vascular damage impairs ventilation and perfusion matching and diffusing capacity. In severe cases, hypoxemia and hypercapnia are present. Chronic adaptation includes polycythemia and hypervolemia. Right heart failure may ensue.

The lungs become shrunken and geometrically distorted because of fibrotic changes in the lungs. These changes can lead to kinking and obstruction of the pulmonary blood vessels and maldistribution of pulmonary blood flow, which further compromises ventilation and perfusion matching.

Tuberculosis may be associated with an obstructive component. An increase in airflow resistance comparable with emphysema can be present. This obstruction results from chronic infection, mucosal edema, retained secretions, and bronchospasm.

Antibiotics can be effective in managing the disease well enough to avoid hospitalization. If detected early, the prognosis is favorable, provided the patient adheres to the medication schedule and the bacilli do not become resistant to the medications. Surgery may be indicated to resect lung segments that are chronically involved. The extent and severity of the disease determines the course of recovery.

Maintenance of good general health is particularly important in the management, control, and prevention of tuberculosis (e.g., sanitation, balanced diet, sleep, regular exercise, and stress control). Finally, smoking has been attributed to a disproportionate number of deaths due to pulmonary tuberculosis, thus smoking cessation education and counseling is essential.[65]

Principles of Physical Therapy Management

Although the acute presentation of tuberculosis is comparable with acute pneumonia (refer to pneumonia section), there are some important differences with respect to physical therapy management.[66] First, tuberculosis is particularly infectious; thus special precautions should be taken by the physical therapist to prevent its spread during its infectious stage. Second, patients may be prone to fatigue; treatments should be selected to promote improved oxygen transport without exceeding the patient's capacity to deliver oxygen and without contributing to excessive fatigue. Stimulation of the oxygen transport system with exercise is necessary to avoid the deleterious effects of deconditioning and further compromise of oxygen transport. The patient warrants being monitored closely.

There are few evidence-based guidelines to inform physical therapy management of a patient with pulmonary tuberculosis. The effects of medication, however, are likely to be enhanced with a healthy diet, exercise, and rest. Based on extent and rate of recovery, regular, moderate-intensity exercise every other day for 30 minutes is the eventual goal. Initially, however, performing simple activities such as brisk walking outdoors can help eliminate the bacteria. For patients whose symptoms have largely subsided, stationary biking or resistance training can augment health. Maintaining a program of maximal health and regular exercise is essential.

Summary

Primary, acute medical conditions that affect the cardiovascular and pulmonary systems can have an impact on an individual's participation in life and its composite physical activities. However, serious limitations of structure and function (impairments) may be present that do not affect life participation and yet are life threatening. Both categories must be managed by the physical therapist. In this chapter, principles are presented for the management of individuals with common acute medical conditions including primary lung dysfunction (e.g., atelectasis, pneumonia, bronchitis, bronchiolitis, acute exacerbations of chronic airflow limitation, asthma, cystic fibrosis, interstitial pulmonary fibrosis, and tuberculosis) and primary cardiovascular dysfunction (e.g., hypertension, uncomplicated angina, and myocardial infarction). The focus of the chapter is the pathophysiology underlying these disorders, along with the mechanisms by which they threaten or impair an individual's heart-lung interaction and oxygen transport. Thus the bases for the principles of physical therapy are described rather than specific treatment prescriptions, which necessitate consideration of particular cases. Treatment prescription is based on the effects (and the underlying pathology) of restricted mobility, recumbency, extrinsic factors, and intrinsic factors on an individual's oxygen transport status. Management is directed at the underlying pathophysiological mechanisms resulting from these four factors wherever possible, secondarily to symptom reduction. To prioritize treatments, the most physiological interventions are exploited foremost because these address multiple steps in the oxygen transport pathway. Less physiological interventions (i.e., conventional cardiovascular and pulmonary physical therapy) are instituted after the most physiological interventions have been exploited or are instituted in conjunction with these. The challenge of clinical problem solving is determining the optimal treatment prescription for a given individual that will effect the best outcomes with respect to oxygen transport and eventual sustained return to full participation in life with the least risk in the shortest period of time.

Review Questions

1. Describe how acute limitations of structure and function of the cardiovascular and pulmonary systems can affect an individual's participation in life and related activities (i.e., from no relationship to potentially extensive relationship). Discuss the role of physical therapy in both circumstances, i.e., no relationship and extensive relationship of these variables.
2. Describe the primary cardiovascular and pulmonary pathophysiology and how a patient is likely to present clinically with the following acute conditions: atelectasis, pneumonia, bronchitis, bronchiolitis, acute exacerbations of chronic airflow limitation, asthma, cystic fibrosis, interstitial pulmonary fibrosis, tuberculosis, hypertension, stable angina, and stable myocardial infarction.
3. Relate physical therapy management and treatment interventions for patients with each of the acute conditions listed in question 2 to the underlying pathophysiology. Provide the rationale for your choices.

Review Questions 499

References 500

The overall success of surgery is not measured according to its technical success alone. Rather, surgical success is based on the following:

- The patient's complete return to full participation in life and the capacity to perform its requisite activities
- Avoidance of recurrence of the problem for which the individual's surgery was indicated
- Reduced subsequent doctor- and hospital-based care and need for medication
- Lifelong health

The physical therapist is involved at all stages of perioperative care as indicated (before, during, and after surgery) and has a primary role in identifying individuals at risk of perioperative complications and preventing those complications as well as ensuring true surgical success as defined previously. A high proportion of surgery is needed for lifestyle-related conditions (e.g., ischemic heart disease, smoking-related conditions, hypertension and stroke, type 2 diabetes mellitus, and obesity). Given the prevalence of these conditions and their risk factors (which necessitate elective surgeries and contribute to their complications and delayed recovery), physical therapists need to lead in developing preoperative preparation programs that include health education (initiating or supporting smoking cessation and optimal nutrition), weight reduction, and judiciously prescribed exercise programs. The healthier that people are, the less likely that they will need surgery for non-accidental reasons. Furthermore, recovery from surgery for any reason will be augmented if the person is healthier; complications will be fewer, and rate of recovery will be improved. In turn, hospital stay will be reduced and the likelihood of recurrence of the initial problem may be also reduced.

The decision as to whether and to what extent physical therapy is indicated is based on the individual's need rather than strictly on his or her condition. The patient's condition is one factor that can determine perioperative risk, operative course, and long-term outcomes. Factors other than the primary indication for surgery, however, can have a more important effect on perioperative course and outcomes. Because of this, the preoperative assessment determines who requires physical therapy management and who does not. Physical therapy prevents complications and addresses oxygen transport threats and deficits. In the long term, physical therapy helps ensure that the individual returns to the highest level of living and regains or surpasses premorbid presurgical

functional status. In cases in which the underlying condition can recur, a prime physical therapy objective is to minimize this possibility. Surgical outcomes, based on the physical therapy perspective within the International Classification of Functioning, Disability and Health,[1] are shown in Box 30-1.

The purpose of this chapter is to review the identification of surgical risk in a given individual and the management of patients with cardiovascular and pulmonary risk factors and dysfunction secondary to acute surgical conditions. Surgery today has become more extreme in two ways. First, minimally invasive surgery has shortened the operative period, hastened discharge, and reduced risk.[2] Second, with advances in instrumentation, monitoring, and anesthesia, more invasive, prolonged, and risky surgery is being performed with improved chances of survival.

The cardiovascular and pulmonary effects of anesthesia and surgery are described. The two types of surgery that have the greatest impact on cardiovascular and pulmonary function, namely thoracic and cardiovascular surgery, are highlighted. These surgeries are particularly invasive and lengthy, often require heavy and prolonged anesthesia and sedation, are typically performed on older people whose health status may be poor, and are generally associated with increased risk. Thus they warrant intensive perioperative physical therapy. Patients are assessed with respect to their presurgical and surgical hemodynamic and oxygen transport status to establish oxygen transport capacity and the degree to which increased metabolic demands associated with the perisurgical conditions as well as interventions can be met. In particular, cardiac output and oxygen delivery (DO_2) will increase to compensate for these increased metabolic demands. Increased metabolic demands, however, are dependent on age, severity of illness, type of surgery, comorbidity, and complications.[3] Furthermore, people who are overweight or obese, a common lifestyle-related condition, are more likely to require surgery. Obesity can reduce arterial oxygen tensions and the compliance of the respiratory system irrespective of the tidal volume or respiratory rate.[4] A detailed analysis of these factors can identify risks, expedite early intervention such as mobilization, and increase survival.

The four categories of factors that threaten or impair oxygen transport are described in Chapter 17. These factors include the underlying pathology, restricted mobility and recumbency, extrinsic factors related to the patient's care, and intrinsic factors related to the patient. This chapter examines in detail the effects of surgery, including the effects of anesthesia and other medications on oxygen transport as well as the impact of the underlying condition, restricted mobility and recumbency, and factors associated with the patient on an individual's status postoperatively. These are described in a format to facilitate assessment and ongoing evaluation.

Treatment principles are presented. These are not intended, however, to be a treatment prescription for a particular patient. The effects of anesthesia and surgery must be considered in addition to the underlying pathology and the effects of restricted mobility, body position, and intrinsic and extrinsic factors (see Chapter 17). All these factors must be considered and integrated in prescribing treatment and defining the specific parameters of the prescription. Such integration is essential for treatment to be targeted to the underlying problems and to be maximally effective.

Box 30-1 Surgical Outcomes and their Components Related to Physical Therapy

Perioperative Goals	Long-Term Goals
Prevent perioperative complications (i.e., oxygen transport, musculoskeletal, neuromuscular, endocrine, gastrointestinal, renal, immunological, skin, and psychological)	Return of the individual to full participation in life and composite activities[1]
Remediate oxygen transport limitations (limitations of structure and function)	Sustained lifelong health
Minimize the need for invasive intervention including mechanical ventilatory support and supplemental oxygen, if these are required	Patient empowerment vis-à-vis self-efficacy
Encourage patient empowerment vis-à-vis self-efficacy	Patient education and assessment of whether education goals were met or warrant modification
Conduct patient education and assessment of whether educational goals were met or warrant modification	Avoidance of recurrence of the original problem
Educate team regarding physical therapy goals and how medical, surgical, and nursing roles can augment noninvasive physical therapy outcomes	Reduction of postoperative doctor- and hospital-based care
Minimize hospital stay	Reduced health care costs
Achieve seamless transition to the community	Reduced burden of disease (suffering and cost) to the individual, family, community, and society
Follow up in the community	

Perioperative Course

Surgery and Its Cardiovascular and Pulmonary Consequences

Factors that place a patient at risk can contribute to perioperative cardiovascular and pulmonary dysfunction if preventive strategies fail (Box 30-2). Cardiovascular and pulmonary complications are the major cause of perioperative morbidity and mortality, particularly in patients undergoing thoracic or cardiovascular surgery.[5] The physical therapist must establish the risk factors based on premorbid health assessment including age, smoking habits, nutrition, weight, regular physical activity and fitness, sleep, and stress, as well as cardiac dysfunction, lung dysfunction, musculoskeletal dysfunction, neuromuscular dysfunction, and endocrine dysfunction—in particular, type 2 diabetes mellitus.[6]

Physical therapy has a role in preparing patients for surgery some weeks in advance—a service that is not being fully exploited in health care. Maximizing a patient's health will lead to fewer complications, will shorten hospital stay, and will hasten recovery and return to full participation in daily life. Interventions can include health education, including initiating or supporting smoking cessation. Smoking cessation or smoking reduction by at least 50% has been shown to improve the outcomes after hip and knee replacements.[7] Comparable benefits could be expected for other types of surgery,

Box 30-2 Surgical Factors that Contribute to Perioperative Cardiopulmonary Risk and Dysfunction

- Type of surgery
- Surgical procedures
- Anesthetics (general, with or without intubation, or regional) and sedation and reduced arousal
- Muscle-relaxant agents and neuromuscular blockade
- Supplemental oxygen and humidification
- Static body position assumed
- Duration of surgery and static body positioning
- Incisions
- Use of the cardiopulmonary bypass machine (CBM)
- Use of the extracorporeal membrane exchanger (ECMO)
- Dressings and binders
- Splints and fixation devices
- Lines and leads
- Monitoring devices
- Chest tube placement and number
- Catheters
- Perioperative anxiety, discomfort, and pain
- Perioperative pain control management
- Perioperative fluid balance management
- Perioperative blood and plasma transfusions

particularly cardiovascular and thoracic procedures. Optimizing nutrition and prescribing an exercise program, even if modified because of the patient's underlying condition, can augment oxygen transport. Thus, when oxygen transport is unavoidably compromised by anesthesia and surgery, the patient has greater reserve capacity.

People who are overweight and obese have direct, serious weight-related morbidity including hypertension, type 2 diabetes mellitus, lipid-related heart conditions, and sleep apnea. In addition, people who require joint replacement surgery because of arthropathy secondary to irreversible joint damage are more likely to be overweight.[8] Thus, overweight and obesity constitute major complications during surgery and recovery. Given their prevalence, overweight and obesity warrant being addressed by physical therapists in every patient, whether surgical or medical (see Chapters 1 and 6). Furthermore, body mass index as well as weight-to-hip ratio and age have been reported to be significant predictors for type 2 diabetes mellitus and hypertension, which further complicates the clinical presentation and management of surgical patients who are overweight or obese.[9]

Early surgery for hip fracture in older adults has not been shown unequivocally to result in improved outcomes—that is, reduced complications (pneumonia and bed sores), earlier recovery, and reduced mortality.[10] It is likely that clinically some patients may benefit whereas others may benefit from some delay. Irrespective, the outcomes of physical therapy will be enhanced in either situation if instituted in a timely manner. Studies are needed to establish the degree to which physical therapy including lifestyle behavior change (weight loss in particular) may avert surgery all together, or appropriately delay it. In some patients, early surgery may be preferable. In this case, some finite period of time in which a course of physical therapy could be instituted prior to surgery, could augment surgical outcomes.

Anesthesia and Supplemental Oxygen

Anesthesia results in depression of breathing. Thoracic respiratory excursion is reduced. The tone and pattern of contraction of the respiratory muscles, particularly the diaphragm and the intercostal muscles, change, which contributes to many secondary cardiovascular and pulmonary effects observed after surgery. The loss of end-expiratory diaphragmatic tone causes the diaphragm to ascend into the chest by 2 cm during anesthesia with or without paralysis.[11] Reductions in functional residual capacity (FRC) are correlated with this change and with altered chest wall configuration and increased thoracic blood volume.[12,13] One of the most pervasive and predictable clinical effects observed in the postoperative period is alveolar collapse. Total lung capacity, FRC, and residual volume are decreased. The FRC is reduced in the supine position compared with the erect sitting position[14,15] and is further reduced with the induction of anesthesia. Anesthesia, however, fails to reduce FRC in the sitting position.

The consequences of reduced FRC with anesthesia and surgery have major implications for postoperative complications and the course of recovery. Airway closure occurs with anesthesia, and this likely contributes to intrapulmonary shunting. Compression atelectasis of the dependent (lowermost) lung fields occurs during surgery.[16] In addition, compression atelectasis occurs when lung tissue and surrounding structures are being physically manipulated by the surgeon. Although reduced airway caliber in areas of low lung volume can be offset by the airway-dilating effect of many inhaled anesthetics, airway resistance is increased by obstruction of the breathing circuits, valves, and tracheal tubes. The airways may also be obstructed with foreign matter such as blood and secretions, or from bronchospasm caused by irritation. Because of the decrease in FRC, lung compliance is decreased and the work of breathing is increased. Hypoxemia secondary to transpulmonary shunting is usually maximal within 72 hours after surgery and may not be completely resolved for several days. Persistent reduction in FRC after surgery delays the restoration of the normal alveolar-arterial oxygen gradient.

Anesthesia and tissue dissection contribute to major changes in lung volume, mechanics, and gas exchange. The extent and duration of these changes increase with the magnitude of the operative procedure and degree of anesthesia required. Tissue oxygenation can be threatened during the intraoperative period, and the relationship between oxygen consumption (V_{O_2}) and delivery (D_{O_2}) compromised.[17] Mismatch between V_{O_2} and D_{O_2} is associated with a complicated clinical course and prolonged intensive care unit stay in the absence of conventional indicators such as low ejection fraction and longer cardiovascular and pulmonary bypass time.[18] Oxygen extraction increases to compensate for reduced D_{O_2}. Early optimization of the ratio of V_{O_2} and D_{O_2} is indicated to reduce perioperative morbidity and mortality.

The fraction of inspired oxygen (F_{iO_2}) depends on the mode of oxygen administration. Low-flow nasal oxygen reduces hypoxemia in the absence of hypercapnia and marked transpulmonary shunting in the postoperative patient. Low oxygen flows and low F_{iO_2} tend to be delivered via nasal

cannula whereas higher flows can deliver higher FiO_2 via oxygen masks and masks with reservoir bags. FiO_2 and the body position of the patient at the time a blood sample is taken must always be considered when arterial blood gas values are interpreted. The FiO_2 is selected to provide adequate oxygenation with the lowest oxygen concentration possible.

After surgery the normal pattern of breathing is disrupted. Shallow, monotonous tidal ventilation without normal occasional, spontaneous deep breaths causes alveolar collapse within an hour.[15] Unless resolved within a few hours, atelectasis becomes increasingly resistant to reinflation. This complication is exacerbated in patients receiving narcotics.

Tachypnea and tachycardia are commonly observed, with gross atelectasis secondary to hypoventilation. Breath sounds are decreased at the bases, and the coarse wheezes associated with mucus obstructing airflow can be heard on auscultation. Left lower lobe atelectasis is common after cardiac surgery.

Immediate Postoperative Period

After surgery the patient is detained in the recovery room until vital signs have stabilized, there is no apparent internal or external bleeding, and the patient is responding to his or her name. Patients recovering from minor surgery are usually transferred to a ward once discharged from the recovery room. A patient is transferred to the intensive care unit after surgery if complications arose during surgery, if the patient cannot be readily stabilized and requires close monitoring, or if the patient had more serious surgery such as cranial, cardiovascular thoracic, or emergency surgery such as that resulting from multiple trauma (see Chapter 35).

Rest during the postoperative period needs to be prescribed as carefully as treatment because rest is the time for healing, repair, and restoration. Sleep deprivation impairs recovery and healing. Sleep at night is biologically more restorative than daytime sleep. Thus daytime and nighttime cues are given to restore the patient's circadian rhythms. Although injudicious and excessive recumbency, bed rest, and prolonged periods in any given body position are deleterious, special attention is given to maximizing the periods of high-quality rest and sleep and minimizing disruption of nighttime sleep. Appropriate rests are interspersed within each treatment according to the patient's needs to avoid reaching suboptimal, suprathreshold physiological states. Suprathreshold states are associated with an inappropriate balance between DO_2 and VO_2 such that the patient's condition becomes compromised (e.g., hemodynamically unstable, cardiovascular and pulmonary distress is precipitated, or both).

Pharmacological Considerations

Common pharmacological agents prescribed for patients perioperatively are described in Chapter 45. Physical therapists need a thorough knowledge of these when managing the surgical patient so management can be optimized.

Several factors are particularly important in managing surgical patients because these factors can affect the patients' sensitivity to narcotic analgesics such as morphine.[19,20] There is considerable intersubject response variability to these agents. Older patients, for example, can be expected to be more sensitive to narcotics. Diverse multisystem pathology has a marked effect on the degradation, absorption, biotransformation, and excretion of morphine. Exaggerated effects of morphine have been reported when administered in conjunction with other agents such as other narcotic analgesics, phenothiazines, tranquilizers, or sedative-hypnotics; in addition, such exaggerated effects have been reported in patients with respiratory depression, hypotension, and sedation and in patients who are unconscious. Situations in which exaggerated drug effects have been reported are commonly encountered in the intensive care setting and can result in unpredictable responses. Finally, the physical dependence and abuse potential of these agents cannot be ignored.

The physical therapist must be familiar with the patient's medications and the indications, side effects, and contraindications of each. The physical therapist can determine to what extent oxygen transport may be compromised by medication effects and whether some recommendation must be made to minimize untoward drug effects on arousal or some other factor that negatively affects oxygen transport and gas exchange. For example, although narcotics are excellent analgesics, they have widespread systemic effects including reduced arousal, cardiovascular and pulmonary depression, gastrointestinal depression, and muscle relaxation, all of which can compromise oxygen transport. Thus, consideration must be given regarding whether other forms of analgesia including non pharmacological interventions can be used. In managing the needs of a patient experiencing postoperative pain, the following questions should be considered:

- Have nonpharmacological means of analgesia been exploited?
- If pharmacological analgesia is indicated, could analgesics other than narcotics be used?
- Can the dose of narcotic be reduced so that satisfactory pain control can be achieved in combination with nonpharmacological interventions?

The administration of narcotics has important implications for physical therapy. These powerful analgesics are often the medications of choice for major pain relief and comfort. Their secondary effects, however, which include reduced arousal and monotonous tidal ventilation, are primary physical therapy concerns. Narcotics interfere with a patient's ability to cooperate with treatment. If narcotics impair the patient's ability to participate in treatment, analgesia with a less systemic effect is indicated. Patient-controlled analgesia (PCA) is an effective means of having the patient regulate the amount of analgesia he or she is receiving.[21] Patients have been reported to administer less medication to themselves than nurses assessing their analgesia needs. Intravenous administration prolongs the peak-effect time of analgesics and therefore helps the patient tolerate longer, more intense treatments. Oversedation must be avoided if the patient is to derive maximal benefit from cardiovascular and pulmonary physical therapy treatments.

Physical therapists have available to them a range of noninvasive pain control interventions that should be considered in the acute surgical ward as well as in postsurgical follow-up in the outpatient clinic. These include relaxation strategies, deep breathing, body positioning, physical support, coordination of treatments, and electrotherapy. Transcutaneous electrical nerve stimulation (TENS), for example, can be a useful adjunct in the management of postoperative pain in some patients. Pain control with TENS may enable the patient to participate more fully in mobilization, deep breathing, and

coughing. Research is needed, however, to evaluate this technique in the management of acute pain and define the prescription parameters necessary to produce an optimal therapeutic effect for a given patient. The role of nonpharmacological means of managing acute pain in place of or in conjunction with pharmacological means warrants greater exploitation clinically to produce the best analgesia with the least side effects and risks. Nonpharmacological analgesia enables patients to participate more fully in physical therapy treatments in the absence of the untoward side effects often associated with drug administration.

Prevention of Complications

Special attention in the postoperative period is given to the prevention or management of cardiovascular and pulmonary complications associated with reduced arousal, surgical pain, and restriction of lung capacity and secondary to dressings, binders, and diminished ability to cooperate, move spontaneously, and hyperventilate the lungs periodically. Patients are prone to aspiration in the immediate postoperative period, particularly while the sedation and anesthetic agents are wearing off. This risk is further increased if an artificial airway is required, or if an artificial airway is needed and mechanical ventilation is instituted. Postextubation atelectasis must be anticipated and avoided. To minimize this risk, patients are asked not to eat or drink fluids the day before surgery.

Endotracheal intubation and mechanical ventilation are indicated if blood gas values fail to improve with conservative management. See Chapter 33 for treatment priorities for a patient during mechanical ventilation and the course of weaning.

A complication of thoracic and upper abdominal surgery is irritation or compression trauma of the phrenic nerve. This complication may be more common than expected. Inhibition of the phrenic nerve impairs the contraction of the affected hemidiaphragm, causing it to ascend into the thorax and contribute to atelectasis on that side. This inhibition may last for several days.

The patient's body position is changed frequently in the initial postoperative period. The patient is usually encouraged to change his or her body position frequently, transfer, sit in a chair, and ambulate as soon as possible after surgery. The importance of frequent postural changes and early ambulation in the initial postoperative period are stressed. Early ambulation is a priority in the management of all surgical patients unless contraindicated.

Factors Determining Surgical Response and Outcomes

A patient's response to and outcome after surgery as well as potential complications depend on multiple factors (see Box 30-2). The type of surgery determines the degree of invasiveness, type or types of anesthetics and sedatives, type and level of respiratory support, static body position assumed during surgery, approximate duration of the surgery and period of anesthesia, incisions, dressings, lines, leads, catheters, monitoring devices, chest tubes, type and degree of pain that can be expected, and necessity for and type of pain control after surgery.

Pathophysiology

The type and severity of underlying cardiovascular and pulmonary dysfunction increase a patient's risk of compromised oxygen transport and gas exchange perioperatively.

Restricted Mobility and Recumbency

Surgery imposes two nonphysiological states on the patient that significantly affect oxygen transport:

- Restricted mobility
- Recumbency, specifically a prolonged period of static positioning with the patient breathing at monotonous tidal volumes

Extrinsic Factors

Surgery and related factors are the primary extrinsic factors contributing to cardiovascular and pulmonary dysfunction in the perioperative period.

Intrinsic Factors

Intrinsic factors that contribute to cardiovascular and pulmonary dysfunction in the surgical patient include a patient's premorbid status (e.g., preexisting cardiovascular and pulmonary, renal, endocrine, and hematological pathology). In addition, lifestyle factors are significant (i.e., preoperative conditioning level, nutrition, hydration, stress levels, weight, and smoking history).

Preoperative Assessment And Preparation For Surgery

To minimize risk, reduce perioperative morbidity and mortality, maximize healing, and shorten postoperative recovery, patients need to be in the best physical and medical condition before anesthesia and surgery. In the case of elective surgery, patients often can be prescribed aerobic training (prescribed to meet the individual's needs and capacity), smoking cessation, and weight-control programs beforehand. A preparatory preoperative role for physical therapy warrants greater attention and is currently underused in terms of improving the perioperative course and achieving optimal, sustainable surgical outcomes.

Preoperative physical therapy management includes the preoperative assessment and education; the primary components are shown in Box 30-3. During this time the physical therapist has an opportunity to develop rapport with the patient. The assessment establishes the risk of complications and prolonged hospital stay and the type and extent of perioperative physical therapy required. Postoperative neurological syndromes are common. Ongoing assessment helps ensure that these are identified and addressed early.[22] The assessment establishes what the postoperative priorities will be; however, these are modified based on the postoperative assessment. The surgical procedures are described and the effects of surgery and anesthesia and sedation on gas exchange are reviewed so that the patient understands the importance of being actively involved in physical therapy, both during and between treatments after surgery.

There are no strict guidelines about which patients should receive perioperative physical therapy. Rather, the need for physical therapy should be made on a case-by-case basis, with the degree of the physical therapist's involvement determined on the basis of the patient's need. Although nonthoracic surgeries are generally associated with few cardiovascular and pulmonary complications (e.g., surgery of the extremities or lower abdomen), patients with preexisting cardiovascular and pulmonary pathology, hematological or neuromuscular pathology, or musculoskeletal pathology of the chest wall are at greater risk even in these relatively low-risk types of surgeries. In addition, patients are at additional risk if they are older or younger, smoke, or are overweight or pregnant. Thus each surgical patient must be assessed individually to establish the degree of relative risk during surgery and the necessity of perioperative physical therapy. In this way perioperative complications can be anticipated and avoided or reduced, which is preferable to managing complications once they have developed. The cardiovascular and pulmonary assessment is particularly important in the older individual, and early mobilization is critical postoperatively.

Even though a patient may have had minimally invasive surgery and an uneventful perioperative course, the physical therapist still may have a critical role in helping to achieve long-term surgical outcomes. Recurrence is possible, particularly if surgery was related to lifestyle factors. The physical therapist can take maximal advantage of contact with the patient and be actively involved in developing a program of sustained, lifelong health.

The importance of a thorough preoperative assessment and teaching by the physical therapist cannot be overstated. The components of preoperative assessment and teaching are summarized in Box 30-3. In cases of elective surgery, preoperative teaching includes a general description of the surgery to be performed, the effect of anesthesia and surgery on cardiovascular and pulmonary function, and the systemic effects of restricted mobility and recumbency. The lines, leads, and catheters usually associated with the surgery are explained. The patient is instructed in breathing control maneuvers, supported coughing, chest wall mobility exercises, mobility exercises for the limbs (e.g., hip and knee and foot and ankle exercises), turning in bed, sitting up, transferring, chair sitting, and walking erect postoperatively. In addition, the patient is taught methods of maximizing comfort with body positioning and supporting the surgical incision. If the bed has controls the patient can manipulate, he or she is taught how to make bed adjustments as required. The postoperative course is explained in general terms so the patient can anticipate this period. If the patient is well informed preoperatively, he or she will be better oriented and capable of cooperating when he or she wakes from the anesthesia.

Preoperative teaching is a central component of physical therapy management of the surgical patient. Such teaching establishes rapport with the physical therapist, who informs the patient about what to expect before and after surgery. In addition to reviewing the surgical procedures, the physical therapist reviews, and has the patient perform, deep breathing and supported coughing maneuvers, relaxation, bed mobility, positioning, transfers, and mobilization. Preoperative teaching reduces the patient's anxiety and encourages the patient to be as active as possible in his or her recovery. Preoperative teaching reduces postoperative complications and the length of the hospital stay. High-risk patients benefit from preoperative teaching, and their cooperation is more easily solicited after the surgery. Understanding the patient's perception of his or her condition, the surgery, expectations, and self-efficacy are also central to postoperative recovery.

Box 30-3 Objectives of the Preoperative Physical Therapy Assessment and Teaching

- Develop rapport with patient
- Assess cognitive status, capacity to cooperate, language and communication skills, and cultural and ethnic beliefs and attitudes toward surgery and care
- Assess the patient and estimate degree of surgical risk (e.g., age, smoking, previous cardiopulmonary dysfunction, neuromuscular dysfunction, musculoskeletal deformity, obesity, substance abuse, pregnancy, nutritional status, hydration status, and pain and discomfort)
- Describe the general preoperative, intraoperative, and postoperative course
- Review specific surgical procedures relevant to physical therapy (e.g., anesthesia, type of surgery, body position during surgery, airway, mechanical ventilation, duration, incisions, infusions, drainage systems, chest tubes, and recovery room)
- Provide the rationale for, describe, demonstrate, and have the patient practice and provide feedback on the following breathing control maneuvers: maximal inspiratory hold, supported coughing maneuvers, relaxation, bed mobility and positioning, transfers, and mobilization
- For patients at risk of postoperative cardiopulmonary dysfunction and complications, review the use of the incentive spirometer and conventional airway clearance interventions (e.g., postural drainage and manual techniques, if indicated)
- Ask for any questions

The physical therapist may be consulted by the surgeon to help make a poor-risk patient into a better-risk patient. Patients with upper–respiratory tract infections before surgery may have their surgeries postponed, depending on the type and extent of surgery to be performed, level of anesthesia indicated, and other medical conditions including cardiovascular and pulmonary disease, age, and smoking history. Patients with preoperative lower–respiratory tract infections constitute a greater operative risk; hence these patients often have their surgeries postponed until the infection has resolved. Patients with chronic cardiovascular and pulmonary diseases require a prolonged period of preoperative physical therapy in preparation for surgery. Elective surgery is not usually considered during an exacerbation of chronic lung disease. Even minor surgery may be potentially hazardous for the patient with previous lung disease. The adverse effects of total anesthesia on these patients are magnified because of their reduced pulmonary reserve capacity. Smoking should be discontinued for as long as possible before surgery. The patient is placed on an exercise conditioning program, a regimen of bronchial hygiene, oxygen if necessary, and prophylactic antibiotics. Even patients with extremely low functional work capacity can enhance the efficiency of the steps in the oxygen transport pathway (see Chapters 18 and 19) with a modified aerobic exercise conditioning program. This preoperative preparation

may take one to several weeks, depending on the patient and the indications for surgery. Patients who are overweight can reduce their risk of perioperative complications by losing weight. Body mass is a major determinant of lung function, respiratory mechanics, and oxygenation during anesthesia,[23] and adverse effects on these can lead to major surgical complications and problems during recovery.

Preoperative inspiratory muscle training has gained renewed interest as a means of preserving respiratory muscle function postoperatively and reducing postoperative pulmonary complications. Although maximal inspiratory pressure can be preserved,[24,25] studies are needed to show that this intervention augments outcomes over and above the benefits of an exercise program before surgery. Furthermore, a narrowly focused intervention such as inspiratory muscle training may overlook the benefits of a more holistic preoperative preparation program. Such training needs to be prescribed judiciously.

Postoperative Management

Goals

The goals of postoperative physical therapy management related to oxygen transport appear in Box 30-4. The patient is mobilized in a systematic sequence that progresses from supine to turning in bed to sitting over the bed to standing to sitting in a chair to walking (Table 30-1). Some patients progress through these steps quickly, whereas others take longer. The rate at which patients are progressed depends on their responses. Pain medications are coordinated as needed with treatments to maximize treatment effectiveness. This progressive sequence is comparable to that of phase I of cardiac rehabilitation, the inpatient phase for surgical as well as medical patients, and includes education, counseling, and treatment as indicated. These goals are addressed between as well as during treatments. The patient is instructed in mobilization and body positioning coordinated with deep breathing and supported coughing maneuvers between treatment sessions, and these

Box 30-4 Goals of Postoperative Physical Therapy Related to Oxygen Transport

- Maximize arousal
- Control anxiety and pain
- Maximize alveolar volume
- Optimize alveolar ventilation
- Optimize perfusion
- Maximize lung volumes and capacities, especially functional residual capacity
- Minimize closing volume
- Minimize intrapulmonary shunting
- Optimize lung compliance
- Optimize mucociliary transport
- Optimize clearance of mucus
- Optimize ventilation and perfusion matching and gas exchange
- Maximize expiratory flow rates
- Maximize chest tube drainage
- Optimize fluid balance systemically (renal function)
- Optimize lung water balance and distribution
- Promote optimal lymphatic draining
- Minimize third spacing and collection of fluid
- Minimize the risk of aspiration
- Minimize undue work of breathing
- Minimize undue work of the heart
- Maximize chest wall mobility and movement in three planes
- Optimize body and posture alignment when sitting, standing, walking, and recumbent
- Optimize circulatory status and tissue perfusion
- Optimize peripheral blood flow and velocity
- Optimize muscle pump action
- Minimize effects of central fluid shifts with recumbency
- Maintain fluid-volume regulating mechanisms
- Minimize pain nonpharmacologically and coordinate with the patient's pain medications as indicated
- Maximize cardiopulmonary endurance
- Optimize relaxation and sleep
- Provide instruction to patient regarding between-treatment 'treatment'

Table 30-1 Template for Progressing Mobilization in Surgical Patients

Level	Date	Activity	Bathroom	Bathing
1		Confined to bed Assessment Body positioning	Portable toilet when possible	Personal care by nurse May wash hands and feet
2		Sit up in chair for 20 minutes, three times per day	Use portable toilet	May wash in bed (not legs, back, or feet)
3		Sit up in chair as much as possible		Bathe at bedside
4			Walk to bathroom	Bathe at sink (sitting)
5		Walk around room as able		Bathe at sink
6		Short walks in hall two or three times per day		
7		Walk in halls as able		Take shower (sitting) or tub bath
8		Walk one flight of stairs with assistance		
9		Discharge		

Adapted from Makrides L: *Cardiac rehabilitation manual,* Halifax, Nova Scotia, Canada, 1997, Cardiac Prevention Research Centre, Dalhousie University.

interventions should be performed hourly during waking hours.[26,27] Such a regimen has been reported to result in favorable outcomes for invasive abdominal surgery.[28]

In addition to the primary treatment goals related to oxygen transport, other postoperative goals include the following:

1. Maximize the patient's ability to perform activities of daily living.
2. Maintain or increase general muscle strength and endurance.
3. Maximize muscle and soft tissue length and ligament integrity.
4. Maintain normal arousal and neurological function.
5. Reduce anxiety and stress.
6. Maintain skin integrity.
7. Maintain normal cognitive function to avoid disorientation and hospital-related psychoses.
8. Prescribe secondary prevention.

These goals are achieved with the prescription of mobilization and its constituent mobility exercises including hip and knee flexion and extension exercises and foot and ankle exercises. These exercises are performed hourly regardless of whether the patient is sitting in the chair or resting in bed.

Finally, there are important preventive goals (e.g., minimizing the effects of restricted mobility and recumbency on all organ systems) (see Chapters 19 and 20). Of particular concern in the surgical patient is the risk of thromboemboli and pulmonary emboli and the risk of pressure points and skin breakdown. Thus mobilization and regular activation of the muscle pumps to minimize circulatory stasis and frequent body-position changes are essential to reduce risks, which can have serious consequences for the patient's recovery. Compression stockings are often put on the patient after surgery. These are not removed, except for cleaning and redistributing pressure, until the patient is consistently up and about. These stockings facilitate venous return and increase blood flow and velocity, thereby minimizing the risk of thrombus formation. Should thrombus formation be suspected, it may be necessary to attach an intermittent compression device to the legs to simulate muscle pump action.

With the exception of patients undergoing thoracic or cardiovascular surgery, patients are usually extubated before leaving the operating room or recovery area. Provided no complications develop, most other patients do not require an airway. Patients undergoing major thoracic surgery or cardiovascular surgery remain intubated and mechanically ventilated from several hours to 24 hours after surgery to minimize the work of breathing and hence the work of the heart required to meet the metabolic demands of respiration. These patients are informed that artificial airway and mechanical ventilation enables them to breathe more efficiently initially. A patient is also informed that he or she will not be able to speak while the airway is in place and may have a sore throat after its removal.

Patients are usually aroused and repositioned before leaving the operating room, although this is seldom remembered by patients. Not recalling the immediate postoperative course is common. Patients are likely to be receiving some form of pharmacological analgesia (e.g., morphine). If blood was required intraoperatively, whole blood, packed cells, or plasma may still be infused in the immediate postoperative period or for a longer period of time. Saline or other solutions are also infused for regulation of fluid balance until the patient is able to drink and eat normally. Once vital signs have stabilized, wounds are stable and not draining, and the patient is reasonably alert, he or she is transferred to the ward. The patient is retained in the recovery area should further monitoring be required. If complications develop and oxygen transport and gas exchange are threatened, the patient may be transferred to the intensive care unit.

The physical therapist may be consulted to assess and treat the patient as soon as he or she leaves the operating room or while in the recovery room. Most frequently the physical therapist sees the patient once he or she has been transferred to the ward and has been settled. The first 24 hours are critical.

The risk of cardiovascular and pulmonary complications is greatest during the perioperative period and diminishes as the patient becomes increasingly upright and mobile. Atelectasis and aspiration after extubation are major risks for the patient who has been intubated. The goal immediately after extubation is to promote optimal alveolar ventilation, maximize lung volumes and capacities (especially FRC), minimize closing volumes, and maximize expiratory flow rates and hence cough effectiveness. Areas most susceptible to atelectasis are those that may have been physically compressed during surgery (e.g., the left lower lobe of the cardiovascular surgical patient and areas adjacent to a lobectomy or segmentectomy area).

Surgery constitutes a major insult to the body. After the trauma of surgery, anesthesia, sedation, fluid loss, incisions, and the increased energy requirements for healing and repair, patients can be expected to be lethargic and challenging to arouse. The relaxed state induced by anesthesia, sedation, and narcotics increases the risk of aspiration. This risk is exacerbated further in some patients by nausea and vomiting associated with anesthesia and narcotics. Moving and positioning the patient upright whenever possible and interacting with the patient stimulate the reticular activating system, making the patient more responsive and aroused. The increased metabolic demands that this requires, along with increased catecholamine release, helps overcome the residual effects of anesthesia, sedation, and muscle relaxants and their threat to oxygen transport, provided the demands are not beyond the capacity of the oxygen transport system to deliver oxygen.

Alternatively, some patients are restless and agitated after the effects of anesthesia have worn off. Hypoxemia can lead to restlessness and agitation. Thus it is important that these patients not be inappropriately sedated. This compounds their need for treatment while making them less able to cooperate with treatment simultaneously.[29,30]

At the outset of any treatment the patient needs to be aroused as much as possible to cooperate fully and derive the maximum benefit from treatment. The physical therapist interacts continuously with the patient to arouse him or her fully, maintain arousal, stimulate normal cognitive function and orientation, and elicit feedback from the patient to assess his or her response to treatment. Narcotics depress respiratory status and arousal, and these effects are accentuated in patients whose metabolic states have been disrupted with illness and in older persons. Thus the physical therapist must be vigilant in detecting untoward residual effects of narcotics in the surgical patient. Balancing sedation and analgesia with the needs of having the patient arousable and alert warrants good communication among the team members.

Early Postoperative Physical Therapy

Rationale

The role of perioperative physical therapy has been debated. Some argue that the nursing staff can assume responsibility for the prevention of postoperative complications, particularly in patients who have undergone minimally invasive and short surgeries. The assessment and goals of the physical therapist, however, are unique and are not duplicated by the medical or nursing staff or respiratory therapist.

Physical therapists identify threats to oxygen transport as well as its limitations and prevent and remediate these by prescribing and exploiting noninvasive interventions. Furthermore, the physical therapist considers multiple factors that threaten the long-term health and function of the patient after discharge. The physical therapist has a primary commitment to returning the patient to full participation in the community and prolonged, sustained health. A decision to institute physical therapy for a given patient is not based on the type of surgery alone. Rather it is determined through a systemic assessment of age, weight, fitness, smoking status, comorbidities, anxiety and stress, and external factors related to the patient's potential response to anesthesia and surgery.

To sustain alveolar inflation and normal FRC postoperatively, mobilization and body positioning coordinated with breathing control and supported coughing must be carried out frequently (i.e., every 1 to 2 hours) to maintain optimal alveolar volume and distribution of ventilation. Maximal inspiratory maneuvers are coordinated with mobilization and body positioning at least every hour as tolerated. Maximal inspiratory maneuvers alone, however, are unlikely to be effective because the inspiratory pressure may be insufficient to inflate atelectatic alveoli. Rather, patent alveoli will tend to be overexpanded. Mobilization and body positioning will directly alter the intrapleural pressure gradient and thereby optimize alveolar expansion. In patients who are obese and anesthetized and paralyzed, the prone position increases FRC, lung compliance, and oxygenation.[23,31] Being prone may have some postoperative role in some patients who are obese, but the hazards of recumbent positions must be weighed against the benefits of being upright.

Normal passive expiratory efforts to end tidal volume are encouraged, and maximal or forced expiratory efforts are usually avoided to prevent airway closure and potential increase of atelectasis. Huffing (glottis open) rather than coughing (glottis closed) also minimizes airway closure. With huffing there is less risk of bronchospasm than with coughing, in which the glottis is closed, transpulmonary pressure is increased, and a compressive phase is involved. If indicated, coughing maneuvers are most effective in the sitting or slightly leaned-forward position, in which lung volumes and forced expiratory flow are maximized and the respiratory muscles are at a mechanical advantage with respect to the length-tension characteristics of the muscle fibers. Airway closure is position-dependent (see Chapter 20); therefore the degree of expiration encouraged by the physical therapist should be based on the patient's body position. Airway closure is potentiated in patients who are older, smoke, or are obese and in patients who are in horizontal as opposed to upright body positions.

Mobilization and body positioning coordinated with breathing control and supported coughing maneuvers offer the greatest benefit to oxygen transport in the postoperative patient. Specific benefits are described in Chapters 18, 19 and 20. They include maximizing FRC, reducing closing volume, maximizing expiratory flow rates, promoting mucociliary transport, promoting airway clearance, optimizing lymphatic drainage, minimizing the effects of increased thoracic blood volume, maintaining fluid-volume regulating mechanisms, and minimizing the work of breathing and of the heart. Sustained maximal inspiration is one intervention that promotes alveolar expansion. Each deep breath is performed to maximal inspiration (i.e., to total lung capacity) with a 3- to 5-second breath hold. This maneuver may reduce pulmonary complications by promoting alveolar inflation and gas exchange. The patient is encouraged to repeat this maneuver several times hourly; frequently during mobilization; and before, during, and after body-position changes.

Although the benefits of incentive spirometry (Figure 30-1) postoperatively are equivocal at least after thoracic surgery,[32] it may be useful in patients who are resistant or unable to cooperate fully with maximal inspiratory efforts or be adequately mobilized. Postoperative hypoxemia may be reduced with this technique, which uses the principle of sustained inspiration using a feedback device (either flow or volume feedback) to achieve maximal inflating pressure in the alveoli and maximal inhaled volume. Spirometers with a volume-controlled device, however, may improve diaphragmatic excursion more than flow-dependent devices.[33] With proper instruction, the incentive spirometer can be used independently by the patient, which can be an advantage. This technique ensures that each inspiration is physiologically optimal and is reproduced precisely from one inspiration to the next. Patients who are surgical risks may benefit from being taught how to use the incentive spirometer preoperatively by the physical therapist in order to promote better inflation of the lungs with incentive spirometry postoperatively. However, use of a spirometer does not replace being upright and moving as

Fig. 30-1 Incentive spirometers. (From Harkreader H, Hogan MA, Thobaben M: *Fundamentals of nursing: Caring and clinical judgment*, ed 3. St. Louis, 2007, Saunders.)

much as possible. The patient continues with a regimen of breathing control and coughing maneuvers in conjunction with being upright and moving until full mobility and activities of daily living are resumed.

The application of intermittent positive pressure breathing (IPPB) appears to be less effective for the postoperative patient than previously believed. The details of this modality are described in Chapter 43.

Exercise testing echocardiography performed early after coronary bypass surgery can identify individuals who are high risk and would benefit from intensive secondary prevention as a particular focus in a cardiac rehabilitation program.[34] Early exercise training improves autonomic nervous system function in addition to aerobic and functional capacity.[35]

Getting the Surgical Patient "Upright and Moving"

Mobilization in the upright position coordinated with breathing control and supported coughing maneuvers is encouraged immediately after the patient is first aroused after surgery, unless contraindicated, to help reverse and mitigate reduced arousal, atelectasis, FRC, and impaired mucociliary transport associated with surgery. Mobilization augments cardiovascular and pulmonary function (see Chapters 18 and 20), particularly when the patient is upright.[36,37] These beneficial effects are enhanced by improved three-dimensional chest wall motion, improved gut motility, and reduced intraabdominal pressure. Extremity movement during ambulation increases alveolar ventilation, enhances ventilation and perfusion matching by increasing zone two of the lungs, and optimizes diffusing capacity through stimulating dilatation and recruitment of alveolar capillaries. The upright position ensures that the spine is erect, upper body musculature is relaxed, and the chest wall is symmetrical. Slouching and leaning, particularly to the affected side, reduce alveolar ventilation and contribute to uneven distribution of ventilation and areas of atelectasis.[38,39] In addition, if this abnormal posture is maintained, mucociliary transport of the area is impaired and mucus collects and stagnates, increasing the risk of bacterial colonization and infection. Symmetrical posture is monitored at all times (i.e., during ambulation, sitting at bedside, bed mobility exercises, sitting up in bed, and lying in bed). Slouching and favoring the affected side will lead to cardiovascular and pulmonary complications and possibly musculoskeletal complications in the short and long term.

Mobilization and active exercise in upright postures whenever possible are prescribed based on the need to enhance multiple steps in the oxygen transport pathway. The priority is to perform as much activity as possible out of bed and upright (i.e., ambulation, transferring, sitting upright in a chair, and chair exercises with or without hand weights or exercise bands). When in bed, similar devices can be used, including a monkey bar to facilitate moving in bed for patients other than cardiovascular thoracic patients (e.g., the orthopedic patient with extremity fractures and traction). In addition, the use of the monkey bar is beneficial to perform repetitive bouts of exercises that maintain upper-extremity strength and some general endurance capacity, relieve pressure and stiffness, and facilitate frequent turning. Cycle pedals can be adapted to chairs for recumbent exercise in bed, if necessary. Patients whose positioning is restricted with fixation and traction devices require hand, wrist, or ankle weights, and possibly pulleys and other devices, to maintain muscle strength and power. Movements performed with moderately heavy weights for multiple sets (e.g., three sets of 10 repetitions) develop muscle strength. Movements performed with lighter weights for multiple sets (e.g., five to 10 sets of 10 repetitions) tend to develop endurance and aerobic capacity. Because of the restrictions imposed by these devices, maintaining joint range is essential (i.e., of the neck, spinal column, and chest wall, as well as the extremities). The rotation component of joint movement is readily compromised; thus this must be an integral component of joint range-of-motion exercises. Proprioceptive neuromuscular facilitation (PNF) movements of the extremities can be beneficial. PNF movements of the chest wall can be coordinated with breathing control and supported coughing maneuvers. Upper body and trunk mobility and strengthening are important goals, particularly in the patient with chest wall incisions. The prescription is progressed gradually in the patient with a chest wall incision, particularly in the patient with a median sternotomy who is usually restricted to unresisted, upper-extremity mobility exercises in the first several weeks.

Prescription of body positioning is essential in the management of the patient postsurgically for two reasons. First, without direction, the patient will tend to assume a deleterious body position (i.e., maintaining a restricted number of body positions that favor the affected side for prolonged periods of time with minimal movement and "stirring up"). Therefore once the effects of mobilization have been exploited in a given treatment session, body positions that continue to enhance oxygen transport for a given patient and discourage excessive time in deleterious body positions are prescribed for "between-treatment" times. When not ambulating, patients are encouraged to assume a wide range of body positions (e.g., semiprone) between treatments, as frequently as possible (i.e., at least every 1 to 2 hours).[40-43]

Thoracic and Cardiovascular Surgery

Thoracic Surgery

Thoracic surgery refers to surgery that necessitates opening the chest wall. By convention this term excludes specialized cardiovascular surgery (i.e., surgery of the heart and great vessels). Thoracic surgery is commonly performed for lung resections secondary to cancer (e.g., pneumonectomy, lobectomy, segmentectomy, and wedge resection). In addition, thoracic surgery is performed to remove an irreversibly damaged area of lung tissue secondary to bronchiectasis, benign tumors, fungal infections, and tuberculosis.

The most common incisions are posterolateral thoracotomy and median sternotomy. The posterolateral thoracotomy procedure requires the patient to assume the side-lying position with the involved side uppermost for the duration of the surgery. The uppermost arm is fully flexed anteriorly. The incision is made through an intercostal space, corresponding to the location of the lesion to be excised. The muscles incised include the latissimus dorsi, serratus anterior, external and internal intercostals laterally, and trapezius and rhomboid posteriorly.

At the conclusion of the surgery, chest tubes are placed to evacuate air and fluid from the pleural space by means of an underwater chest tube drainage system. The chest tube and drainage system resolve the pneumothorax created by reestablishing negative pressure in the pleural space and help to reinflate the remaining atelectatic lung tissue. After thoracic surgery, two chest tubes are usually inserted, one at the apex of the lung to evacuate air and one at the base of the lung to drain serosanguineous fluid. The therapist should become familiar with the various drainage systems, how drainage can be facilitated with mobilization and body positioning coordinated with breathing control and supported coughing maneuvers, and certain precautions that must be observed to avoid impairing drainage or disconnecting the tubing. Physical therapy for patients undergoing thoracic surgery has been reported to be cost-effective when a primary component of an interprofessional patient care management strategy[44] as well as when administered prophylactically.[45]

Provided the chest tubes are not kinked, there is no contraindication to lying on the side of the chest tubes. Lying on this side, which is usually the side of the surgery and incision, is typically avoided by the patient. Consistent with the adage down with the good lung, a patient prefers to lie on the nonsurgical side. Prolonged periods in any position, however, particularly lying on the unaffected side, places these lung fields at risk. To minimize the risk of positional complications and hypoxemia, the patient is encouraged to turn to both sides. The specific positions and the duration of time spent within each, however, are based on a comprehensive assessment of the patient's condition and the indications and contraindications for each body position.

Patients may appear to splint themselves, thereby restricting chest wall motion, to avoid pain when moving and deep breathing. They also may resist maximal inspiratory efforts when coughing. Although pain likely contributes to breathing at low lung volumes and ineffective coughing, phrenic nerve inhibition in patients with thoracic and upper abdominal surgeries is likely a more important factor restricting lung expansion. Being upright and moving is associated with increased FRC and tidal volume. Although modalities such as incentive spirometry may have a role in improving lung function in some high risk patients, generally it does not enhance recovery after thoracic surgery.[32]

Postoperative complaints of pain are both musculoskeletal and pleural in origin. The large number of muscles incised, particularly in the posterolateral thoracotomy incision, combined with the operative position, contribute to the patient's complaints of chest wall pain, shoulder soreness, and restricted movement. Deep breathing and coughing maneuvers may be associated with considerable discomfort after surgery. Pain is accentuated by apprehension and anxiety. Therefore treatments are coordinated with relaxation, noninvasive pain control modalities, and pain medication schedules to elicit the full cooperation of the patient.

Cardiovascular Surgery

Cardiovascular surgery is specialized thoracic surgery involving the heart and great vessels, most commonly for lifestyle-related ischemic heart disease. Even for individuals over 90 years of age, outcomes can be favorable.[46]

Because the flow of blood through the cardiovascular and pulmonary system is interrupted, the patient is placed on a cardiovascular and pulmonary bypass machine or on a machine called an *extracorporeal membrane oxygenator.* Cardiovascular surgery is most commonly performed for coronary artery bypass grafting, valve replacements, and aneurysm repairs. Because patients acquire an oxygen debt during the bypass procedure, high oxygen demands are present postsurgically.[47]

After bypass surgery, patients in whom the saphenous vein is excised for graft material have the added complication of surgery and wound healing in one leg. Mobility exercises on that leg are often restricted until there is no risk of bleeding or interference with healing. Comparable with the thoracic surgical patient, a cardiovascular patient leaves the operating room with various monitoring lines and leads, intravenous fluid infusion apparatus, possible blood or plasma infusion devices, a Swan-Ganz catheter (see Chapter 16), a central venous pressure line, an arterial line, a Foley catheter, and oxygen cannulas.

The preoperative preparation and teaching and the postoperative physical therapy management are intensive. Because of the invasiveness of cardiovascular surgery, patients are usually treated postoperatively in a specialized intensive care unit (see Chapter 33). The preoperative and postoperative physical therapy management of patients in the intensive care unit is a specialized area and is described in Chapters 34, 35 and 36.

Providing the patient with information about what to expect during the perioperative course relieves fear and anxiety. In addition, relaxation procedures can be useful. Patients must be reassured that their incisions and suture lines will not be disrupted with movement and physical therapy and that supported coughing and supporting themselves when moving will maximize comfort. Until the patient's condition has stabilized, the patient's mobility is restricted to low-intensity mobilization to promote its benefits on gas exchange and reduce metabolic demands and body positioning to optimize alveolar ventilation coordinated with deep breathing and supported coughing maneuvers. Although breathing exercises have been shown not to augment the benefits of body positioning and mobilization in patients after cardiac surgery,[48] synchronizing breathing control with these interventions will ensure that the secretions stimulated with changing body position and moving are removed. Conventional airway clearance interventions (e.g., postural drainage and manual techniques) may be prescribed in the presence of excessive secretions or difficulty in mobilizing secretions and in the event of productive hydrostatic pneumonia. One systematic review concluded that so-called "prophylactic respiratory physiotherapy" after cardiac surgery was unsubstantiated.[49] Critical components of contemporary physical therapy in the management of patients after cardiac surgery, however, include body positioning and early mobilization, which were not included as key words. The systematic review limited physical therapy simply to breathing exercises and nonspecific chest physiotherapy, which is not consistent with contemporary practice.

Patients undergoing cardiovascular surgery are transferred from the cardiovascular intensive care unit to the ward as quickly as possible. From the ward, these patients should be referred to a physical therapist and a cardiac rehabilitation program in the community for continuity of care and to

maximize the functional gains resulting from the surgery. Established performance measures can be useful to streamline care and to help the patient sustain healthy living and medication adherence as needed.[50]

From the hospital to the community, exercise is prescribed progressively to maximize oxygen transport at each step of the rehabilitation period (i.e., acute, before and immediately after discharge, and in the long term). The conditioning effects of exercise enable the patient to resume various activities of daily living commensurate with an increasing oxygen transport system capacity. Activities involving straining and isometric contractions are avoided. Weight lifting may be introduced in a long-term rehabilitation program, but the weights must not be sufficient to cause strain. Patients with median sternotomy incisions are usually prohibited from using their arms to support themselves when sitting or driving and during activities that may strain the incision site for several weeks or more.

Finally, comparable to high-risk patients undergoing thoracic surgery, preoperative inspiratory muscle training has been examined in the management of high-risk patients undergoing cardiovascular surgery, in whom it has been shown to improve surgical outcomes.[51] Gven the benefits of an exercise program before surgery as well as early mobilization, inspiratory muscle training needs to be shown to augment the benefits of these established interventions. Given the multisystem benefits of exercise before and after surgery, inspiratory muscle training is not an alternative.

Summary

Optimal surgical outcome is a team effort that extends beyond the technical success of the surgery. It is based on the return of the individual to full participation in life and long-term health, including no recurrence of the patient's problem and reduced need for biomedical care and drugs in the short and long term; these also are primary physical therapy outcomes. This chapter reviews the principles of perioperative physical therapy management in individuals slated for surgery with a view to maximizing both short- and long-term outcomes. The physical therapy has a key role in risk factor identification and early intervention. Although risk is increased with more invasive and prolonged surgeries, this should not be assumed. Even minor surgery with an apparently uneventful immediate postoperative period can have an untoward outcome because of underlying risk factors. Indication for physical therapy is based on risk factors rather than condition or type of surgery. Given the prevalence of lifestyle-related conditions and their risk factors (e.g., ischemic heart disease, smoking-related conditions, hypertension and stroke, type 2 diabetes mellitus and obesity) that both necessitate elective surgeries and contribute to their complications and delayed recovery, physical therapists need to lead in developing preoperative preparation programs that include health education (initiating or supporting smoking cessation and optimal nutrition), weight reduction, and judiciously prescribed exercise programs.

Teamwork is the essence of successful surgical outcomes. The physical therapist is highly involved from assessment of the patient preoperatively with respect to anticipated necessity of treatment afterward based on a detailed assessment of perioperative risks, to treatment postoperatively, to, most important, postdischarge follow-up to ensure function is regained and the benefits of surgical and related management are sustained over the long term. Physical therapy intervention for the surgical patient is based on indications for that individual rather than the type of surgery.

The four categories of factors contributing to or threatening oxygen transport were described in Chapter 17 and are evaluated in the preoperative and postoperative assessments. These factors include pathology, restricted mobility and recumbency, extrinsic factors related to the patient's care, and intrinsic factors related to the patient. This chapter examines in detail those factors related to surgery and anesthesia in particular, and the impact of underlying disease, restricted mobility, recumbency, and intrinsic factors on the effects of surgery and anesthesia. The role of the physical therapist, an integral member of the surgical team, is to ensure optimal long-term outcomes well beyond the technical success of the surgery, particularly in individuals who have undergone cardiovascular and thoracic surgery. A prime physical therapy outcome in patients who have undergone thoracic or cardiovascular surgery is prevention of both recurrence of the patient's problem and repeated surgery.

Surgery and its physiological effects are described. Special reference is made to two specialized types of surgery that unfortunately have become all too common—namely, thoracic and cardiovascular surgery. These have the greatest impact on cardiovascular and pulmonary function.

Review Questions

1. Describe what is meant by "surgical outcome is a team effort."
2. Given the prevalence of lifestyle-related conditions and their risk factors, describe the role of physical therapists in the 21st century with respect to their role in preparing patients for elective surgery.
3. Why is it that the decision for the physical therapist to treat a patient postoperatively cannot be made based on the type of surgery alone?
4. Describe the physiological effects of surgery including the specific surgical procedure; type, depth, and duration of anesthesia; sedation; types of respiratory support; static body position assumed during surgery; length of surgery; number and type of invasive perioperative procedures; and incisions.
5. Describe surgical risk factors. Why are detection of these of primary importance in the physical therapy assessment and management of the surgical patient?
6. Relate cardiovascular and pulmonary physical therapy management and treatment interventions to the underlying pathophysiology associated with surgery and those factors listed in Question 3, and provide the rationale for your choice.
7. Differentiate the role of physical therapists on the surgical team from the role of the medical and surgical staff and the nursing staff, specifically in terms of their unique noninvasive perspective and related clinical competencies.
8. Describe the role of physical therapy follow-up in the management of the patient who has had surgery, including return to the community.

This chapter reviews the pathophysiology and medical management in relation to the comprehensive physical therapy management of individuals with chronic primary cardiovascular and pulmonary pathology. Exercise testing and training are major components of the comprehensive physical therapy management of individuals with chronic primary cardiovascular and pulmonary conditions, and this topic is presented in detail in Chapter 24.

Because the heart and lungs are interdependent and function as a single unit, primary lung or heart disease must be considered with respect to the other organ and in the context of oxygen transport overall.[1,2] Despite a plethora of research and numerous official position statements and clinical practice guidelines, the definition and diagnoses of chronic heart disease and chronic lung disease and their management remain inconsistent in practice.[3] Although there is consensus regarding the effectiveness of both cardiac and pulmonary rehabilitation,[4] this inconsistent practice is associated with the underuse, overuse, and misuse of therapies regardless of their established effectiveness.

Although there is no clear line between obstructive and restrictive patterns of lung disease, the distinction is based on the primary underlying pathophysiological problems. The primary conditions that are discussed include obstructive lung disease (i.e., chronic airflow limitation, asthma, bronchiectasis, and cystic fibrosis) and restrictive lung disease (i.e., interstitial pulmonary fibrosis). Lung cancer, which has the characteristics of both obstructive and restrictive patterns of pathology, is also presented.

The long-term physical therapy management of people with heart disease is then presented, with special attention given to angina, myocardial infarction, and heart valve disease. Chronic vascular conditions including peripheral vascular disease (PVD), hypertension, and type 2 diabetes mellitus with its associated angiopathies are also presented.

The principles of the physical therapy management of people with various chronic primary cardiovascular and pulmonary conditions are presented rather than treatment prescriptions, which cannot be discussed without consideration

of a specific patient (see Case Study Guide to accompany the text on-line). In this context, the general goals of the long-term management of people with each condition are presented, followed by the essential monitoring required and the primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport. The selection of interventions for any given patient is based on the physiological hierarchy. The most physiological interventions are exploited first, followed by less physiological interventions and those whose effectiveness is less well documented (see Chapter 17).

The principles outlined in this chapter also apply to the individual who has a secondary diagnosis of one or more chronic primary cardiovascular and pulmonary conditions. These principles can be used to modify physical therapy management prescribed for some other condition or indicate the need for special monitoring.

A template of care is shown in Table 31-1. Although there are many commonalities of physical therapy management across patients, only a detailed knowledge of each specific patient, in terms of his or her underlying pathologies and other factors, will lead to the optimal management plan and treatment prescriptions.

Table 31-1 Template of Principles of Comprehensive Physical Therapy Management for Chronic Primary Cardiovascular and Pulmonary Dysfunction

Levels of the International Classification of Function, Disability and Health	Related Objective of Therapeutic Goals
Participation	Life participation (capacity to fulfill life's roles) Empowerment and self-efficacy
Activities	Self-care Ambulation Home management Employment Vocational activities
Structure and Function	Impairments of structure and function of oxygen transport and related factors (see Chapter 2)
Level of Goal	Examples of Focus of Physical Therapy Management
Prevention	Preserve oxygen transport function and prevent threat to this system Assess readiness to change health behavior
Short-term	Identify and treat limitations of structure and function of the oxygen transport system (associated with the greatest risk of future morbidity and mortality) Identify other factors that impair participation and activity (see Chapters 1 and 17)
Long-term	Develop a lifelong health plan Achieve maintenance stage of readiness to change (see Chapter 1) Develop plan for follow-up

Individuals with Primary Cardiovascular Disease

Angina

Pathophysiology and Medical Management

Angina pectoris refers to pain resulting from reduced blood flow to the myocardium. Even though it is usually elicited during exercise, angina may be triggered by stress or in severe cases may occur at rest. Atherosclerosis of one or more of the coronary arteries is the principal cause. Coronary vasospasm is a less common cause of angina. The pathophysiology of angina is described in detail in Chapter 5. A history of angina necessitates further examination to establish the severity of the coronary artery occlusion. Individuals with manifestations of heart disease are categorized according to their limitation during physical activity based on the New York Heart Association (NYHA) Functional Classification (Table 31-2).

If angina is severe and refractory to medical management, the patient is scheduled for coronary bypass surgery (Chapters 29 and 30) to restore normal coronary blood flow. The acute and long-term management of the surgical cardiac patient is presented in Chapter 30. In less severe cases, angina is managed conservatively with medications (e.g., sublingual nitroglycerin, nitroglycerin patch, education, and physical therapy). After the patient's condition has stabilized, a graded exercise tolerance test may be conducted under supervision in a cardiac stress testing facility where 12-lead electrocardiogram (ECG) monitoring can be performed. The exercise intensity at which the patient exhibits angina (i.e., the anginal threshold) can be quantified and serve as the basis for the prescription of physical activity and exercise.

Principles of Physical Therapy Management

Patients may be referred to physical therapy with a history of angina as a primary or secondary problem. Regardless, angina is managed with the same care and vigilance because it can be a life-threatening condition either way. A patient for whom antianginal medication is prescribed must have the medication present. The medication must not have expired and must be within visible access during treatment. The physical therapist should examine the medication before treatment to ensure that the expiratory date has not passed and to take responsibility for positioning the medication near the patient

Table 31-2 New York Heart Association Functional Classification

Classification	Characteristics
I	No symptoms and no limitation in ordinary physical activity.
II	Mild symptoms and slight limitation during ordinary physical activity.
III	Marked limitation in activity as a result of symptoms, even during less-than-ordinary activity. Comfortable only at rest.
IV	Severe limitations. Experiences symptoms even while at rest.

for access to it should the patient develop angina during treatment.

The goals of long-term management of the patient with angina include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing physiological reserve capacity
- Educate regarding heart disease, self-management, nutrition, weight control, smoking reduction and cessation, anger and stress management, disease prevention, risk factors, medications and their use, physical activity, and exercise
- Maximize aerobic capacity and efficiency of oxygen transport of all steps in the pathway
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the patient

Patient monitoring includes hemodynamic monitoring (i.e., heart rate, blood pressure, rate-pressure product, and dyspnea). Subjective responses to treatment, particularly exercise, should also be recorded (e.g., Borg's rating of perceived exertion). Signs of chest pain, dyspnea, anxiety, lightheadedness, dizziness, disorientation, discoordination, cyanosis, coughing, and chest sound changes (i.e., a gallop) must be monitored. Angina is not an acceptable symptom under any circumstance. Should it occur, treatment is immediately discontinued and emergency measures instituted as indicated. Treatments will be safer and more precisely prescribed with continuous ECG monitoring. Without ECG monitoring, treatments must be conservative. If there is any doubt at any time concerning the hemodynamic stability of a patient and his or her ability to tolerate treatment safely, the patient should be referred to a general practitioner or cardiologist for clearance before being treated.

Medication that is necessary to maximize treatment response is administered before treatment. Knowledge of the type of medication, its administration route, and time to as well as duration of peak efficacy is essential if treatment is to be maximally effective.

For the long-term management of patients with angina, interventions include some combination of education, aerobic exercises, strengthening exercises, chest wall mobility exercises, relaxation, activity pacing, and energy conservation. Education includes information about heart disease and risk factors (i.e., smoking, diet, stress, weight, alcohol, coffee, and being physically active in hot environments) and appropriate preventative strategies (i.e., smoking reduction and cessation, low-fat diet, reduced alcohol consumption, exercise, relaxation, activity pacing, and stress management).

Patients with angina are at risk of having an infarction; therefore vigilance and stringent monitoring are necessary to detect angina or frank myocardial infarction. These patients are potentially hemodynamically unstable; thus their hemodynamic responses before, during, and after treatment, particularly aerobic and strengthening exercises, should be monitored and recorded. Minimally, heart rate, blood pressure, and rate-pressure product should be recorded, along with the patient's subjective responses to treatment. Heavy lifting, static exercise, straining, the Valsalva maneuver, and heavy, repetitive upper-extremity work are avoided during physical activity and exercise. These activities are associated with a disproportionate hemodynamic response. Physical activity and aerobic exercise are prescribed at a target heart rate or perceived exertion ranges that are below the anginal threshold based on a graded exercise tolerance test (see Chapters 19 and 24). Peak exercise tests in patients with cardiac dysfunction that may elicit angina or ST-segment changes are performed in a cardiac stress testing laboratory, usually under the supervision of a cardiologist unless in a specialized facility where physical therapists perform such testing.

The body position in which aerobic exercise is performed is important in patients with heart disease. Positions of recumbency increase the volume of fluid shifted from the periphery to the central circulation. This increases venous return and the work of the heart. Therefore upright body positions have long been known to minimize cardiac work during exercise in these patients and during rest after exercise.[5,6]

Sexual dysfunction is common in individuals with systemic atherosclerosis owing in part to underlying pathology (dyslipidemia, vascular insufficiency, and diabetes), medication, and the psychological impact of heart disease.[7] In terms of energy demands, those of sexual activity are comparable to those of other daily activities (e.g., walking 1 mile on the level). Optimizing health in general with diet and exercise can contribute to regression of atherosclerosis and improved peripheral circulation. Breathing control, body positioning, and energy conservation strategies such as exercising at a high energy time of day may also help minimize symptoms. Also, patients should be advised to avoid sexual activity within an hour of eating, and even then not to consume a heavy meal.

Myocardial Infarction

Pathophysiology and Medical Management

Angina frequently precedes frank myocardial ischemia and infarction. Myocardial ischemia is reversible, whereas infarction denotes myocardial injury and cell death (i.e., necrosis). Injured myocardial cells either recover or die during the healing period. Thus minimizing further damage and maximizing the healing during this 6-week period is critical. Myocardial infarctions can range from being silent and unnoticed by the patient to being life-threatening. They can occur anywhere in the myocardium but occur primarily in the ventricles (in the left more frequently than in the right ventricle). The greater the severity, the greater the risk of ventricular insufficiency, acute pulmonary edema, and left ventricular failure. Because myocardial ischemia and infarction impair the pumping action of the heart and thus cardiac output, patients tend to be hypoxemic and in need of oxygen. Even after the oxygen has been discontinued and the myocardium has healed, the patient may continue to be vulnerable hemodynamically. The myocardium will have some scarring that will affect both the electrical excitability (producing dysrhythmias) and the mechanical function of the heart. In addition, the patient may continue to have low-normal arterial blood gases. Hypoxemia is lethal in that it triggers dysrhythmias and predisposes tissues to hypoxia. Thus hypoxemia must be avoided. After myocardial infarction, patients are usually discharged home on several medications (e.g., nitroglycerin, calcium antagonists, beta blockers, and diuretics). Depending on the severity of involvement, patients usually continue to

require one or more of these medications over the long term. The need for oxygen is usually short term and restricted to the patient's hospital stay.

The patient's ECG will be important for determining the parameters of exercise, the level of monitoring required, and education. Dysrhythmias are described in Chapter 4, and basic ECG reading is presented in Chapter 12. Ventricular dysrhythmias can be lethal. Occasional premature ventricular contractions must be monitored to ensure that their frequency remains low and that coupling does not occur. Atrial fibrillation is considered a relatively serious dysrhythmia. It is associated with a high incidence of coronary disease, stroke, and overall mortality.[8] Medication or a pacemaker may be necessary.

Central sleep-disordered breathing is highly prevalent in individuals with left ventricular dysfunction and is associated with abnormal cardiac autonomic control and increased dysrhythmias.[9] Although sleep-disordered breathing may not be related to the severity of hemodynamic dysfunction, loss of recuperative sleep will affect functional capacity as well as capacity and motivation to participate in an exercise program and be physically active.

Health-related quality of life reported by individuals with chronic heart failure is associated with function and exercise capacity, not with ejection fraction.[10] Health-related quality of life should be an outcome measure for all individuals managed for heart failure because it provides important supplemental information that is independent of physiological indices of cardiac function and the NYHA classification of function (see Table 31-2).

Nonpharmacological approaches to the management of individuals with heart failure are an essential component to the overall management of the condition.[11] These measures are incorporated into an individualized program of health behavior change, and include the following:

- Promote adherence to the recommendations
- Maintain an adequate diet
- Maintain a normal weight
- Avoid added sodium (salt and preservatives)
- Maintain optimal blood cholesterol and triglyceride levels
- Maintain normal blood sugar
- Maintain normal blood pressure
- Restrict fluid in the presence of congestive heart failure
- Avoid smoking
- Exercise regularly
- Restrict alcohol use to a moderate amount, if any
- Receive flu and pneumococcal vaccinations

All patients with cardiovascular risk factors can benefit from cardiac rehabilitation. After a cardiac event, patients are typically discharged with drugs, the prospect of surgery, and rather infrequently with referral to an individual physical therapist or one who is a member of the cardiac rehabilitation team. There is a high incidence of recurrence and repeated surgery with further associated mortality and burden of disease. The physical therapist as a noninvasive practitioner has a primary responsibility to help avoid recurrence of symptoms and repeated surgeries. This is consistent with the physical therapist's overriding objective of reducing the need for invasive care (i.e., drugs and surgery) and developing a sustainable, lifelong health plan with the patient.

Risk factor modification is a major goal. A marker of inflammation such as C-reactive protein along with appropriate lipid testing findings may be a more discriminating risk factor than lipid profiling alone.[12] Refining the risk factor definition on the basis of C-reactive protein level will help target management (e.g., indicate necessity for intensified exercise programs, weight loss, and smoking cessation).

Principles of Physical Therapy Management

After discharge from the hospital, many patients who have had a myocardial infarction see a physical therapist either privately or through a cardiac rehabilitation program. Patients may remain on a supervised rehabilitation program, including an exercise program, for 6 to 12 months in a specialized center (see Chapter 24).

Regardless of the setting, physical therapy includes education, psychosocial support, and a supervised setting for exercising safely and developing confidence during physical exertion. In addition, an exercise program is specifically prescribed for the patient to enhance oxygen transport (i.e., delivery, uptake, and utilization at the tissue level), thereby minimizing the metabolic demand on the heart.

Depression is a common symptom reported by individuals with coronary artery disease and is associated with increased morbidity and mortality. Individuals with depressive symptoms are more likely to exhibit myocardial ischemia during mental stress testing and during activities of daily living.[13] Myocardial ischemia induced by mental stress may be a mechanism by which depression increases the risk of morbidity and mortality in individuals with coronary artery disease. Although aggressive type A individuals are thought to have an increased incidence of heart disease compared with passive type B personalities, anger and hostility have been identified as the toxic negative emotions most implicated in morbidity and mortality related to heart disease.[14]

A graded exercise tolerance test is conducted before the patient leaves the hospital or when he or she is enrolled in an exercise program. The time between the exercise test and the exercise prescription and implementation of the exercise program should be minimal. Peak (formerly referred to as *maximal*) exercise tests are conducted in the presence of a cardiologist (unless in a specialized facility where physical therapists may do such testing) and provide the optimal basis for an exercise prescription. Submaximal exercise tests can be conducted by the physical therapist and can provide the basis for an exercise program; however, the prescription should be conservative compared with the prescription based on the peak exercise test. The principles and practice of exercise testing are described in Chapters 19, 24, and 25. Such testing is both an art and an exacting science and should be carried out in a rigidly standardized manner to ensure the test results are maximally valid, reliable, and useful.

As with the patient with angina and no overt infarction, the following caution must be adhered to with the patient who has a history of myocardial infarction. A patient for whom antianginal medication is prescribed must have the medication present. The medication must not have expired and must be within visible access during treatment. The physical therapist should examine the medication before treatment to ensure that the expiratory date has not passed and take responsibility for positioning the medication near the patient for access to it should the patient develop angina during treatment.

The goals of long-term management of the patient with myocardial infarction include the following:

- Maximize the patient's quality of life, general health, capacity to return to work, and well-being through maximizing physiological reserve capacity
- Educate regarding myocardial infarction, self-management, nutrition, weight control, smoking reduction and cessation, relaxation and stress management, risk factors, disease prevention, medications, lifestyle, activities of daily living, and avoidance of static exercise, straining, and the Valsalva maneuver
- Maximize aerobic capacity and efficiency of oxygen transport
- Reduce the work of the heart
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the patient

Patient monitoring includes hemodynamic monitoring (i.e., heart rate, blood pressure, and rate-pressure product). Subjective responses to treatment, particularly exercise, should also be recorded (e.g., Borg's rating of perceived exertion). Angina is not an acceptable symptom under any circumstance. Should it occur, treatment is immediately discontinued and emergency measures instituted. Treatments will be safer and more precisely prescribed with continuous ECG monitoring. Without ECG monitoring, treatments must be conservative. If there is any doubt at any time about the hemodynamic stability of a patient and his or her ability to tolerate treatment safely, the patient should be referred to a general practitioner for clearance before being treated.

Medication that is needed to maximize treatment response is administered before treatment (e.g., antidysrhythmic agents). Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally efficacious.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with myocardial infarction include some combination of education, aerobic exercise, strengthening exercises, chest wall mobility exercises, body positioning, breathing control and coughing maneuvers, relaxation, activity pacing, and energy conservation. An ergonomic assessment of both work and home environments may be indicated to minimize myocardial strain.

Education focuses on teaching the basic pathophysiology of heart disease, its risk factors, and prevention. Health promotion practices are advocated (e.g., smoking reduction and cessation, good nutrition, weight control, hydration, high-quality rest, and sleep periods). In addition, types of physical activity that impose undue myocardial strain, increase intrathoracic pressure, and restrict venous return and cardiac output, such as heaving lifting, straining, or the Valsalva maneuver, are avoided. The patient is taught to monitor and practice vigilance in monitoring his or her own condition (e.g., new signs of infarction). These patients are potentially hemodynamically unstable and thus their hemodynamic responses before, during, and after treatments, particularly exercise, should be monitored and recorded (i.e., heart rate, blood pressure, and rate-pressure product should be taken, along with their subjective responses to treatment).

Peak exercise tests in cardiac patients that may elicit angina or ST-segment changes are performed in a cardiac stress testing laboratory under the supervision of a cardiologist. The parameters of the exercise prescription are set based on a peak exercise test. Intensity is set within a heart rate, oxygen consumption, and exertion range (e.g., 70% to 85% of the anginal threshold) (see Chapter 19).

Aerobic exercise of large muscle groups rather than small muscle groups (e.g., arm ergometry) is selected to minimize the increased hemodynamic demand and strain and the increased work of the heart associated with working smaller, upper-body muscles. Hot and humid conditions also place additional stress on the heart; therefore exercising under these conditions should be avoided.

As with patients with angina, the body position in which aerobic exercise is performed by patients with myocardial infarction is important. Positions of recumbency increase the volume of fluid shifted from the periphery to the central circulation. This increases venous return and the work of the heart. Therefore upright body positions are selected for these patients to minimize cardiac work during exercise and during rest after exercise.[5,6,15]

Valve Disease

Pathophysiology and Medical Management

Valve dysfunction is either congenital or acquired and may require treatment as a primary condition or be present as a secondary condition. Any of the heart and pulmonary valves may be affected. Rheumatic fever was a common cause of rheumatic heart disease and in particular mitral valve insufficiency. Interconnecting lymphatic vessels between the tonsils and the heart are thought to be responsible. Calcification of valves that impairs opening and closing is another example of an acquired valve dysfunction.

Clinically, patients with valve disease may demonstrate exertional dyspnea, excessive fatigue, palpitations, fluid retention, and orthopnea. These signs and symptoms are often relieved when exertion is discontinued. Aerobic exercise, however, has been shown to reduce the symptoms of prolapsed valve.[16] Anxiety has been reported to decrease general well-being. If effectively managed, however, reduced anxiety can improve or reduce chest pain, fatigue, and dizziness.

Prophylactic antibiotics against endocarditis are administered to most patients with significant valvular involvement and in mild disease before procedures such as dental work.

Principles of Physical Therapy Management

The goals of long-term management of the patient with valvular heart disease include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing physiological reserve capacity
- Educate regarding cardiac valvular disease, self-management, nutrition, weight control, smoking reduction and cessation, relaxation and stress management, cardiac risk factors, disease prevention, medications, lifestyle, activities of daily living, and avoidance of static exercise, straining, and the Valsalva maneuver
- Maximize aerobic capacity and efficiency of oxygen transport

- Optimize physical endurance and exercise capacity
- Reduce the work of the heart
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the patient

Physical therapists are involved in the management of patients with valve defects with regard to both the medical aspects, either as a primary or secondary problem, and surgical aspects. After surgery these patients progress well; the principles of their management are presented in Chapter 30. With respect to the medical management of valve defects, the goal is to optimize oxygen transport in the patient for whom surgery is not indicated either because the defect is not sufficiently severe or because the patient cannot or refuses to undergo surgery. Although the mechanical defect cannot be improved, oxygen transport may be improved in some patients with judicious exercise prescription. The parameters of the exercise prescription are usually moderate in that inappropriate exercise doses can further disrupt the inappropriate balance between oxygen demand and supply and thus further exacerbate symptoms. In addition, there is the potential for further valvular dysfunction if the myocardium is mechanically strained.

The goal of the aerobic exercise prescription is to identify the exercise dose that will optimize the efficiency of other steps in the oxygen transport pathway such that the available oxygen delivered to the peripheral tissues is maximally used without constituting a significant mechanical strain on the heart. Maximizing work output over time is the goal. Thus, the severely compromised patient will perform a greater volume of functional work over time with short, frequent sessions of exercise rather than longer, less-frequent sessions.

If the valve defect is a secondary problem, the physical therapist must assess the severity of the defect and its functional consequences. The following questions must be addressed:

1. Does the defect preclude treatment?
2. Does the defect require that treatment be modified? If so, how?
3. What special precautions should be taken?
4. What signs and symptoms would indicate the patient is distressed?
5. What parameters should be monitored?
6. Is the patient taking medications as prescribed? How might these medications alter the patient's response to treatment?
7. Is there any evidence of heart failure? If so, what will the effects of exercise be?
8. If there is no evidence of heart failure at rest, what is the chance that insufficiency will develop with exercise?

Comparable with management of the patient with a history of angina with or without a history of myocardial infarction, body positions, activities, and respiratory maneuvers that are associated with increased hemodynamic strain are avoided.

Medication that is necessary to maximize treatment response is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

Patients with valve disease are potentially hemodynamically unstable; thus their hemodynamic responses before, during, and after treatments, particularly exercise, should be monitored and recorded. Monitoring includes hemodynamic monitoring (i.e., heart rate, blood pressure, and rate-pressure product). Subjective responses to treatment (e.g., rating of perceived exertion) should also be recorded. Signs of dyspnea, chest pain, lightheadedness, dizziness, disorientation, discoordination, cyanosis, coughing, and chest sound changes (i.e., a gallop) must be monitored. Treatments will be safer and more precisely prescribed with continuous ECG monitoring. Without ECG monitoring, treatments must be conservative. If there is any doubt about the hemodynamic stability of a patient and his or her ability to tolerate treatment safely, the patient should be referred to his or her general practitioner for clearance before being treated.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with cardiac defects include some combination of education, aerobic exercise, strengthening exercises, chest wall mobility exercises, body positioning, breathing control, coughing maneuvers, relaxation, activity pacing, and energy conservation. An ergonomic assessment of both work and home environments may be indicated to minimize myocardial strain.

Exercise prescription for patients with valvular heart disease is modified to ensure that the energy demand is commensurate with oxygen supply. Otherwise excessive oxygen demand will worsen the patient's response to physical activity and lead to further distress and possibly to reduced functional capacity. Aerobic exercise of large muscle groups rather than small muscle groups (e.g., arm ergometry) is selected to minimize the increased hemodynamic demand and strain and the increased work of the heart associated with working smaller, upper-body muscles. As for other types of cardiac conditions, exercising in hot and humid conditions should be avoided.

The body position in which aerobic exercise is performed is important in patients with heart disease. Positions of recumbency increase the volume of fluid shifted from the periphery to the central circulation. This increases venous return and the work of the heart. Therefore upright body positions are selected for these patients to minimize cardiac work during exercise and during rest after exercise.[5,6]

Peripheral Vascular Disease

Pathophysiology and Medical Management

Peripheral vascular disease refers to diseases of the arteries and the veins. Peripheral arterial disease results primarily from atherosclerosis and occlusion of the peripheral arteries (e.g., thoracic aorta, femoral artery, and popliteal artery).[17] The diagnosis may be overlooked until serious limb ischemia is evident.[18] Diabetes mellitus, which can result in microangiopathy and autonomic polyneuropathy, is another important cause of PVD in the lower extremities. Venous disease results in phlebitis, venous stasis, and thromboembolus and leads to valvular incompetence of the veins of the legs.

Arterial occlusion results in reduced blood flow to the extremities and hence reduced segmental blood pressure distal to the occlusion (i.e., lower ankle-brachial index). In mild cases of arterial stenosis the patient may be asymptomatic because considerable stenosis has to occur before there is significant reduction in peripheral blood flow. If atherosclerosis develops gradually, collateral circulation may develop

sufficiently to offset progressive vessel narrowing. Clinically the patient reports limb pain on exercise, coldness in the affected leg, and possibly numbness. The characteristic limb pain results from ischemia and is referred to as *intermittent claudication.* Mild to moderately severe cases are managed conservatively. Pain at rest is suggestive of severe stenosis and significant reduction of blood flow to the limb. Significantly reduced blood flow leads to ischemic color changes, skin breakdown, ulceration, and eventually gangrene. Bypass surgery is performed to revascularize a threatened limb. In severe cases in which gangrene has developed, amputation of the limb is indicated. The severity of PVD is a significant predictor of cardiovascular mortality. Individuals with PVD show a systemic endothelial dysfunction and an increase in the serum concentration of white blood cells, endothelin, and C-reactive protein that may trigger acute coronary syndromes.

Individuals with intermittent claudication can have a marked decrease in exercise tolerance and thus can benefit from aerobic exercise, which may stimulate the development of collateral blood vessels around the stenosed vessel. This condition can severely restrict mobility, which reduces function in addition to aerobic capacity and efficient oxygen transport overall.

Individuals with PVD from diffuse systemic atherosclerosis can be expected to have stenosis of the coronary arteries even though they may be asymptomatic. These individuals are monitored as stringently as if they had overt ischemic heart disease.

Venous insufficiency can lead to thromboemboli, skin lesions, and poorly healing ulcers of the lower extremities. Furthermore, the risk of infection and slow healing is increased.

Individuals with PVD secondary to diabetes mellitus have accelerated atherosclerosis compared with age-matched individuals without diabetes. Diabetes affects the macrocirculation and microcirculation; thus wounds must be prevented, particularly in the lower legs and feet, and managed aggressively should they occur. These individuals may be at risk for lower extremity lesions because of autonomic neuropathy and angiopathy. To restore insulin sensitivity and promote weight loss, activity levels must be significantly increased, and a formal exercise program instituted. Weight-bearing activities are safe for individuals with poor sensation in the feet and do not increase the risk of reulceration.[19]

Principles of Physical Therapy Management

It should be assumed that individuals with peripheral arterial disease have coronary and cerebral arterial disease necessitating aggressive risk factor management to reduce the risk of myocardial infarction, stroke, and death.[20] Primary interventions include smoking cessation; treatment of hypertension, glucose intolerance, and diabetes; and management of low-density lipoprotein cholesterol.

The goals of long-term management of the patient with PVD secondary to atherosclerosis include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing physiological reserve capacity
- Educate regarding atherosclerosis, heart disease, and other sequelae, self-management, nutrition, weight control, smoking reduction and cessation, risk factors, disease prevention, medications, lifestyle, activities of daily living, and avoidance of static exercise, straining, and the Valsalva maneuver
- If impaired peripheral perfusion of the limbs is present, educate regarding self-assessment of the skin; sock type, care, and cleanliness; shoe fitting; and wound care if indicated
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize the work of the heart
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the patient

The goals of long-term management of the patient with PVD secondary to diabetes mellitus must incorporate both the principles for the management of the patient with PVD secondary to atherosclerosis and secondary to diabetes mellitus.

Patient monitoring includes hemodynamic monitoring (i.e., heart rate, blood pressure, and rate-pressure product). Subjective responses to treatment, particularly exercise, should also be recorded (e.g., pain scale and Borg's rating of perceived exertion). These patients have an increased risk of angina. Angina is not an acceptable symptom under any circumstance. Thus, before undertaking a therapeutic exercise program, patients should be cleared by their physicians or cardiologists. Individuals with diabetes are potentially hemodynamically unstable; thus their hemodynamic responses before, during, and after treatment, particularly exercise, should be monitored and recorded (i.e., heart rate, blood pressure, and rate-pressure product should be taken), along with their subjective responses to exercise (e.g., pain and perceived exertion). If there is any doubt at any time about the hemodynamic stability of a patient and his or her ability to tolerate treatment safely, the patient should be referred to a general practitioner for clearance to begin or continue treatment.

Medication that is needed to maximize treatment response is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with PVD secondary to atherosclerosis include some combination of education, aerobic exercises, strengthening exercises, relaxation, activity pacing, and energy conservation. Exercise, in particular walking, is an important component of management to ameliorate symptoms and improve functional capacity and quality of life.[18,21] Pharmacotherapy may help relieve symptoms in the short term, whereas exercise benefits are likely to be long term in terms of addressing systemic atherosclerosis. An ergonomic assessment of both work and home environments may be indicated to minimize myocardial strain.

Individuals with PVD may underestimate their increased risk of cardiovascular disease[22]; thus education focuses on teaching the basic pathophysiology of atherosclerosis, its risk factors, prevention, and reversal. Health promotion practices are advocated (e.g., smoking reduction and cessation, nutrition, weight control, and regular physical activity and exercise). In addition, types of physical activity that impose undue

myocardial strain, increase intrathoracic pressure, and restrict venous return and cardiac output, such as heavy lifting, straining, or the Valsalva maneuver, are avoided. The patient is taught to practice vigilance in monitoring for signs and symptoms of vascular insufficiency in the affected limb and intermittent claudication. Any sign of skin redness in the feet should be monitored closely. In the patient with diabetes, any threat of skin breakdown requires medical attention and discontinuation of exercise until medical clearance has been obtained. Patients with peripheral artery disease are taught to take special care of their feet before and after exercise. The feet and footwear should be kept clean. The inner surfaces of shoes and socks should be smooth.

During peak exercise tests, patients with PVD secondary to atherosclerosis have an increased risk of angina or ST-segment changes. Such tests therefore should be performed in a peripheral vascular laboratory or cardiac stress testing laboratory under the supervision of a peripheral vascular specialist or cardiologist. The parameters of the exercise prescription are based on a peak exercise test. Walking is the activity or exercise of choice because this activity is most severely limited by intermittent claudication, which has implications for function. Intensity of the training stimulus is based on pain rating in conjunction with hemodynamic and other subjective responses. The patient walks at a comfortable, even cadence within his or her pain tolerance (objectively defined on the pain scale) so that limping and gait deviation are minimized.

The body position in which aerobic exercise is performed is important in patients with PVD. Positions of recumbency eliminate the vertical gravitational gradient. This gradient increases blood pressure in the lower extremities. Therefore the claudication threshold is lowered in recumbent positions. Recumbent positions also increase venous return and the work of the heart. Therefore upright body positions are selected for these patients to maximize blood pressure in the lower extremities and to minimize cardiac work during exercise and during rest after exercise.[5]

The management of venous stasis and disease requires patient involvement to promote healthy lifestyle (exercise and smoking cessation). Compression garments may help to facilitate venous return. Good foot and skin care and shoes that fit well are essential. The patient is taught to assess the skin of the lower extremities daily for signs of skin breakdown and abrasions. Because of impaired peripheral perfusion, skin lesions can occur quickly and then may be resistant to healing and at increased risk of infection.

Hypertension

Pathophysiology and Medical Management

Systemic hypertension or high blood pressure is a serious condition. Most patients experience no symptoms; thus adherence to medication regimens is often poor. Approximately 90% of hypertension is termed *essential hypertension* (i.e., no known cause). Hypertension predisposes a patient to stroke, myocardial infarction, renal dysfunction and failure, hemorrhage, and infarction of other vital organs. Blood pressure tends to increase with age. With the aging of the population, the incidence of hypertension is increasing. Increased blood pressure results from increased peripheral vascular resistance; therefore medications are prescribed that reduce myocardial afterload and peripheral vascular resistance. Hypertension and antihypertensive medication are risk factors for type 2 diabetes mellitus.[23] Therefore avoiding a patient's need for medication or at least reducing it is a singularly important physical therapy outcome.

There are other serious consequences of chronic high blood pressure. Patients with existing cardiovascular disease (i.e., hypertension) are at risk for multisystemic manifestations that must be assessed, e.g., signs and symptoms of cerebrovascular and renal impairments. In addition, this population tends to be older, and older populations are known to have a higher prevalence of cardiac dysrhythmias. Thus such patients' cardiac status, including ECG history, should be obtained.

Pulmonary hypertension may occur in the absence of primary cardiac disease. So-called "primary pulmonary hypertension" is often associated with altered resting lung function. Abnormal lung mechanics and diffusing capacity are directly associated with disease severity and may contribute to the dyspnea and fatigue reported by individuals with primary pulmonary hypertension.[24]

Principles of Physical Therapy Management

Physical therapy contributes to increased metabolic demands and therefore imposes a hemodynamic load resulting in increased heart rate and blood pressure. The assessment should document the history of hypertension, its medical management, and the patient's response. Regardless of the condition being treated, the hypertensive patient's blood pressure must be monitored accurately and treatment modified accordingly.[25] Blood pressure medications, however, are known to attenuate hemodynamic responses to exercise (Chapter 44); thus blood pressure as an index of hemodynamic status may be limited in some individuals.

Interventions for the physical therapy management of hypertension are cause specific. Lifestyle factors are exploited to help reduce blood pressure and optimize long-term health. A program of aerobic exercise can effectively reduce high blood pressure in some patients. The parameters of the exercise prescription necessary to control hypertension include an aerobic type of exercise that is rhythmic and involves large muscle groups, an intensity of 60% to 75% of the patient's age-predicted maximal heart rate, 60 to 90 minutes' duration, and performance of the exercise five to seven times weekly for 3 months to achieve an optimal effect. The exercise intensity should be equivalent to a perceived exertion rating of 3 to 5 on the Borg scale (the patient is able to speak while exercising without gasping), provided that blood pressure does not increase excessively. Only modest exercise intensities are prescribed if the patient has extremely high resting blood pressure to ensure that blood pressure does not rise excessively and is not maintained at a high level for a prolonged period. If the patient's hypertension responds to the exercise regimen, exercise must be included in the patient's lifestyle in order for the effects to be maintained. In addition to exercise, many patients lose weight, adopt healthier lifestyle habits, and learn stress management and coping skills concurrently. When exercise is combined with a weight loss program, both resting and stress-induced blood pressures are reduced. The resulting hemodynamic profile resembles that of successful control with pharmacotherapy.[26]

Elderly individuals with hypertension may exhibit hypotension for almost 24 hours after exercise, along with lower cardiac output, stroke volume, and left ventricular end diastolic volume.[27] Thus such individuals should be examined for this effect, and exercise should be modified accordingly.

The goals of long-term management of the patient with hypertension include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing physiological reserve capacity
- Educate regarding hypertension, self-management, nutrition, weight control, smoking reduction and cessation, relaxation and stress management, risk factors, lifestyle factors, disease prevention, and medications and their applications and side effects
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- With the effects of lifestyle changes (physical activity, weight loss, nutrition, smoking cessation, and potentially stress management), medication must be weaned correspondingly
- Design comprehensive, lifelong health and rehabilitation programs with the patient

Patient monitoring includes hemodynamic monitoring (i.e., heart rate, blood pressure, and rate-pressure product). Subjective responses to treatment, particularly exercise, should also be recorded. Signs of dyspnea, headache, lightheadedness, dizziness, disorientation, discoordination, cyanosis, coughing, and chest sound changes (i.e., a gallop) must be monitored. Blood pressure responses that fail to increase with increasing work load and power output may be indicative of congestive heart failure.

Treatments will be safer and more precisely prescribed with continuous ECG monitoring. Without ECG monitoring, treatments must be conservative. If there is any doubt about the hemodynamic stability of a patient and his or her ability to tolerate treatment safely, the patient should be referred to a general practitioner or cardiologist for clearance before being treated.

Medication that is necessary to maximize treatment response is administered before treatment (i.e., hypertension medications). Knowledge of the type of medication, its administration route, and time to and duration of peak effectiveness is essential if treatment is to be maximally effective. A primary goal of noninvasive approaches to blood pressure control is to eliminate or minimize medication. The physical therapist monitors the blood pressure closely within and between visits. The patient is taught to log morning blood pressures at home and to log medication. A close working relationship is needed with the patient's invasive practitioner during weaning of the medication.

The primary interventions in the long-term management of hypertension include education, aerobic exercise, general body strengthening, range-of-motion exercises, body mechanics, relaxation, stress management, pacing, and energy conservation. The patient is instructed in self-monitoring blood pressure as well as recording his or her blood pressure, those factors associated with both high and low pressures, and blood pressure changes that occur after medication has been taken. Such monitoring enables the patient to self-manage his or her hypertension and thereby reduces, if not entirely eliminates, need for medication. Patients, however, should alter their medications only with their physicians' approval. Physical therapists work closely with both hypertensive patients and physicians.

Systemic blood pressure responses to dynamic exercise are greater for upper-extremity than lower-extremity work.[28] Thus exercise prescription includes aerobic exercise of the large muscle groups. Avoiding small muscle group work avoids increases in peripheral vascular resistance and hence hemodynamic work, as well as the increased exertion, strain, and work of the heart experienced with upper-extremity work. Exercise is also performed in erect and upright positions rather than recumbent positions to minimize the increased work of the heart secondary to central fluid shifts that occur when the patient is lying in recumbent positions.

Self-monitoring is an important responsibility of the individual with hypertension, given the need to establish valid measures on which interventions are based and modified.[25] The most valid blood pressures are recorded by a well-trained individual with a reliable and accurate automatic blood pressure measurement system. The physical therapist can calibrate the home unit against a sphygmomanometer in the clinic or hospital. The individual is advised to measure his or her blood pressure first thing in the morning and record it.

Type 2 Diabetes Mellitus and Metabolic Syndrome

Pathophysiology and Medical Management

Type 2 diabetes mellitus is a condition associated with impaired insulin metabolism that can result in serious long-term multisystem consequences.[29] The disease is classified as either insulin-dependent or non–insulin-dependent diabetes mellitus. Insulin is the carrier responsible for transporting glucose into the cells to undergo oxidation. Juvenile-onset diabetes is frequently the insulin-dependent type, whereas adult-onset diabetes often is the non–insulin-dependent type. The underlying pathophysiology of juvenile- and adult-onset diabetes, however, is distinct. Juvenile-onset (type 1) diabetes results from an inadequate number of islets of Langerhans in the pancreas, which are responsible for insulin production. Adult-onset (type 2) diabetes, on the other hand, results from reduced insulin sensitivity. In Western industrialized countries, adult-onset diabetes is associated with obesity, inactivity, poor diet, and stress. In addition, medications can contribute to blood sugar disturbances. The sequelae of type 2 diabetes mellitus that frequently result from poor regulation and management of the disease include angiopathy, peripheral neuropathy, autonomic neuropathy, gastrointestinal paresis, visual disturbance, and renal dysfunction.[30]

Individuals with type 2 diabetes mellitus have an accelerated rate of atherosclerotic changes in the vasculature compared with age- and sex-matched individuals without diabetes. These individuals are also prone to PVD secondary to microangiopathy, macroangiopathy, and autonomic neuropathy. People with type 2 diabetes mellitus constitute a significant proportion of patients with PVD who require surgical amputation of affected limbs as a consequence of peripheral ischemia. Muscle infarction is a less common but clinically

important complication of longstanding diabetes.[31] Muscle infarction manifests with pain and swelling over the affected area and at times a palpable mass and elevated creatine kinase levels. The symptoms resolve with conservative management including analgesics and relative immobility of the affected muscle.

Abnormalities of blood sugar metabolism can also be observed in individuals without diabetes. Diabetogenic factors, such as restricted mobility and stress, lead to glucose intolerance and insulin oversecretion.[32,33] In the individual without diabetes, these effects can be tolerated over the short term. These factors, however, may result in a critical situation for the individual with diabetes.

Metabolic syndrome is increasingly common and includes central obesity, low high-density-lipoprotein cholesterol, hypertension, and often insulin resistance and hypertriglyceridemia.[34]

Principles of Physical Therapy Management

Patients with type 2 diabetes mellitus may be referred to a physical therapist for several reasons. First, a newly diagnosed diabetic patient may be referred so that the physical therapist can expose the patient to a quantified exercise stimulus under supervised conditions and thereby help refine the prescription of insulin. Second, a patient may be referred for an exercise prescription to help minimize the insulin dose or avoid insulin administration entirely, depending on disease type and severity and the patient's response. Third but most frequently, patients are seen by a physical therapist for the treatment of some other condition and also report type 2 diabetes mellitus in their histories. A history of type 2 diabetes mellitus must be considered in the treatment of a patient who is referred for any reason to either improve or at least not contribute to abnormal blood glucose levels and late complications.

Patients with type 2 diabetes mellitus are treated cautiously. Exercise increases metabolic demand commensurate with intensity and hence cellular demand for glucose.[35] Usually insulin administration is increased in preparation for exercise. Many active individuals who have type 2 diabetes mellitus are closely attuned to their dietary and insulin needs, which permits them to be as physically active as people without diabetes. Individuals with type 2 diabetes mellitus seen by physical therapists, however, are often labile and less well managed. Thus a readily available sugar source must be nearby for insulin regulation when a person with diabetes exercises or when the physical therapist exercises a patient with type 2 diabetes mellitus on an ergometer after anterior cruciate ligament repair.

In addition, people with type 2 diabetes mellitus may have hemodynamic disturbances because of an autonomic neuropathy and may exhibit impaired fluid-volume regulation during exercise.[30] Patients may experience postural hypotension and become dizzy and lightheaded. In addition, diabetic patients may require a longer cool-down period to adjust hemodynamically after exercise.

Hypoglycemia or low blood sugar is one of the most common complications of type 2 diabetes mellitus. This condition results from excess administration of insulin or oral hypoglycemic agent, insufficient food in relation to insulin dose, or an abnormal increase in physical activity or exercise. Hyperglycemia is common in patients who are obese and have adult-onset diabetes. High insulin levels are associated with a higher risk of coronary artery disease. Myocardial infarction and stroke are common causes of death. Another complication is cardiac hypertrophy secondary to hypertension and cardiomyopathy, which predisposes the patient to congestive heart failure. The incidence of PVD is also increased in diabetic patients.

The goals of the long-term management of type 2 diabetes mellitus and metabolic syndrome include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing physiological reserve capacity
- Educate regarding type 2 diabetes mellitus or metabolic syndrome, self-management, nutrition (good nutrition with optimal lipid and triglyceride dietary control), weight control, blood sugar regulation and its management (i.e., the balance among nutrition, diet, exercise, stress, and insulin requirements), medications, smoking reduction or cessation, relaxation, stress management, and foot care, if necessary, in conjunction with hygiene and infection control
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thus peripheral oxygen extraction
- With the effects of lifestyle changes (physical activity, weight loss, nutrition, smoking cessation, and, potentially, stress management), medication must be weaned correspondingly
- Design comprehensive lifelong health and rehabilitation programs with the patient

Monitoring includes signs and symptoms of hypoglycemia (e.g., lightheadedness, weakness, fatigue, disorientation, and glucose tolerance test results) or hyperglycemia (e.g., glucose tolerance test results).

Hemodynamic responses (i.e., heart rate, blood pressure, and rate-pressure product) provide an index of the intensity of an exercise stimulus; however, these responses may be attenuated in the diabetic patient because of the autonomic neuropathy (both parasympathetic and sympathetic neuropathies).

Subjective responses to exercise, including the rating of perceived exertion, may be more valid indicators of exercise intensity than hemodynamic responses in the person with type 2 diabetes mellitus. The patient is taught to be vigilant in monitoring for signs and symptoms of vascular insufficiency in the affected limb. Any sign of skin redness in the feet should be monitored closely. In individuals with type 2 diabetes mellitus, any threat of skin breakdown requires medical attention and discontinuation of exercise until medical clearance has been obtained. Healing is considerably delayed in the so-called "diabetic foot." Without appropriate attention, infection and potential necrosis can ensue. Individuals with peripheral autonomic neuropathy are taught to monitor their footwear and socks diligently, to ensure the inner surfaces are clean and smooth before each exercise session, and to check for areas of redness or abrasion on their feet after exercise.

Medication that is necessary to maximize treatment response is administered before treatment (e.g., insulin or oral hypoglycemic agents). Knowledge of the type of medication, its administration route, and time to and duration of

peak efficacy is essential if treatment is to be maximally effective. With lifestyle changes, including physical activity and weight loss, the physical therapist works closely with the invasive practitioner to monitor medication and the patient's changing requirements consistent with the medication weaning process.

The primary interventions in the long-term management of type 2 diabetes mellitus include education, maintenance of a log of diet and insulin regimens, activity and exercise, aerobic exercise, strengthening exercises, relaxation, stress management, activity pacing, and energy conservation.[36] It may be necessary to consult a nutritionist to assist with promoting lifelong change.

Generally there are no contraindications to patients with type 2 diabetes mellitus being physically active and participating in an exercise program. Daily exercise is advocated for insulin-dependent and non–insulin-dependent diabetic patients to optimize glucose control. The exercise prescription parameters are set at 40% to 85% of peak functional work capacity.[35] If the patient is exercising daily, the exercise parameters are set at the lower end of this range. If the exercise sessions are less frequent (e.g., in the case of an individual with non–insulin-dependent diabetes whose blood glucose is well maintained and whose weight is acceptable), exercise intensity is set at the higher end of this range.

The risk of hypoglycemia can be reduced by observing the following precautions: frequently monitor blood glucose, decrease the insulin dose (in consultation with the physician) or increase carbohydrate intake before exercise, avoid injecting insulin into areas that are active during exercise, avoid exercise during peak insulin activity, consume carbohydrates before, during, and after prolonged aerobic activity, and be knowledgeable about the signs and symptoms of hypoglycemia.[35]

Individuals with Primary Pulmonary Disease: Obstructive Patterns

Chronic Airflow Limitation

Chronic airflow limitation is a descriptive term that refers to those disorders that previously were termed *chronic obstructive pulmonary disease* (COPD) (e.g., chronic bronchitis, emphysema, bronchiectasis, and cystic fibrosis). Although there may be a reversible component, airflow obstruction associated with these disorders is largely irreversible. The pathophysiology of these conditions is reviewed in Chapter 5, and special considerations with respect to exercise testing and training are detailed in Chapter 24.

Bates[37] described the syndrome of chronic airflow limitation as being caused by four external factors, mediated by four primary tissue responses, and modified by four physiological responses. The principal external causative factors include inhaled irritants, allergens, infections, and climate. The four principal tissue responses include large and small airway changes, airway hyperreactivity, bronchiolar damage, and alveolar destruction. The principal physiological responses include a reversible increased airway reactivity component, pulmonary vascular response to alveolar hypoventilation, control of breathing response to ventilation-perfusion imbalance and hypoxemia, and tissue defenses against elastase. Decline in pulmonary function and rate of development of the syndrome depend on the combination of causative factors and individual responses.

Management of chronic lung disease should be an integrated and comprehensive program that depends on teamwork, good communication, an approach focused on the individual, and his or her adherence to health recommendations.[3] Because of the primary contribution of lifestyle to most cases of heart and lung conditions, there is a long but variable latency before clinical signs and symptoms manifest.[38] Therefore advocating healthy lifestyles and working with each individual to embrace such a lifestyle as health insurance will ultimately reduce the burden of the diseases of civilization.

Chronic Bronchitis

Pathophysiology and Medical Management

Chronic bronchitis is usually associated with a history of smoking and is defined as mucous hypersecretion and cough producing sputum for 3 months or more over a 2-year period.[39] Over the first few years of smoking, reversible airway changes occur. Over 10 to 15 years of smoking, mucous hypersecretion and chronic bronchitis become apparent. After 25 to 35 years of smoking, irreversible airway damage and chronic disability occur. Smoking is the major cause of emphysema and lung cancer.

The patient with chronic bronchitis is prone to infection and repeated periods of morbidity. Deterioration of aerobic capacity and functional capacity is related to the severity of the condition. Nutrition and hydration may be impaired, particularly in severe cases, because of neglect and the excessive energy cost of activities of daily living. Sleep may be irregular; thus the patient's symptoms are worsened (e.g., reduced endurance, fatigue, and lethargy) because of lack of normal physiological restoration from sleep.

The natural history of chronic bronchitis related to smoking includes mucous hypersecretion, reduction in forced expiratory volume in 1 second (FEV_1), and increased heterogeneity of the distributions of ventilation, perfusion, ventilation-perfusion matching, and diffusion.[40,41] General debility and deconditioning ensue.

Smoking contributes to increased mucus production in the small airways, increased mucus in the large airways, respiratory bronchiolitis, reduced elastic recoil, increased airway reactivity, and vascular changes.[37] These changes lead to nonuniformity of time constants in the lung, with consequent inhomogeneous distribution of inspired gas and premature small airway closure, and to nonuniformity of ventilation, perfusion, and diffusion distributions. Although variable among smokers, pulmonary function changes generally correspond to the amount smoked and duration of smoking history. Over time the pulmonary function profile becomes increasingly consistent with chronic airflow limitation (i.e., reduced FEV_1 and reduced FEV_1/forced vital capacity); however, these are late indicators of pulmonary changes. Signs of uneven distribution of ventilation and increased closing volumes, indicative of small airway involvement, are early pulmonary function changes in smokers. Exercise diffusing capacity is reduced, which explains in part the reduced maximal volume of oxygen use of smokers. Dynamic compliance with breathing frequency is also reduced. Residual

volume is increased as a percent of total lung capacity (TLC). Tracheal mucous velocity is reduced, and secretion clearance is impaired. Any patient with a smoking history, regardless of a diagnosis, has some degree of chronic airflow limitation, which must be considered when these patients receive medical or surgical care, as well as physical therapy.

The cardiac manifestations of chronic bronchitis stem from airway obstruction, secretion accumulation and reduced capacity to expectorate effectively, polycythemia, low arterial oxygen tension, and cardiovascular and pulmonary deconditioning. Increased airway resistance secondary to obstruction increases oxygen demand and hence the work of breathing. This increased demand is superimposed on an oxygen transport system that is already compromised. The cardiovascular system attempts to compensate for chronically reduced arterial oxygen tension by increasing cardiac output (i.e., stroke volume and heart rate). As blood gases deteriorate, the production of red blood cells increases (i.e., polycythemia) to enhance the oxygen-carrying capacity of the blood. Polycythemia increases the viscosity of the blood, however, and in turn, the work of the heart to pump blood to the pulmonary and systemic circulations. Furthermore, viscous blood is prone to circulatory stasis and clotting.

Low arterial oxygen tension leads to hypoxic pulmonary vasoconstriction and increased pulmonary vascular resistance (i.e., pulmonary hypertension). This also increases the work of the right side of the heart in terms of ejecting blood to the lungs. Chronic overwork of the right ventricle leads to hypertrophy, insufficiency, and eventual failure of the right heart (cor pulmonale). Chronically reduced arterial oxygen can increase the demand on the left side of the heart to maintain cardiac output. Similar to right-sided failure, the left side of the heart may become hypertrophied and over time may fail.

The increased intrathoracic pressures generated during chronic coughing reduce venous return, cardiac output, and coronary perfusion and increase blood pressure. These effects exert additional myocardial strain, lead to arterial desaturation, and increase the potential for cardiac dysrhythmias.

The complications of chronic bronchitis are exacerbated by cardiovascular and pulmonary deconditioning. Despite the pathology, the efficiency of oxygen transport along the steps in the pathway is suboptimal. This reduced efficiency results in an overall increase in the oxygen demands of the patient, who is unable to adequately supply oxygen.

Pharmacological support in the long-term management of chronic bronchitis includes bronchodilators (e.g., oral, metered-dose inhalant, inhaled powdered, or aerosol), corticosteroids (e.g., oral or inhaled), expectorants, antibiotics, inotropic agents (e.g., digitalis), beta blockers, antidysrhythmic agents, and diuretics. Patients with chronic lung disease must be monitored closely during exercise because of the potential cardiac effects of disease and medications (e.g., beta-blocker agents attenuate the normal hemodynamic responses to exercise; bronchodilators, such as albuterol (Ventolin), elicit tachycardia).

Principles of Physical Therapy Management

Based on a comprehensive patient assessment, the goals of long-term management for the patient with chronic bronchitis may include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing his or her physiological reserve capacity
- Assess lifestyle-related health risk factors
- As indicated, address multisystem conditions that affect presenting signs and symptoms (regarding comorbidity, see Chapters 6, 13, 25, and 32)
- Educate the patient about chronic bronchitis; self-management; effects of smoking, nutrition, weight control, smoking reduction or cessation, stress management, and other lifestyle factors; medications; infection control, and role of a long-term rehabilitation program
- Facilitate mucociliary transport
- Optimize secretion clearance
- Optimize alveolar ventilation
- Optimize lung volumes and capacities and flow rates
- Optimize ventilation and perfusion matching and gas exchange
- Reduce the work of breathing
- Reduce the work of the heart
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the patient

Patients are monitored for dyspnea, respiratory distress, symptomatic breathing pattern (depth and frequency), arterial desaturation, cyanosis (delayed sign of desaturation); as well as heart rate, blood pressure, and rate-pressure product are monitored. Patients with cardiac dysfunction or low arterial oxygen tensions require ECG monitoring, particularly during exercise. If supplemental oxygen is used, the fraction of inspired oxygen (Fi_{O_2}) administered is recorded. Subjectively, breathlessness is assessed using a modified version of the Borg scale of perceived exertion.

Medication that is needed to maximize treatment response (e.g., bronchodilators) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak effectiveness is essential if treatment is to be maximally effective.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with chronic bronchitis include some combination of education, aerobic exercise, strengthening exercise, chest wall mobility exercise, range-of-motion exercises, body positioning, breathing control and coughing maneuvers, airway clearance interventions, relaxation, activity pacing, and energy conservation. An ergonomic assessment of the patient's work and home environments may be indicated to minimize oxygen demand and energy expenditure in these settings.

The use of supplemental oxygen depends on the severity of the disease. Some patients have no need for supplemental oxygen, some need it only during exercise, and some patients require continuous oxygen with proportionately more delivered during activity and exercise compared with rest. Supplemental oxygen is not usually required until lung damage becomes extreme (i.e., the morphological changes are consistent with the irreversible changes associated with emphysema).

Education is a principal focus of the long-term management of the patient with chronic bronchitis. Education includes the reinforcement of preventive health practices (e.g., smoking reduction and cessation, cold and flu prevention, flu shots, aerobic exercise, strengthening exercises, nutrition, weight control, hydration, pacing of activities, energy conservation, relaxation, and stress management). Chronic bronchitis and emphysema are often associated with sleep disturbances. Obstructive sleep apnea is increasingly prevalent with disease severity. Thus activity and sleep patterns must be assessed to ensure that sleep is maximally restorative and not contributing to the patient's symptoms. Integral to an exercise prescription is the time of day it is to be performed. Exercise is prescribed when the patient is least fatigued, when he or she is most energetic, and when performing such a program is most convenient.

Aerobic exercise is a well-established essential component of the long-term management of the patient with chronic bronchitis to optimize the efficiency of oxygen transport overall including mobilization and removal of secretions.[42] The goal is to increase the exercise threshold intensity at which incapacitating dyspnea, perceived exertion, and desaturation occur.

Emphysema

Pathophysiology and Medical Management

Emphysema is associated with a prolonged history of smoking and chronic bronchitis and indicates significant irreversible lung damage. A less common type of emphysema not associated with smoking is alpha$_1$-antitrypsin deficiency. Antitrypsin is essential in balancing elastin production and degradation and in preserving optimal lung compliance. A deficiency of antitrypsin reduces lung elasticity and contributes to the characteristic increase in lung compliance that is the hallmark of emphysema. The pathophysiology of emphysema is detailed in Chapter 5. The principal pathophysiological deficits include irreversible alveolar damage resulting from loss of elastic recoil and the normal tethering of the alveoli, which renders the lung parenchyma excessively compliant and floppy. Excessive distension and dilatation of the terminal bronchioles and destruction of alveoli reduce the surface area for gas exchange. Hence diffusing capacity is correspondingly reduced. The dead space in the lungs and TLC increase significantly. Breathing at normal tidal volume, the patient's airways close beyond the degree normally occurring with aging, and this contributes to ventilation and perfusion mismatch and hypoxemia. Time constants are altered such that alveolar units are not evenly ventilated. In the nonacute, chronic stages the primary problems include inadequate and inefficient gas exchange resulting from the structural damage to the lungs and altered respiratory mechanics of the lungs and chest wall and their interaction. The lungs are hyperinflated, the chest wall becomes rigidly fixed in a hyperinflated position, the normal bucket handle and pump handle motions of the chest wall are impaired, the hemidiaphragms are flattened, the mediastinal structures are shifted, and the heart is displaced and rotated, making it mechanically inefficient.[40] The normal mucociliary transport system is ineffective because years of smoking destroy the cilia, reduce their number, and alter their configuration and orientation; thus their function is correspondingly obliterated or impaired. In addition, these patients are unable to generate high transpulmonary pressures and forced expiratory flow rates because of altered respiratory mechanics. Consequently, coughing is weak and ineffective. The administration of supplemental oxygen is limited because these patients rely on their hypoxic drive to breathe. This life-preserving drive can be attenuated with even moderate levels of oxygen. Thus oxygen administration is limited to low flows. The respiratory muscles are often weak, if not fatigued from being in a flattened position, and hence suboptimal on the length-tension curve.[43] The clinical consequences of hyperinflation include abnormal chest wall movement, impaired inspiratory muscle function, increased oxygen cost of breathing, impaired exercise capacity, hypoxemia and hypercapnia, and breathlessness. Overall, patients with emphysema, particularly severe emphysema, tend to be inactive and deconditioned, which further compromises the efficiency of the oxygen transport system and the capacity of other steps in the pathway to compensate.

Several physiological compensations occur in response to chronic hypoxemia. Stroke volume and cardiac output are increased. The red blood cell count increases (polycythemia); however, the blood becomes more viscous and requires more work to eject and distribute throughout the body. Thus the stroke work of the heart is further increased. This load on the heart occurs in addition to the increased afterload of the right ventricle because of an increase in pulmonary vascular resistance secondary to hypoxic vasoconstriction in the lungs. Over time the heart becomes enlarged and pumps even less efficiently. In the long-term management of the patient with emphysema, the primary pathophysiological problems are impaired alveolar ventilation, impaired gas exchange, reduced oxygen transport efficiency, and the work of breathing and of the heart. Unlike in chronic bronchitis, secretion accumulation may be less problematic in patients with emphysema during nonacute periods. Nonetheless, optimizing mucociliary transport is an ongoing goal of prevention in that the consequences of mucous retention and infection can be life-threatening.

Noninvasive positive pressure mechanical ventilation (NPPV) has been an important advance in the management of individuals with chronic lung disease.[44] Those with daytime hypercapnia with nocturnal hypoventilation may benefit most.[45] The efficacy of NPPV, however, is jeopardized by poor adherence to its use. Predictors of successful use include ability to protect the airway, acuteness of illness, and a good initial response within the first couple of hours. Barriers include discomfort of the nose piece or face mask, patient-ventilator asynchrony, excess sternocleidomastoid activity, unstable vital signs, prolonged hours of ventilator use, problems with adaptation, symptoms, and poor gas exchange. In addition to immediate clinical benefits, NPPV may help avoid or postpone respiratory failure and invasive mechanical ventilation and weaning in this population. Other benefits that may be associated with NPPV include improved sleep and quality of life and reduced hospitalization. The physical therapist needs to identify potential barriers and address these to maximize adaptation and adherence to NPPV. Patient subgroups of those who will benefit from NPPV must be identified. Technology research must improve comfort and adherence to NPPV.

Long-term outcome of lung volume reduction surgery for people with severe emphysema has been positive. Six months

after surgery, right ventricular performance increases, particularly during exercise.[46]

Principles of Physical Therapy Management

The goals for long-term management of the patient with emphysema include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing his or her physiological reserve capacity
- Educate regarding emphysema, self-management, smoking reduction and cessation, medications, nutrition, weight control, stress management, infection control, and the role of a long-term rehabilitation program
- Optimize alveolar ventilation
- Optimize lung volumes and capacities and flow rates
- Optimize ventilation and perfusion matching
- Reduce the work of breathing
- Reduce the work of the heart
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Optimize respiratory muscle strength and endurance and overall respiratory muscle efficiency
- Ensure that sleep and rest are optimal
- Design comprehensive lifelong health and rehabilitation programs with the patient

Education focuses on teaching the patient about emphysema, self-management of the disease, the effect of smoking and smoking cessation, nutrition, weight control, hydration, relaxation, sleep and rest, stress management, activity pacing, energy conservation, and prevention (e.g., cold and flu prevention, flu shots, aerobic exercise, diet, sleep, and stress management).

Comparable to the patient with chronic bronchitis, sleep disturbances are common in the patient with emphysema. Activity and sleep patterns are assessed to ensure sleep is maximally restorative. If obstructive sleep apnea is disturbing the patient's sleep, recommendations can be made regarding optimal body positioning during sleep. Back elevation improves airway instability, and in some instances side-lying positions may reduce symptoms.[47] If noninvasive mechanical ventilation (e.g., nasal continuous positive airway pressure) is necessary, these body positions may help reduce the amount of ventilatory support required.

Patients are monitored for dyspnea, respiratory distress, inappropriate breathing pattern (depth and frequency), arterial desaturation, lightheadedness, discoordination; heart rate, blood pressure, and rate-pressure product also are monitored. Patients with cardiac dysfunction or low arterial oxygen tension require ECG monitoring, particularly during exercise. Subjectively, breathlessness is assessed using a modified version of the Borg scale of perceived exertion.

Medication that is necessary to maximize treatment response (e.g., bronchodilator) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally efficacious. When patients are on multiple medications, the interactions and implications for treatment response must be identified.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with emphysema include some combination of education, aerobic exercise, strengthening exercise, ventilatory muscle training (strength and endurance) or ventilatory muscle rest, low flow oxygen, mechanical ventilatory support for home use, chest wall mobility exercises, range-of-motion exercises, body positioning, breathing control and coughing maneuvers, airway-clearance techniques, relaxation, activity pacing, and energy conservation. An ergonomic assessment of work and home environments may be indicated to minimize oxygen demands in these settings.

The benefits of aerobic and strengthening exercise in the long-term management of airflow limitation to optimize oxygen transport in patients with compromised oxygen delivery are well established.[48–50] Patients with severe limitations are often unable to exercise at a sufficient intensity to effect aerobic adaptations to the exercise stimulus. Benefits of exercise in these patients may be explained by desensitization of dyspnea, improved movement efficiency and hence movement economy, improved anaerobic capacity, improved ventilatory muscle strength and endurance, and increased motivation.[51,52] Exercise intensity is prescribed based on rating of breathlessness (modified Borg scale) (Chapters 18 and 19), in conjunction with objective and other subjective responses from the exercise test. Objective and subjective responses to exercise in patient populations, however, reflect many factors in addition to pathophysiology (see Chapter 19 for guidelines to maximize test validity).

Patients with chronic airflow limitation alter their breathing patterns so that they breathe on the most metabolically efficient portion of the pressure relaxation curve (see Chapters 5 and 31). These patients tend to breathe with prolonged expiratory phases to maximize gas transfer and mixing in the lungs in order to minimize the effects of altered ventilatory time constants. To facilitate such a breathing pattern, the patient tends to breathe through pursed lips, which may create back pressure to maintain the patency of the airways. The metabolic efficiency of the patient's breathing pattern may be improved further by altering breathing mechanics rather than imposing a different breathing pattern that may be suboptimal.[53] Altering breathing mechanics involves manipulating the patient's body position to promote alveolar ventilation, perfusion, and ventilation and perfusion matching, thereby reducing the work of the heart.

The increased intrathoracic pressures generated during chronic coughing limit venous return, cardiac output, and coronary perfusion. Blood pressure is also increased. These effects exert additional myocardial strain, lead to arterial desaturation, and increase the potential for cardiac dysrhythmias. Breathing control and coughing maneuvers coupled with body positioning and exercise are taught such that the work of breathing is minimized (i.e., alveolar ventilation and gas transfer are as efficient as possible) and coughing is as efficient as possible (i.e., maximally productive with the least energy expenditure).

Physical therapy is one component of a comprehensive rehabilitation program in the long-term management of people with emphysema. Such a program also needs to include information on health promotion and maintenance, ongoing review and a log of medications, respiratory support (e.g., oxygen aerosol therapy and mechanical ventilatory support),

occupational therapy, sexual rehabilitation, psychosocial rehabilitation, and vocational rehabilitation.

Breathing control maneuvers (breathing exercises) warrant special mention. Breathing control has been thought to reduce the work of breathing. Inadvertent use of breathing exercises, however, can increase the work of breathing. Diaphragmatic breathing can reduce ventilatory efficiency in people with COPD.[54] Furthermore, these exercises are associated with greater oxygen cost than spontaneous breathing in stable patients with COPD.[53] The fact that patients do not breathe with the most energetically economic breathing pattern is of considerable clinical interest and suggests that biomechanical efficiency overrides economic efficiency. These findings support that an altered breathing pattern is the consequence of the underlying problem rather than the problem itself. Thus management should be focused on the factors that determine biomechanical efficiency and breathing pattern. Other than pursed-lip breathing, evidence for retraining breathing patterns in people with stable COPD is not well supported.[55]

Body positioning is a primary determinant of pulmonary function. Thus patients should be encouraged to perform coughing and other forced expiratory maneuvers in upright positions.[56] Leaning forward can increase intraabdominal and intrathoracic pressures, elevate the diaphragm, and increase expiratory flow rate.

Obstructive sleep apnea is often associated with COPD. This is complicated further by obesity in some patients. Upright positioning and weight loss can improve respiratory mechanics and oxygenation.[57] A more upright sleeping posture could improve nighttime oxygenation in this patient group.

Asthma

Pathophysiology and Medical Management

Asthma is a common respiratory condition that is characterized by hypersensitivity of the airways to various triggers resulting in reversible airway obstruction (i.e., bronchospasm and bronchial edema) (see Chapter 5).[39] In mild cases, no treatment other than prophylaxis may be needed. In severe cases, asthma can be life-threatening. Once affected by the trigger, the airways narrow, increasing the resistance to airflow and reducing oxygen delivery. Breathing through narrowed airways contributes to wheezing, reduced alveolar ventilation, rapid shallow breathing, shortness of breath, increased work of breathing, desaturation, and cyanosis. Increased inhomogeneity of the distribution of ventilation is present in some patients with nonacute asthma.[58] Expiratory flow-volume loops remain the cornerstone of monitoring asthma.[59] Although some triggers may produce mucous hypersecretion, even normal amounts of pulmonary secretions can obstruct narrowed airways and lead to atelectasis. Asthma that has well-defined triggers is easier to manage than cases in which the triggers are less specific.

Principles of Physical Therapy Management

The goals of long-term management of the patient with asthma include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing his or her physiological reserve capacity
- Educate regarding asthma, self-management, nutrition, weight control, air quality including smoking reduction and cessation, stress management, medications and their uses, prevention of asthmatic attacks, and infection control
- Reduce the work of breathing
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the patient

Patients are monitored for dyspnea, respiratory distress, inappropriate breathing pattern (depth and frequency), arterial desaturation, and cyanosis (delayed sign of desaturation); heart rate, blood pressure, and rate-pressure product are monitored. Patients with cardiac dysfunction or low arterial oxygen tension require ECG monitoring, particularly during exercise. Subjectively, breathlessness is assessed using a modified version of the Borg scale of perceived exertion.

Medication that is needed to maximize treatment response (e.g., bronchodilators and antiinflammatories) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally efficacious. When patients are taking multiple medications, their interactions and the implications for management must be known.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with asthma include education, aerobic exercise, strengthening exercise, chest wall mobility exercises, range-of-motion exercises, relaxation, activity pacing, and stress management.

Education is central to self-management of asthma. The patient is taught the basic pathophysiology of the disease and its triggers. Other central topics, including preventive health practices, are also taught (e.g., cold and flu prevention; flu shots; medication types, administration, and effects; aerobic exercise; nutrition; weight control; hydration; air quality control including smoking reduction and cessation; relaxation and stress management; and the benefits of an integrative, lifelong, self-management rehabilitation program).

Special mention must be made regarding the use of medications and inhalers. These are frequently used unknowledgeably (i.e., the patient is unfamiliar with the basic pharmacokinetics of the medications being used and thus is not deriving optimal effects). Inhalers are often used improperly; therefore the patient does not derive the full benefit of the medication. The instructions provided by the supplier of the inhalers should be strictly followed. There are numerous types of inhalers, all with different applications. In not adhering to the instructions, the patient's time and effort are wasted by using the inhaler ineffectively, the patient does not derive the full benefit of the medication, an excessive amount of inhaler may be used to compensate for ineffective application, there may be increased exposure of the patient to the side effects of the medication, and there is considerable economic waste.

Knowledge of the triggers of increased airway sensitivity enables the patient to exert control over bronchospastic

attacks. The patient is taught to record the frequency of bronchospastic attacks and identify what triggers and relieves them. In this way the patient learns to avoid or minimize their frequency, severity, and duration and minimizes the amount of medication required. In turn, doctor and hospital visits may be minimized. These are significant benefits.

The exercise prescription parameters are set below the bronchospasm threshold, which is established based on an exercise test (see Chapters 19 and 24). Specialized challenge tests are performed in a pulmonary function laboratory. Exercise training enables the patient to determine the balance between optimal aerobic capacity and medication and the optimal physical environment for exercise. Temperature and humidity can have significant effects on work output in patients with asthma.

Bronchiectasis

Pathophysiology and Medical Management

Bronchiectasis is characterized by dilatation and anatomical distortion of the airways and obliteration of the peripheral bronchial tree.[41] Bronchiectasis is often the sequela of prolonged chronic lung infection. The associated inflammation leads to occlusion of the airways, which results in atelectasis of the parenchyma and consequent dilatation of central airways by increased traction on the peribronchial sheath. In addition, chronic inflammation weakens the walls of the airways, leading to further dilatation. Fibrotic connective tissue changes in the wall contribute further to dilatation and airway distortion. These anatomical changes adversely affect normal respiratory mechanics and hence pressure volume characteristics of the lung. The chest wall becomes hyperinflated and assumes the barrel shape associated with chronic airflow limitation. The overall severity of bronchiectasis depends on the number of lung segments involved. There is often some reversible airflow limitation associated with bronchiectasis.

The patient with bronchiectasis has copious tenacious secretions, lung hyperinflation and impaired respiratory mechanics, an inefficient breathing pattern, reduced ability to clear secretions, and reduced aerobic capacity and is generally debilitated.

The increased intrathoracic pressures generated during bouts of chronic coughing limit venous return, cardiac output, and coronary perfusion. Blood pressure is also increased. These effects exert additional myocardial strain, lead to arterial desaturation, and increase the potential for cardiac dysrhythmias and dysfunction.

Principles of Physical Therapy Management

The goals of long-term management of the patient with bronchiectasis include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing his or her physiological reserve capacity and function
- Educate regarding bronchiectasis, self-management, nutrition, weight control, smoking reduction and cessation, stress management, medications and their use, and infection control
- Facilitate mucociliary transport
- Optimize secretion clearance
- Optimize alveolar ventilation
- Optimize lung volumes and capacities and flow rates
- Optimize ventilation and perfusion matching
- Reduce the work of breathing
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thus peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the patient

Patients are monitored for dyspnea, respiratory distress, inappropriate breathing pattern (depth and frequency), arterial desaturation, and cyanosis (a delayed sign of desaturation); heart rate, blood pressure, and rate-pressure product are monitored. Patients with cardiac dysfunction or low arterial oxygen tension require ECG monitoring, particularly during exercise. Subjectively, breathlessness is assessed using a modified version of the Borg scale of perceived exertion.

Medication that is needed to maximize treatment response is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally efficacious.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with bronchiectasis include some combination of education, aerobic exercises, strengthening exercises, chest wall mobility exercises, range-of-motion exercises, body positioning, breathing control and coughing maneuvers, airway clearance interventions, optimizing rest and sleep, relaxation, pacing, and energy conservation. Factors that trigger symptoms are identified and avoided. An ergonomic assessment of the patient's work and home environments may be indicated to maximize function in these settings.

Education is a central component of the patient's long-term, self-management rehabilitation program. Preventative health practices are taught (e.g., cold and flu prevention, flu shots, smoking cessation, sleep, aerobic exercise, nutrition, weight control, hydration, relaxation, stress management, and the long-term benefits of an integrative rehabilitation program).

Cystic Fibrosis

Pathophysiology and Medical Management

Cystic fibrosis is a complex exocrine disease that has significant systemic effects.[39] The disease is congenital and is hallmarked by nutritional deficits contributing to impaired growth and development. Pulmonary function shows progressive decline with commensurate reductions in homogeneity of ventilation and inspiratory pressures.[58] Cardiovascular and pulmonary involvement can be classified into three groups: no physical signs in the chest; occasional cough and sputum; and constant cough, sputum, and other signs. Patients in each classification can benefit from physical therapy with respect to enhancing oxygen transport. Moderate and severe disease is characterized by significant airflow obstruction secondary to copious, tenacious secretions. In addition, pulmonary hypertension and right heart insufficiency may be

manifested and eventual failure may ensue. Left ventricular diastolic failure may also be a feature of advanced disease.[60]

Between exacerbations, the medical priorities are to reduce the risk of infection and morbidity and promote optimal health, growth, and development.

Principles of Physical Therapy Management

The goals of long-term management of the patient with cystic fibrosis include the following:

- Maximize the patient's quality of life, general health, well-being, and growth and development through maximizing his or her physiological reserve capacity
- Educate the patient and family regarding cystic fibrosis, self-management, nutrition, avoidance of smokers, stress management and relaxation, prevention of acute exacerbations of the disease, infection control, and medication uses, modes of administration, pharmacokinetics, and times to peak efficacies
- Facilitate mucociliary transport
- Optimize secretion clearance
- Optimize alveolar ventilation
- Optimize lung volumes and capacities and flow rates
- Optimize ventilation and perfusion matching
- Reduce the work of breathing
- Reduce the work of and strain on the heart
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the individual (and the family if the patient is a child)

Patients are monitored for dyspnea, respiratory distress, inappropriate breathing pattern (depth and frequency), arterial desaturation, and cyanosis (a delayed sign of desaturation); heart rate, blood pressure, and rate-pressure product are monitored. Patients with cardiac dysfunction or low arterial oxygen tension require ECG monitoring, particularly during exercise. Subjectively, breathlessness is assessed using a modified version of the Borg scale of perceived exertion.

Medication that is needed to maximize treatment response is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally efficacious.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with cystic fibrosis include some combination of education, aerobic exercises, strengthening exercises, ventilatory muscle training (strength and endurance), ventilatory muscle rest, supplemental oxygen, mechanical ventilation for home use, chest wall mobility exercises, range-of-motion exercises, body positioning, breathing control and coughing maneuvers, airway clearance interventions, relaxation, pacing, and energy conservation.

Education focuses on teaching preventative health practices and infection control (e.g., avoidance of cold and flu, flu shots, aerobic exercise, nutrition, hydration, relaxation, stress management, activity pacing, and energy conservation).

Physical activity and aerobic exercise must be integrated early into the lifestyle of the child with cystic fibrosis.[61] As much as possible, the child is integrated into activities of his or her peer group. A prescribed aerobic exercise program is designed to optimize the efficiency of oxygen transport at all steps in the pathway and thereby enhance functional capacity overall. Physical activity and aerobic exercise enhance mucociliary transport and mucociliary clearance, maximize alveolar ventilation and ventilation and perfusion matching, increase ventilatory muscle strength and endurance and airway diameter, and stimulate a productive effective cough. Furthermore, physical activity and exercise have been associated with improved immunity and reduced risks of infection.[62,63] These are significant outcomes for patients with cystic fibrosis, who have thick, copious secretions.

In addition, breathing control and coughing maneuvers are included as a component of a long-term, self-management rehabilitation program. Postural drainage and manual techniques have been the mainstay of airway clearance in the past. Exercise, however, has a primary role in secretion mobilization and as an airway clearance intervention. Breathing control and coughing strategies are coupled with exercise to facilitate secretion clearance. The principles of autogenic drainage can be integrated into breathing control. This procedure focuses on eliciting coughing when it will be most productive, thereby minimizing less productive, exhaustive coughing. Patients with cystic fibrosis often cough so violently and uncontrollably that it leads to significant arterial desaturation, vomiting, and exhaustion and impedes venous return and cardiac output.

Ventilatory devices such as the positive expiratory pressure (PEP) mask and the flutter valve have shown benefit in some patients with cystic fibrosis with respect to reducing airway closure, clearing secretions, and enhancing gas exchange.[64,65] Such aids may be useful adjuncts in some patients; however, they do not replace the multiple benefits (including mobilizing and removing secretions) of physical activity and exercise on optimizing oxygen transport.

Individuals with Primary Pulmonary Disease: Restrictive Patterns

Interstitial Lung Disease

Pathophysiology and Medical Management

The pathophysiology of restrictive lung disorders and interstitial lung disease (ILD) in particular is described in Chapter 5. This classification of lung disease is associated with various occupations and the inhalation of inorganic and organic dust. As the disease progresses, TLC and vital capacity are reduced. Residual volume often remains the same. Maximal flow rates tend to be increased as compliance is reduced. The drive to breathe, breathing frequency, and the ratio of tidal volume to TLC are increased. Glandular hyperplasia may be present, leading to mucous hypersecretion in some patients. Diffusing capacity may be reduced, but this may be apparent only during exercise (i.e., arterial desaturation and dyspnea). Exercise-induced desaturation and reduction in partial pressure of arterial oxygen may also reflect shunt and ventilation and perfusion mismatch.

Hemodynamic changes may be present (e.g., increased pulmonary artery pressure). Chronically increased pulmonary artery pressures, and hence increased pulmonary vascular resistance, lead to increased right ventricular stroke work, hypertrophy, and right ventricular insufficiency. Partial pressure of oxygen in mixed venous blood may fall significantly during exercise, contributing to arterial hypoxemia.

Principles of Physical Therapy Management

The goals of long-term management of the patient with ILD include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing his or her physiological reserve capacity
- Educate regarding ILD, self-management, nutrition, weight control, smoking reduction and cessation, relaxation and stress management, medications and their uses, prevention, health promotion, and infection control
- Optimize alveolar ventilation
- Optimize lung volumes and capacities
- Optimize ventilation and perfusion matching
- Optimize mucociliary transport
- Reduce the work of breathing
- Reduce the work of the heart
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Design comprehensive lifelong health and rehabilitation programs with the patient

Patients are monitored for dyspnea, respiratory distress, and inappropriate breathing pattern (depth and frequency); arterial desaturation; in addition heart rate, blood pressure, and rate-pressure product are monitored. Patients with cardiac dysfunction or low arterial oxygen tension require ECG monitoring, particularly during exercise. Subjectively, breathlessness is assessed using a modified version of the Borg scale of perceived exertion.

Medication that is needed to maximize treatment response is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with ILD include some combination of education, aerobic exercises, strengthening exercises, chest wall mobility exercises, range-of-motion exercises, body positioning, breathing control and coughing maneuvers, relaxation, pacing, and energy conservation. An ergonomic assessment of the patient's work and home environments may be indicated to maximize function in these settings.

Education is a central component of a comprehensive rehabilitation program for the management of ILD. Education includes information on preventative health practices (e.g., removal from the causative environment, cold and influenza prevention shots, triggers of disease exacerbations and their prevention, smoking reduction and cessation, nutrition, weight control, hydration, relaxation, activity pacing, and energy conservation).

During aerobic exercise, patients with ILD are prone to arterial desaturation.[66] Patients who desaturate during sleep require supplemental oxygen during exercise. The intensity of the exercise prescribed is based on arterial saturation, breathlessness, and work of the heart, in conjunction with other objective responses.

Lung Cancer

Pathophysiology and Medical Management

Lung cancer is a leading cause of death for men and the incidence is increasing for women. Once diagnosed, 80% of patients survive 1 year. Lung cancer is highly correlated with a history of smoking and exposure to coal tars, asbestos, and radioactive dusts. The majority of primary malignant tumors are bronchogenic carcinomas. They are centrally located and thus contribute to bronchial obstruction, atelectasis, and pneumonia. Pathophysiologically, lung cancer has features of both obstructive and restrictive lung disease. Presenting signs include airway obstruction, dyspnea, cough, and hemoptysis.[39] Treatment is limited to surgery, if metastasis has been ruled out, or conservative management with radiation and chemotherapy.

Bronchogenic carcinomas metastasize readily through the circulation and lymphatic channels to other organs including the brain, bone, liver, kidneys, and adrenal glands.

If detected early, thoracic surgery may be performed to excise the cancerous tumor (see Chapter 29). If inoperable, or in the case of metastases, a patient may be managed at home or in a hospice. Patients are debilitated, often undernourished, fatigued, short of breath, lethargic, depressed, and in pain. Although these patients are often extremely ill, there is a growing trend to manage these patients in the community whenever possible. As the disease progresses, maintaining function and reducing the rate of deterioration become primary goals.

End-of-life issues and palliative care must be discussed. If the patient is managed at home, these principles of care can be practiced in this setting, and they are common to other conditions as well.

Principles of Physical Therapy Management

The goals of long-term management of the medical patient with lung cancer include the following:

- Maximize the patient's quality of life, general health, and well-being through maximizing his or her physiological reserve capacity
- Educate the patient and family about the benefits of a palliative program
- Promote self-determination and pay particular attention to being an active listener
- Provide supportive care
- Optimize pain control
- Facilitate mucociliary transport
- Optimize secretion clearance and protect the airways
- Optimize alveolar ventilation
- Optimize lung volumes and capacities and flow rates
- Optimize ventilation and perfusion matching
- Reduce the work of breathing

- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction
- Optimize the benefits of sleep and rest
- Minimize the effects of restricted mobility and recumbency
- Design a rehabilitation program with the patient that is suited to his or her fluctuating needs

Patients are monitored for dyspnea, respiratory distress, inappropriate breathing pattern (depth and frequency), arterial desaturation, and cyanosis (a delayed sign of desaturation); heart rate, blood pressure, and rate-pressure product also are monitored. Patients who can be mobilized but have cardiac dysfunction or low arterial oxygen tensions require ECG monitoring. Subjectively, breathlessness is assessed using a modified version of the Borg scale of perceived exertion.

Medication that is necessary to maximize treatment response (e.g., analgesics or bronchodilators) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in patients with lung cancer include some combination of education, mobilization, strengthening exercises, chest wall mobility exercises, body positioning, supplemental oxygen, mechanical respiratory support, breathing control and coughing maneuvers, airway clearance interventions, sleep and rest, relaxation, activity pacing, and energy conservation. Treatments are timed whenever possible to coincide with patients' peak energy level during the day.

Patients with lung cancer may benefit from the immunological effects, as well as oxygen transport effects, of mobilization and physical activity. The prescriptive parameters are adjusted each session, given the rapid changes in these patients' conditions.

Patients with lung cancer often cough up and expectorate blood in their sputum. The airways must be as clear as possible to avoid obstruction, atelectasis, infection, and pneumonia. Although airway clearance is an important goal, treatments should avoid contributing to bleeding and blood loss, if possible. This blood loss may contribute to anemia and fatigue.

Manual airway clearance interventions may be indicated in some patients. Postural drainage may be coupled with percussion and manual vibration. The impact of manual interventions, however, may contribute to bleeding; thus the patient requires stringent monitoring. Despite lack of evidence, metastases to the thoracic cavity and the ribs in particular may preclude percussion in favor of manual vibration being performed over unaffected areas. Treatment duration may be limited by the patient's tolerance. Tolerance may be improved by modifying body position or by shortening treatments but increasing their frequency.

Summary

This chapter reviews the pathophysiology, medical management, and comprehensive physical therapy management of individuals with chronic primary cardiovascular and pulmonary pathology. Exercise testing and training are major components of the comprehensive management of these conditions, and this topic is presented separately in Chapter 24. Given that the heart and lungs are interdependent and function as a single unit, primary lung or heart disease is considered with respect to the other organ and in the context of oxygen transport overall.

The principles of long-term management of people with chronic primary lung disease are presented first. Although there is no clear line between obstructive and restrictive patterns of lung disease as they often coexist, pathology can be generally defined based on the primary underlying pathophysiological problems. Thus the primary conditions presented included obstructive lung disease (i.e., chronic airflow limitation, asthma, bronchiectasis, and cystic fibrosis) and restrictive lung disease (i.e., interstitial pulmonary fibrosis). Lung cancer, which has the characteristics of both obstructive and restrictive patterns of pathology, is also presented.

The long-term cardiovascular and pulmonary management of people with chronic primary heart disease is then presented, with special attention to angina, myocardial infarction, and heart valve disease. Chronic vascular diseases including PVD, hypertension, and type 2 diabetes mellitus are also presented.

The principles of management of people with various chronic primary cardiovascular and pulmonary conditions are presented rather than treatment prescriptions, which cannot be discussed without consideration of a specific patient. These principles also are applied when one or more chronic primary cardiovascular and pulmonary conditions are secondary diagnoses for a patient, as such dysfunction may necessitate modifying the treatment prescription for some other condition or, minimally, indicate special monitoring.

Review Questions

1. Describe the chronic primary cardiovascular and pulmonary pathophysiology associated with airflow limitation (i.e., COPD), asthma, bronchiectasis, cystic fibrosis, interstitial pulmonary fibrosis, lung cancer, angina, myocardial infarction, valvular heart disease, PVD, hypertension, and type 2 diabetes mellitus, and how such pathology may affect an individual's participation in life or be a threat to it.
2. Relate cardiovascular and pulmonary physical therapy treatment interventions for individuals with each of the chronic conditions listed in question 1, and provide the rationale for your choice.

This chapter reviews the pathophysiology and medical management in relation to the comprehensive physical therapy management of individuals with chronic secondary cardiovascular and pulmonary pathology. Exercise testing and training are major components of the comprehensive physical therapy management of individuals with chronic secondary cardiovascular and pulmonary conditions, and this topic is presented separately in Chapter 25.

This chapter specifically addresses the comprehensive physical therapy management of chronic cardiovascular and pulmonary dysfunction secondary to neuromuscular, musculoskeletal, collagen vascular and connective tissue, and renal dysfunction. Considerations in the management of people who are overweight or obese are also addressed. The neuromuscular conditions that are presented include stroke, Parkinson syndrome, multiple sclerosis, cerebral palsy, spinal cord injury, chronic effects of poliomyelitis, and muscular dystrophy. The musculoskeletal conditions that are presented include thoracic deformity (kyphoscoliosis) and osteoporosis. The collagen vascular and connective tissue conditions that are presented include systemic lupus erythematosus (SLE), scleroderma, ankylosing spondylitis, and rheumatoid arthritis (RA). Finally, management of the patient with chronic renal insufficiency and management of the person who is obese are presented. The principles of physical therapy management are presented rather than treatment prescriptions, which cannot be given without consideration of a specific patient (see online Case Study Guide). In this context the goals of long-term management of each condition are presented, followed by the essential monitoring required and the primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport. The selection of interventions for any given patient is based on the physiological hierarchy. The most

physiological interventions are exploited, followed by less physiological interventions and those whose effectiveness is less well documented (see Chapter 17). With respect to physical therapy treatment prescription and monitoring, these principles must be considered when chronic secondary cardiopulmonary dysfunction is the diagnosis.

Principles of Physical Therapy Management in Chronic Secondary Dysfunction

Long-Term Physical Therapy Management Goals

Although short-term goals for patients with chronic cardiovascular and pulmonary secondary dysfunction are the immediate priority, long-term goals need to be considered from the outset. In addition to considering the patient's activity and participation needs, identifying the long-term goals early may help identify short-term component goals.

Physiological Management Goals

- Optimize lung volumes and capacities and flow rates
- Optimize ventilation and perfusion matching and gas exchange
- Facilitate mucociliary transport as needed
- Maximize aerobic capacity and efficiency of oxygen transport
- Optimize physical endurance and exercise capacity
- Optimize general muscle strength and thereby peripheral oxygen extraction

Psychosocial Management Goals

- Maximize the patient's quality of life, general health, and well-being through maximizing physiological reserve capacity
- Educate patient and/or family or caregiver regarding:
  - Cardiovascular and pulmonary manifestations of the condition
  - Self-management
  - Medication
  - Nutrition
  - Weight control
  - Smoking reduction and cessation
  - Stress management
  - Infection control
  - The role of a rehabilitation program
- As indicated, address multisystem conditions that affect presenting signs and symptoms (regarding comorbidities, see Chapters 6, 24, 25, and 31 and related parts of this chapter)
- Design lifelong health and rehabilitation programs with the patient

Among the primary goals in managing the needs of people with chronic conditions are teaching self-management skills and promoting lifestyle self-efficacy. Without attention to these components of management, short- and particularly long-term outcomes will be suboptimal.

Patient Monitoring

Patients with chronic secondary cardiovascular and pulmonary dysfunction should be monitored in a number of ways to ensure success in a rehabilitation program. These data points are necessary with most conditions discussed in this chapter, but not all. Dyspnea, for example, is not monitored for as part of an examination for osteoporosis because dyspnea is generally not part of the disease process. Exceptions to the data points mentioned are discussed in the individual monitoring discussions.

In general, patients with chronic secondary cardiovascular and pulmonary dysfunction should be monitored for the following:

- Dyspnea
- Respiratory distress
- Inappropriate breathing pattern (depth, symmetry, and frequency)
- Arterial saturation
- Cyanosis (delayed sign of desaturation)

The following values should be monitored:

- Heart rate
- Blood pressure
- Rate pressure product

The Borg scale for measuring perceived exertion is well established as a reliable tool for assessing and evaluating patients at rest and during and after exercise. Reduced exertion for a given level of work after training is an important indicator of improved oxygen transport capacity and fitness.

Medication Use

Medication(s), if necessary to maximize response, should be administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

Primary Interventions

The primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport in individuals with chronic secondary dysfunction are a combination of the following:

- Education
- Aerobic exercise
- Strengthening exercises
- Postural correction exercises
- Chest wall mobility exercises
- Range-of-motion exercises
- Airway clearance interventions
- Activity pacing
- Energy conservation

An ergonomic assessment of the patient's work and home environments may be indicated to minimize oxygen demand and energy expenditure in these settings for all patients with chronic secondary dysfunction.

Specific conditions require specific interventions; interventions particular to each condition are discussed in further detail in this chapter.

Patient Education

Education is a principal focus of the long-term management of all patients (see general principles and guidelines in Chapter 28), but it is especially important for those with secondary dysfunction. Patients should receive instruction in and information on the following health promotion and preventative practices:

- Infection control
- Smoking reduction and cessation
- Cold and flu prevention (including flu shots)
- Aerobic exercise
- Strengthening exercises
- Nutrition
- Weight control
- Hydration
- Pacing of activities
- Energy conservation

Information or instruction particular to each secondary condition is discussed in further detail in this chapter.

Individuals with Neuromuscular Conditions

Stroke

Pathophysiology and Medical Management

Stroke or hemiplegia affects cardiovascular and pulmonary function of the survivors either directly or indirectly. A cerebral infarct involving the vital centers of the brain can affect cardiovascular and pulmonary function. Such infarctions, however, are likely to be lethal or leave a person in a refractory vegetative state. More commonly, after a stroke, chest wall movement on the affected side is reduced, and myoelectrical activity can be reduced (flaccidity) or increased (spasticity). Facial and pharyngeal weakness contributes to an inability to control oral secretions, swallow effectively, and protect the upper airway. Altered respiratory mechanics and efficiency reflect impaired chest wall movement, asymmetry, and the degree of muscle paresis and spasm.

Individuals with stroke have associated problems that contribute to cardiovascular and pulmonary dysfunction. These patients tend to be older and hypertensive and have a high incidence of cardiac dysfunction. Muscle disuse and restricted mobility secondary to stroke lead to reduced cardiovascular and pulmonary conditioning and inefficient oxygen transport. Spasticity increases metabolic and oxygen demand. Hemiparesis results in gait deviations, which reduce movement efficiency and movement economy. Reduced movement economy results in an increased energy cost associated with ambulation, which may reduce exercise tolerance because of fatigue.[1] In addition, ambulating with a walking aid is associated with increased energy cost compared with normal walking. This increased energy cost reduces the patient's exercise tolerance further and increases fatigue.

The notion of a motor recovery plateau in the management of individuals with stroke has been challenged.[2,3] It has been argued that individuals adapt to the training stimulus and plateau when that stimulus no longer changes. Thus individuals are deprived of therapy unless they are responding. Capacity to improve can be augmented with changes in type of activity and the introduction of new exercises, as well as changes in the intensity, duration, and frequency of the exercises. Computer-assisted motivating rehabilitation employs the use of games and unconscious limb activation and movement, rather than engaging the patient in specific limb exercises.[2]

Individuals with stroke are at increased risk of having intercurrent ischemic heart disease, which compromises long-term survival and increases the risk of illness and inactivity.[4] Furthermore, concurrent congestive heart failure will adversely affect outcomes after stroke rehabilitation. Clinical assessment, even if patients are asymptomatic, must include a cardiac work-up to establish the degree to which cardiac insufficiency limits mobility, endurance, recovery, balance, and fatigue. An integrated multisystem approach will ensure improved rehabilitation outcomes and prevent complications.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

The management of people with stroke is shifting from a primary sensorimotor focus to an integrated management approach of which aerobic conditioning is an integral component. Long-term management goals particular to patients with stroke include the following, in addition to the long-term management goals of all patients with secondary dysfunction:

- Optimizing aids and devices to reduce unnecessary energy demands by optimizing postural alignment
- Maximizing balance to also reduce unnecessary energy demands to maintain alignment
- Optimizing chest wall excursion and ventilation
- Optimizing secretion clearance as needed
- Reducing the work of breathing
- Reducing the work of the heart
- Protecting the airways from aspiration

Structured, progressive rehabilitation programs for people with stroke augment therapeutic gains with respect to endurance, mobility, and balance, compared with spontaneous recovery.[5]

Body weight support has been examined to support an individual with stroke in the upright position to facilitate treadmill walking as a means of conditioning and gait reeducation.[6]

Treadmill training with support appears to have a somewhat greater effect in ambulatory individuals with respect to improved walking speed than other interventions.

PATIENT MONITORING

Stroke is often associated with sleep disturbances (e.g., obstructive sleep apnea). Thus activity and sleep patterns must be assessed to ensure sleep is maximally restorative and not contributing to the patient's symptoms.

Traditional management approaches to stroke incorporate little exercise testing and monitoring; however, given stroke results from dysfunction of the cerebral vessels secondary to the same common pathway as ischemic heart disease and intermittent claudication, comparable monitoring and precautions must be instituted during treatment.

In addition to the monitoring necessary for all patients, patients with stroke and cardiac dysfunction require clearance from a cardiologist before participating in a rehabilitation program and may require electrocardiogram (ECG) monitoring, particularly during exercise.

MEDICATION

Medication that is needed to maximize treatment response (e.g., antihypertensive and cardiac medications) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

PRIMARY INTERVENTIONS

Primary interventions for patients with stroke include the combination of global interventions previously discussed, and in addition they require the following:

- Body positioning instruction
- Breathing control and coughing maneuvers
- Spasticity control
- Gait reeducation

An ergonomic assessment of the patient's work and home, if applicable, may also help ensure the safety of the patient in those environments.

PATIENT EDUCATION

Patients with stroke will require the same instruction common to all patients with chronic secondary dysfunction.

Engagement of the social support network can have an important role in maximizing a patient's outcomes. Social support is recognized clinically as an important component of the comprehensive management of people with chronic conditions; however the literature in this area is scant. Family participation has been reported to improve the strength and mobility of an individual with stroke.[7]

EXERCISE

Aerobic exercise is an essential component of long-term management of the individual with stroke to optimize the efficiency of oxygen transport overall. Maximizing ventilation with mobilization is limited if the patient has severe generalized muscular weakness and increased fatigue. Although aggressive mobilization can be supported in these patients,[8] appropriate selection of patients for such a regimen, judicious exercise prescription, and monitoring must be instituted to ensure the treatment is optimally therapeutic and poses no risk to a patient in this high-risk group. Chest wall exercises include movement in all planes combined with rotation. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning. Exercise is conducted with the patient in upright positions to minimize the work of the heart and of breathing during physical exertion. Recumbent positions reduce lung volumes and expiratory flow rates, impair respiratory mechanics, increase closing volumes, increase thoracic blood volume, and increase compressive forces on both the lungs and the heart.[9] Thus, aerobic exercise for significant periods and intensities should be performed standing or sitting. Lower-extremity work is preferable to upper-extremity work in that the latter is associated with increased hemodynamic stress. Rhythmic exercise of large muscle groups is preferable to static exercise and exercise of small muscle groups, such as the arms, which produces smaller hemodynamic effects. Yoga-based exercise programs may be of some benefit for people with chronic stroke.[10] Resistance muscle training for the limbs increases their muscle power in a dose-dependent relationship without increasing spasticity.[11] Muscle training should be combined with aerobic training for optimal benefit and functional benefit.[12]

Ambulation or wheelchair locomotion should be as efficient as possible so that the metabolic demand of these functional activities is reduced. Performing these activities inefficiently on a frequent basis contributes to an excessive oxygen demand. The patient expends considerable energy in performing these activities uneconomically, which impairs the patient's tolerance and contributes to excessive fatigue. Conserving energy by performing these activities more economically from an energetic perspective will provide more energy to perform more of these or other activities.

PROPHYLACTIC MANAGEMENT

Patients with generalized neuromuscular weakness require prophylactic management because of their high risk of developing life-threatening respiratory infections and complications. Prophylaxis should include flu shots; avoidance of polluted, smoky environments; smoking reduction and cessation; control of the types of food eaten and chewing well to avoid choking; and regular deep breathing, frequent movement, and change in body positions (even just shifting and taking some deeper breaths while seated in a wheelchair) to promote mucociliary transport. An optimal time to take deep breaths and to cough is during transfers, which usually are physically exerting and stimulate hyperpnea.

Parkinson Syndrome

Pathophysiology and Medical Management

Parkinson syndrome is associated with reduced dopamine in the basal ganglia, resulting in the loss of normal reciprocal inhibitory and facilitatory neuronal input in the execution of smooth coordinated movement. The clinical manifestations of the disease include stooped posture; stiffness and slowed motion; a fixed, mask-like expression; and tremor of the limbs. Patients with Parkinson syndrome are hypertonic, rigid, and inflexible. Movement initiation is impaired, and once initiated, movement is not fluid. The patient walks with a quick, shuffling gait. These factors contribute to an increased energy cost of movement. Physical activity is restricted and function is compromised, contributing to impaired aerobic capacity, reduced movement efficiency, and hence reduced movement economy.

Although chest wall rigidity and respiratory muscle weakness are associated with a restrictive pattern of lung disease in the patient with Parkinson syndrome, the obstructive type of respiratory dysfunction has been reported (e.g., reduced midtidal flow rates, increase airway resistance, impaired distribution of ventilation, and an increase in functional residual

capacity).[13] This obstructive defect may reflect parasympathetic hyperactivity, which has been associated with the disease. The degree to which these cardiovascular and pulmonary manifestations of the disease are offset with anticholinergic drugs (used to treat rest tremor and reverse dystonia) has not been reported.

The upper extremities are rigid and held slightly abducted from the chest wall during locomotion. The rigidity and dyskinesia associated with Parkinson syndrome lead to restricted movement and body positioning. The patient becomes deconditioned from disuse. Although the rigid, immobile chest coupled with reduced body position changes can contribute to restrictive cardiovascular and pulmonary pathology in this syndrome, chemoreceptor dysfunction has been documented.[14]

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

The goals of long-term management for the patient with Parkinson syndrome include all of the elements common to all other conditions, but also include the following:

- Optimize secretion clearance as needed
- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration

PATIENT MONITORING

Patients with Parkinson syndrome require the same monitoring parameters common to all of the secondary conditions discussed in this chapter. Patients with additional cardiac dysfunction require ECG monitoring, particularly during exercise.

MEDICATION

Medication that is needed to maximize treatment response (e.g., L-dopa) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally efficacious. In addition, patients with Parkinson syndrome may be taking a beta blocker to suppress action tremor. Because such medication reduces the heart rate and blood pressure, these patients are prone to orthostatic intolerance. In addition, heart rate and blood pressure responses to treatment and exercises will be less valid.

PRIMARY INTERVENTIONS

Primary interventions for patients with Parkinson syndrome include the combination of global interventions previously discussed, and in addition they require the following:

- Body positioning instruction
- Breathing control and coughing maneuvers
- Gait reeducation
- Flexibility exercise to facilitate participation in regular physical activity and exercise

For optimal functional outcomes, prescriptive parameters focus on cross training rather than a single aerobic type of exercise, and frequent, longer, less intense physical activity rather than less frequent, short, intense exercise.

PATIENT EDUCATION

Patients with Parkinson syndrome will require the same instruction common to all patients with chronic secondary dysfunction and in addition will likely also need instruction on airway protection.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with Parkinson syndrome to optimize the efficiency of oxygen transport overall, including maximizing alveolar ventilation and mobilizing secretions, as well as for its musculoskeletal benefits. Maximizing ventilation with mobilization is limited by the degree of hypertonicity and rigidity. Chest wall exercises include all planes of movement with a rotational component. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning.

Multiple Sclerosis

Pathophysiology and Medical Management

Multiple sclerosis is a demyelinating disease of the central nervous system. The focal or patchy destruction of myelin sheaths is accompanied by an inflammatory response. The course of the disease consists of a variable number of exacerbations and remissions over the years from early adulthood. Exacerbations are also variable with respect to severity. The neurological deficits include visual disturbance; paresis of one or more limbs; spasticity; discoordination; ataxia; dysarthria; weak, ineffective cough; reduced perception of vibration and position sense; bowel and bladder dysfunction; and sexual dysfunction.[15] Breathing disturbances, including diaphragmatic paresis, may occur. Autonomic disturbance in the form of impaired cardiovascular reflex function at rest and attenuated heart rate and blood pressure responses during exercise are relatively common in patients with multiple sclerosis.[16]

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

In addition to all of the long-term management goals common to all other conditions, there are several more goals associated with this population:

- Protect the airways from aspiration
- Optimize secretion clearance as needed
- Reduce the work of breathing
- Reduce the work of the heart

Patients with multiple sclerosis may need prescriptive aids and devices to optimize function and activity.

PATIENT MONITORING

Patients with multiple sclerosis require the same monitoring parameters common to all of the secondary conditions discussed in this chapter. Patients with additional cardiac dysfunction require ECG monitoring, particularly during exercise.

Multiple sclerosis is associated with significant fatigue; thus activity and sleep patterns need to be assessed to ensure sleep is maximally restorative and not contributing to the patient's symptoms. Fatigue can be assessed subjectively using a modified version of the Borg scale or assessed objectively using a log of activity and rest. The log will help the patient identify the optimal time to rest.

MEDICATION

Medication that is needed to maximize treatment response (e.g., antispasticity medications) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective. In addition, knowledge of the cardiovascular and pulmonary side effects of other medications is needed.

PRIMARY INTERVENTIONS

Primary interventions for patients with multiple sclerosis include the combination of global interventions previously discussed, and in addition these patients require the following:

- Body positioning instruction
- Breathing control and coughing maneuvers
- Gait reeducation
- Fatigue management

Prescriptive parameters are comparable to those for individuals with increased muscle tone—that is, frequent, less intense exercise, rather than the less frequent, intense exercise that might be appropriate for someone without such a condition.

PATIENT EDUCATION

Patients with multiple sclerosis require the same instruction common to all patients with chronic secondary dysfunction and in addition they will likely need instruction on fatigue management, as multiple sclerosis is associated with significant fatigue.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with multiple sclerosis to optimize the efficiency of oxygen transport overall. In mild-to-moderate cases the goals of aerobic exercise are to optimize cardiovascular and pulmonary conditioning and enhance movement economy. Optimizing cadence of walking or cycling is important to minimize discoordination, energy expenditure, and fatigue and to maximize safety. In more severe cases the goal is to maximize ventilation and gas exchange in the patient who has severe generalized muscular weakness, spasm, and excessive fatigue. Subjective parameters (i.e., fatigue and exertion) provide the basis for the intensity of the exercise program in conjunction with objective measures. Parameters such as intensity and duration may vary from session to session depending on the patient's general status, which tends to be variable. Aquatic exercise may be an alternative for patients whose discoordination precludes ambulation and cycling or who are troubled by heat. The use of a fan may also enhance the patient's work output.

Chest wall exercises include all planes of movement with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are coupled with body movement and positioning. If mucociliary clearance is impaired, leading to secretion retention, postural drainage may need to be instituted coupled with deep breathing and coughing maneuvers.

VENTILATORY STRATEGIES

Methods of facilitating effective coughing in patients with neuromuscular diseases are extremely important because they constitute life-preserving measures. Supported and unsupported coughing methods are described in detail in Chapters 22 and 23. Whenever possible, deep breathing and coughing are coordinated with chest wall movement to facilitate maximal inflation of the lungs before coughing and maximal exhalation of the lungs during coughing. Body positions are varied and changed frequently to simulate as much as possible the shifts in alveolar volume and ventilation and perfusion that occur with normal movement and body position changes.[17] In addition, body positioning is used to maximize the patient's coughing efforts.

PROPHYLACTIC MANAGEMENT

Patients with generalized neuromuscular weakness require prophylactic management, given their high risk of developing life-threatening respiratory infections and complications. Prophylaxis should include flu shots; avoiding polluted, smoky environments; smoking reduction and cessation; controlling the types of food eaten and chewing well to avoid choking; and regular deep breathing, frequent movement, and change in body positions (even just shifting and taking some deeper breaths while seated in a wheelchair) to promote mucociliary transport. An optimal time to take deep breaths and to cough is during transfers, which usually are physically exerting and stimulate hyperpnea.

Patients with multiple sclerosis often have remissions and exacerbations of their symptoms. Physical therapy focuses on all phases, with more intense treatment during stable periods. In this way it is hoped that periods between remissions are increased and exacerbations are less severe and shorter.

Cerebral Palsy

Pathophysiology and Medical Management

Cerebral palsy results from insult to the central nervous system that usually occurs before birth (e.g., from substance abuse and perinatal underoxygenation).[15] The clinical presentation includes spasticity and residual deformity from severe muscle imbalance, hyperreflexia, and mental retardation. Although there are varying degrees of cerebral palsy severity, patients most frequently seen by the physical therapist have significant functional deficits and require long-term care. The loss of motor control and hypertonicity of peripheral muscles often restrict the mobility of patients such that they are wheelchair dependent. Loss of motor function limits physical activity and the exercise stimulus needed to maintain an aerobic stimulus and optimal aerobic capacity. Often coupled with motor deficits are cognitive deficits and mental retardation. These

afflictions limit the degree to which the patient can follow instructions, perform treatments, and participate actively in a long-term rehabilitation program. Patients with cerebral palsy who are able to ambulate do so at exceptional energy expenditure both with and without walking aids.[18] Central neurological deficits, generalized hypertonicity, and musculoskeletal deformity contribute to increased metabolic demand for oxygen and oxygen transport.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

In addition to all of the long-term management goals common to all other conditions, patients with cerebral palsy should have several additional goals:

- Reduce spasticity to minimize undue energy cost
- Optimize secretion clearance as needed
- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration

Maximizing aerobic capacity and efficiency of oxygen transport and optimizing general muscle strength pertain to the patient with cerebral palsy that is mild in severity. Many patients seen by physical therapists have poorly controlled spasticity and marked intellectual limitations, which preclude full participation in aerobic and strengthening exercise programs. These patients are at risk for the sequelae of restricted mobility and recumbency.

PATIENT MONITORING

Patients with cerebral palsy require the same monitoring parameters common to all of the secondary conditions discussed in this chapter. Physical therapists must keep in mind that unless the patient is only mildly affected, and not mentally incapacitated, patients with cerebral palsy are less able to provide subjective ratings of treatment response. The therapist must then rely particularly on clinical judgment in conjunction with the patient's objective responses to treatment.

MEDICATION

Medication that is needed to maximize treatment response (e.g., antispasticity medications) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

PRIMARY INTERVENTIONS

Primary interventions for patients with cerebral palsy include the combination of global interventions previously discussed; in addition, they require the following:

- Body positioning instruction
- Breathing control and coughing maneuvers
- Mobilization and coordinated activity (aerobic stimulation)
- Strengthening exercises

Note that strength is often difficult to assess and treat because of overwhelming spasticity in patients with cerebral palsy.

PATIENT EDUCATION

In the case of patients with cerebral palsy, education should be directed at the patient whenever possible, but it more likely will be directed at the parents and/or care providers. Patients with cerebral palsy will require the same instruction common to all patients with chronic secondary dysfunction, and in addition will likely also need instruction on mobilization and coordinated activity.

Education on the importance of sleep and rest will also be important for patients in this population; individuals with cerebral palsy can be expected to have abnormal sleep patterns. Sleep patterns are often disrupted for the following reasons:

- Central cerebral involvement may affect the periodicity of breathing. During sleep, the effects of such dysfunction are accentuated. Loss of normal periodic breathing and interspersed sighs impairs mucociliary transport. Secretions may accumulate and contribute to airway obstruction and areas of atelectasis.
- Individuals with cerebral palsy are unable to reposition themselves during the night in response to cardiovascular-pulmonary and musculoskeletal stimuli.
- Patients often have poor swallowing and saliva control and thus are prone to aspiration and microatelectasis, particularly when recumbent at night. Inability to reposition themselves at night further increases the risk of aspiration and its sequelae.

MOBILIZATION

Mobilization is an essential component of the long-term management of the patient with cerebral palsy in order to stimulate aerobic metabolism and optimize the efficiency of oxygen transport overall, including maximizing alveolar ventilation and mobilizing and removing secretions.[19] Maximizing ventilation with mobilization is limited if the patient has generalized spasticity. Furthermore, mobilization stimuli are selected specifically to minimize eliciting further muscle spasm. Prescriptive hydrotherapy and equinotherapy (horseback riding) can provide effective stimulation to the cardiovascular and pulmonary system in the individual with multiple handicaps and can minimize the effects of spasticity. With training, coordination of ambulatory patients can be improved and aerobic energy expenditure reduced. In addition, energy is conserved for performing more activity. Chest wall exercises include all planes of movement with rotation. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning. If mucociliary transport is impaired and this leads to secretion retention, postural drainage and manual techniques may need to be instituted with appropriate monitoring to ensure they do not have a detrimental effect.[20]

VENTILATORY STRATEGIES

In this patient population, clearing oral secretions and coughing maneuvers require special attention. Ventilatory strategies for facilitating effective coughing in patients with neuromuscular diseases are extremely important because they constitute life-preserving measures. Supported and unsupported

coughing methods are described in detail in Chapters 22 and 23. Whenever possible, deep breathing and coughing are coupled with chest wall movement to facilitate maximal inflation of the lungs before coughing and maximal exhalation of the lungs during coughing. Body positions are varied and changed frequently to simulate as much as possible shifts in alveolar volume and ventilation and perfusion that occur with normal movement and body position changes. Microaspirations are likely a common occurrence in this patient population, particularly at night. Nighttime positioning must be prescribed for a given patient to minimize aspiration.

PROPHYLACTIC MANAGEMENT

Individuals with generalized neuromuscular weakness require prophylactic management, given their high risk of developing life-threatening respiratory infections and complications. Prophylaxis should include flu shots; avoidance of polluted, smoky environments; control of the types of food eaten and chewing well to avoid choking; and stimulation of deep breathing, airway clearance, and frequent movement and change in body positions (even just shifting and eliciting deeper breaths while seated in a wheelchair) to promote mucociliary transport. Wheelchair design and seating are also important areas of concern in which the physical therapist is actively involved.

Spinal Cord Injury

Pathophysiology and Medical Management

The cardiovascular and pulmonary manifestations and complications of spinal cord injury are directly related to the level of the lesion.[21] Cardiovascular and pulmonary impairment results from the loss of supraspinal control of the respiratory muscles and the heart below the spinal cord lesion. Loss of diaphragmatic innervation results in ventilator dependency. Loss of abdominal and intercostal innervation reduces the ability to cough, mucociliary transport, and the ability to clear the airways. Denervation of the heart and orthostatism are less problematic in that the heart's autonomous function and increased responsiveness of the heart and blood vessels to circulating catecholamines adequately compensate. The cough mechanism of people with quadriplegia is ineffective in clearing the airways.[22]

Patients with quadriplegia are particularly prone to the effects of restricted mobility, given the extent of their functional motor loss and sensory deficits, particularly on cardiovascular and pulmonary function. Mobilization and physical activity are essential for the patient with a spinal cord injury to maintain optimal cardiovascular and pulmonary function and oxygen transport efficiency and the optimal strength and endurance of the respiratory muscles. Patients with partial cord lesions will have a greater probability of ambulation with or without aids. Walking with aids is enormously costly in terms of energy cost,[23] however, and may not be practical in daily life.

Because of the complexity and multisystem involvement of spinal cord lesions, the team works closely together. Even though the nurse may be primarily responsible for teaching and monitoring bowel and bladder routines, the physical therapist keeps informed of these because genitourinary and gastrointestinal problems can jeopardize physical therapy goals.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

In addition to all of the long-term management goals common to all other neuromuscular conditions, patients with spinal cord injury have the following additional goals:

- Ensure that walking aids or wheelchairs used by the patient are optimal for the patient's needs for minimized energy cost, for optimal posture, and for safety.
- Optimize secretion clearance as needed
- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration

PATIENT MONITORING

Patients with spinal cord injury require the same monitoring parameters common to all of the secondary conditions discussed in this chapter.

Patients with high spinal cord injuries are somewhat more hemodynamically unstable and have more ECG irregularities than age-matched control individuals; thus their cardiovascular and pulmonary status should be monitored during treatment.

MEDICATION

Medication that is needed to maximize treatment response (e.g., antispasticity agents) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally efficacious.

PRIMARY INTERVENTIONS

Patients with spinal cord injury require a combination of the global primary interventions common to the secondary conditions discussed in this chapter. In addition, these patients will also need body positioning instruction and breathing control and coughing maneuvers.

PATIENT EDUCATION

Patients with spinal cord injury will require the same instruction common to all patients with chronic secondary dysfunction.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with spinal cord injury in order to optimize the efficiency of oxygen transport overall, including maximizing alveolar ventilation and mobilizing and removing secretions. With higher lesions, exercise is usually confined to upper-extremity work in the form of wheelchair ambulation. Preservation of upper-extremity muscle function and minimization of overuse are primary goals from the outset. Patients can maintain adequate cardiovascular and pulmonary conditioning with wheelchair exercise; however,

exercise prescription should be conservative to maximize the benefit-to-risk ratio of cardiovascular and pulmonary conditioning that relies on upper-extremity work. Patients who are able to walk with leg braces and crutches expend considerable energy doing so. A decision must be made regarding the benefits of walking at high energy demand versus conserving energy for other activities. Chest wall exercises can be used and should include all planes of movement with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning. Coordination of respiration with aerobic activity and wheeling is taught to maximize work output.

VENTILATORY STRATEGIES

Ventilatory muscle training has a role in the long-term rehabilitation of some patients with high spinal cord lesions. Such muscle training has long been known to increase the strength and endurance of the respiratory muscles[24] and may improve the functional capacity of some patients. A stronger, endurance-trained diaphragm will not fatigue as readily as an untrained diaphragm. Standardizing the resistance of the training stimulus alone, however, is not sufficient to produce a training effect. It is essential that flow rate be controlled using a gauge.

Methods of facilitating effective coughing in patients with neuromuscular diseases are extremely important because they constitute life-preserving measures. Supported and unsupported coughing methods are described in detail in Chapters 22 and 23. Whenever possible, deep breathing and coughing are coupled with chest wall movement to facilitate maximal inflation of the lungs before coughing and maximal exhalation of the lungs during coughing. Body positions are varied and changed frequently to simulate as much as possible shifts in alveolar volume and ventilation and perfusion that occur with normal movement and body position changes.

A comprehensive program includes stretching of the chest wall and passive range-of-motion exercises of the shoulder girdle. Maximal insufflations are encouraged in optimal body positions. Glossopharyngeal breathing can enable high quadriplegic patients to be freed from mechanical ventilation for hours at a time. Assisted or unassisted coughing is coordinated with deep breathing and rhythmic rocking motion. Manual assisted coughing and mechanical coughing aids, including functional electrical stimulation and insufflation-exsufflation devices, can be useful.[25] The pneumobelt is a device that can facilitate ventilation without a tracheostomy. This device counters loss of abdominal tone and helps preserve normal thoracoabdominal interaction during respiration, which is lost because of reduced rib cage compliance and increased abdominal compliance.

PROPHYLACTIC MANAGEMENT

Patients with spinal cord injuries, particularly those with high lesions, require prophylactic management, given their risk of developing life-threatening respiratory infections and complications. Prophylaxis should include flu shots; avoiding polluted, smoky environments; smoking reduction and cessation; controlling the types of food eaten and chewing well to avoid choking; and regular deep breathing, airway clearance, and frequent movement and change in body positions (even just shifting and taking some deeper breaths while seated in a wheelchair are beneficial). An optimal time to take deep breaths and cough is during transfers, which usually are physically exerting and stimulate hyperpnea.

Chronic Effects of Poliomyelitis

Pathophysiology and Medical Management

The chronic effects of poliomyelitis affect a high proportion of survivors of poliomyelitis who contracted the disease during the epidemic of the 1950s. Three types of poliomyelitis were prevalent during the epidemic in the middle of the 20th century, namely, spinal (the majority of cases), bulbar, and encephalitic. Half of survivors report new symptoms consistent with postpolio syndrome (PPS) (see Chapter 6). New delayed symptoms include disproportionate fatigue, increased weakness, deformity, pain, reduced endurance, breathing and swallowing problems, and respiratory insufficiency. Although cardiovascular and pulmonary complications were not associated with the spinal form of poliomyelitis at onset, late-onset breathing and swallowing complications can appear as a late effect of the disease.[26] In addition, these patients may be deconditioned and have poor movement economy (i.e., expend excessive energy because of postural deformities).[1] Therefore, delayed-onset cardiovascular and pulmonary complications, coupled with the effects of overuse and general deconditioning, increase the risk of cardiovascular and pulmonary compromise, reduce the ability to recover from these, and increase surgical and anesthetic risk.

Because of the nonspecific symptoms associated with PPS, it is a diagnosis of exclusion based on a detailed history.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

In addition to all of the long-term management goals common to other neuromuscular conditions, there are additional goals for patients with chronic effects of poliomyelitis:

- Ensure that the aids and devices used by the patient provide an optimal level of support for a specific muscle or extremity, or whole body as necessary
- Optimize movement economy
- Optimize secretion clearance as needed
- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration

Although there are commonalities between the management of individuals with a history of poliomyelitis with and without PPS, injudicious management of the individual with PPS can lead to further deterioration. Special attention is therefore given to balancing rest with physical activity and developing modified exercise programs if they are indicated. Such programs are not indicated if an individual is exploiting maximal physiologic reserve capacity to meet the needs of each day. This individual has little reserve capacity and thus can lose functional capacity by increasing metabolic demands. With appropriate self-management and adherence to judicious recommendations, the prognosis for an individual with PPS can be favorable.

PATIENT MONITORING

Patients with chronic effects of poliomyelitis require the same monitoring parameters common to all of the secondary conditions discussed in this chapter, though additional monitoring of pain and fatigue is necessary as well.

Activity and sleep patterns must be monitored to ensure sleep is maximally restorative and not contributing to the patient's symptoms. Functional work capacity and activity tolerance may be increased by balancing activity with rest and maintaining fatigue below the patient's critical fatigue threshold (i.e., threshold requiring prolonged recovery time).

Subjective assessments of fatigue, breathlessness, and pain can all be made using analog scales, including modified versions of the Borg scale.

MEDICATION

Medication that is needed to maximize treatment response (e.g., analgesia) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

PRIMARY INTERVENTIONS

Primary interventions for patients with PPS include the combination of global interventions previously discussed, and in addition these patients require the following:

- Body positioning instruction
- Breathing control and coughing maneuvers

Aids and devices should be reviewed to optimize energy expenditure (e.g., electric wheelchair or scooter versus manual wheelchair) and to reduce cardiovascular and pulmonary distress (e.g., home mechanical ventilation).

PATIENT EDUCATION

Patients with PPS will require the same instruction common to all patients with chronic secondary dysfunction; they will also need information on the importance of rest and monitoring sleep. Patients require varying schedules of activity to rest over the course of a day.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with the late sequelae of poliomyelitis to optimize the efficiency of oxygen transport overall. The two principal goals of exercise are to optimize cardiovascular and pulmonary conditioning and movement economy. Maximizing ventilation with exercise is limited if the patient has severe generalized muscular weakness and increased fatigue. Disproportionate fatigue and other symptoms experienced by patients with the late sequelae of poliomyelitis have been attributed to overwork of affected and unaffected muscles, terminal axon degeneration, and impaired impulse transmission. Exercise is therefore prescribed judiciously to provide an optimal aerobic training effect without contributing to further other use abuse (i.e., prescriptive parameters based on subjective responses using semiquantitative scales in conjunction with objective responses). Walking is the most functional type of aerobic exercise; however, aquatic exercise provides a useful medium for individuals with lower-extremity paresis who require crutches to walk or are confined to a wheelchair. Reducing physical activity and exercise is indicated in some patients to optimize aerobic and muscle power. The effect of resting affected and unaffected muscles enhances functional capacity.

Individuals with PPS are likely to experience greater functional decline over time compared with survivors of poliomyelitis without the syndrome. The need for aids, devices, manual wheelchairs, and electric wheelchairs and scooters should be anticipated for some people. These, however, can be introduced with their intermittent use to provide rest to overused muscles and joints, minimize local and general fatigue, and preserve remaining muscle function to the greatest degree. Excessive use as well as underuse of such aids can contribute to rapid deterioration and decline. Thus the rehabilitation program includes recommendations about the appropriate use of aids and devices to optimize function, and these recommendations require periodic review.

VENTILATORY STRATEGIES

Ventilatory strategies for facilitating effective coughing in patients with neuromuscular diseases are extremely important because they constitute a life-preserving measure. Supported and unsupported coughing methods are described in detail in Chapters 22 and 23. Whenever possible, deep breathing and coughing are coupled with chest wall movement to facilitate maximal inflation of the lungs before coughing and maximal exhalation of the lungs during coughing. Body positions are varied and changed frequently to simulate as much as possible shifts in alveolar volume and ventilation and perfusion that occur with normal movement and body position changes.

Progressive loss of pulmonary function in patients with ventilatory compromise at onset can lead to respiratory insufficiency. Comparable with other neuromuscular conditions, invasive mechanical ventilation is avoided. Alternatives include nasal and oral methods of noninvasive assisted mechanical ventilation. In addition, airway clearance can be further assisted with manual assisted coughing, glossopharyngeal breathing, mechanical exsufflation, and mechanical insufflation-exsufflation.[27]

Survivors of poliomyelitis with ventilatory compromise are comparable with other patients with generalized muscle weakness. Of particular concern in this population is the necessity to establish the role of mobilization and exercise as a first line of defense in the management and prevention of cardiovascular and pulmonary dysfunction. For patients with PPS and overuse abuse, however, additional exercise may be detrimental, though modified mobilization and exercise may be prescribed on an interval schedule (see Chapters 19 and 25).[28] The patient exercises for a period of time and then rests or reduces to a lower intensity of exercise to allow the muscles to rest. In addition to the multitude of benefits of mobilization and exercise on oxygen transport overall, these interventions also optimize respiratory muscle strength and endurance. If the patient does not recover within a few hours, the mobilization or exercise stimuli are excessive and should be modified. Chest wall mobility exercises to facilitate breathing and coughing may have a role.

PROPHYLACTIC MANAGEMENT

Patients with generalized neuromuscular weakness require respiratory prophylactic management, given their high risk of developing life-threatening respiratory infections and complications. Prophylaxis should include flu shots; avoiding polluted, smoky environments; controlling the types of food eaten and chewing well to avoid choking; and regular deep breathing, airway clearance, and frequent movement and change in body positions (even just shifting and taking some deeper breaths while seated in a wheelchair are beneficial). An optimal time to take deep breaths and cough is during transfers, which usually are physically exerting and stimulate hyperpnea.

Muscular Dystrophy

Pathophysiology and Medical Management

Individuals with muscular dystrophy and other types of degenerative neurological and muscular diseases have increased life expectancy and thus can expect prolonged morbidity. Prevention of complications as an individual becomes weaker and more limited in terms of participation in life is a priority. In addition to peripheral weakness, these conditions can lead to respiratory muscle weakness and alveolar hypoventilation. Vital capacity, forced expiratory volume, airflow rates, and maximum inspiratory and expiratory pressures are reduced. These patients are at risk for the development of atelectasis, impaired mucociliary transport, and pneumonia. In addition, long-term generalized muscular weakness, particularly of the thoracic cavity and abdomen, as well as restricted mobility and confinement to a wheelchair predispose the patient to thoracic deformities (e.g., scoliosis and dropping of the ribs and further muscle disuse). Patients with Duchenne muscular dystrophy are susceptible to dysphagia and upper airway obstruction secondary to gag reflex depression and hypotonia of the pharyngeal structures.[21] These factors further compromise or threaten cardiovascular and pulmonary function and oxygen transport.

Cardiac dysfunction has also long been reported in progressive muscular dystrophy.[29] Although the majority of patients have no clinical evidence of cardiac dysfunction, a high proportion have abnormal ECGs at rest or during exercise and abnormal echocardiograms and radionuclide ventriculograms showing reduced left ventricular ejection fraction and abnormal ventricular wall motion. Fatty and fibrous tissue infiltrate the myocardium and conduction system, and electrical conduction is slowed. Thus subclinical cardiac involvement is prevalent in patients with muscular dystrophy and may explain sudden death in this patient population.

Chronic respiratory muscle weakness is characteristic of muscular dystrophy and other neuromuscular disorders. Because the cardiovascular and pulmonary systems are seldom stressed owing to musculoskeletal dysfunction in these patients, respiratory muscle weakness is seldom detected. Such weakness is significant, however, in that it contributes to several other serious problems, including thoracic mechanical abnormalities, diffuse microatelectasis, reduced lung compliance, a weak cough with impaired mucociliary transport and secretion accumulation, ventilation and perfusion imbalance, and nocturnal hypoxemia. Progressive respiratory muscle weakness has long been known to increase the risk of respiratory muscle fatigue and failure.[30,31]

The severity of disease is not consistently correlated with compromised pulmonary function; thus cardiovascular and pulmonary function must be assessed individually in each patient. Patients with mild-to-moderate involvement of peripheral muscles may exhibit disproportionate respiratory compromise. This may be explained by differential changes in the degree of involvement of the diaphragm and the abdominal and intercostal muscles. Over time, musculoskeletal changes of the chest wall lead to spinal deformity and stiffness with loss of its elastic recoil. Chronic alveolar hypoventilation leads to respiratory insufficiency and the need for ventilatory assistance. With progressive respiratory insufficiency, nocturnal hypoventilation with hypercapnia and hypoxemia develop. Nocturnal respiratory support should be considered early to postpone the need for intubation and mechanical ventilation, which is associated with a poor prognostic outcome in patients who have chronically reduced vital capacities and weak cough.

Clinically, patients with muscular dystrophy demonstrate low functional capacity commensurate with the extent of muscle weakness and impaired cardiovascular and pulmonary function, including alveolar hypoventilation, orthopnea (shortness of breath on reclining), impaired mucociliary transport, difficulty clearing secretions, and increased work of breathing. Abdominal muscle strength provides an index of pulmonary function in that it is correlated with vital capacity and expiratory flow rates. The significant progressive functional loss associated with Duchenne muscular dystrophy increases the patient's susceptibility to the sequelae of restricted mobility, including cardiovascular and pulmonary deconditioning and reduced efficiency of oxygen transport, circulatory stasis, muscular weakness, and bone loss.

Improved medical management of the complications of myopathies has significantly increased the life expectancy of patients such as those with Duchenne muscular dystrophy over the past 20 years. With advancing age, further complications will arise from age-related changes in cardiovascular and pulmonary function.[32,33] Thus in the years ahead an increasing number of patients with myopathies will be requiring cardiovascular and pulmonary management and prophylaxis.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

The goals of long-term management for the patient with muscular dystrophy are to reduce the impact of progressive debility and prolonged morbidity throughout their longer life spans. Respiratory complications may advance from mild respiratory distress to the need for nocturnal noninvasive mechanical ventilation. Respiratory failure is the primary cause of death.

In addition to all of the long-term management goals common to other neuromuscular conditions, the following are additional goals for patients with muscular dystrophy:

- Optimize capacity with judiciously prescribed and appropriately introduced aids and devices consistent with the patient's changing needs (e.g., walking aids, wheelchair, and dressing and activities of daily living aids)

- Optimize aerobic capacity with a balance of judicious exercise, energy conservation, and rest
- Optimize secretion clearance as needed
- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration

PATIENT MONITORING

Patients with muscular dystrophy require the same monitoring parameters common to all of the secondary conditions discussed in this chapter; however, those with additional cardiac dysfunction need to be cleared by a cardiologist before starting a rehabilitation program, particularly when it involves a mobilization or exercise program, to refine the prescriptive parameters of the program.

If supplemental oxygen is used, the fraction of inspired oxygen (Fi_{O_2}) administered is recorded.

Assessment of nighttime and daytime cardiovascular and pulmonary function is needed because respiratory insufficiency often begins with nocturnal hypoxemia in patients with Duchenne muscular dystrophy.

Activity and sleep patterns must be assessed to ensure sleep is maximally restorative and not contributing to the patient's symptoms; obstructive sleep apnea is related to hypotonia of the upper airway musculature and obesity.

MEDICATION

Medication that is needed to maximize treatment response is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

PRIMARY INTERVENTIONS

Primary interventions for patients with muscular dystrophy include the combination of global interventions previously discussed; in addition, they require the following:

- Body positioning instruction
- Breathing control and coughing maneuvers
- Mobilization, primarily in the form of functional activities
- Strengthening exercises, primarily in the form of functional activities (to maintain strength or reduce rate of decline)
- Ventilatory muscle training
- Deformity prevention

An assessment of the patient's living and working environments should include a review of aids and devices (e.g., wheelchair type, weight, and size and noninvasive mechanical ventilation). Aids and devices are selected to minimize energy demand such that energy is conserved for other activities and undue fatigue is reduced.

The use of supplemental oxygen depends on the severity of the disease. Some patients have no need for supplemental oxygen, some need it only during exercise, and some patients require continuous oxygen with proportionately more delivered during activity and exercise compared with rest.

PATIENT EDUCATION

Patients with muscular dystrophy will require the same instruction common to all patients with chronic secondary dysfunction and would additionally benefit from information on weight control.

Weight control is an important goal in patients with chronic neuromuscular diseases because they have the least capacity to compensate for the cardiovascular and pulmonary sequelae of obesity. Obesity is also related to obstructive sleep apnea.

MOBILIZATION

Mobilization is an essential component of long-term management of the patient with muscular dystrophy. It is prescribed to optimize the efficiency of oxygen transport overall and minimize the sequelae of restricted mobility. Maximizing ventilation with mobilization is limited if the patient has severe generalized muscular weakness and increased fatigue. Functional activities provide the basis for the mobilization prescription. Although heavy resistive strengthening exercise has been advocated for these patients,[34,35] a conservative approach including an exercise program based on functional goals and energy conservation is more justifiable physiologically.[36] Chest wall mobility exercises include all planes of movement combined with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are coupled with body movement and positioning. If mucociliary transport is impaired and leads to secretion accumulation, which is refractory to mobilization and body positioning, it may be necessary to institute postural drainage coupled with deep breathing and coughing maneuvers.

VENTILATORY STRATEGIES

Although the primary factor contributing to respiratory compromise is respiratory muscle weakness, ventilatory muscle training may have a role in selected patients (Chapter 26). Improved respiratory muscle endurance and strength may have a generalized effect on functional capacity. The effect of walking alone, however, may be superior to the effect of ventilatory muscle training on ventilatory muscle strength and endurance. Ventilatory muscle training should therefore be used selectively to elicit effects over and above those resulting from functional activities such as walking, given the multisystem and functional benefits of walking.

Patients with signs of ventilatory muscle fatigue, as opposed to weakness, benefit from ventilatory support at night. Rest of the respiratory muscles at night with continuous positive airway pressure or bi-level positive airway pressure optimizes their function during the daytime.

EXERCISE

Methods of facilitating effective coughing in individuals with neuromuscular diseases are extremely important because they constitute life-preserving measures. Supported and unsupported coughing methods are described in detail in Chapters 22 and 23. Patients on noninvasive ventilatory support who

are unable to generate adequate peak cough expiratory flow rates can benefit from manual assisted coughing and mechanical insufflation-exsufflation, thereby minimizing the need for endotracheal suctioning.[37] Tracheostomy is delayed as long as possible. Significantly reduced maximal insufflation capacity, however, is an indication for tracheostomy.

Whenever possible, deep breathing and coughing are coupled with chest wall movement. This facilitates maximal inflation of the lungs before coughing by increasing pulmonary compliance[38] and maximal exhalation of the lungs during coughing. Body positions are varied and changed frequently to simulate shifts in alveolar volume and ventilation and perfusion that occur with normal movement and body position changes. Glossopharyngeal breathing is a nonmechanical method of assisting ventilation. The patient is taught to use the tongue and pharyngeal muscles to swallow boluses of air past the vocal cords and into the trachea. The efficiency of training is monitored with spirometry to ensure the patient is able to achieve acceptable vital capacities. Some patients are able to support their ventilation, ventilator-free, for several hours in a day.

One intervention that is prolonging the life of patients with muscular dystrophy, as well as of patients with other progressive neuromuscular diseases, is the use of mechanical ventilatory support.[39] Home mechanical ventilation provides a noninvasive method of providing positive airway pressure through an oral or nasal mask. This provides considerable advantage over invasive, full body or tracheostomy ventilatory support. If used in conjunction with an insufflation-exsufflation device, pulmonary complications can be minimized and life expectancy increased. Other forms of noninvasive mechanical ventilation include intermittent abdominal pressure ventilation, rocking bed, negative pressure tank ventilator, and chest shell ventilator. The type of ventilation is determined individually based on the indications for ventilation and the patient's status. The use of ventilatory aids as a component of a comprehensive rehabilitation program maintains pulmonary compliance and cough efficacy. Introduction of these devices early will facilitate increased use as the respiratory muscles progressively weaken. These aids are introduced to meet the individual's needs and are changed over time. Excessive use or dependence can contribute to deterioration.

PROPHYLACTIC MANAGEMENT

Patients with generalized neuromuscular weakness require prophylactic management because of their high risk of developing life-threatening respiratory infections and complications. Prophylaxis should include flu shots; avoidance of polluted, smoky environments; smoking reduction and cessation; controlling the types of food eaten and chewing well to avoid choking; and regular deep breathing, frequent movement, and change in body positions (even just shifting and taking some deep breaths while seated in a wheelchair) to promote mucociliary transport. An optimal time to take deep breaths and to cough is during transfers, which usually are physically exerting and stimulate hyperpnea. Wheelchair design is important for comfort, biomechanical and metabolic efficiency, and reduction of unnecessary energy expenditure.

Individuals with Musculoskeletal Conditions

Thoracic Deformities

Pathophysiology and Medical Management

Respiratory insufficiency can result from abnormalities of the chest wall secondary to congenital deformity, acquired neuromuscular disease, and trauma.[21] Congenital deformity of the chest wall reduces the mobility of the bony thorax, thereby increasing the work of breathing. Shallow, rapid breathing often results. Minute ventilation is increased at the expense of alveolar ventilation. Severe deformity leads to compression of the mediastinal structures. The heart can be displaced and rotated, impeding its mechanical function. Examples of chronic deformities that impinge on pulmonary function are kyphoscoliosis secondary to poliomyelitis, tuberculous osteomyelitis, and other causes and ankylosing spondylitis. Other examples of deformity include traumatic injury of the vertebral column, ribs, and sternum. Routine cardiovascular and pulmonary assessment should include a musculoskeletal examination of the spinal column and thoracic cavity.

Normal pulmonary function and gas exchange depend on symmetry of cardiovascular and pulmonary anatomy and physiological function. Asymmetry of the chest wall interferes with normal lung mechanics, regional gradients of ventilation and perfusion in the lungs, and the distribution of inspired gas. Significant decrease in lung compliance and increase in work performed against the elastic resistance of the lung are characteristic of kyphoscoliosis. Altered pressure gradients and uneven lung movement during the respiratory cycle may contribute to altered lung water balance and impaired lymphatic drainage. The effects of physiological dead space and shunt may be magnified, producing hypoxemia and hypercapnia. With severe chest deformity, a cycle of respiratory acidosis, pulmonary hypertension, and right-sided heart failure can result in a life-threatening situation.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

In addition to all of the long-term management goals common to all other musculoskeletal conditions, there are five additional goals for patients with thoracic deformity:

- Optimize secretion clearance
- Optimize movement economy
- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration

Treatment is directed at the underlying problem contributing to threatened or impaired oxygen transport. In addition, the underlying problems that limit the individual's activities and participation are addressed primarily, with the exception of life-threatening impairments.

PATIENT MONITORING

Patients with thoracic deformities require the same monitoring parameters common to all of the secondary conditions discussed in this chapter. Patients with additional cardiac

dysfunction require ECG monitoring, particularly during exercise.

PRIMARY INTERVENTIONS

Primary interventions for patients with thoracic deformity include the combination of global interventions previously discussed, and in addition they require the following:

- Body positioning instruction
- Breathing control and coughing maneuvers
- Gait reeducation
- Postural correction exercises

PATIENT EDUCATION

Patients with thoracic deformity will require the same instruction common to all patients with chronic secondary dysfunction.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with thoracic deformity in order to optimize the efficiency of oxygen transport overall. Abnormal postural alignment may contribute to excessive energy cost and reduced movement economy. Improving alignment will help offset this effect. In severe cases, surgical correction is indicated.

Maximizing ventilation with exercise in patients with severe deformity may be limited. Optimizing alignment to minimize the cardiovascular and pulmonary limitations of the deformity during physical activity, exercise, and rest is a priority. Chest wall exercises include all planes of movement with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning. If mucociliary transport is impaired leading to secretion retention, postural drainage may need to be instituted, coupled with deep breathing and coughing maneuvers.

Ventilatory muscle training may have a role in the management of patients with reduced inspiratory pressures and associated decreases in total lung capacity and hypoxemia.

Methods of facilitating effective coughing in patients with musculoskeletal deformity are extremely important because they constitute life-preserving measures. Supported and unsupported coughing methods are described in detail in Chapters 22 and 23. Whenever possible, deep breathing and coughing are coupled with chest wall movement to facilitate maximal inflation of the lungs before and maximal exhalation during coughing. Body positions are varied and changed frequently to simulate as much as possible shifts in alveolar volume and ventilation and perfusion that occur with normal movement and body position changes.

PROPHYLACTIC MANAGEMENT

Patients with chest wall deformities secondary to neuromuscular conditions require prophylactic management because of their high risk of developing life-threatening respiratory infections and complications. Prophylaxis should include flu shots; avoidance of polluted, smoky environments; smoking reduction and cessation; control of the types of food eaten and chewing well to avoid choking; and regular deep breathing, airway clearance, and frequent movement and change in body positions (even just shifting and taking some deep breaths while seated in a wheelchair are beneficial). An optimal time to take deep breaths and cough is during transfers, which usually are physically exerting and stimulate hyperpnea.

Osteoporosis

Pathophysiology and Medical Management

Osteoporosis is a condition associated with reduced bone mass per unit volume and appears to be on the increase (see Chapter 1). Age-related bone loss begins earlier and accelerates faster in women, particularly after menopause, than in men. Lifestyle factors, such as diet, exercise, and smoking, have a significant role in reducing bone mass. Caffeine has also been implicated as a contributing factor to bone loss secondary to increasing urinary calcium loss.

Osteoporosis is classified as idiopathic osteoporosis unassociated with other conditions, osteoporosis associated with other conditions (e.g., malabsorption, calcium deficiency, immobilization, or metabolic bone disease), osteoporosis as a feature of an inherited condition (e.g., osteogenesis imperfecta and Marfan syndrome), osteoporosis associated with paralytic conditions prohibiting weight bearing and activity, and osteoporosis associated with other conditions but with a pathogenesis that is not understood (e.g., RA, alcoholism, diabetes mellitus, or chronic airflow limitation).[15]

The most common clinical features are vertebral pain and spinal deformity resulting from vertebral compression and collapse. Vertebral bodies tend to collapse anteriorly, contributing to cervical lordosis, thoracic kyphosis, postural slumping, and loss of height. Acute episodes may be relieved by restricted mobility. Straining and sudden changes in position can exacerbate an acute episode. Cardiovascular and pulmonary complications of osteoporosis are secondary to spinal deformity, chest wall rigidity, and cardiovascular and pulmonary deconditioning resulting from restricted mobility. Vertebral compression fractures are also a feature of advanced osteoporosis. Collapse of the anterior surfaces of the vertebrae leads to kyphosis.

Osteoporosis is a condition associated with aging and older age groups. The pain of acute episodes leads to periods of restricted mobility and significant cardiovascular and pulmonary dysfunction in older persons.[32,40] Exercise that is weight bearing and loads the muscles around bone maintains bone density and decelerates bone loss and thus has a central role in preserving bone health. Generally, the growth and remodeling of bone depends highly on the exercise prescription parameters (e.g., type of exercise, intensity, duration, and frequency). Bone mineral content is more closely related to cardiovascular and pulmonary conditioning than physical activity level. Furthermore, any detrimental effect of exercise on osteoporosis appears to relate more to malalignment and injury rather than activity itself.

The primary physiological mechanism underlying osteopenia and osteoporosis is negative calcium balance. Loss of calcium is associated with lack of exercise, smoking, alcohol consumption, consumption of caffeine, and meat consumption. Calcium supplementation is only part of the remedy, as calcium loss may be the greater concern.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

The etiology of osteoporosis is diverse; thus management must consider the underlying pathophysiology and that several factors may be contributing to the presentation of osteoporosis in the same patient.

In addition to all of the long-term management goals common to all other musculoskeletal conditions, patients with osteoporosis should have as an additional goal the reduction of the risk of falls and instruction on fall prevention strategies.

PATIENT MONITORING

Patients with osteoporosis require most of the monitoring parameters common to other secondary cardiovascular and pulmonary conditions discussed in this chapter; monitoring for dyspnea, respiratory distress, inappropriate breathing pattern or arterial desaturation, and cyanosis may be less indicated.

These patients also require serial bone density assessments conducted over time. It is essential to obtain a bone density assessment early for reference over time.

MEDICATION

Medication that is needed to maximize treatment response (e.g., analgesics) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

PRIMARY INTERVENTIONS

Patients with osteoporosis require the same global interventions common to all of the secondary conditions discussed in this chapter.

PATIENT EDUCATION

Patients with osteoporosis will require the same instruction common to other patients with chronic secondary cardiovascular and pulmonary dysfunction.

EXERCISE

Aerobic and strength training are essential components of the long-term management of the individual with osteoporosis to optimize the efficiency of oxygen transport overall. Upright, weight-bearing aerobic exercise is essential to maintain bone density or reduce the rate of bone loss. Maximizing ventilation with exercise is limited if the patient has severe generalized muscular weakness and increased fatigue. Balance problems have also been identified in patients with osteoporosis, and these need to be addressed to minimize the risk of falling and its severe complications.

Chest wall exercises may have a role and include all planes of movement with a rotational component. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning. Straining, Valsalva maneuvers, and jarring activity and exercise are contraindicated.

Methods of facilitating effective coughing in patients with osteoporosis are extremely important because they constitute life-preserving measures. Some patients fracture ribs and vertebrae during coughing. Patients at risk should rely on huffing maneuvers that do not require closing the glottis and do not generate high intrathoracic pressures.

Individuals with Collagen Vascular, Connective Tissue, and Rheumatoid Conditions

Systemic Lupus Erythematosus

Pathophysiology and Medical Management

SLE is a condition characterized by the presence of multiple antibodies that contribute to immunologically mediated tissue inflammation and damage.[41] The condition affects the major organ systems, including the central nervous, musculoskeletal, pulmonary, vascular, and renal systems. Symptoms include arthralgic and myalgic stiffness, pain, and fatigue.

The cardiovascular and pulmonary manifestations of SLE include atelectasis, which results from inflammation of the alveolar walls and perivascular and peribronchial connective tissue, effusions secondary to lung infarction, reduced surface tension, and splinting secondary to pleuritic pain. Other manifestations include pleuritis with or without effusion, pneumonitis, interstitial fibrosis, pulmonary hypertension, diaphragmatic dysfunction, pulmonary hemorrhage, systemic hypertension, myocarditis, constrictive pericarditis, dysrhythmias, tamponade, pericardial pain, arteritis, and defects of the mitral and aortic valves.[42] Other manifestations that affect cardiovascular and pulmonary function include anemia, leukopenia, thrombocytopenia, thrombosis, splenomegaly, ascites, gastrointestinal bleeding, nephritis, and renal insufficiency.[15]

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

In addition to all of the long-term management goals common to all other collagen vascular and connective tissue diseases, there are four additional goals for patients with SLE:

- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration
- Optimize secretion clearance

PATIENT MONITORING

Patients with SLE require all of the monitoring parameters common to all of the secondary conditions discussed in this chapter. Patients with additional cardiac dysfunction should be cleared by a cardiologist before being prescribed an exercise program.

Subjectively, discomfort, pain, and fatigue can be assessed using analog scales.

MEDICATION

Medication that is needed to maximize treatment response (e.g., analgesic and antiinflammatory agents) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

PRIMARY INTERVENTIONS

Primary interventions for patients with SLE include the combination of global interventions previously discussed, and in addition these patients require instruction in body positioning and breathing control and coughing maneuvers.

PATIENT EDUCATION

Patients with SLE will require the same instruction common to all patients with chronic secondary dysfunction.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with SLE in order to optimize the efficiency of oxygen transport overall, including maximizing alveolar ventilation and mobilizing and removing secretions. Parameters of the exercise prescription are based on subjective responses (e.g., discomfort, pain, breathlessness, and perceived exertion in conjunction with objective responses). Optimal types of aerobic exercise include walking and cycling. Aquatic exercise may be preferable for patients with musculoskeletal involvement that precludes walking and cycling. Chest wall exercises can be used and should include all planes of movement with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning. If mucociliary transport is impaired, leading to secretion retention, it may be necessary to institute postural drainage coupled with deep breathing and coughing maneuvers.

Scleroderma

Pathophysiology and Medical Management

Scleroderma is characterized by the overproduction of collagen and progressive fibrosis of cutaneous and subcutaneous tissues.[43] The cardiovascular and pulmonary manifestations of this condition result in interstitial pulmonary fibrosis with significantly reduced vital capacity, diffusing capacity, and arterial oxygen tension.[15] Reduced static compliance is the primary mechanical deficit. Pulmonary hypertension may be a complicating factor. Bronchoalveolar lavage is consistent with an acute inflammatory process. Cardiomyopathy is associated with ischemia, areas of infarction, and myocardial fibrosis.[43] Fibrosis of the conduction system predisposes the patient to conduction defects and dysrhythmias. Other cardiovascular and pulmonary manifestations include pericarditis with or without effusion and pulmonary and systemic hypertension from renal involvement. Half of patients with scleroderma have renal involvement including intimal hyperplasia, fibrinous necrosis of the afferent arterioles, and thickening of the glomerular basement membrane. Fibrotic changes and stenoses occur in the small arteries and arterioles systemically. Similar changes in the lymphatic vessels may obliterate lymph flow.

Esophageal involvement contributes to regurgitation of gastric contents, which is exacerbated when the patient is recumbent or bends over. Bloating and abdominal discomfort may reflect paralytic ileus and intestinal obstruction. Ascites and fluid accumulation in the gut increase abdominal pressure and encroach on diaphragmatic motion.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

In addition to all of the long-term management goals common to all other collagen vascular and connective tissue diseases, there are four additional goals for patients with scleroderma:

- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration
- Optimize secretion clearance

PATIENT MONITORING

Patients with scleroderma require all of the monitoring parameters common to all of the secondary conditions discussed in this chapter. Patients with additional cardiac dysfunction require ECG monitoring, particularly during exercise. If supplemental oxygen is used, the Fi_{O_2} administered is recorded.

MEDICATION

Medication that is needed to maximize treatment response (e.g., immunosuppressive agents and antiplatelet therapy) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective.

PRIMARY INTERVENTIONS

Primary interventions for patients with scleroderma include the combination of global interventions previously discussed; in addition, these patients require instruction in body positioning and breathing control and coughing maneuvers.

Patients with esophageal involvement are not treated or exercised immediately after a meal. These patients have frequent, small meals, take antacids between meals, and do not lie down for a few hours after eating. When recumbent, these patients have the head of bed elevated to minimize the risk of aspiration of gastric contents.

PATIENT EDUCATION

Patients with scleroderma will require the same instruction common to all patients with chronic secondary dysfunction.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with scleroderma to optimize the efficiency of oxygen transport overall. The exercise

program is modified according to the signs and symptoms (see Chapter 25). Chest wall exercises can be used and should include all planes of movement with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning. If mucociliary transport is impaired and this leads to secretion retention, it may be necessary to institute postural drainage coupled with deep breathing and coughing maneuvers.

Ankylosing Spondylitis

Pathophysiology and Medical Management

Ankylosing spondylitis results in reduced total lung capacity, vital capacity, and inspiratory muscle function. Ventilatory capacity is preserved, given that the respiratory muscles are not involved. The condition can result in spinal and chest wall rigidity; thus there is greater reliance on diaphragmatic contribution to ventilation (84%) compared with healthy persons (68%). The patient with ankylosing spondylitis has an increased dependence on diaphragmatic function and therefore is at risk if administered respiratory depressant medications or if he or she undergoes thoracic or upper abdominal surgery. These changes can lead to an increased respiratory rate during exercise to meet ventilatory demands. In combination with impaired respiratory mechanics, the work of breathing can increase.

During exercise, patients with ankylosing spondylitis show minimal chest wall expansion compared with otherwise healthy people. Although peak workload is reduced, diaphragmatic fatigue is more likely to be the limiting factor than ventilatory capacity, ventilation-perfusion mismatch, or abnormal blood gases.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

In addition to all of the long-term management goals common to all other collagen vascular and connective tissue diseases, there are two additional goals for patients with ankylosing spondylitis:

- Optimize alveolar ventilation
- Optimize spinal mobility

PATIENT MONITORING

Patients with ankylosing spondylitis require all of the monitoring parameters common to all of the secondary conditions discussed in this chapter.

PRIMARY INTERVENTIONS

Primary interventions for patients with ankylosing spondylitis include the combination of global interventions previously discussed; in addition, these patients require the following:

- Body positioning instruction
- Breathing control and coughing maneuvers
- Gait reeducation
- Ventilatory muscle training

PATIENT EDUCATION

Patients with ankylosing spondylitis will require the same instruction common to all patients with chronic secondary dysfunction.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with ankylosing spondylitis in order to optimize the efficiency of oxygen transport overall. Maximizing ventilation with mobilization is limited if the patient has extreme spinal rigidity. Chest wall exercises can be used and should include all planes of movement with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning. Ventilatory muscle training in conjunction with exercise may have some additional benefit in maximizing aerobic capacity.

Consistent with the physical activity and exercise pyramid recommendations of daily exercise, individuals with ankylosing spondylitis can benefit from frequent, prolonged, low-intensity cross training to offset the potential for loss of flexibility and range.

Rheumatoid Arthritis

Pathophysiology and Medical Management

RA is a multisystemic condition that is associated with well-documented cardiovascular-pulmonary effects, including pleuritis with or without effusions, interstitial fibrosis, pulmonary vasculitis, an increased incidence of bronchitis and pneumonia myocarditis, epicarditis, endocarditis, dysrhythmias, neuritis, and vasculitis.[44]

Individuals with RA have significant cardiovascular risk factors. Compared with individuals without RA, diastolic blood pressure and levels of thrombotic variables are elevated.[45] Risk factor modification has an important role in the comprehensive management of individuals with RA.

Functional capacity is limited by pain and stiffness in the affected muscles and joints, weakness, the number of joints affected, fatigue, and whether the patient is having an acute episode. Self-limited physical activity and exercise contributes to cardiovascular and pulmonary deconditioning. Movement such as walking is often inefficient because of limping. Peak exercise tests are limited by musculoskeletal complaints; thus submaximal tests are more functional in this population. Tests of cardiovascular status must be non–weight bearing to enable the patient to reach an acceptable stress level without confounding joint pain.

Prolonged use of steroids contributes to bone fragility. Thus physical activity and exercise prescriptions are modified accordingly.

RA is hallmarked by exacerbations and remissions. A lifelong health program helps to reduce the frequency and severity of exacerbations and enhance recovery from these.

Furthermore, such a program may help reduce the need for potent medication.

Principles of Physical Therapy Management

GOALS OF LONG-TERM MANAGEMENT

Traditionally the approach to the physical therapy management of RA has been largely from the orthopedic perspective. Exercise and stress of the oxygen transport system, however, are major components of overall management. Thus the secondary cardiovascular and pulmonary manifestations must be assessed to ensure that exercise prescription is safe as well as maximally therapeutic.

In addition to all of the long-term management goals common to all other collagen vascular and connective tissue diseases, there are five additional goals for patients with RA:

- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration
- Optimize secretion clearance
- Optimize alveolar ventilation

PATIENT MONITORING

Patients with RA require all of the monitoring parameters common to all of the secondary conditions discussed in this chapter.

MEDICATION

Medication that is needed to maximize treatment response (e.g., steroids, nonsteroidal antiinflammatory drugs, and analgesics) is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally efficacious. Gentle, rhythmic, nonjarring exercise is prescribed, particularly for patients at risk of loss of bone mass secondary to long-term steroid use.

PRIMARY INTERVENTIONS

Primary interventions for patients with RA include the combination of global interventions previously discussed; in addition, these patients require instruction in body positioning and breathing control and coughing maneuvers. A review of mobility aids and devices is carried out to maximize the patient's function and exercise tolerance.

PATIENT EDUCATION

Patients with RA will require the same instruction common to all patients with chronic secondary dysfunction.

EXERCISE

Aerobic exercise is an essential component of the long-term management of the patient with RA in order to optimize the efficiency of oxygen transport overall with respect to both cardiovascular and pulmonary conditioning and improving movement economy. Mild-to-moderate exercise during subacute periods can be beneficial. Cycling efficiency of patients with RA is comparable to that of healthy persons. The efficiency of walking, however, is less in patients with RA because of limping and associated deformity and pain. Non–weight-bearing exercise is beneficial in patients with severe deformity and pain (e.g., aquatic exercise or water walking). Given the fluctuations in the patient's condition from day to day, exercise prescription is modified frequently in consideration of the patient's changing condition. Chest wall exercises include all planes of movement with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning.

For patients with RA, 15 to 35 minutes of graded, low-intensity aerobic exercise performed three times a week can be sufficient to enhance aerobic capacity. In addition to improving aerobic capacity, such an exercise prescription results in increased exercise time, reduced affected joint count, improved activities of daily living, and reduced joint pain and general fatigue. Should a joint flare-up occur while the patient is participating in an exercise program, a few days or weeks of restricted mobility and abstinence from exercise frequently ameliorate the symptoms. Gentle mobilization (preferably weight bearing) coupled with range-of-motion exercises during this period will minimize the negative effects of reduced activity.

Individuals with Chronic Renal Insufficiency

Pathophysiology and Medical Management

Patients with chronic renal disease have significant systemic complications. Cardiovascular and pulmonary manifestations include left ventricular hypertrophy and congestive heart failure secondary to chronic volume and pressure overload. Patients have a high incidence of atherosclerosis, coronary artery disease, glucose intolerance, and diabetes. Also, generalized muscle weakness and fatigue compromise functional work capacity.

Chronically increased fluid volume, although regulated with dialysis, contributes to increased stroke work of the heart and cardiomegaly and hypertension. With respect to pulmonary function, increased fluid volume increases peribronchial fluid and airway closure. After dialysis, the reduction in body weight is related to a reduction in closing volume, increased vital capacity, and forced expiratory flow rates.

The pulmonary-renal syndromes reflect the close relationship between the lungs and kidneys. These syndromes are characterized by altered immunological status, alveolar hemorrhage, interstitial and alveolar inflammation, and pulmonary vascular involvement.

The kidneys have a primary role in the production and regulation of certain humoral regulators of metabolism, hemodynamics, fluid balance, and oxygen transport. Thus pathology of the kidneys affects those life-sustaining processes. Patients may be taking potent medications that are associated with severe side effects that can further compromise function.

Principles of Physical Therapy Management

Goals of Long-Term Management

In addition to all of the long-term management goals common to all other collagen vascular and connective tissue diseases, there are five additional goals for patients with chronic renal insufficiency:

- Reduce the work of breathing
- Reduce the work of the heart
- Protect the airways from aspiration
- Optimize secretion clearance
- Optimize alveolar ventilation

Patient Monitoring

Patients with chronic renal insufficiency require all of the monitoring parameters common to all of the secondary conditions discussed in this chapter.

Medication

Medication that is needed to maximize treatment response is administered before treatment. Knowledge of the type of medication, its administration route, and time to and duration of peak efficacy is essential if treatment is to be maximally effective. A lifelong health program has the potential to reduce the need for potent medications for renal dysfunction.

Primary Interventions

Postural correction exercises, chest wall mobility exercises, range-of-motion exercises, airway clearance interventions, activity pacing, and energy conservation techniques, which were all mentioned as global primary interventions, are not strictly necessary for patients with chronic renal insufficiency. These patients do require a combination of the other global interventions previously discussed; they will in addition need instruction on body positioning and breathing control and coughing maneuvers.

Patient Education

Patients with chronic renal insufficiency will require the same instruction common to all patients with chronic secondary dysfunction.

Exercise

Aerobic exercise is an essential component of the long-term management of the patient with chronic renal insufficiency in order to optimize the efficiency of oxygen transport overall. Maximizing ventilation with exercise is limited if the patient has severe generalized muscular weakness and increased fatigue. Maximal oxygen uptake increases in hemodialysis patients along with improvement in other indices of cardiovascular and pulmonary conditioning. Patients may decrease or eliminate the need for antihypertension medications. Exercise carried out during hemodialysis treatment sessions is feasible and safe for appropriate patients. Because hemodialysis treatments require sessions of several hours multiple times weekly, aerobic training (e.g., cycle ergometry) can be effectively incorporated into treatment time. The exercise prescription of patients with blood glucose abnormalities and coronary artery disease is modified accordingly.

Chest wall exercises can be used and should include all planes of movement with a rotational component. Body positioning to optimize lung volumes and airflow rates is a priority. Breathing control and coughing maneuvers are essential and should be coupled with body movement and positioning.

Individuals Who Are Obese

Pathophysiology and Medical Management

Obesity and its multisystem sequelae are epidemic in industrialized countries; thus obesity must be managed by the physical therapist as a primary condition as well as secondary to other diagnoses. Any other pathology or problem is accentuated when compounded with obesity, and morbidity and mortality are increased for all health concerns.[46,47]

A detailed assessment is conducted to identify organ systems that are affected and may limit exercise. Central abdominal obesity (apple obesity) constitutes a greater cardiovascular risk than hip obesity (pear obesity).[48,49] In younger people, low aerobic fitness in people who are obese appears to reflect deconditioning rather than a primary cardiac problem.[50] Individuals who are morbidly obese, however, may develop heart failure. Noninvasive approaches to weight control are superior to invasive approaches in terms of promoting lifelong change and multisystem benefit, health and well-being, and cost-effectiveness.

Pharmacological approaches and surgery are extreme measures whose use is generally not restricted to those with morbid obesity. Vertical banded gastroplasty is increasingly being performed on patients with morbid obesity. One study that compared exercise responses before and 6 months after weight loss with surgery showed that cardiac diastolic function is improved, along with V_{O_2} and anaerobic threshold.[51] The extent to which these and additional benefits would have occurred with conservative weight loss, however, and the long-term changes effected by both, were not studied.

Health risks associated with obesity are multisystemic (see Chapters 1 and 6). The cardiovascular and pulmonary risks are life-threatening. In particular, the work of breathing, owing to alveolar hypoventilation, and the work of the heart are increased with increasing body mass. The heart may enlarge to accommodate increased workload, even at rest. Body mass over the chest wall can lead to alveolar hypoventilation and airway closure and reduced oxygenation. Individuals who are obese have problems when recumbent, particularly during sleep (e.g., obstructive sleep apnea, dysrhythmias, and shortness of breath). These problems are identified in the comprehensive assessment.

Principles of Physical Therapy Management

Goals of Long-Term Management

Obesity can be a primary referred problem or a secondary condition. Physical therapists are uniquely suited to counsel and coach patients with weight problems and promote physically active lifestyles, recommend exercise programs, and provide basic knowledge on nutrition and diet commensurate with supporting these activities. Lessons learnt from tobacco control and smoking cessation have been extrapolated for use in the management of the obesity epidemic.[52]

Physical activity through the course of the day must be increased, and patients who are obese need to participate in a regular program of exercise. The goals of long-term management for the obese patient include all of the elements common to all other conditions.

Patient Monitoring

Patients with obesity require all of the monitoring parameters common to all of the secondary conditions discussed in this chapter.

Maintaining a healthy weight is a function of optimal nutrition and exercise (see recommendations in Chapter 1). The individual's readiness to change dietary and activity patterns must be assessed to determine the optimal time to introduce a structured program to maximize and sustain long-term outcomes (see Chapters 1 and 28).

A weight loss program is introduced concurrently with an increasing volume of regular physical activity and a structured exercise program. The parameters of the prescription, however, may require modification because of biomechanical stress and discomfort. As weight is lost, the prescriptive parameters are modified to increase the intensity and volume of exercise that is performed. Also, the individual's movement economy and efficiency will improve as the body's biomechanics normalize. Initially the hemodynamic responses to even low levels of exercise are likely to be excessive because of the weight that the individual carries during the performance of the activity. Before significant loss of weight, cycling may initially be preferable to walking if the person's biomechanics limit endurance. Physical activity must be comfortable both for sustainability and injury avoidance.

The role of the physical therapist as health coach is critically important in providing both support to the individual who is obese and long-term follow-up. The probability of success is increased with the involvement of a health care provider and follow-up. Facilitating weight loss and adopting long-term healthy lifestyle behaviors can be lifesaving for a patient. Given the current epidemic of obesity, assisting an individual to attain a healthy lifestyle through optimal nutrition, exercise, and weight loss is a singularly important health outcome.

Summary

This chapter reviews pathophysiology and medical management as they relate to the comprehensive physical therapy management of individuals with chronic secondary cardiovascular and pulmonary pathology. Exercise testing and training are major components of the comprehensive management of these conditions and are presented separately in Chapter 25.

This chapter specifically presents the comprehensive physical therapy management of chronic cardiovascular and pulmonary dysfunction secondary to neuromuscular, musculoskeletal, collagen vascular and connective tissue, and renal dysfunction. The neuromuscular conditions that are presented include stroke, Parkinson syndrome, multiple sclerosis, cerebral palsy, spinal cord injury, chronic effects of poliomyelitis, and muscular dystrophy. The musculoskeletal conditions that are presented include thoracic deformity (kyphoscoliosis) and osteoporosis. The collagen vascular and connective tissue conditions that are presented include SLE, scleroderma, ankylosing spondylitis, and RA. Finally, management of the patient with chronic renal insufficiency and the person who is obese is presented.

The principles of patient management are presented rather than treatment prescriptions, which cannot be given without specific consideration of an individual patient. In this context, the goals of long-term management of patients with each condition are presented, followed by the essential monitoring required, and the primary interventions for maximizing cardiovascular and pulmonary function and oxygen transport. The selection of interventions for any given patient is based on the physiological hierarchy. The most physiological interventions are exploited, followed by less physiological interventions and those whose effectiveness is less well documented.

These principles must be considered if a patient has a chronic secondary cardiovascular and pulmonary condition as a secondary diagnosis for which the patient is being treated by the physical therapist. These principles have implications for treatment prescription and monitoring in the management of the condition for which the patient is being primarily treated.

Review Questions

1. Analyze the limitations in participation and related activities that are associated with chronic cardiovascular and pulmonary pathophysiology that occurs secondary to stroke, Parkinson syndrome, multiple sclerosis, cerebral palsy, spinal cord injury, late sequelae of poliomyelitis, muscular dystrophy, kyphoscoliosis, osteoporosis, SLE, scleroderma, ankylosing spondylitis, RA, chronic renal insufficiency, and obesity.
2. Relate cardiovascular and pulmonary physical therapy treatment interventions to the underlying pathophysiology of each of the chronic conditions listed in question 1 that a person may have, and provide the rationale for your choice.

Cardiovascular and pulmonary physical therapy in the intensive care unit (ICU) is a subspecialty within cardiovascular and pulmonary physical therapy. This chapter presents the principles of clinical and nonclinical aspects of patient management in this setting. An overview of the general goals of management and the rationale for prioritizing treatments according to a physiological hierarchy is described. End-of-life issues are also addressed.

The thrust toward evidence-based practice in health care and the development of conceptual bases for practice have had major implications for cardiovascular and pulmonary physical therapy in the ICU.[1-4] Superior knowledge of cardiovascular and pulmonary physiology, pathophysiology, pharmacology, multisystem dysfunction and its medical management, and ICU equipment and changing technology is essential. Clinical decision making in the ICU and rational management of patients is based on a tripod approach: knowledge of the underlying pathophysiology and basis for general care; knowledge of the physiological and scientific evidence for treatment interventions; and clinical reasoning and decision making in prioritizing treatments, prescribing their parameters, and performing serial evaluation to assess outcomes and further modify treatment (Figure 33-1). High-quality care is a function of these three areas of knowledge and expertise. Evidence-based practice and excellent problem-solving ability

will optimize outcomes[5] and maximize the benefit-to-risk ratio of cardiovascular and pulmonary physical therapy interventions.

Specialized Expertise of the Intensive Care Unit Physical Therapist

Effective clinical decision making and practice in the ICU demand specialized expertise and skill, including advanced, state-of-the-art knowledge in cardiovascular and pulmonary and multisystem physiology and pathophysiology and in medical, surgical, nursing, and pharmacological management (Box 33-1). Physical therapists in the ICU need to be first-rate diagnosticians and observers. Given the multitude of factors that contribute to impaired oxygen transport,[6] the physical therapist needs to analyze these to define the patient's specific oxygen transport deficits and problems. Optimizing oxygen delivery in the patient who is critically ill[7] by exploiting noninvasive interventions is the priority.

The role of the ICU physical therapist is to promote healing and recovery and to return the patient to the highest possible level of life participation and satisfaction. Therefore the physical therapist must be capable of processing considerable amounts of objective information quickly, interpreting this information, and integrating it to provide the basis for a treatment prescription (i.e., the specific selection, prioritization, and implementation of treatment interventions). The ability to integrate and interpret the vast amount of multiorgan system data is perhaps the single most important skill in ICU practice and treatment prescription. With these data the physical therapist identifies the indications for treatment, contraindications, and optimal timing of interventions. The condition of the patient in the ICU can change rapidly. The physical therapist works within narrow windows of opportunity to effect an optimal treatment response. Treatments are variable with respect to their intensity, duration, and frequency. The maximally beneficial outcome with the least risk to the patient is the objective of every treatment. Although principles of management may be the same, specific knowledge requirements will differ depending on the type of critical care setting (e.g., burn, coronary care, neurosurgery, spinal cord injury, and trauma). Alternatively, a community hospital with a small general ICU will have a cross section of patients that the physical therapist will need to manage.

Box 33-1 Specialized Expertise and Skill of the Intensive Care Unit Physical Therapist

- Detailed, comprehensive knowledge of cardiopulmonary physiology and pathophysiology and pharmacology.
- Thorough working knowledge of the monitoring systems routinely used in the intensive care unit (ICU) and an understanding of the interpretation of the output of these monitoring systems (e.g., electrocardiogram [ECG], arterial blood gases, fluid and electrolyte balance, hemodynamic monitoring, chest-tube drainage systems, intracranial pressure monitoring). This information is an integral component for assessing the underlying problems and selecting, prioritizing, and progressing or modifying treatment.
- Extensive expertise in cardiopulmonary assessment and treatment prescription; general experience in medicine and surgery is recommended.
- Detailed understanding of multisystem physiology and pathophysiology and the cardiopulmonary manifestations of systemic disease.
- Ability to practice effectively under pressure and in congested, suboptimal working conditions.
- Knowledge regarding all emergency procedures, including those for respiratory and cardiac arrest, equipment problems, and power failure.
- Knowledge regarding the paging system used in the unit for being contacted as well as for contacting other team members when they are out of the unit or out of the hospital.
- On-call service, 24 hours a day, 7 days a week, is a common practice and should be considered in units without this service.
- Knowledge regarding the roles of all team members.
- Sensitivity toward each patient's psychosocial situation, culture, and values and promotion of active involvement of the patient and family in clinical decision making, whenever feasible.
- Superior communication skills (e.g., ability to work cooperatively with other members of the ICU team [Figure 33-3] and give verbal presentations and discuss patients at rounds).

Goals and General Basis of Management

The ultimate goals of cardiovascular and pulmonary physical therapy in the ICU include the following:

1. Return the patient to his or her premorbid functional level or a higher level if possible
2. Reduce complications, morbidity, premature mortality, and length of ICU and overall hospital stay

As precursors to achieving these goals, the immediate goals relate initially to maximizing oxygen transport, hence, cardiovascular and pulmonary function; and second to maximizing musculoskeletal and neurological function. In the ICU the physical therapist needs to recognize the implications of cardiovascular and pulmonary insufficiency on neuromuscular status and that apparent impairment of neuromuscular status is not necessarily indicative of neurological dysfunction.

Rather, reduced cardiac output and blood pressure, hypoxemia, hypercapnia, and increased intracranial pressure (ICP) may be responsible for these changes indirectly. Musculoskeletal and neurological complications can become life-threatening and therefore need to be detected early and managed.

Key elements of the assessment of the patient in the ICU include risk factors for a suboptimal clinical outcome. In addition to age and comorbidity, risk factors include poor indices of PaO_2 with a high FIO_2, platelet count, cardiac index, blood urea nitrogen, creatinine, and renal function. Other risk factors include peritoneal dialysis or hemodialysis, continuous infusion of antidysrhythmic agents, base deficit, reduced consciousness, pain, and cardiac arrest. Thus patients with one or more of these risk factors, conditions and interventions, require close monitoring and management.

Many elements of the assessment of patients in the ICU are comparable to those for patients with acute conditions who are not critically ill but require respiratory support and mechanical ventilation (see Chapter 44). The primary difference is that for patients in the ICU the adequacy of the steps in the oxygen transport pathway are monitored closely, and the status and function of multiple organ systems are monitored in a serial (repeated at regular or judicious intervals) manner to observe trends over time so that treatment modifications can be titrated to the patient's responses. Serial vital signs including pain and distress are recorded along with arousal and cognitive status, neuromuscular status, musculoskeletal status, and functional mobility. Assessment of functional mobility ranges from the smallest movement to walking (see Figure 33-2 and Box 33-4). Often it includes bed mobility, transfers to chair, and walking, which may require assistive devices. Related laboratory investigations are noted, including the electrocardiogram (ECG), radiographs, scans, blood work, blood sugar level, and fluid and electrolyte balance, and are followed closely to quickly detect improvement or deterioration so that treatment can be correspondingly modified.

Mechanical ventilation and its modes and parameters are described in Chapter 44. The ventilator settings including the fraction of inspired oxygen (FIO_2) are important indicators of changes in the patient's status and therefore must be included in the assessment and recorded at each treatment. Similarly, changes in FIO_2 are important outcomes and indicators of treatment response. This information is used collectively in clinical decision making before, during, and after weaning from mechanical ventilation.

In patients who are medically stable, invasive mechanical ventilation is titrated judiciously to ensure that the patient is initiating breaths as much as possible, which facilitates weaning. Depending on the patient's response to ventilation, however, sedation and neuromuscular blockade may be indicated. These interventions limit the patient's capacity to cooperate fully with treatment. Breathing patterns imposed by the mode of mechanical ventilation influence venous return and aortic pressures[8]; thus mobilization needs to be prescribed accordingly. Furthermore, weaning patients with chronic obstructive pulmonary disease (COPD) and neuromuscular conditions is complicated by respiratory muscle weakness and fatigue (see Chapter 26), which may indicate respiratory muscle training or rest. Because of these challenges, weaning necessitates close cooperation and coordination within the team to maximize weaning success.

As for patients who are not critically ill, the assessment data are evaluated, problems and diagnoses made, and interventions prescribed based on the patient's needs and goals. Physical therapy has a prominent role in the management of patients who are on mechanical ventilation.[9,10] With each treatment, the responses are reviewed and prescription parameters of the interventions are refined to progress the patient

Restricted Mobility and Recumbency

Hospitalization, particularly in the ICU, is associated with a considerable reduction in mobility (i.e., loss of exercise stimulus) and recumbency (i.e., loss of gravitational stimulus) (see Chapters 18 and 20).[11-13] These two factors are essential for normal oxygen transport; thus their removal has dire consequences for the patient with or without cardiovascular and pulmonary dysfunction.

In terms of a physiological hierarchy of treatment interventions (see Chapter 17), exploiting the physiological effects of acute mobilization, upright positioning, and their combination is the most physiologically justifiable primary intervention to maximize oxygen transport and prevent its impairment in patients who are critically ill.

Recumbency is nonphysiological; it is a position in which, all too often, most patients are injudiciously confined. Changing the position of the body from erect to supine positions results in significant physiological changes that may jeopardize the patient's already compromised or threatened oxygen transport system (Box 33-2) (see Chapter 20).

The culmination of these deleterious effects offsets the increased homogeneity of ventilation and perfusion and their

Box 33-2 Physiological Changes When Changing from the Upright to the Supine Position

- Cephalad displacement of the visceral contents and diaphragm
- Compression of the dependent lung fields
- Cephalad fluid shift to the central circulation
- Increased stroke volume and cardiac output and over days a reduction caused by renal compensation
- Decreased total lung capacity
- Decreased vital capacity
- Decreased functional residual capacity
- Decreased residual volume
- Decreased forced expiratory volumes
- Increased airway resistance
- Increased closing volumes of small airways
- Increased restriction of chest wall and decreased diaphragmatic excursion
- Decreased pulmonary and chest wall compliance
- Decreased arterial oxygen levels
- Decreased cough effectiveness
- Increased preload, afterload, and myocardial work
- Decreased myocardial efficiency
- Decreased sympathetic stimulation and decreased peripheral vascular resistance

matching in the supine position. These effects compound the superimposed factors of restricted mobility, recumbency-induced central fluid shifts, prolonged lying without the normal stimulation or will to turn the body, and underlying pathophysiology or trauma that may contribute to impaired cardiovascular and pulmonary function and oxygen transport. Theoretically, the more compromised the patient, the greater the priority to maximize time spent in the upright position in conjunction with exploiting the benefits of acute mobilization.

Specificity of Cardiovascular and Pulmonary Physical Therapy

Physical therapy interventions in the ICU (see Chapter 17 and Part III) are more specifically geared toward the status of each organ system, taking into consideration the pathophysiological basis for the patient's signs and symptoms, the rationale for each intervention, and the physiological and scientific evidence supporting the effectiveness of the intervention.[14] Physical therapy provides both prophylactic and therapeutic interventions for the patient in the ICU. Conservative, noninvasive measures constitute initial treatments of choice to avert or delay the need for additional invasive monitoring and treatment including supplemental oxygen, pharmacological agents, and the need for intubation and mechanical ventilation. The physical therapist aims to avoid, reduce, or postpone for as long as possible the need for respiratory support. Even if the patient is mechanically ventilated, maintaining some level of spontaneous breathing, no matter how minimal, is associated with improved oxygenation and outcomes.[15] In addition, the physical therapist helps to prevent the multitude of side effects of restricted mobility and recumbency during bed rest. A summary of general information required before treatment of the patient in the ICU is presented in Box 33-3. This provides the basis for establishing a patient's readiness to be mobilized and the progressive steps for doing so (Box 33-4 and Figure 33-2).

Box 33-3 General Information Required before Treatment of the Patient in the Intensive Care Unit

- Sex and age
- Premorbid status (e.g., lifestyle, ethnicity, culture, work situation, stress, cardiopulmonary conditioning, and oxygen transport reserve capacity)
- Knowledge of patient's life roles and related activities for optimal return to daily life
- Medical and surgical histories
- General multisystem assessment findings
- Pharmacological support
- Smoking history
- Hydration and nutritional status: deficiencies, obesity, or asthenia
- Time of onset and course of present condition
- Existing or potential medical instability
- Indications or necessity for intubation and mechanical ventilation
- Mode and parameters of mechanical ventilation
- F_{IO_2}
- Invasive monitoring, lines, leads, and catheters
- Existence of or potential for complications and multiorgan system failure
- Cognition or coma scale score
- Presence of elevated intracranial pressure (ICP) and the need for ICP monitoring
- Risk or presence and site(s) of infection
- Quality of sleep and rest periods
- Nutritional support during intensive care unit stay
- Pain control regimen

Fig. 33-2 Progressive sequence for mobilizing patients (i.e., being upright and moving).

Maximizing Function

Maximizing function refers to maximizing the capacity to participate in one's life roles and associated activities. This necessitates promotion of optimal physiological functioning at an organ system level, as well as promoting maximal functioning of the patient as a whole. In critical care, primary goals related to function optimization are initially focused on cardiovascular and pulmonary function. With improvement in oxygen transport, increased attention is given to optimal functioning of the patient with respect to self-care, self-positioning, sitting up, and walking. General physical therapy goals related to function optimization are shown in Box 33-5. Outcomes can be tracked objectively by recording the length of time a patient sits over the edge of the bed, sits in a chair at bedside, stands, and walks. Also, the weight a patient lifts as well as the number of repetitions and sets he or she performs can be readily quantified.

Consistent with being primarily a noninvasive practitioner, the physical therapist exploits noninvasive interventions to achieve therapeutic goals. Outcomes related to reduced reliance on invasive interventions are important physical therapy outcomes. These include reducing F_{IO_2}; avoiding mechanical ventilation; minimizing mechanical ventilator support; increasing the amount of spontaneous breathing, even minimally, if the patient is mechanically ventilated; and reducing medication (e.g., bronchodilators, inotropes, chronotropes, sedation, narcotics, and analgesics).

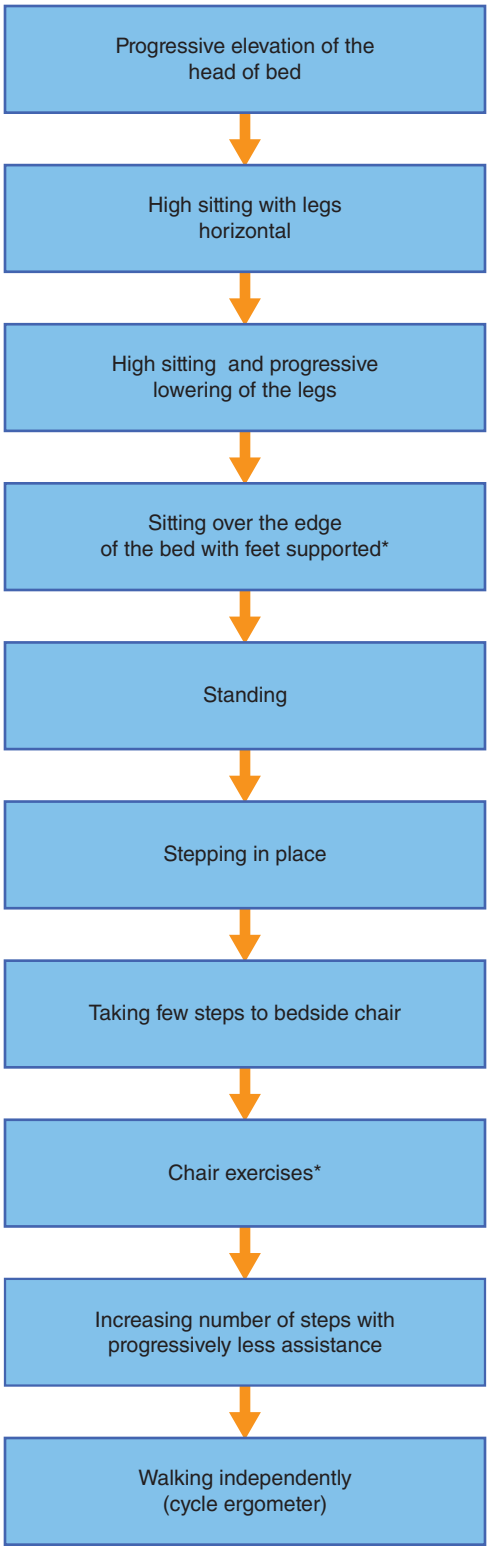

Fig. 33-3 Multidisciplinary rounds in the intensive care unit (ICU). Team work in the ICU is essential to facilitate communication and patient outcome. Note the presence of the nurse, respiratory therapist, pharmacist, social worker, physical therapist, and physician. *When indicated, add resistance muscle exercise with aids and devices such as weights, belts, leg press, and ergometer pedals; progression is based on safety considerations and anticipated therapeutic responses.

Box 33-4 Guiding Principles for Mobilizing Patients in the Intensive Care Unit

Based on a multisystem assessment and discussion with the team:

- Determine the patient's readiness for mobilization—that is, perform multisystem assessment including arousal, medications, lines and leads, mechanical ventilation and respiratory support; responses to gravitational and mobilization challenge tests; contraindications and precautions and clearance by team.
- Establish therapeutic and safe parameters for a given patient based on objective and subjective measures.
- Prescribe the parameters of the gravitational and mobilization stimuli (types of mobilization and exercise, their intensities, duration, and frequencies) by titrating them to the patient's immediate and longer term responses (see Fig 33-2 for progression of mobilization). Principles for progressing the mobilization stimulus:
  - Progression to successive steps is based on the patient's responses.
  - If the patient's physiological responses change appropriately and commensurately with the increment in mobilization load and the patient's condition remains stable, then the next step may be attempted.
  - If untoward responses occur, then the patient can return to the previous level or potentially to sitting or supine to regain resting status.
  - The patient is reassessed before each bout of mobilization and evaluated throughout and afterward.
- Monitor the patient during and after each of the levels shown in the following schema, and record the responses and outcomes.
- Progress patient:
  - Increased intensity. Increase is commensurate with reduction of support and assistance, and increased duration to increase volume of exercise overall, and with improvement—that is, the patient tolerates greater gravitational stress and exercise stress with reduced physiologic demands within therapeutic and safe limits)
  - With increased intensity and increased duration, frequency of the mobilization sessions may be reduced.
  - Some patients quickly progress through these steps, and others progress more slowly based on their individual responses.
- Monitor response to recovery and rest and qualitative and quantitative evaluation of return to resting baseline.

Prophylaxis

General aspects of patient care related to physical therapy practice include the role of prophylaxis or prevention. The complications of restricted mobility and recumbency are described in Chapter 18 and relate primarily to the status of the cardiovascular and pulmonary, neuromuscular, and musculoskeletal systems and overall functional capacity. In the ICU the negative physiological effects of restricted mobility are amplified in patients who are severely ill and older. A primary objective of the physical therapist therefore is to avoid or reduce these untoward effects on the patient's recovery and

Box 33-5 General Physical Therapy Goals toward Function Optimization in the Patient in the Intensive Care Unit

- Establish a detailed baseline of outcome measures and measures to be recorded serially to assess change.
- Maintain or restore adequate alveolar ventilation and perfusion and their matching in unaffected and affected lung fields and thereby optimize oxygen transport overall.
- Prolong spontaneous breathing (to the extent that is therapeutically indicated) and thereby avoid, postpone, or minimize need for mechanical ventilation.
- Minimize the work of breathing.
- Minimize the work of the heart.
- Design a positioning schedule to maintain comfort and postural alignment (distinct from therapeutic body positioning to optimize oxygen transport).
- Maintain or restore general mobility, strength, endurance, and coordination within the limitations of the patient's condition and consistent with the patient's anticipated rehabilitation prognosis (distinct from therapeutic mobilization to optimize oxygen transport).
- Maximally involve the patient in a daily routine including self-care, changing body position, standing, transferring, sitting in a chair, and ambulating in patients for whom these activities are indicated.
- Optimize treatment outcome by interfacing physical therapy with the goals and patient-related activities of other team members; coordinating treatments with medication schedules; and treating the patient specifically, on the basis of both results of objective monitoring available in the intensive care unit and subjective findings.

the patient's length of stay in the ICU. Ventilator-associated pneumonia (VAP) is the most common nosocomial infection in the ICU and is associated with poor outcomes and high cost of ICU care.

Preventive physical therapy goals include reducing the deleterious effects of restricted mobility and pathology on cardiovascular and pulmonary and neuromuscular function and reducing the risk of musculoskeletal deformity, neurological dysfunction, and decubitus ulcers over pressure areas (back of the head, shoulders, elbows, sacrum, and heels). Special mattresses or a special bed may be indicated. The negative sequelae of recumbency and restricted mobility, which can be life-threatening in people who are critically ill, are largely preventable. Particular care must be taken to avoid pressure sores because these increase the risk of infection and deterioration and can be life-threatening. Physical therapists as well as nurses need to pay particular attention to individuals at risk and to examine routinely for sites of redness, pressure, and potential skin lesions in every patient, regardless of expected length of stay in the ICU.[16] The texture of bed covers, their smoothness, bunching of the bed gown, and irritation from lines and catheters to the patient must be routinely monitored. Prevention is key, given the potentially reduced immunity and capacity to heal of patients in the ICU.[17] Although pressure sores are largely preventable, the need to be vigilant remains, given the deleterious consequences they may have on recovery. Unrelieved pressure and equipment failure have been identified as key causes of pressure sores in the patient after trauma.[18] These causes of pressure sores are 100% avoidable with vigilance and monitoring. Physical therapists have a role for making recommendations about patient positioning between treatments in the interest of preventing deleterious sequelae of recumbency and restricted mobility.

Preparation for Treating the Patient in the Intensive Care Unit

Patients in the ICU are generally characterized by some degree of life-threatening medical instability or its risk. Before treating a given patient in the ICU, the physical therapist should be thoroughly familiar with the specific information shown in Box 33-6. Depending on the level of care in the ICU, nursing care is usually 1:1 or 1:2. Coordinating treatment with nursing interventions is efficient. It is helpful to have the nurse at hand to assist as required, particularly if the patient is beginning physical therapy. Alternatively, if the nursing care proved strenuous for the patient, physical therapy may be more beneficial if delayed.

General Clinical Aspects of the Management of the Intensive Care Unit Patient

Assessment and Evaluation

The fundamental assessment procedures for the cardiovascular and pulmonary systems are described in detail in Part II. Laboratory reports, procedures, sputum culture, and radiographs supplement the findings of inspection, palpation, and auscultation of the chest. Of particular importance are the blood work, arterial blood gases (including Sa_{O_2}), ECG, fluid and electrolyte balance, hemodynamic monitoring, and ICP monitoring. These are the most commonly monitored parameters in the ICU in addition to vital signs, temperature, respiration rate, heart rate, blood pressure, respiratory distress, and pain.

Although the priority in the ICU is survival, greater attention is now being placed on thriving after the episodes of care in the ICU and hospital (see Chapters 16 and 17). Therefore assessment and evaluation in the ICU focus on activity, participation, and quality of life as well as factors related to conventional oxygen transport deficits and multisystem function, in anticipation of the patient's return to community living.

Monitoring

Maximizing the effects of physical therapy treatment depends on exploiting information from the ICU monitoring systems. Monitoring systems can be used to establish the indications and contraindications for treatment as well as parameters of the treatment prescription and progression, and to assess the patient. Physical therapy uses of monitoring systems in the ICU are summarized in Box 33-7. Physical therapists need to exploit the considerable amount of objective data available to them in patient management. A thorough knowledge and routine use of monitoring systems for each patient in the ICU cannot be overemphasized in terms of contributing to

Box 33-6 Specific Patient Information Required before Treatment of the Patient in the Intensive Care Unit

- Detailed knowledge of the patient's history, including the differential diagnosis on admission to the intensive care unit (ICU) and relevant medical, surgical, and social histories.
- Knowledge of premorbid status related to the International Classification of Functioning, Disability and Health (see Chapters 1 and 17) (i.e., limitations of structure and function [impairment], activities, and social participation [health-related quality of life]—these will provide a baseline of outcome measures on which clinical decisions about ICU discharge and hospital discharge will be made).
- Detailed understanding and knowledge of the medications administered to the patient, their indications, and side effects (especially those affecting response to physical therapy).
- Knowledge regarding the stability of vital signs since admission, including heart rate and rhythm, respiration rate and rhythm, blood pressure, skin color, core temperature, and hemodynamic stability.
- Detailed knowledge of relevant findings of laboratory tests, procedures, and biopsies, including arterial blood gases, blood analysis, fluid and electrolyte balance, electrocardiogram (ECG), radiographs, thoracentesis, central venous pressure (CVP), left atrial pressure (LAP), pulmonary artery wedge pressure (PAWP), microbiology and biochemistry reports, and urinalysis.
- Detailed understanding of the rationale for the ventilatory mode and parameters used if the patient is ventilated.
- With respect to establishing a patient database:
  - Conduct a thorough, detailed clinical assessment specific to the patient's condition(s), including inspection, palpation, percussion, and auscultation of the chest, as well as a neuromusculoskeletal assessment to rule out any secondary effects of cardiopulmonary dysfunction and to establish rehabilitation prognosis.
  - Establish a physical diagnosis and problem list and prioritize the treatment goals and overall treatment plan.
  - Determine the optimal assessment and treatment outcome measures and be knowledgeable about their interpretation.
  - Conduct serial measurements to predict the patient's oxygen transport reserve capacity before treatment and stressing the oxygen transport system.
- As treatment progresses, record objective and relevant subjective treatment outcome measures and revise treatment goals as indicated by the patient's progress.

Box 33-7 Physical Therapy Uses of Monitoring Systems in the Intensive Care Unit

- Establish the indications for and contraindications to cardiopulmonary physical therapy
- Define treatment intensity, duration, and frequency for optimal treatment outcome
- Determine the appropriateness of response to a specific intervention
- Assess the need for supplemental oxygen before, during, and after treatment
- Determine appropriate patient positioning between, during, and after treatments
- Establish whether the patient is responding positively or negatively to treatment or there is no change and whether treatment should be modified or discontinued

improved quality of care with less risk to the patient. Subjective responses of the patient are particularly important in the ICU, where the patient's power and self-responsibility are compromised. Eliciting subjective responses can be achieved through a sign system, use of analog scales, and communication devices. The patient needs to be able to communicate basic needs if possible (e.g., discomfort or /pain, anxiety, fear, and general distress). Patients have been reported to experience significant levels of stress when being managed in the ICU—in turn, worsening outcomes.[19]

The monitoring systems described in Chapter 16 provide essential information with respect to the management of the patient in the ICU. Information regarding arousal, acid-base imbalance, and fluid and electrolyte balance helps to establish specific treatment goals. The Swan-Ganz catheter in situ permits measurement of pulmonary artery pressure and wedge pressure, which provide an index of myocardial sufficiency and specifically left-sided heart function. Central venous pressure gives an indication of fluid loading and the ability of the right side of the heart to cope with changes in circulating body fluids. Pressures related to heart function give the physical therapist an indication of pulmonary status and help to determine whether heart dysfunction is affecting lung function or lung dysfunction is affecting heart function, or both. Cardiovascular and pulmonary stress alerts the physical therapist to modify workloads or the physical demands of treatment to keep the patient medically stable and avoid undue fatigue and deterioration. The physical therapist conducts ongoing monitoring of the patient's responses to invasive care in the ICU (e.g., responses to medication and fluid resuscitation, indications for intervention and refinement of its prescription) to ensure patient safety.

Changes in ECG may reflect heart disease, lung disease, altered acid-base, and electrolyte and fluid balance. The physical therapist is responsible for identifying the patient's heart rhythm and ECG changes, which can be expected with improvement or deterioration in oxygen transport and secondary to medical management, drug intervention, changes in the course of the disease, and response to treatment generally.

Pharmacological Agents

The physical therapist needs a thorough knowledge of the common pharmacological agents used in intensive care (see Chapter 45). With this knowledge, the physical therapist can augment the effects of these agents and optimize physical therapy treatment response when treatments are coordinated with medication schedules. Most medications have optimal dosages for any given patient, optimal sensitivity, and peak response time. Most medications have side effects. Side effects

may cause deterioration in the patient's condition, create apparent signs and symptoms suggestive of other disorders, or alter response to treatment. The physical therapist therefore needs to identify the medications each patient is taking and their side effects. Medication that contributes to suboptimal therapeutic outcomes warrants discussion with the team in terms of finding an alternative. One physical therapy outcome is the minimization of medication with effective physical therapy.

Certain medications, such as anxiolytics, bronchodilators, sedatives, mucolytic agents, antianginal medications, and analgesics, help the patient to cooperate and tolerate treatment. Special consideration must always be given to the different peak response times of different medications. The patient can cooperate more actively in the treatment if pain and anxiety are reduced and breathing is easy. An enhanced treatment effect is therefore more likely. These advantages can result in shorter, more cost-effective treatment and more effective use of the physical therapist's time.

Some medication can attenuate a patient's response to mobilization and exercise and activity. Patients on beta-blocking agents, for example, may not show the normal changes in heart rate and blood pressure in response to exercise. In addition, beta-blockers contribute to fatigue. Therefore, caution needs to be observed when prescribing exercise for patients taking beta-blockers. Another classification of drugs called *vasopressor agents* regulates blood pressure and heart rate. Patients taking these agents may also exhibit abnormal mobilization and exercise responses. Monitoring is essential; however, vital signs to assess treatment response may be rather limited for patients taking drugs that act on the cardiovascular system.

Narcotics are a commonly used classification of drug in the ICU and are often administered for their analgesic effects jointly with sedatives and tranquilizers. Despite pain relief, narcotics, particularly in combination with other sedative-type drugs, interfere with physical therapy treatments because of the patient's reduced arousal, monotonous ventilation, and inability to cooperate with treatment. Furthermore, narcotics tend to have multisystem effects rather than localized effects. Because physical therapy is the most physiological and noninvasive intervention available to the patient in the ICU, it behooves the physical therapist to ensure that pharmacological agents that are effective and more selective than narcotics in achieving the desired effect have been considered. Thus as a team member the physical therapist has a major role during rounds to ensure an integrative management program for each patient.

Treatment Prescription in the Intensive Care Unit

Physical therapy treatments in the ICU are judiciously selected in a goal-specific manner. As a general guideline, treatments descend in a physiological hierarchy (Chapter 17). Mobilization, exercise, and body positioning are exploited first with respect to their direct and potent effects on oxygen transport overall.[20] Early mobilization and walking are priorities regardless of whether the patient is mechanically ventilated.[21-23] At the other end of the treatment intervention hierarchy (i.e., least physiological interventions that have a more limited effect on the steps in the oxygen transport pathway overall) are conventional interventions such as airway clearance techniques and suctioning. Assessment of the oxygen uptake and delivery relationship is essential given the high metabolic demands of patients in the ICU[24] and the documented associated exercise and stress responses associated with physical therapy.[25]

Supplemental Oxygen

Supplemental oxygen is usually administered continuously, whether the patient is ventilated or not, to maintain Pa_{O_2} level within an optimal range.[26] Oxygen concentrations can be increased before treatment to help compensate for associated stress. Oxygen, however, should always be increased to 100% and inspired for at least 3 minutes before and after suctioning. Should arterial desaturation be apparent during treatment, oxygen may need to be increased. If the patient is spontaneously breathing without oxygen, supplemental oxygen may also be indicated during treatment to avoid desaturation. Oxygen administration is regulated by the ICU team based on arterial blood gas levels including arterial saturation and subjective distress. Severe hypoxemia is known to result in irreversible tissue damage within minutes, but hyperoxia can also produce harmful effects within hours. By maximizing alveolar ventilation, gas exchange, and ventilation and perfusion matching, supplemental oxygen can be optimally used and the effects of acidemia minimized.

Treatment for respiratory acidosis in individuals with chronic pulmonary disease is aimed at increasing alveolar ventilation to improve the exchange of carbon dioxide and oxygen. Because the respiratory center is depressed by increased amounts of carbon dioxide (carbon dioxide narcosis), the lowered oxygen tension of the blood becomes the stimulus for respiration. If the patient inhales high concentrations of oxygen, the stimulation for respiration may be removed. For this reason, oxygen is never given to patients with carbon dioxide narcosis.

Low-flow oxygen (1 to 3 L/min) is given to a patient with chronic pulmonary disease who maintains a chronically elevated arterial P_{CO_2} in the presence of arterial hypoxemia. If intermittent positive pressure breathing is indicated, compressed or room air is used instead of oxygen.

Severe hypoxemia usually suppresses cardiac output to some degree. Cardiac output may be further compromised immediately after a patient has been placed on a mechanical ventilator because of impaired venous return resulting from the elevated transpulmonary pressure.[27] An attempt is made to carefully balance ventilation with an optimal or adequate cardiac output by shortening inspiratory time and minimizing transpulmonary pressures by using lower tidal volumes.

Breathing and Coughing Maneuvers

If the patient is nonventilated or was recently extubated, breathing and coughing maneuvers in conjunction with moving and body positioning are emphasized to promote ventilation, flow rates, and secretion clearance; decrease minute ventilation and respiratory rate; increase tidal volume; and improve arterial blood gases. Breathing exercises for individuals who breathe with long-time constants (e.g., patients with chronic pulmonary disease) are believed to be most effective

if pursed-lip breathing is performed in conjunction with mechanical pressure applied over the abdomen. To derive the maximum benefits, breathing and coughing maneuvers should be performed in body positions that are most mechanically and physiologically optimal. In addition, they can be performed in the postural drainage positions to augment mucociliary clearance. To avoid airway closure, patients should not breathe below the end of normal tidal ventilation.

Mucociliary Transport and Secretion Clearance

The patient in the ICU needs special attention regarding fluid balance to carefully regulate hydration and fluid volume. Inhaled humidified air is a significant additional source of body fluid. Normally the alveolar gas is saturated with water vapor. The lining of the tracheobronchial tree is therefore protected from erosion and potential infection. This is particularly important in the patient who requires frequent suctioning. The effect of humidification can be assessed by the consistency of the patient's secretions. Thick secretions suggest humidification may be inadequate, and the patient may be dehydrated.

If the effects of mobilization on mucociliary transport and secretion accumulation have been exploited and further secretion clearance is warranted, postural drainage may be indicated. Postural drainage may be contraindicated in patients with unstable vital signs and is usually contraindicated immediately after feedings and meals. In some institutions, however, patients on continuous 24-hour tube feedings are tipped after feeding has been discontinued for 15 minutes. The cuff in the artificial airway is inflated to avoid aspiration. The specific postural drainage positions to be used are determined on the basis of the pathology, radiographs, and clinical examination. The recommended positions for the bronchopulmonary segments involved should be approximated as closely as possible (see Chapter 21) and modified as needed. Frequently, specific positioning in the ICU is compromised as a result of the patient's status, intolerance to lying flat or being tipped, or limitations imposed by the monitoring apparatus or ventilator.

The role of manual techniques has long been questioned because they have been associated with desaturation, atelectasis, musculoskeletal trauma, discomfort, cardiac dysrhythmias, and cardiac arrest.[28] Thus these techniques must be applied rationally, with appropriate monitoring, and modified accordingly. The precise sequence, duration, intensity, and frequency of treatment are based on treatment outcome rather than time. Oxygen demand has been shown to increase with manual airway techniques, and the hemodynamic and metabolic responses have been reported to resemble the response to exercise.[24] The increases in cardiac output and blood pressure are thought to reflect increased sympathetic activity from stress as well as the exercise-like response.[25] The stressful responses to ICU procedures as well as conventional airway clearance procedures have been reported to be effectively modulated with medication.[29] A recent study reported no significant changes in $\dot{V}O_2$ and mean arterial pressure with conventional airway clearance interventions compared with undisturbed side-lying positions.[30] These discrepant findings may reflect differences in the intervention and subjects studied (stable patients who are ventilated). The application of manual techniques in the head-down position is contraindicated in patients with acute myocardial infarction and increased ICP. Relative contraindications include hemorrhage, bronchopulmonary fistula, acute chest trauma, lung abscess, and gastric reflux.[31] Given the adverse effects of manual airway clearance interventions that have been reported, the physical therapist needs to ensure that more physiological alternatives associated with fewer risks have been exploited.

Bagging or Manual Hyperinflation

Although not universally accepted, bagging is practiced to varying degrees in ICUs. The purpose of manually hyperinflating the lungs with a resuscitation bag is to provide extra-large breaths during treatment, to maintain some degree of positive end-expiratory pressure, to assess lung compliance, and to facilitate the effect of instillation of a small volume of saline solution into the tracheobronchial tree to loosen secretions. A self-inflating breathing bag is temporarily connected to the airway. Bagging must be performed cautiously. Aggressive bagging can produce bronchospasm. The lungs are manually inflated for a few breaths. The use of bagging in conjunction with suctioning is controversial. Some clinicians prefer to bag after suctioning to avoid the possibility of the positive pressure pushing the mucus distally. Others maintain that because the mucus adheres to the walls of the airways and because the airways dilate in response to positive pressure, bagging does not propel the mucus distally. Rather, it is believed that bagging before suctioning promotes air entry distal to the mucous plugs and movement of plugs centrally on expiration.

Certain body positions present a particular problem when a pressure-cycled ventilator is being used. The efficiency of the ventilator is greatly reduced when the patient's head is positioned below the hips because of an increase in total pulmonary resistance caused by the pressure of the abdominal contents. Therefore the use of a self-inflating breathing bag may be required to maintain pressure when changing from one position to another and during some postural drainage positions. Adequate tidal volume can be maintained by an assistant while the physical therapist assists the patient with bronchial drainage. With the use of the self-inflating bag, the physical therapist needs to ensure the patient is adequately ventilated and takes a larger than tidal breath every minute or so.

As soon as possible, spontaneous breathing is encouraged in conjunction with postural drainage. The small airways dilate slightly on inspiration and cause mucus to peel away from the walls; thus during expiration, mucus plugs are moved centrally toward the trachea. The degree to which chest wall percussion, shaking, and vibration facilitate this movement has remained equivocal in the literature.[14,28] Thus these less substantiated, less physiological conventional procedures (i.e., manual techniques) should be considered carefully and only after other more supported and physiological treatments have been exploited. Furthermore, because of their documented hemodynamic and adverse effects,[32] it is essential that the patient be continuously monitored for safety reasons and to establish a favorable treatment outcome. For the patient who is unconscious or paralyzed, the ventilator or self-inflating bag can be used to increase inflation volumes. Research is needed to examine the role of bagging in removal of mucus.

Instillation

Instillation is another procedure that should be used selectively in patients. A mucolytic effect of saline has not been well established. Beneficial effects may be more apparent in neonates.

Weaning from the Mechanical Ventilator

Depending on the institution and country, the physical therapist, the respiratory therapist, or both are often responsible for assisting physicians in weaning the patient from mechanical ventilation. Coordinating goals and working with the ICU team to ensure that the weaning process is carried out expediently and with the least risk of weaning complications (e.g., postextubation atelectasis, aspiration, and hypoxemia) are priorities. Expediting weaning is an important ICU goal, as patient outcomes improve with shorter periods of mechanical ventilation.[33] Evidence-based guidelines have been documented.

Weaning can increase cardiovascular and psychological stress, and in turn $\dot{V}O_2$. Patients at particular risk of weaning failure must be identified and monitored by the physical therapist during this process. One study reported that cardiovascular responses to weaning in patients after heart surgery depended on the type of surgery.[34] Cardiac index, for example, was greater after abdominal aortic surgery than after bypass or transplantation surgery. Although the oxygen extraction ratio remained stable after aortic surgery, it increased somewhat after bypass surgery and markedly after transplantation surgery. Weaning patients with cardiac dysfunction from mechanical ventilation can lead to pulmonary edema because of increased venous return and release of catecholamines, reduced left ventricular compliance, compression of the heart by the lungs, and increased left ventricular afterload.

Because of its profound effect on pulmonary function and gas exchange, body position must be optimized for weaning to maximize weaning success and avoid the need for reintubation because of weaning failure. Patients who are overweight warrant particular attention. Low tidal volume and high respiratory rates can jeopardize weaning success. In patients who are obese, a semirecumbent position may favor weaning, compared with a 90-degree upright position, which may cause the abdomen to encroach on the underside of the diaphragm and limit its excursion.[35]

Blood gas analysis and pulmonary function provide the indications for weaning. Ideally the patient's spontaneous tidal volume should approximate that delivered by the ventilator. Forced vital capacity should be two to three times the patient's required tidal volume. Weaning is not usually indicated if the patient requires positive end-expiratory pressure greater than 5 cm H_2O or if F_{IO_2} is greater than 0.4. In addition, patients who are unable to generate a negative inspiratory pressure of −20 mm Hg or greater are unlikely to be able to generate sufficient intrathoracic pressures for deep breathing and airway clearance and thus are poor candidates for weaning. Minute ventilation and maximum voluntary ventilation can be measured at bedside and contribute to the decision regarding whether to wean. Although weaning protocols differ depending on the patient and the ventilatory mode used, general guidelines for this common ICU procedure are outlined in Box 33-8.

Box 33-8 General Steps in Weaning a Patient from the Mechanical Ventilator

1. An individualized weaning schedule is designed for each patient in which periods of time are spent off the ventilator and on a T tube that delivers appropriate oxygen and humidity.
2. The initial time period off the ventilator is carefully selected; mornings are often good times.
3. (a) Physical activity should be at a minimum during this period (e.g., not during or after physical therapy, not after meals, tests, or procedures, and not during family visits). (b) Supplemental oxygen and humidity are given.
4. The physical therapist offers support and reassurance.
5. Monitoring of vital signs and for signs and symptoms of respiratory distress is performed continuously during weaning.
6. The patient is not left unattended in the initial weaning sessions until periods off the ventilator are reliably tolerated well for several successive minutes.
7. (a) Deterioration of vital signs or blood gases and evidence of distress indicate that the patient will have to return to ventilatory assistance imminently. (b) Rest periods of at least an hour are strategically interspersed in the weaning schedule.
8. Blood gas evaluations are performed at regular intervals (e.g., 15, 30, 60, 90, and 120 minutes, or more or less frequently as indicated).
9. If blood gas levels stabilize to within acceptable limits during the weaning period and the patient is generally tolerating the procedure well, the time off the ventilator is increased.
10. Patients with underlying cardiopulmonary disease who are older, malnourished, or obese or who smoke can be expected to take longer to be completely weaned from the ventilator.
11. Weaning is generally faster in patients who have required a shorter period of mechanical ventilation.
12. To hasten the weaning process, synchronized intermittent mandatory ventilation (SIMV) has been reported to be useful in some patients. Others, however, have observed that the use of SIMV tends to fatigue the patient and delay the patient's progress in weaning. Thus SIMV is used cautiously, and individual variability is considered in terms of its effectiveness. Assist-control ventilation is a well-tolerated alternative.

Special Noninvasive Intensive Care Unit Priorities and Considerations

Intubation and mechanical ventilation are usually delayed as long as possible, particularly in individuals with COPD. These individuals have poor blood gas levels in combination with poor CO_2 ventilatory drive. Once mechanically ventilated, the patient tends to deteriorate rapidly, and the risk of failure to wean is increased. Noninvasive mechanical ventilation (see Chapter 44) has been a more recent advance to provide low-risk ventilatory support as a means of avoiding associated risks of invasive ventilation. It is used for patients in whom short-term mechanical ventilation is anticipated.

Discharge from the Intensive Care Unit

Every ICU should have and use admission and discharge criteria. The criteria may differ from ICU to ICU and hospital to hospital. The discharge criteria are likely to be met in situations in which there is no need for mechanical ventilation, airway protection, or invasive hemodynamic monitoring and there is resolution of the medical problems that necessitated the admission.

The physical therapist is responsible for documenting the physical therapy treatment priorities and frequent progress notes during the ICU stay so that the team responsible for the patient after discharge can continue management with reduced risk of disruption of care or regression of the patient's condition. The patient should be informed continually of his or her progress and the plans made by the team and family.[36] The patient should be given as many choices as possible about his or her care and should be actively involved in long-term management planning.

Nonclinical Aspects of the Management of the Patient in the Intensive Care Unit

Teamwork

Comprehensive patient care in the ICU must include a multidisciplinary team. The ICU team usually includes non–health care professionals and health care professionals. The non–health care professionals include the patient, family or immediate support network, case manager, and possibly a spiritual or religious leader. The health care professionals typically include dieticians, nurses and nursing assistants, occupational therapists, physical therapists, physicians, respiratory therapists, social workers, and speech therapists. Teamwork is the essence of maximal patient care and must include the patient and family as much as possible, particularly in the ICU. The physical therapist interacts frequently with other team members, particularly the medical staff, nurses, and respiratory therapists if in the ICU, regarding observations and changes in the patient's condition, medications, mechanical ventilation requirements, treatment goals, and treatment response (see Figure 33-2). In addition to providing therapy for patients and planning for discharge, the physical therapist is often consulted regarding early mobility, ambulation, body positioning, transferring, chair sitting, and self-care.

Nutrition

Patients who are critically ill are hypermetabolic. Metabolic demand and oxygen consumption are increased after surgery and secondary to healing and repair, increased temperature, and altered thermoregulation. Patients with chronic cardiovascular and pulmonary limitation who are admitted to the ICU are often undernourished because of the effort required to purchase, prepare, and consume food. Furthermore, these patients have increased $\dot{V}O_2$ and energy expenditure secondary to the increased work of breathing. Without adequate nutrition, patients incur the effects of deconditioning faster and are debilitated, less capable of responding optimally to therapy, and more susceptible to infection. Intravenous or external hyperalimentation is typically instituted early to maintain optimal nutritional status and avoid excessive physical wasting and deterioration. If a tracheostomy has been performed, the patient is able to eat normally, provided risk of aspiration is minimal.

Regardless of the means by which nutritional support is provided, carbohydrate may be limited because of the increased CO_2 production resulting from its metabolism.

Infection Control

Infection control has become an even greater concern in hospitals and particularly ICUs now that "superbugs" have become prevalent. Superbugs are microorganisms that are resistant to broad-spectrum antibiotics. The prevalence of these microorganisms has been attributed to the fact that many people today, over the course of their lives, have taken antibiotics, which has made them more susceptible to certain microorganisms and less sensitive to antibiotics. In addition, more patients with critical illness are surviving owing to advances in management. Personal hygiene and good hygienic practice on the part of the physical therapist are mandatory because of the inherently high rate of infection in the ICU and compromised immunity of the patients. Patients in the ICU are prone to infection. Meticulous hand washing with an antiseptic detergent between patients is essential. Soaping for 30 seconds or more with a thorough scrubbing motion followed by thorough rinsing should be carried out. After contact with infected wounds, saliva, blood, pus, vomit, urine, or stool, the physical therapist must be particularly conscientious about washing immediately. Physical protection, including gowning, gloving, capping, and masking, is often required, given the concerns regarding infection, and has in fact become routine practice in many ICUs.

There are several levels of infection control, and there may be differences across ICUs in different hospitals. Some patients need to be protected from infection transmitted across patients in the ICU by health care staff—hence the need for meticulous hand washing. Some patients have types of infections from which the health care staff need protection. Often a combination of both types of precautions is indicated. The physical therapist needs to know the different level of infection control and precautions for each patient. In respiratory isolation, the patient remains in an isolated room for treatment. Masking and gloving will be required, and possibly gowning. Depending on the patient's diagnoses, eye protection may also be required. Contact isolation requires maximal infection control by those who come into contact with the patient; however, the patient can leave the room or restricted area according to the hospital's policies.

The Patient as a Person

Although constraints do exist in the high technology environment of the ICU, the patient's dignity is observed as much as possible regardless of the reason for admission, the level of consciousness, or combative behavior directed toward the ICU staff. Gestures such as using the patient's preferred name, explaining aspects of the patient's care, continually orienting the patient regarding person, place, time, and day, and having an interpreter available if necessary are widely practiced. A supportive caring atmosphere is created in which the patient

is free to make choices and ask questions as much as possible. With endotracheal intubation, patients are unable to talk. Communication strategies are assessed to ensure the patient is maximally able to communicate his or her needs and maintain a sense of perceived control. Some strategies include mouthing (silent speech), use of a spelling board, writing, pointing to pictures, and responding with yes and no signs.

Other considerations that must be observed are related to disrobing, modesty, and privacy. These may reflect sex, age, physical image, culture, and individual differences. The patient needs to be asked about his or her comfort level with these and also whether he or she is more comfortable with family present during treatment. Accommodating these individual differences is extremely important if the patient is to be maximally motivated to participate in treatment and adhere to recommendations between treatment sessions.

Patients may be in varying stages of cognitive awareness, from completely comatose to semicomatose to a reduced state of arousal. Patients who are comatose have been reported to have some awareness of their environment and later can recall having been talked about or wanting to communicate and having been unable to do so. In addition, mechanical ventilation is a barrier to communication; thus methods of communicating need to be identified.

The Intensive Care Unit as a Healing Environment

The physical environment of the ICU has a profound effect on the patient's recovery independent of the level of care received. Outside windows with daylight orient the patient to day and night. Other benefits include reduced number and types of complications and reduced length of stay in the ICU and in the hospital overall.[37,38] Also, exposure to daylight may reduce the need for analgesia.[39] Minimizing the sense of social isolation is important, so family is encouraged to be present as much as permitted by the ICU visiting policy. Pet therapy may have some role in the ICU, as it has been shown to have benefits in other care settings.[40] Circadian rhythms are associated with fluctuations in physiological and hormonal functions important to the patient's healing, recovery, and well-being, and these are compromised with bed rest deconditioning. Normalizing circadian rhythms can be achieved by optimizing a sleep schedule with more wakeful periods during the day and reduction of noise at night.[41]

End-of-Life Issues

Palliative care is provided to patients in the ICU with the goal of improving the quality of life of patients and their families facing life-threatening illness. Palliative care treatment focuses on the prevention, assessment, and treatment of pain and other symptoms, as well as the provision of psychological, spiritual, and emotional support. Anticipation of dying and death are traumatic for the patient, family and friends, and the health care team. The phases of dying[42] that can be anticipated when caring for the patient who is at the end of life are presented in Box 33-9.

The psychosocial issues in conjunction with support of the patient's physical status and comfort are priorities.[43] Communicating effectively and being responsive to an individual's dignity and needs are important. Each individual differs with respect to his or her needs, and time must be taken to identify these in an open and honest environment. Touching has a particularly important role in providing support and comfort as the end of life nears.

As the goal shifts from the provision of active treatment to supportive palliative care, the physical therapist needs to adjust treatment accordingly. Comfort and symptom management are the primary goals toward the end of an individual's life. If the patient is able to participate, modified active treatment in conjunction with a high level of support and attention to comfort can be of benefit. As the goals are revised, and if appropriate for the patient, he or she may remain actively engaged in planning and scheduling treatments.

If the patient is unable to cooperate actively with treatment, physical and psychological comfort and symptom management are maximized from a noninvasive perspective to support pharmacological support. Treatments may include relaxation, provision of comfort and human contact, noninvasive pain control strategies, breathing control and coughing maneuvers, and family education.

Box 33-9 Characteristics of the Patient Who Is at the End of Life

- Failure of the peripheral circulation and profuse sweating, causing body cooling
- Loss of strength, motion, and reflexes in the legs and then in the arms
- Decreased sensitivity to touch, deep pressure, and pain tends to remain
- May experience pain, acute loneliness, and fear
- May have increased spiritual needs, particularly at night
- An interval of quiescence just before death
- Can be conscious until death

From Kinney MR, Packa DR: Andreoli's comprehensive cardiac care, *ed 8, St. Louis, Mosby, 1996.*

Principles of Physical Therapy Management

The family and friends of the patient who is dying have special needs that must be considered, and in fact constitute an integral part of the patient's overall care. In general the physical comfort and personal hygiene of the patient, as well as the quality of the immediate psychosocial environment, are paramount concerns. Optimal functional capacity is maintained as much as possible[44] and has been shown to improve even in patients whose course is unstable.[45] Nonetheless, the individual's priorities and needs may change quickly. The physical therapist needs to be flexible to accommodate these fluctuations and sensitive to indications for no intervention. This may be a time for providing support and touching, if the patient wishes. Compassion, understanding, and respect for the patient and the family must be forthcoming from the ICU team as a whole. The ability to be attentive, comforting, and compassionate is an invaluable personal quality that needs to be developed to a high degree in the critical care area. The team members need to attend to how the patient, if

sufficiently alert, is dealing with the possibility of dying and must take their cues from the patient with respect to the role they need to play. If requested by the patient or family, spiritual care leaders are summoned.

If life support systems are being continued, the physical therapist may provide treatment to keep the patient as comfortable as possible. Conservative prophylactic cardiovascular and pulmonary physical therapy may be provided to reduce the work of breathing (body positioning and stress reduction, both of which can minimize oxygen cost). Treatments are kept to a minimum in terms of number and duration if death is inevitable. Range-of-motion exercises and skin care may help to reduce the discomfort of restricted mobility, facilitate nursing management and the basic care of the patient, and prevent complications. Analgesics may be continued along with other medications to reduce pain and suffering and maximize comfort. If so, these are prudently coordinated with treatments, if appropriate. In the presence of life supports the patient's needs may have to be anticipated somewhat more than without life supports because they severely limit communication. The dignity and modesty of the patient continue to be observed even after death.

The patient who has had life supports removed receives the same level of palliative care as the patient with supports. Weakness and wasting may contribute to the fatigue induced by treatment and coughing. Facilitated and supported coughing may help reduce the effort required to cough productively.

One's humanity is one of the most important attributes a health care provider can bring to the care of patients, and this is particularly true in palliative care. The use of human touch and talking (or being silent) may be the most important means of communicating with and providing support to the patient who is dying and may be unable to communicate or disinterested in doing so. Supportive touching and handholding may be even more important to the patient on life support systems, as the supports may be experienced as a physical barrier between the patient and those around him or her.

Summary

Cardiovascular and pulmonary physical therapy in the ICU is a unique subspecialty. Despite the high-tech environment and severity of illness, most people are discharged after their ICU stays, which are highly variable in duration. Management focuses on returning the patient to a premorbid level of function or higher and in the process minimizing morbidity, premature mortality, and length of hospital stay. The general goals of critical care are maximizing function (consistent with the International Classification of Functioning, Disability and Health) and prophylaxis. Specific primary goals are defined by the underlying cardiovascular and pulmonary pathophysiology and multisystem dysfunction and their sequelae. Specific secondary goals are defined by the presence of or the potential for complications including musculoskeletal and neuromuscular dysfunction. Early mobilization that is safe, feasible, and effectively prescribed is essential both for its direct and potent effects of oxygen transport and minimization of complications and as a precursor for transitioning the patient effectively to community living. Strong interprofessional teamwork and an ICU culture that promotes early mobilization can maximize the effectiveness of this intervention. This chapter elaborated on general aspects of managing the physical therapy priorities of patients in the ICU. The knowledge base and experience of physical therapists practicing in the ICU were presented. A broad overview of the objectives of treatment and the rationale for prioritizing treatments according to a physiological hierarchy were described. General clinical and nonclinical aspects of patient management were discussed. Finally, end-of-life issues of relevance to the physical therapist in the ICU were presented.

Review Questions

1. Describe the elements of evidence-based practice in cardiovascular and pulmonary physical therapy.
2. Describe the general goals and principles of cardiovascular and pulmonary physical therapy in the ICU.
3. How do these goals reflect the International Classification of Functioning, Disability and Health (i.e., limitations in participation and activity as well as structure and function)?
4. Explain the role of monitoring in cardiovascular and pulmonary physical therapy of the patient who is critically ill.
5. Describe what is meant by "bringing one's humanity" to the management of people who are critically ill.
6. End-of-life issues are not a concern in only the ICU. What attributes of the physical therapist are especially important in managing an individual at the end of life, irrespective of setting?

This chapter presents the principles of cardiovascular and pulmonary physical therapy in the management of patients who are critically ill with primary cardiovascular and pulmonary dysfunction that can lead to cardiovascular and pulmonary failure. Common conditions seen by physical therapists in the intensive care unit (ICU) that are presented include obstructive lung disease, status asthmaticus, restrictive lung disease, and coronary artery disease (medical and surgical conditions). Each condition is presented in two parts. The related pathophysiology and pertinent aspects of the medical management of each condition are presented as a basis for and in relation to the principles of physical therapy management. These are not mutually exclusive for each category because considerable overlap may exist when conditions coexist. Invasive care and noninvasive care have common goals and thus are complementary. Special considerations for the physical therapy management of patients in the ICU, predominantly for mobilization and body positioning, are highlighted for the conditions described.

The principles of physical therapy management that are described are not treatment prescriptions. Rather, each patient must be assessed and treated individually, taking into consideration all factors that contribute to impaired oxygen transport (i.e., recumbency, restricted mobility, extrinsic factors related to the patient's care, intrinsic factors related to the patient, and the underlying pathophysiology) (see Chapter 2).

Cardiovascular and Pulmonary Failure

Pathophysiology and Medical Management

The heart and lungs work interdependently; thus failure of one organ has implications for the function of the other organ. Insufficiency or failure of the cardiovascular and pulmonary

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

systems refers to the inability of these systems to maintain adequate oxygen and carbon dioxide homeostasis.

Pulmonary failure reflects a gas exchange defect or defect of the ventilatory pump. Table 34-1 shows the classification of pulmonary failure by specific causes and the mechanisms involved. Some common predisposing conditions include primary cardiovascular and pulmonary conditions (e.g., chronic lung disease, overwhelming pneumonia, and myocardial infarction [MI]) and cardiovascular and pulmonary conditions that are secondary to other conditions (e.g., motor neuron diseases, spinal cord injury, stroke, and muscular dystrophy) (see Chapter 35). The oxygen and carbon dioxide tensions that have been used to define failure are variable because they depend on factors such as premorbid status, general health, age, prior blood gas profile, and the time frame for the development of failure. Arterial blood gases and pH are essential in the assessment of cardiovascular and pulmonary failure, which is usually diagnosed when the PaO_2 falls below 50 to 60 mm Hg and the $PaCO_2$ rises above 50 mm Hg.[1]

Primary cardiac failure reflects failure of the myocardium to pump blood to the pulmonary and systemic circulations and maintain adequate tissue perfusion. Significant dysfunction of the left ventricle can lead to pulmonary vascular congestion and cardiogenic pulmonary edema (i.e., congestive heart failure). Conditions affecting the heart that can lead to failure include significant myocardial damage as a result of infarction or myopathy, valvular heart disease, and congenital defects.

Both primary pulmonary and cardiac failure can be classified into acute and chronic stages. The compensation mechanisms that occur in the two stages are distinct. With adequate physiological compensation, patients can tolerate some degree of chronic failure. Patients with a mild degree of failure can live reasonably independent lives. Moderate failure is significantly more limiting; these patients may require home ventilatory support (e.g., supplemental oxygen and nighttime ventilation). Severe failure necessitates hospitalization, mechanical ventilatory support, and supplemental oxygen support.

Obstructive Lung Disease

Pathophysiology and Medical Management

Obstructive lung disease can result in ventilatory failure and admission of the patient to the ICU, or it can complicate management if the patient is admitted for other reasons.[2] If conservative management fails or is unlikely to improve critically impaired oxygen transport and gas exchange and to adequately remove copious and tenacious secretions, intubation and mechanical ventilation are indicated (see Chapter 43). Complicating factors include impaired oxygen delivery, polycythemia, impaired respiratory mechanics secondary to lung damage and increased time constants impairing optimal inhalation and exhalation, flattened hemidiaphragms, rigid barrel-shaped chest wall, increased accessory muscle use and work of breathing, reduced diffusing capacity, impaired mucociliary transport, secretion accumulation, ineffective cough mechanism, increased oxygen consumption, increased work of the heart, and general debility and weakness.

Fig. 34-1 Patient receiving mechanical ventilation.

The goal of intubation and mechanical ventilation is to support breathing by providing an airway and adequate alveolar ventilation and is based on arterial blood gas analysis. A tidal volume and a respiratory rate that provide satisfactory blood gas and pH values are established and maintained unless the clinical condition changes. The precise regulation of mechanical ventilation helps to restore adequate blood gases and cardiovascular and pulmonary function, reduce the work of breathing, rest fatigued ventilatory muscles, and provide an optimal fraction of inspired oxygen (FIO_2) and humidification (Figure 34-1).

Minute ventilation can be seriously impaired with a leak in the mechanical ventilator circuitry. The tubes connecting sites are often the sites of air leakage. Complete disconnection at the endotracheal or tracheostomy connection may inadvertently occur in patients with high pulmonary resistance. Close monitoring of the exhaled tidal volume and end-tidal carbon dioxide will ensure that the patient is receiving sufficient ventilation.

Positive end-expiratory pressure (PEEP) is useful in promoting greater opportunity for gas exchange at end-expiration in mechanically ventilated patients. Venous return, myocardial perfusion, and cardiac output, however, may be impaired during positive-pressure ventilation with PEEP administration.[3] Excessive stimulation to cough in these ventilated patients should be avoided because this accentuates the cardiovascular side effects of PEEP. Continuous positive airway pressure (CPAP) can maintain airway patency during spontaneous ventilation. This mode of ventilation, however, seems to be preferred in children, whereas PEEP is used more commonly in adults.

Interference with the gag reflex in the patient with an endotracheal tube increases the risk of aspiration of the oropharyngeal and gastric contents and can result in pneumonitis and pneumonia. Risk of aspiration from the oropharyngeal cavity can be reduced by suctioning through the airway with the cuff of the airway inflated, in addition to suctioning the oropharynx after suctioning via the airway.

Suctioning can be performed frequently in a patient with an artificial airway and is less traumatic. Patients should be suctioned only as indicated because this procedure can

Table 34-1 Classification of Respiratory Failure by Cause and Mechanism

Origin	Drugs	Metabolic	Neoplasms	Infections	Trauma	Other

produce significant desaturation (up to 60%), particularly in the ventilated patient.[4] Administration of 100% oxygen for 3 minutes before and after suctioning (i.e., hyperoxygenation) minimizes this desaturation effect. This can be accomplished by manual bagging before treatment (i.e., manual hyperventilation) or by presetting of the mechanical ventilator. Risk of aspiration of gastric contents is reduced by the use of a nasogastric tube.

A common cause of acute respiratory failure is advanced chronic airflow limitation.[5] The pathophysiological deficits include significant loss of alveolar tissue, increased compliance of alveolar tissue, hyperinflated chest wall, impaired respiratory mechanics, flattened hemidiaphragms, impaired breathing efficiency, and reduced diffusing capacity. Proportional changes in lung volumes and capacities in patients with chronic airway limitation compared with healthy persons are presented in Figure 9-5. The primary abnormalities are significantly increased residual volume and inspiratory reserve volume and hence total lung capacity. Failure of oxygen transport ensues secondary to ventilation and perfusion mismatch, ventilatory muscle fatigue, reactive pulmonary hypertension, and right ventricular failure. Correcting the complications of respiratory failure, however, is often more problematic than treating the specific cause. Hypoxemia and hypercapnia are often present. Hypoxemia is usually improved with supplemental oxygen in the absence of significant diffusion defect or shunt.

Cardiovascular complications are among the most prevalent observed in ventilatory failure. Marked hypercapnia (increased arterial P_{CO_2}) with acidemia (reduced pH) can produce extreme vasodilatation and hypotension resulting from the local action on blood vessels.[2] Mild hypercapnia can produce reflex vasoconstriction and hypertension. Occasionally, systemic hypertension is observed during weaning from the ventilator with the presence of a moderate degree of hypercapnia.

Right-sided heart failure (formerly called cor pulmonale) is a well-known complication of chronic lung disease and congestive heart failure. Both hypoxia and reduced pH cause pulmonary vasoconstriction and an increase in pulmonary artery pressure. Consequently, reversing bronchospasm, hypoxemia, hypercapnia, and acidemia can often reduce pulmonary vasoconstriction, lower pulmonary artery pressure, and thereby improve hemodynamics.

End-stage respiratory failure results in a progressive increase in airway resistance, work of breathing, oxygen consumption, and carbon dioxide production. In areas of bronchial obstruction, marked alveolar hypoventilation results and ventilation and perfusion are severely mismatched. Hypoxemia and respiratory acidosis produce reactive pulmonary hypertension and further ventilatory failure. Profound carbon dioxide retention, refractory hypoxemia, and respiratory acidemia may terminate in a fatal dysrhythmia.[6]

Acidemia from respiratory causes with a pH of less than 7.25 is often harmful with respect to dysrhythmia production. Conversely, hypoventilation is equally harmful, and pH elevations greater than 7.5 may cause neurological and cardiovascular complications. In acute respiratory failure with profound acidemia, intravenous bicarbonate is used to buffer the hydrogen ion concentration until the underlying disorder has been corrected. Bicarbonate infusion is guided by frequent pH measurements.

Transport of oxygen and carbon dioxide to and from the tissues depends on adequate pulmonary and systemic circulation. Frequently, blood volume has to be restored by fluids or blood replacement or both. Inotropic agents are used to maintain adequate circulation by augmenting myocardial contractility.

Of increasing interest in recent years has been the experience of illness and its contribution to disability. After their first episode of respiratory failure, patients with chronic obstructive pulmonary disease (COPD) report worse cognitive function and overall health status. After several months, however, these conditions may return to levels reported by individuals with similar disease severity who are being conservatively managed and have had no ICU admission.[7] The Nottingham Health Profile and Mini-Mental State Examination can be useful tools for ongoing assessment of perceived health and cognition.

Principles of Physical Therapy Management

The principles of management of acute respiratory failure secondary to an exacerbation of COPD are based on interventions that will enhance oxygen transport (i.e., oxygen delivery, oxygen consumption, and oxygen extraction) and facilitate carbon dioxide removal. Thus the steps of the oxygen transport pathway that have been identified as impaired or threatened by the patient's condition (i.e., restricted mobility, recumbency, and extrinsic and intrinsic factors in addition to the underlying pathophysiology) (see Chapter 2) are the focus of treatment.[8] On the basis of a detailed analysis of these factors, treatments are selected, prioritized, and applied to optimize the steps in the pathway that are affected. These may include treatments to maximize the patency of the airways, increase alveolar ventilation, facilitate mucociliary transport, facilitate airway clearance, optimize the mechanical position of the diaphragm, optimize ventilation and perfusion matching, optimize pH, eliminate carbon dioxide, optimize peripheral circulation and tissue perfusion, and reduce the work of breathing and of the heart. To optimize oxygen transport, the primary goals of physical therapy management include the following:

1. Improve or maintain arterial oxygen tension (Pa_{O_2}) or prevent its deterioration
2. Improve or maintain arterial oxygen saturation (Sa_{O_2}) or prevent its deterioration
3. Improve or maintain arterial carbon dioxide levels (Pa_{CO_2}) and pH or prevent their deterioration
4. Optimize oxygen delivery and oxygen consumption relationship

The means by which these goals are fulfilled depends on each patient's clinical presentation and the specific factors that contribute to cardiovascular and pulmonary dysfunction.

Mobilization: Special Considerations

Mobilization and ambulation are required for normal physiological functioning of the human body (i.e., to stimulate exercise stress and gravitational stress and thereby optimize oxygen transport).[9,10] Although patients in the ICU are encouraged to move, exercise, sit up, stand, sit in chairs, take a few steps, and in some circumstances ambulate across the unit

even if they are ventilated, therapeutic mobilization is prescribed to exploit its acute effects, long-term cumulative effects, and preventive effects (see Chapter 18). These effects are physiologically distinct and need to be prescribed specifically to address each patient's problems. With the monitoring capability in the ICU to ensure safety, patients who are critically ill can move and be moved within safe as well as therapeutic limits.

Given that cardiovascular and pulmonary physical therapy is among those activities that are the most metabolically demanding for patients in the ICU,[11-14] the patient's capacity to meet a given increase in oxygen demand must be determined before treatment. Even though cardiovascular and pulmonary physical therapy stresses the oxygen transport system as a means of improving the function and efficiency of this system, unnecessary or excessive energy expenditure is undesirable and thus should be minimized. Interventions that can minimize oxygen demand include relaxation, judicious body positioning to facilitate oxygen transport, coordination of treatments with other interventions, scheduling of treatments at appropriate times, timing of treatments with medications so the maximal effect is achieved, pain control, and coordination of treatments with peak energy periods and around rest periods.

Mobilization and exercise are at the top of the hierarchy of physiological treatments in the management of patients in the ICU[15-17]; therefore the potent and direct effects of these interventions are exploited first (see Chapter 17). Being moved to (passive) or moving into (active) the upright position promotes improved cardiovascular and pulmonary function and gas exchange. A supported chair should be available beside every ICU bed to provide greater opportunity for the patient to be upright when out of bed. The benefits of the upright sitting position are different from those of sitting propped up in bed. Stretcher chairs are particularly useful for patients who are unable to bear weight (Figure 34-2). There are also beds that are designed to position patients sitting. Even minimal ability of the patient to assist with his or her bed mobility and transferring must be exploited, even if the maneuver takes several minutes and multiple assistants. These minimal efforts must be exploited, or the patient's oxygen transport system will decondition further, which also will reduce the patient's tolerance for being mobilized. What justifies this time and personnel cost is the greater therapeutic outcome that can be expected compared with passive interventions. The ultimate goal is enhanced recovery, reduced discomfort, reduced morbidity and mortality, and reduced ICU and hospital stay.

Significant benefit can be gained from standing the ventilated patient, provided there are no absolute contraindications to being upright in terms of cardiovascular and pulmonary function, neuromuscular and musculoskeletal status, and skin integrity. Ambulating the patient who is ventilated is the priority whenever possible.[18-20] The potential risks, however, must be recognized. In a prospective study, Bailey and colleagues (2007)[21] documented a total of 1449 "activity events" in 103 patients with respiratory failure. These activity events included 233 (16%) instances of sitting on the bed, 454 (31%) instances of sitting in a chair, and 762 (53%) instances of ambulating. In patients with an endotracheal tube, there were 593 activity events reported, of which 249 (42%) were ambulation. Fewer than 1% adverse activity-related events were reported (including fall to the knees without injury, feeding tube removal, systolic blood pressure greater than 200 mm Hg, systolic blood pressure less than 90 mm Hg, and desaturation less than 80%). No patient was extubated during an activity event. Thus activity and mobilization are feasible and safe in patients with respiratory failure. Of note, the majority of survivors (69%) were able to ambulate over 100 feet at discharge from the ICU. These findings have been corroborated by others.[22,23] Mobilization and exercise must be prescribed specifically, however, to ensure that the exercise stimulus is therapeutic (i.e., provides an adequate stressor to the oxygen transport pathway yet is not hazardous).

Fig. 34-2 Intensive care unit patient sitting in a stretcher chair.

Standing and walking even a few steps can be extremely strenuous with respect to oxygen demand for the patient in the ICU. Such activities need to be introduced gradually and with continuous monitoring to ensure that the patient does not exceed the prescribed therapeutic intensity needed to maximize oxygen transport. Standing and walking are coordinated with other aspects of the patient's care and should be carried out in several stages (Figure 34-3). Monitoring of the electrocardiogram (ECG) and arterial saturation of the critically ill patient while he or she performs activities such as standing or walking cannot be overemphasized. In anticipation of an increased workload, ventilatory parameters for ventilated patients may require adjusting. A greater concentration of oxygen should be delivered for at least 3 to 5 minutes before the activity and continued afterward for 10 minutes or so until the patient has recovered from the increased exertion and the heart rate and blood pressure have returned to within 5% to 10% of baseline values.

Fig. 34-3 Intensive care unit patient receiving physical therapy. **A,** Patient is on mechanical ventilation with an oral endotracheal tube. **B,** Patient sitting on the edge of the bed. **C,** Standing at the edge of bed with walker and assistance of two people. **D,** Walking around the bed. **E,** Patient sitting on a bedside chair after physical therapy treatment. Specific safety precautions must be followed at all times to safely mobilize the patient and to prevent accidental extubation.

Active movements have greater therapeutic effect on oxygen transport than assisted or passive movements; thus the benefits of active movements are exploited first. Movement recruiting large muscle groups minimizes the disproportionate hemodynamic stress associated with movement of small muscle groups or movements requiring excessive dynamic stabilization. If active movements cannot be performed or excessively stress the oxygen transport system, then active assisted movements are indicated. A recent randomized controlled clinical trial reported evidence supporting that early exercise training (including use of a bedside ergometer for 20 minutes daily either passively or actively) enhanced the recovery of functional exercise capacity in patients in the ICU, their self-perceived functional status, and their muscle force at hospital discharge.[24]

Passive movements have a role primarily when the patient is paralyzed or so hemodynamically unstable that his or her condition deteriorates with active movement. With respect to cardiovascular and pulmonary benefits, passive movement stimulates changes in ventilatory and circulatory patterns.[25] These can be particularly beneficial in patients who have significant mobility restriction; however, they should not substitute for active and active-assisted movements, which are associated with even greater benefit because they are higher-order activities on the physiologically based treatment hierarchy (see Chapter 17).

A study reported on the use of electrical stimulation in combination with active exercise of the limbs in patients with severe COPD who were mechanically ventilated.[26] Muscle strength was improved, and the number of days to transfer from bed to chair was reduced. The study's design precludes electrical stimulation as being superior to extended active exercise and progressive mobilization to the chair and ambulation. Another recent study demonstrated that electrical stimulation is well tolerated and seems to preserve the muscle mass of critically ill patients.[27] The use of electrical stimulation as a preventive and rehabilitative tool in patients in the ICU with polyneuromyopathies, however, needs to be further investigated and should not replace mobilization. Deep sedation and bed rest are common in the routine medical care for many mechanically ventilated patients[20] and need to be reconsidered in light of rehabilitation initiatives to prevent iatrogenic effects of care and to maximize short- and long-term functional outcomes.

Body Positioning: Special Considerations

Body positioning is a potent therapeutic intervention that promotes optimal oxygen transport and gas exchange in two ways: one, from the physiological benefits accrued from the specific positions themselves, and two, from the physiological benefits accrued from physically changing from one position to another (see Chapter 20). Body position can be used preferentially to augment alveolar volume, alveolar ventilation, ventilation and perfusion matching, respiratory mechanics, cough effectiveness, central and peripheral hemodynamics and fluid shifts, mucociliary transport, and secretion clearance (see Chapter 20). Both ventilation and perfusion are enhanced in the inferior lung fields. Therefore in postural drainage positions the superior lung being treated is neither preferentially ventilated nor perfused. The less-affected lung fields therefore may be contributing more substantially to improving arterial gases. Hence the physical therapist must consider the goals of treatment with respect to pulmonary function in both the involved and less-involved lung fields. During postural drainage, the length of time in a given position needs to be monitored to avoid drainage of secretions into the less-involved, functional, inferior lung fields and to avoid the possibility of compression atelectasis in the inferior lung.

Although positions can be predicted that will optimize ventilation and perfusion matching, each patient will respond differently, depending on such factors as pathology, age, weight, depth of breathing, and mechanical ventilation.[28,29] Therefore the patient's response to specific positioning must be observed, documented, and objectively monitored with respect to the effect on oxygen transport variables.

Another important goal of body positioning is to potentiate position-dependent fluid shifts to optimize cardiovascular function. For this reason the patient should be positioned upright as often as possible commensurate with tolerance and hemodynamic stability. There are other beneficial effects of the upright position on pulmonary function (e.g., maximize lung volumes and capacities, minimize alveolar collapse, decrease airway resistance, increase lung compliance and thereby reduce ventilator system pressure). To maximize the effect of gravity on promoting fluid shifts, the legs should be positioned dependently at frequent intervals. In a patient who is not self-supporting with or without assistance, fluid shifts can be stimulated with a high Fowler position coupled with the use of the bed knee-break. Between sessions of therapeutic body positioning, a schedule of four-point turning (supine, left side, prone, right side) is ideal and should be attempted even in the ventilated patient if not strictly contraindicated.[30]

Extreme 360-degree body position changes (e.g., randomized positioning in supine, prone, right and left side-lying) have been reported to have beneficial effects on oxygen transport in patients with acute respiratory failure.[31] The head-down position has been shown to reduce respiratory distress in some patients with obstructive lung disease.[32] The abdominal viscera are displaced cephalad, thereby elevating the typically flattened hemidiaphragms and placing them in a mechanically advantageous position. This effect may be mimicked in other body positions by manual abdominal compression and abdominal binders. In some patients, however, the additional load imposed by the increased intraabdominal pressure on the underside of the diaphragm may inadvertently increase the work of breathing and increase respiratory distress. The prone position has been reported to be beneficial in patients with hypoxemia and acute respiratory failure.[33-35] A variant of the prone position, semiprone, may be more beneficial in some patients by reducing intraabdominal pressure. In addition, the semiprone position may be safer and more comfortable for the mechanically ventilated patient. The prescription of any body positioning must be based on its anticipated benefits on oxygen transport. The more extreme positions should be introduced in progressive stages and the patient's response monitored to ensure the response is favorable.

Time alone is an inadequate parameter for prescribing the duration a patient should remain in one position. Adverse responses including discomfort should serve as guides in addition to the therapeutic goals. Although patients tend to be

turned every 2 hours or less across ICUs, there is considerable variability with respect to this practice.[36] Positioning is a clinically important evidence-based intervention for maximizing oxygen transport and minimizing multisystemic complications when a patient is unable to be mobilized or between mobilization episodes.

Status Asthmaticus

Pathophysiology and Medical Management

Status asthmaticus is a potentially life-threatening situation. The pathophysiological features include marked airway resistance secondary to bronchospasm, edema, and mucous secretion and retention. The work of breathing is markedly increased, resulting in respiratory distress. A cycle results in which the patient becomes more hypoxemic and hypercapnic secondary to alveolar hypoventilation, bronchospasm increases, and reactive pulmonary hypertension may ensue, along with a further increase in the work of breathing and anxiety.

The classic signs and symptoms of a severe asthmatic attack that may progress to status asthmaticus include tachypnea, dyspnea, labored breathing, audible wheezing, tachycardia, cyanosis, anxiety, and panic. If the patient is able to cooperate with spirometric testing, the degree of reduced vital capacity, peak flow, and forced expiratory volume provide indices of the severity of airway obstruction.

Medical management is aimed at administering drugs and fluids to reduce hypoxemia with oxygen, decrease airway inflammation and resistance, and hence reduce the work of breathing and anxiety. Intravenous sodium bicarbonate helps to reverse respiratory acidosis and possibly metabolic acidosis.[5]

Principles of Physical Therapy Management

The prime objective of physical therapy is to optimize oxygen transport and avoid or delay the need for mechanical ventilation. Physical therapy can augment the medical management of the patient with status asthmaticus. In an attempt to avert intubation and mechanical ventilation the physical therapist coordinates treatment with the patient's medications (i.e., bronchodilators, muscle relaxants, steroids, and supplemental oxygen). The physical therapist promotes breathing control, enhances ventilation and perfusion matching, promotes mucociliary transport and secretion clearance, reduces hypoxemia, and teaches the patient to coordinate relaxed breathing with general body movement. Caution needs to be observed to avoid stimuli that potentiate bronchospasm and deterioration of the patient's condition (e.g., body positions that increase respiratory distress rather than relieve it, chest wall percussion, forced expiration maneuvers, aggressive bagging, and possibly instillation). Attention to relaxation and reduction of excessive oxygen demands is a priority, as was described for the patient with chronic airflow limitation. Certain body positions may have to be avoided (e.g., because of the patient's intolerance and exacerbation of symptoms in those positions). Because of the altered pulmonary function in different positions, positioning (especially in patients in respiratory distress) must be applied cautiously within the patient's tolerance. Body positions that reduce respiratory distress and the work of breathing and maximize alveolar ventilation, oxygen saturation, and blood gases are the positions of choice.

Major problems in status asthmaticus are alveolar hypoventilation, airway obstruction secondary to bronchospasm, mucosal edema, and secretions. Therefore maximizing alveolar ventilation and facilitating mucociliary transport are priorities. Other problems include significantly increased work of breathing because of an inefficient breathing pattern and an ineffective cough. Obtaining a productive cough without augmenting bronchospasm is a challenge. Deep breathing with pursed-lip expiration helps to prolong expiration and maintain the patency of the small airways. Deep, slow, and relaxed breathing is emphasized, along with periodic effective, controlled huffing, and avoidance of forced expiratory maneuvers.[37]

Despite aggressive noninvasive management, blood gases may deteriorate and mechanical ventilation may be inevitable. Relaxation, maximizing alveolar ventilation, and reducing airway collapse and obstruction continue to be the primary goals; however, the means of achieving these goals differ when the patient is mechanically ventilated. Optimal prescriptive body positioning is the intervention of choice. Secretion clearance is achieved by judicious suctioning. Suctioning is performed as required because it can contribute to reduced oxygenation, airway collapse, atelectasis, increased arousal, increased work of breathing, and generally increased respiratory distress. Once the patient is medically stable, a progressive mobilization program is initiated to prevent the side effects of bed rest as well as augment oxygen transport.

Restrictive Lung Disease

Pathophysiology and Medical Management

Acute respiratory failure can be associated with primary restrictive lung disease (i.e., interstitial pulmonary fibrosis). This is distinct from restrictive defects secondary to neuromuscular and musculoskeletal diseases (e.g., Guillain-Barré syndrome, myasthenia gravis, and neuromuscular poisonings are common neuromuscular disorders that can precipitate respiratory failure in the absence of underlying primary lung disease) (see Chapter 35).

Restrictive lung dysfunction may complicate the management of patients admitted to the ICU for reasons other than cardiovascular and pulmonary disease. The lung parenchyma, the chest wall, or both may be involved. The underlying cause of respiratory failure may therefore reflect ventilatory pump failure, gas exchange failure, or both. The specific restrictions to cardiovascular and pulmonary function need to be identified and treated individually to optimize treatment. Obstructive and restrictive patterns of cardiovascular and pulmonary function frequently coexist; thus the contribution of both types of defects to a patient's oxygen transport must be determined. Typically in restrictive lung disease, all lung volumes and capacities are reduced, although tidal volume can be relatively normal (see Figure 9-5). Patients with severe interstitial

pulmonary fibrosis have increased pulmonary artery pressures with an associated increase in right ventricular work. These patients are at high risk of desaturating with minimal activity.

Principles of Physical Therapy Management

Restrictive ventilatory dysfunction is commonly associated with both medical and surgical conditions. The principles of management of acute respiratory failure associated with these differ in that medical conditions are associated with underlying irreversible lung damage, whereas in the surgical patient the pulmonary restriction is reversible. The natural course of disease in the medical patient will be determined in part by the patient's premorbid status. The majority of surgical patients, however, will have had normal lung function before surgery and the development of cardiovascular and pulmonary complications (see Chapter 30). Regardless of whether mechanical ventilation is indicated, tissue oxygenation, carbon dioxide removal, regulation of blood pH, and an effective cardiac output are priorities. Supplemental oxygen is often effective in improving tissue oxygenation in conditions associated with restrictive lung disease in the absence of a right-to-left shunt. In the presence of shunt, supplemental oxygen does not reverse hypoxemia.

A judicious turning regimen can also be designed to optimize cardiovascular and pulmonary function (even if the patient is mechanically ventilated), reduce risks of cardiovascular and pulmonary complications, reduce musculoskeletal deformities and skin breakdown, and promote comfort. It is essential with body positioning for any purpose that the patient not be confined unnecessarily and not assume any position for too long. Although lines, leads, monitoring devices, and catheters may be required, these are anchored as securely as possible with sufficient length to allow the patient to move spontaneously, be mobilized as much as possible, undergo as many positioning changes as possible, and facilitate routine patient care.

Mobilization and general body movement, particularly in upright positions, are always priorities in the ICU, as much and as often as possible given the patient's condition and safety considerations. Owing to the possibility of activity-induced desaturation, an appropriate plan of care for oxygen titration during physical therapy interventions should be established in coordination with the ICU team. Movements may be totally assisted but more often are likely to be active-assisted and active. No matter how weak the patient may be, active-assisted and active movements are the mainstay of the movement interventions performed by the physical therapist, particularly if these can be performed in near-upright positions. Assisted or passive movements should not be performed unless specifically indicated (i.e., the patient is unable to execute these movements completely alone). Even modest attempts at active-assisted movements, with perhaps only a minimal number of repetitions, benefit the patient considerably more, in terms of treatment goals related to both cardiovascular and pulmonary and musculoskeletal function, than assisted movements that do not contribute to muscle strength, endurance, and coordination. Injudicious application of totally assisted movements will contribute to the patient's deconditioning and physical deterioration. Regardless of the type of mobilization, the patient is observed closely for arterial desaturation, discomfort, respiratory distress, cyanosis, fatigue, and extent of cooperation if assisted-active and active movements are being performed.

Assisted movements are indicated to promote oxygen transport via their effects on ventilatory and circulatory patterns.[25] In addition the goal is to maintain joint range of motion and prevent adaptive shortening of periarticular soft tissue in particular. Care must therefore be taken to perform these movements through the complete range of movement for each joint, with special attention to rotary components of joint movement. Lax joints can maintain range with one complete range of motion daily. Lax joints are unprotected and vulnerable to excessive strain. Protection may best be effected in these joints by moving the joint more slowly through the extremes of joint range and just short of complete range. In the presence of spasticity or limb splinting because of discomfort, the involved joints will benefit from two or more excursions through full range daily.

One approach that may be particularly beneficial in altering the distribution of ventilation and blood flow is use of general body and range-of-motion exercises, particularly of the upper limbs. If the patient is able to assist, however, greater cardiovascular and pulmonary stress occurs with upper limb exercise; thus heart rate, ECG, and blood pressure must be monitored. Lower-extremity movements, such as hip and knee flexion, may help to position the diaphragm for improved excursion. Lower-extremity movements will also increase venous return, which may or may not be desirable, depending on the patient. The goals of upper- or lower-extremity work must therefore be clearly defined. Possible benefits and untoward effects must be identified to ensure that the patient benefits optimally from the prescribed exercise.

The treatment of choice in all patients is to simulate conditions that maintain optimal oxygen transport in health or approximate those conditions as closely as possible. That is, the most physiological interventions are exploited first and the least physiological interventions are exploited last or when more physiological interventions are not possible. Physiological interventions such as mobilization may be contraindicated in patients whose oxygen delivery is too low. Without some reserve capacity in oxygen transport, the patient cannot sustain the additional metabolic load that mobilization imposes. Patients whose condition is this critical are often put on neuromuscular blocking agents to reduce muscle tone and thereby reduce oxygen demand. Because these patients are in induced paralytic states, mobilization is not possible. In such cases, optimizing oxygen transport using body positioning and then nonphysiological interventions may be considered. Extreme caution must be observed when positioning these patients and moving their limbs because they are at risk of joint subluxation, strains, bruising, and pressure sores.

Interventions to promote mucociliary transport and secretion clearance are applicable to all situations in which secretions, mucosal edema, bronchospasm, or a combination of these factors is present. If postural drainage is indicated to further facilitate mucociliary transport and secretion clearance, caution needs to be exercised to avoid inducing bronchospasm and hypoxemia; thus the use of percussion should be considered carefully.

Myocardial Infarction

Pathophysiology and Medical Management

The initial priority of management in the acute phase of MI is the correction of the immediate problems including dysrhythmias, myocardial insufficiency, reduced cardiac output, hypoxemia, chest pain, and anxiety, followed by implementation of a progressive rehabilitation program ranging from the acute medically stable phase to the postdischarge rehabilitation phase.[38,39] On admission to the coronary care unit or medical ICU, continuous monitoring of the heart rate and rhythm is established. An intravenous line is routinely started for the administration of medications and fluids. An arterial line may be started for serial blood sampling for blood gases and enzyme measures. Initially pain medications, coronary vasodilators, and diuretics are frequently used to minimize the work of the heart, anginal pain, and discomfort. Drugs such as morphine serve to depress the respiratory drive; thus the physical therapist must be aware of corresponding changes in vital signs. Less-potent sedatives and tranquilizers are more routinely prescribed. Increased pain and anxiety potentially worsen the patient's cardiac status by increasing myocardial oxygen demand and altering normal breathing pattern and gas exchange.

The primary purpose of oxygen administration to the cardiac patient is to reduce hypoxemia, myocardial work, and angina. Dyspnea, however, is commonly observed in the initial phases of MI and can be effectively controlled by supplemental oxygen administered by nasal cannula or mask. Oxygen may also correct potential ventilation-perfusion mismatching and hypoxemia. Oxygen is always administered with humidity to avoid drying the airways.

Blood gas analysis is performed within an hour of initiating oxygen therapy to establish a baseline of arterial saturation. In this way the oxygen dose can be altered to regulate blood gases and acid-base balance.

Myocardial Infarction Conservatively Managed

Principles of Physical Therapy Management

A primary principle of the management of the patient after MI is to reduce myocardial oxygen demand and workload. The myocardium needs rest for optimal healing. Judicious rest of the myocardium is a priority that can often be balanced with gentle rhythmic, nonstatic movements. Box 34-1 illustrates several ways of reducing myocardial workload in patients with cardiovascular and pulmonary conditions.

Physical therapists need to work closely with the interprofessional team members in the ICU to provide safe and effective therapeutic interventions. The physical therapist should also be watchful at all times for signs of impending or silent infarction, including generalized or localized pain anywhere over the thorax, upper limbs, and neck, palpitations, dyspnea, lightheadedness, syncope, sensation of indigestion, hiccups, and nausea.

Box 34-1 Means of Reducing Myocardial Workload in Patients with Cardiopulmonary Dysfunction

- Provide a quiet environment without excessive noise and stimulation.
- Prescribe low-intensity activity until medical stability has been maintained and patient shows signs of physical improvement.
- Begin progressive mobilization in conjunction with patient's medical status, electrocardiographic stability, and unchanging or resolving enzyme levels.
- Reduce patient's anxiety about his or her condition, self-care activities, and family and work responsibilities.
- In general, begin gentle mobilization exercises, deep breathing, and coughing immediately as prophylactic measures unless, as frequently is the case in coronary patients, crepitations are audible in the bases of the lungs; treatments need to minimize pulmonary congestion and cardiac stress.
- Promote relaxation with low-intensity activity.
- All levels of activity, including breathing exercises, are to be performed in a coordinated, rhythmic manner.
- Breath holding, Valsalva maneuvers, and intense isometric muscle contractions (i.e., isometric exercise and exercise involving significant muscle or postural stabilization) are contraindicated during all activities in patients with coronary artery disease and should not be performed.

Depending on the degree of MI and damage, varying lengths of modified mobility may be recommended.[38] Shorter initial periods of restricted mobility are safe and promote faster functional recovery.[40] During this period the physical therapist concentrates on rhythmic breathing exercises, gentle coughing exercises or huffing, and modified positioning with the bed head elevated at least 30 degrees to facilitate the gravity-dependent mechanical action of the heart and thereby reduce myocardial oxygen demand. Intermittent exposure to orthostatic stress by imposing the upright position is recommended for patients after acute MI.[41] The patient is encouraged to perform deep breathing and coughing every hour during the day. Bed exercises including rhythmic, unresisted hip, knee, foot, and ankle exercises are usually performed as frequently as possible by the patient or when the patient turns in bed. The patient is cautioned to exercise one leg at a time, sliding one heel up and down the bed and guarding against lifting the leg off the bed. These exercises, when performed correctly and coordinated with inspiration and expiration, require relatively little effort from and induce little additional physical stress on the individual with MI. Comparable with the management of the postoperative patient, these exercises are performed prophylactically to reduce the risk of venous stasis and formation of thromboemboli. In addition, they may help to regulate more coordinated breathing, encourage deep breaths and mucociliary transport, and reduce atelectasis. The patient is cautioned against performing the Valsalva maneuver and straining because these activities increase intrathoracic pressure and reduce cardiac output.

Electrocardiographic monitoring of the patient with cardiac disease is the responsibility of all members of the health care team involved in the patient's care. The physical therapist has

a special responsibility to be proficient in ECG interpretation in the coronary care unit because physical therapy is one of the most metabolically demanding interventions for patients.[11,14] The physical therapist often has the responsibility of initiating new activities with the cardiac patient, which might include sitting over the edge of the bed, engaging in self-care (particularly involving the arms being maintained in a raised position), getting in and out of bed, sitting in a chair, going to the bathroom, walking around the room or in the hallways, and eventually exercising on the treadmill or ergometer. Changes in the ECG must be watched for, particularly in introducing new activities and increasing the intensity of workload in activities. Careful attention to ECG changes and serum enzyme levels will contribute to enhanced physical therapy care of the acute MI patient by optimizing the treatments prescribed and the margin of safety with which activities are performed.

Congestive heart failure may be unavoidable in cases of severe infarction or even milder infarction coupled with lung disease. Fluid intake and output and daily weight measurements promote early detection of congestive heart failure. Signs of imminent and established congestive heart failure are listed in Box 34-2. The work of the heart can be significantly reduced in the upright position.[42]

Patients with cardiac conditions are prone to anxiety about their conditions and prognoses. The patient is given realistic guidelines at each stage of recovery with respect to the level of activity that can be safely performed, which can potentially avert deterioration and promote recovery. Involving the patient in rehabilitation planning from the outset facilitates the patient's planning realistically for the future and may help to reduce the depression often experienced by the acute MI patient.

The initial rehabilitation program is planned with the long-range rehabilitation goals in mind. The program designed for the cardiac patient is progressive in terms of types of activities, usually beginning with activities of daily living, and with respect to the intensity, duration, and frequency of these activities.[39] The patient's tolerance and changes in ECG and vital signs are used as indicators for establishing and modifying the treatment program. These physiological parameters must be observed carefully as the patient progresses to optimize the potential benefits of the therapeutic regimens as early as possible without endangering the patient.

Patient education and prevention of infarction are particularly important for the cardiac patient. As soon as the patient is alert and able to cooperate, information about his or her condition with guidelines about activity, diet, and stress management is reinforced. The more involved and informed the patient is in self-management, the greater the likelihood of receptivity and adherence to a rehabilitation regimen after discharge.

Box 34-2 Signs of Imminent Congestive Heart Failure

- Development of tachydysrhythmias
- Development of a ventricular gallop
- Pulmonary crackles and other persistent adventitiae
- Development of dyspnea
- Development of increased jugular venous pressure and distension

Open Heart Surgery

Principles of Physical Therapy Management

Patients scheduled for open heart surgery are considered moderately risky surgical candidates because of the nature and invasiveness of this type of surgery (Figure 34-4), regardless of their general level of health before surgery. Whenever possible, patients prepare for surgery in advance by decreasing or stopping smoking, by avoiding exposure to respiratory tract infections, by avoiding stress, by eating a balanced diet, and by getting adequate sleep. Patients can benefit from a modified, prescriptive exercise program before surgery to maximize their aerobic capacity and thereby improve their perioperative course.

Preoperative teaching coupled with a conditioning program before hospitalization has a role in reducing hospital stay and complications (see Chapters 18, 29, and 30). During the preoperative period the physical therapist may spend additional time with patients scheduled for open heart surgery to provide teaching of the basic anatomy and physiology related to the surgery to be performed; the effect of anesthesia; the role of intubation and mechanical ventilation; the incision lines to be expected over the chest, and the legs if veins are to be removed for bypass surgery; the lines, leads, chest tubes, and catheters that will be in place after surgery; interventions beginning during the postanesthesia and recovery period (breathing control and coughing maneuvers, body positioning, foot and ankle exercises, and early mobilization); and the course of recovery the patient might expect, barring complications (see Chapter 17). The emphasis on patient education in most open heart surgery units may contribute to the generally low incidence of complications and mortality.

Some special considerations in physical therapy management of the patient after open heart surgery appear in

Fig. 34-4 Patient after open heart surgery. Note mechanical ventilator, mediastinal drains and chest tubes, intraaortic balloon pump, and multiple intravenous drips.

Table 34-2 and these expand on the concurrent medical course of patients in phase I cardiac rehabilitation (see Chapter 31). Patients are extubated early, and rehabilitation is commenced as soon as possible.[43] These guidelines are to be applied thoughtfully and cautiously with regard to each specific patient's condition and observed recovery. Intermittent orthostatic stress and exercise stress are encouraged.[41] These guidelines suggest the upper limit of intensity of physical therapy, which should be applied if all is progressing well initially and reduced if warranted by the patient's condition. Progression from one stage to the next is based on an optimal and reliable treatment response at each level before

Table 34-2 Stages of and Guidelines for Physical Therapy for the Patient after Open Heart Surgery

Stage 1	Postanesthesia and recovery is where the patient is hemodynamically stabilized. The patient may be seen in the postanesthesia and recovery room for a physical therapy assessment; the patient is usually extubated within 24 hours after surgery. Although the patient must be permitted to rest as much as possible in the initial 24-hour period, judicious body positioning is instituted to stimulate physiological "stir-up." Usually, once extubated, the patient is positioned side to side for deep breathing and coughing at least four times in the first 24 hours, is progressively positioned in the upright position, and low-intensity mobilization is initiated. Medications are administered before treatment to ensure optimal effect during treatment. Depending on the findings of radiography, physical examination, and arterial blood gases, the patient may require vibrations and possibly percussion. If postural drainage is indicated, positions are modified to avoid tipping the patient head-down and causing increased myocardial strain. A sputum sample for culture and sensitivity testing may be taken at this time. The patient can usually tolerate being dangled over the edge of the bed for a few minutes. Special care is taken for all heart patients to avoid the Valsalva maneuver, forced coughing, and huffing and to maintain a semirecumbent or upright position for treatment. Blood pressure is checked before, during, and after treatment. Mobilization is progressed.
Stage 2	Deep breathing and coughing maneuvers coupled with mobilization are continued. Positioning for enhanced alveolar ventilation and ventilation and perfusion matching may be indicated. If secretion accumulation is a problem and the patient is too unstable to be optimally mobilized or positioned, postural drainage and possibly percussion and/or vibration may be indicated. Upper limb and neck exercises are introduced. Neck exercises are withheld if central venous pressure lines are still in place in the neck veins. The patient can sit in a chair at bedside as tolerated. The patient is encouraged to stand erect for a minute or so on transferring back and forth to the chair.
Stage 3	The patient takes short walks as tolerated. Ambulation is usually commenced after the arterial lines and the Swan-Ganz catheter have been capped or removed, respectively (policies may differ across ICUs). Vital signs are monitored before and after standing and walking. Deep breathing and coughing maneuvers are continued even if the chest is clear, until the patient is up and about within reasonable limits as tolerated. The patient is encouraged in grooming and self-care.
Stage 4	Deep breathing and coughing should be done by the patient without supervision. The presence of atelectasis on radiograph or from assessment findings, however, would indicate the need for continuation of mobilization and body positioning with breathing exercises. Ambulation is increased as tolerated.*
Stage 5	The patient can participate in individual or class activities, concentrating on trunk mobility, range of motion, coordinated breathing activities, posture, biomechanics, and gradually increasing endurance.
Stage 6	The patient can attempt six to eight stairs if progress has been satisfactory and as indicated. Aortic repairs in the first week or so are prone to rupture. Elevation of the blood pressure is therefore avoided to reduce the risk of breakdown of the aortic suture line. Vital signs are always monitored.
Stage 7	The patient depends primarily on ambulation for maintaining optimal alveolar ventilation and mucociliary transport rather than breathing and coughing exercises. The patient is cautioned to balance a period of exertion with a period of rest. The patient may be discharged. The physical therapist ensures that the patient fully understands the specific details of the home exercise program. The emphasis of exercise for cardiac patients continues to be on rhythmic, coordinated dynamic movements on discharge, avoiding isometric, static exercise, in conjunction with breathing control. Precautions are reinforced with respect to avoiding stress to the incision, and this includes postponing driving for several weeks. If possible, the patient is invited to participate in a reconditioning and health promotion program as an outpatient in a physical therapy department. Follow-up medical and physical therapy visits are arranged before discharge for 4 to 6 weeks after surgery.

*The physical therapist must guard against excessively intense treatment of post–open heart surgery patients as well as other patients receiving prophylactic anticoagulants.

proceeding. Different institutions may advocate different practices, depending on their facilities, the experience of the surgical and ICU team, and the incidence of postoperative complications and survival for that institution.

The physical therapist must guard against excessively intense treatment of both patients after open heart surgery and patients for whom periods of relatively restricted mobility are anticipated. In addition to the fact that these patients may be hemodynamically unstable initially, they may be susceptible to soft tissue bruising from being on a prophylactic course of anticoagulants.

Patients are monitored for complications (see Chapters 16 and 36) and to guide treatment progression and detect untoward responses to treatment. After cardiac surgery, $\dot{V}O_2$ tends to increase owing to increased cardiac output and oxygen delivery.[44] The oxygen extraction ratio may increase and $S\bar{v}O_2$ decrease if cardiac function deteriorates.

Depression has been reported in patients in the ICU, particularly in those admitted for coronary care who are experiencing a physiological loss.[45] Signs and symptoms of depression warrant monitoring and reporting to the team to maximize clinical and psychosocial outcomes.

Complications do occur in high-risk ICU settings. Risk assessment is a fundamental component of the assessment (see Chapter 17). Common complications often related to premorbid status include restricted mobility, inability to wean from mechanical ventilation, deep vein thrombosis, pulmonary emboli, and stroke. Other complications are related to surgery (e.g., internal bleeding, overwhelming pneumonia, and lung collapse) or medication reaction. Complications are better managed if anticipated and detected early. Depending on the nature of the complication, physical therapy interventions may be stepped up in terms of intensity, duration, and frequency; modified; or discontinued until the patient is cleared with respect to stability.

Physical therapy follow-up should continue for several months beyond discharge, at which point the patient should be well integrated into a cardiac rehabilitation program. Continuity and continuation of physical therapy throughout the entire rehabilitation period, from the acute period to long term, cannot be overemphasized, given that achieving maximal recovery from surgery is the priority.

Summary

This chapter described the principles of cardiovascular and pulmonary physical therapy in the management of critically ill patients with primary cardiovascular and pulmonary dysfunction. Cardiovascular and pulmonary failure secondary to chronic lung disease and heart disease were described. Cardiovascular and pulmonary physical therapy management is based on the specific underlying pathophysiological mechanisms of these various disorders. These principles, however, cannot be interpreted to be guidelines for specific treatment because each patient is an individual whose condition reflects multiple factors contributing to impaired cardiovascular and pulmonary function or threatening to cause it (i.e., the effects of recumbency, restricted mobility, extrinsic factors related to the patient's care, and intrinsic factors related to the patient in addition to the underlying pathophysiology). Special considerations with respect to body positioning and mobilizing patients with primary cardiovascular and pulmonary dysfunction are described.

Review Questions

1. With respect to the management of patients in the ICU with conditions associated with primary cardiovascular and pulmonary dysfunction (e.g., cardiovascular and pulmonary failure, obstructive lung disease, status asthmaticus, restrictive lung disease, and coronary artery disease), describe the pathophysiology of primary cardiovascular and pulmonary dysfunction or threats associated with each condition and how these threaten life.
2. Relate cardiovascular and pulmonary physical therapy treatment interventions to the underlying pathophysiology of each of the conditions listed in question 1 in the individual who is critically ill, and provide the rationale for your choice.
3. Identify special considerations with respect to positioning and mobilizing a patient with each condition.

This chapter describes the principles and practice of cardiovascular and pulmonary physical therapy in the management of cardiovascular and pulmonary dysfunction secondary to other conditions that can lead to cardiovascular and pulmonary failure. Some common categories of conditions described include neuromuscular disease, morbid obesity, musculoskeletal trauma, head injury, spinal cord injury, and burns. Each category of condition is presented in two parts. The related pathophysiology and pertinent aspects of the medical management of the condition are presented in relation to the principles of physical therapy management. Invasive care and noninvasive care have common goals and thus are complementary. The principles presented are not treatment prescriptions. Each patient must be assessed and treated individually, taking into consideration the contribution of recumbency, restricted mobility, extrinsic factors related to the patient's care, and intrinsic factors related to the individual patient (see Chapter 17) in addition to the underlying pathophysiology. Special considerations related to physical therapy intervention such as body positioning and mobilization for cardiovascular and pulmonary failure secondary to other conditions are emphasized.

Neuromuscular Conditions

Pathophysiology and Medical Management

Amyolateral sclerosis, Guillain-Barré syndrome, myasthenia gravis, muscular dystrophy, multiple sclerosis, stroke, poliomyelitis, and neuromuscular poisonings are common neuromuscular disorders that can precipitate respiratory failure in the absence of underlying primary heart and lung disease. If paralyzed, the patient will likely be dependent on ventilatory assistance. Noninvasive mechanical ventilation has been an important advance in prolonging the lives of individuals with these serious progressive conditions. As respiratory failure

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

becomes imminent, however, invasive mechanical ventilation is warranted.

Cardiovascular and pulmonary physical therapy has a central role in minimizing the need for mechanical ventilation in these patients because their prognosis for weaning is poor. Progressive respiratory insufficiency is best addressed early with the institution of nighttime ventilation at home before the development of failure and necessity for hospitalization. Patients with progressive neuromuscular conditions (e.g., muscular dystrophy) are living longer; thus cardiovascular and pulmonary insufficiency will be compounded by age-related changes of the cardiovascular and pulmonary system.[1,2]

Neuromuscular conditions contribute to cardiovascular and pulmonary dysfunction in numerous ways (see Chapters 6, 22, and 23).[3] With progressive deterioration of inspiratory and expiratory muscle strength and endurance, respiratory insufficiency and failure can ensue. Depending on the specific pathology, such deficits include reduced lung volumes and flow rates, reduced alveolar ventilation, increased airway resistance, ventilation and perfusion mismatch, impaired mucociliary transport, accumulation of mucus, reduced cough and gag reflexes, relatively unprotected airway secondary to impaired glottic closure and weakness of the pharyngeal and laryngeal structures, and increased work of breathing.

Iatrogenic effects of medications can confound muscle weakness. Muscle relaxants and corticosteroids are used commonly in the intensive care unit (ICU) and can lead to muscle weakness. The clinical diagnosis of ICU-acquired weakness is achieved by clinical assessment, electrophysiological studies, and morphologic analysis of muscle and nerve tissue.[4]

Principles of Physical Therapy Management

A patient with restrictive pulmonary disease secondary to neuromuscular conditions is at considerable risk of succumbing to the negative cardiovascular and pulmonary sequelae of reduced mobility and recumbency, in addition to the pathophysiological consequences of respiratory failure. Provided the patient has some residual muscle power, the balance between oxygen demand and supply will determine the degree to which mobilization can be exploited to maximize oxygen transport.[5] The treatment goals for these patients are to maximize oxygen delivery, enhance the efficiency of oxygen uptake and usage, and thereby reduce the work of breathing. In these patients, minimizing oxygen demand overall (i.e., during mobilization as well as at rest) is a priority. Mobilization needs to be prescribed in body positions that enhance oxygen transport and its efficiency so that the benefits of mobilization can be exploited more fully without worsening arterial oxygenation. The patient requires continuous monitoring of oxygen transport and hemodynamic monitoring to ensure the exercise stimulus is optimally therapeutic and not excessive.

Although the mechanisms are different, patients with neuromuscular dysfunction, much like patients with chronic airflow limitation, can benefit from body positioning to reduce respiratory distress. Upright and lean-forward positions will reduce distress to the greatest extent.

The patient's body position and length of time in any one position must be carefully monitored and recorded to minimize the risks of positions that are deleterious to oxygenation and ensure that a beneficial position is not assumed for too long because of the diminishing benefits over time. This is particularly important for the patient who is incapable of positioning himself or herself, who is incapable of communicating a need to turn, and in whom muscle wasting, bony prominences, and thinning of the skin may predispose the patient to skin breakdown. Educating the family and caregiver to work with the patient is an essential component of the physical therapy management of patients with neuromuscular conditions.

Patients who are hypotonic and generally weak and debilitated fail to adapt normally to position-dependent fluid shifts and thus are more prone to orthostatic intolerance.[6] Gravitational stimulation is essential to maintain the volume-regulating mechanisms. Tilt tables should be used judiciously given the potential risks in these patients, which are compounded by the loss of the lower-extremity muscle pump mechanism. Stretcher chairs may be preferable. Because of potential adverse reactions to fluid shifts and the potential for desaturation, falling Pa_{O_2} levels, and dysrhythmias, the patient's hemodynamic status must be monitored closely during gravitational challenges.

The importance of chest wall mobility to optimize three-dimensional chest wall excursion in individuals with chronic neurological conditions is emphasized in Chapters 22 and 23. This goal is particularly challenging if complicated by acute respiratory insufficiency. The goal is to promote alveolar ventilation, reduce areas of atelectasis, and optimize ventilation and perfusion matching and breathing efficiency to augment and minimize reliance on respiratory support (i.e., supplemental oxygen and mechanical ventilation) while minimizing respiratory distress. This is especially important because patients with neuromuscular conditions are poor candidates for being weaned off mechanical ventilation. In addition, these patients are prone to microaspiration. Promotion of mucociliary transport is therefore essential to facilitate clearing of aspirate and minimize bacterial colonization and risk of infection.

Another major problem for patients with restrictive lung disease secondary to generalized weakness and neuromuscular disease is an ineffective cough. Cough facilitation techniques (e.g., body positioning, abdominal counter pressure, and tracheal tickle; see Chapters 22 and 23) can be used to increase intraabdominal and intrathoracic pressures and cough effectiveness. A natural cough, even when facilitated, is preferable and more effective in dislodging mucus from the sixth or seventh generation of bronchi than repeated suctioning. Even a weak, facilitated cough may be effective in dislodging secretions to the central airways for removal by suctioning or for redistribution of peripheral secretions.[7] Huffing, a modified cough performed with the glottis open and with abdominal support, may help mobilize secretions in patients with generalized weakness. In some cases suctioning may be the only means of eliciting a cough and clearing secretions simultaneously. Coughing attempts are usually exhausting for these patients. Thus ample rest periods must be interspersed during treatment, particularly for the ventilated patient. Coughing maneuvers must be strategically planned. Even though the patient may be able to effect only a series of a few weak coughs, it is essential that these attempts be maximized (i.e., the patient, optimally rested and medicated [e.g., bronchodilators, analgesia, reduced sedation and narcotics], is physically positioned to optimize length-tension relationship of the

diaphragm and abdominal muscles; is positioned vertically to optimize inspiratory lung volumes and expiratory flows and avoid aspiration; and is provided thoracic and abdominal support during expiration to maximize intrathoracic and intraabdominal pressures) (see Chapter 22). These supportive measures will ensure that the benefits of the normal physiological cough mechanism, which is the single best secretion clearance technique, are maximized (i.e., the most productive cough with the least energy expenditure).[8] Forced chest wall compression or forced expiratory maneuvers are contraindicated because of airway closure and impairment of gas exchange.[9]

Impaired mobility, inability to cough effectively, decreased airway diameter, and bronchospasm contribute to impaired mucociliary transport and secretion accumulation. In addition, impaired glottic closure and increased risk of reflux in this patient population expose the airway to risk of aspiration. Prophylactically, multiple body positions and frequent position changes will minimize the risk of secretion accumulation and stasis. If mechanically ventilated, these patients are suctioned as indicated. If pulmonary secretions become a significant problem despite these preventative measures, postural drainage positions are selected to achieve the optimal effect (i.e., secretion mobilization and optimal gas exchange). Given the treatment response, manual techniques, of which manual vibration would have the greatest physiological justification, may yield some benefit.

Patients with chronic neuromuscular dysfunction and residual musculoskeletal deformity pose an additional challenge to the cardiovascular and pulmonary physical therapist in that cardiovascular and pulmonary function is less predictable because of altered lung mechanics and possibly cardiac dynamics. Thus, clinical decision making is more experiential in these patients, and they require close monitoring.

Obesity

Pathophysiology and Medical Management

Restriction of cardiovascular and pulmonary function secondary to morbid obesity is called the *alveolar hypoventilation syndrome.* In this syndrome the weight of excess adipose tissue over the thoracic cage and abdominal cavity restricts chest wall movement and movement of the diaphragm and abdominal contents, respectively, during respiration. In very heavy individuals, cardiovascular and pulmonary function can be significantly impaired, resulting in hypoxemia and cardiovascular and pulmonary failure. The major pathophysiological mechanisms include significant alveolar hypoventilation, reactive hypoxic pulmonary vasoconstriction, increased pulmonary vascular resistance, myocardial hypertrophy, increased right ventricular work, altered position of the thoracic structures, abnormal compression of the heart, lungs, and mediastinal structures, abnormal position of the heart, cardiomegaly, increased intraabdominal pressure, elevated hemidiaphragms with resulting pressure on the underside of the diaphragm, impaired cough effectiveness, impaired mucociliary transport, mucous obstruction of airways, airway narrowing, bronchospasm, impaired mechanical efficiency of diaphragmatic excursion, and impaired respiratory mechanics and breathing efficiency. In addition, such patients are likely to have poor cardiovascular and pulmonary reserve capacity secondary to increased metabolic rate and minute ventilation at submaximal work rates, increased metabolic cost of breathing, and increased work of breathing. Moderately heavy patients whose pulmonary function is normally not compromised may exhibit cardiovascular and pulmonary dysfunction when their oxygen transport systems are stressed because of illness.

Mechanical ventilation can be a challenge in that the system pressure required to inflate the lungs may predispose the patient to barotrauma. Furthermore, high system pressures contribute to reduced stroke volume and cardiac output. Adequate circulation is essential to fulfill the goals of medical management (i.e., to optimize tissue oxygenation and carbon dioxide removal). Thus a delicate balance among adequate alveolar ventilation, cardiac output, and peripheral circulation is maintained.

Principles of Physical Therapy Management

The patient who is obese can be treated aggressively provided there are no contraindications and he or she is being fully monitored. Treatments must be intense, to the limits of the patient's tolerance, provided this is not contraindicated. An aggressive approach is essential given that the obese patient is at greater risk of deteriorating between treatments than a nonobese patient. Recumbency is tolerated poorly by an individual who is obese. Positional decrements in Pa_{O_2} and Sa_{O_2} can induce dysrhythmias. The weight of the abdominal viscera limits diaphragmatic descent and elevates the resting position of the diaphragm, impeding its mechanical efficiency. Furthermore, these patients are likely to become distressed if positioned prone because of restriction of chest wall mobility. Half-prone positions in which the abdominal contents are displaced forward, however, may be well tolerated.

These patients need to be aggressively mobilized; both whole-body exercise stress and range-of-motion exercises between mobilization sessions are required. Active and active-assisted upper-extremity range-of-motion exercises are associated with increased hemodynamic stress; thus the patient must be monitored closely. Lower-extremity exercise, such as pedaling and hip and knee flexion and extension exercises may help position and improve the excursion of the diaphragm. Lower-extremity movement will augment venous return. Depending on the patient and the work of the heart, the effect of lower-extremity movement will require monitoring to ensure that myocardial work is not increased excessively.

The patient should be encouraged to sit out of bed as much as possible when tolerated. The erect upright position is optimal to augment ventilation and reduce the work of the mechanical ventilator and the risk of barotrauma. The upright position coupled with leaning forward displaces the abdominal contents forward, thereby reducing intraabdominal pressure and facilitating diaphragmatic descent. The posterior lung fields, particularly of the bases, are at risk for dynamic airway closure and atelectasis. Numerous positions and position changes ensure that the dependent alveoli remain open. The time spent in the supine position should be minimized. In fact, greater emphasis should be placed on nursing these patients in the upright position (i.e., the position of least risk and its variants). In addition to its pulmonary benefits, the

upright position can reduce compression of the heart and mediastinal structures, and there is a potential decrease in stroke volume and cardiac output. The weight of the chest wall, in addition to the weight of internal fat deposits in and around the cardiovascular and pulmonary unit, can compromise cardiac output and contribute to dysrhythmias. Thus during all body position changes the patient should be monitored hemodynamically to ensure the position is being tolerated well. People who are obese often slump after being positioned in the upright position. It is crucial that the position of these patients be checked frequently and corrected. The slumped position can be counterproductive in that the benefits of the upright position are significantly reduced and can lead to deterioration.

Although patients who are obese do not tolerate the prone position well, the semiprone position can be beneficial by simulating the benefits of the upright lean-forward position on the displacement of the abdominal viscera.[10] This position also simulates the prone abdomen-free position, which is associated with even greater benefit than the prone abdomen-restricted position. The benefits of the prone position for the obese individual include increased lung compliance and enhanced gas exchange and oxygenation. The full prone abdomen-restricted position is contraindicated in the obese individual with cardiovascular and pulmonary failure, however, because this position can compromise diaphragmatic descent and contribute to further cardiovascular and pulmonary distress and failure and possibly cardiac arrest.

Mucociliary transport is slowed and ineffective in individuals who are obese with cardiovascular and pulmonary failure. Frequent body positioning will facilitate mucociliary transport and lymphatic drainage. The postural drainage positions can be effective in mobilizing secretions should accumulation become a problem. Manual techniques are not likely to add much benefit, particularly in the person who is morbidly obese. Suctioning is essential to clear pulmonary secretions from the central airways.

A person who is obese is at risk for postextubation atelectasis. Thus, aggressive mobilization, numerous positions, and frequent position changes must be continued.

The spontaneously breathing patient who is obese may have a weak ineffective cough, which will be even less effective after a period of intubation and mechanical ventilation. These patients are taught deep breathing and coughing maneuvers comparable with those described for the patient with neuromuscular disease. Body positioning to facilitate coughing and supported coughing must be instituted to maximize cough effectiveness. These maneuvers should be carried out in conjunction with hourly extreme position shifts.

People who are morbidly obese have a high incidence of upper airway obstruction and sleep apnea secondary to floppy compliant pharyngeal tissue. Thus the quality of their sleep and rest is suboptimal, and they are apt to desaturate while sleeping. These patients are also at high risk for esophageal reflux and aspiration. The optimal resting position is with the head of the bed up.

Individuals who are obese must be positioned upright and mobilized particularly aggressively because of their cardiovascular and pulmonary risks. Positioning and mobilizing can be facilitated with hinged beds, heavy-duty lifts, and reinforced stretcher chairs and walking frames. These items are essential to ensure that the patients are physiologically perturbed as much as possible and to minimize biomechanical injury to staff. The physical therapist has to ensure that the optimal devices are selected such that the individual is actively involved as much as possible and optimal but not excessive support is provided. The care of the individual who is morbidity obese is a particular challenge in the ICU and places increased demand on coordinated teamwork in the unit.

Musculoskeletal Trauma

Pathophysiology and Medical Management

Crush and penetrating injuries of the chest are commonly seen in the ICU. Damage to the chest wall, lung parenchyma, and heart contributes to the risk of cardiovascular and pulmonary failure (Table 35-1). Associated injuries of the head, spinal cord, and abdomen may also contribute. Fractures of long bones and the pelvis are associated with fat emboli, which pose the threat of pulmonary embolism. In addition, fluid loss in multiple trauma contributes to loss of blood volume, hypovolemia, and hemodynamic instability. The more extensive the injuries, the greater the pain and requirement for analgesia. Pain contributes significantly to reduced alveolar ventilation, airway closure, and inefficient breathing patterns.

Paradoxical motion of the chest wall associated with flail chest and rib fractures results from instability of portions of the rib cage after trauma to the chest. If severe, patients may require surgical stabilization of the ribs or stabilization by continuous ventilatory management. Chest wall injuries and rib fractures are particularly painful.

The presence of blood or air in the chest cavity and in the potential spaces of the pericardial sac and intrapleural cavity impairs cardiac distension and contraction, impairs

Table 35-1 Factors Contributing to Cardiovascular and Pulmonary Failure after Trauma and Their Diagnostic Signs

Airway obstruction	Respiratory insufficiency Respiratory distress Impaired blood gases
Inadequate ventilation	Reduced thoracic movement Paradoxical thoracoabdominal movement
Tension pneumothorax	Cyanosis Unilaterally absent breath sounds Distended neck veins Subcutaneous emphysema
Cardiac tamponade	Distended neck veins Muffled heart sounds Narrowed pulse pressure Paradoxical pulse
Open pneumothorax	Decreased breath sounds Penetration of thoracic wall
Myocardial contusion	Dysrhythmia
Flail chest	Loose segment Multiple palpable fractured ribs Decreased or moist breath sounds Hemoptysis

ventilation, promotes retention of secretions, interferes with effective clearance, and impairs lymphatic drainage.

The presence of a pneumothorax or hemothorax can severely compromise lung expansion. A tension pneumothorax results when air collects under tension in the pleural cavity. The tension pneumothorax promotes lung collapse on both the ipsilateral and contralateral sides, which further threatens respiratory failure. Phrenic nerve injuries inhibit diaphragmatic function. The affected hemidiaphragm rests higher in the thoracic cavity, a position that may restrict ventilation to the lung base and contribute to airway closure and basal atelectasis. Diaphragmatic injuries directly affect ventilation in two ways. First, the bellows action of the lungs is compromised. Second, the lung is displaced by herniation of the abdominal contents into the thoracic cavity.

Analysis of blood gases in the patient who has sustained traumatic injuries to the chest often shows severe hypoxemia and moderate elevations of arterial P_{CO_2}. The presence of acidemia is common, which may have both respiratory and metabolic components. Patients with severe injuries have improved outcomes if hemodynamic status can be optimized.[11] Being less than 40 years of age is the best predictor of achieving optimal levels. Increasing D_{O_2} and maintaining normal S_{VO_2} are particularly relevant goals.[12]

Principles of Physical Therapy Management

Severe restlessness and dyspnea in a patient with chest injury are classic indications of respiratory failure. Auscultation and percussion can usually reveal an underlying pneumothorax or hemothorax. Tension pneumothorax is confirmed by chest radiograph or aspiration of the chest with a needle and syringe.

Flail chest refers to the asynchronous movement of the chest wall with two or more fractured ribs at two or more sites. This results in instability of the chest wall. The so-called "flail segment" is usually apparent on physical examination. Paradoxical movement of the flail segment can often be observed. The chest is depressed rather than elevated over the site during inspiration. Rib fractures are indicated by tenderness and crepitations on physical examination and from x-ray examination findings. Nonventilatory management of chest injuries in the absence of severe hypoxemia is preferred in these patients.

Analgesia is timed such that peak effect is achieved at the time of treatment to maximize comfort, minimize distress, and maximize cooperation, motivation, and tolerance for as well as duration of treatment.

Rib Fractures

Simple uncomplicated rib fractures often receive no specific treatment. Pain from complicated fractures may be treated with intercostal nerve blocks and transcutaneous electrical nerve stimulation and analgesia. Optimizing alveolar ventilation and mucociliary transport and avoiding pulmonary complications are primary goals. Strapping the chest is avoided because this further restricts and compromises chest wall expansion.

The current method of therapy for flail chest is internal stabilization of the chest and use of a mechanical ventilator. Slight hyperventilation will usually reduce the respiratory drive of most patients to allow the ventilator to take over the full work of breathing. The flail segment is then stabilized by internal expansion of the lungs. The treatment ensures adequate ventilation with the least pain possible. After 2 weeks the flail segment is usually stable.

When the patient can maintain a reasonable tidal volume and normal blood gases, weaning is begun. As soon as tidal volume and forced vital capacity are within acceptable limits, oxygen can be administered through an endotracheal tube with a T-tube assembly. Arterial blood gases are monitored closely during T-tube trials. Once the blood gases are in acceptable ranges over a reasonable period of time (i.e., 12 to 24 hours), the endotracheal tube is removed.

Pneumothorax and Hemothorax

Air or blood in the pleural cavity after chest trauma must be removed through a chest tube. For a pneumothorax the chest tube is positioned in the second or third intercostal space in the midclavicular line. For a hemothorax the chest tube is positioned in the sixth intercostal space in the posterior axillary line. Usually the chest tubes are sutured and taped into position and therefore are not easily dislodged. If the tubes are pulled out, subcutaneous emphysema or a pneumothorax results. A pneumothorax will also result if the tube is disconnected from the underwater seal. This is the reason for securing the collecting reservoirs of a chest tube drainage system to the floor with tape. Mobilizing and frequently repositioning the patient facilitates chest tube drainage and reexpansion of collapsed alveoli. Care must be taken to avoid kinking or straining chest tubes during patient treatment.

A bronchopulmonary fistula can be responsible for a major loss of the tidal volume delivered by the ventilator. Small leaks can be tolerated and are usually compensated for by an increase in tidal or minute ventilation.

Multiple Trauma

The management of multiple trauma is a major challenge for the ICU team. Multisystem involvement and complications often present a precarious situation in which priorities have to be defined for each individual situation. Multiple trauma can include head injury, chest wall injuries, fractures, lung contusions, diaphragm injury, pleural space disorders, internal injuries, thromboemboli, fat emboli, and cardiac contusions. Deep vein thrombosis occurs in 20% to 40% of patients in the absence of prophylaxis.[13] Shock and acute respiratory distress syndrome (ARDS) may ensue (see Chapter 36). Early intervention with body positioning significantly lowers the incidence of ARDS compared with later intervention in patients with multiple trauma.[14] The clinical picture of the patient with multiple trauma is compounded by the mobilization and positioning restrictions imposed.[15] Positive end-expiratory pressure (PEEP) is frequently used to reduce the effects of lung congestion secondary to shock or ARDS. Arterial blood gases are assessed to evaluate the effectiveness of PEEP in effecting improved oxygen transfer.

Multiple Fractures

Multiple trauma patients are assumed to have spinal involvement, particularly of the cervical spine, until ruled out with appropriate scans and radiographs. Meanwhile the physical

therapist performs repeated assessments to establish a baseline position for the patient and recommend positions that will maximize oxygen transport. Treatment to enhance oxygen transport and mucociliary transport is primarily restricted to body positioning using log-rolling maneuvers and selected range-of-motion exercises (i.e., not of the head or neck, nor possibly the shoulders).

Fixation, traction, and casting of fractures and dislocations of the limbs complicate the management of the trauma patient. Restrictions to mobilization and body positioning are primary concerns of the physical therapist. Mobilization in the upright position provides both a gravitational stimulus and an exercise stimulus, both of which are essential to optimize oxygen transport. This is preferable to mobilization exercises in the recumbent position. In some cases, traction can be transferred from over the end of the bed to over a chair. A strict routine of body positioning is maintained, although severe limitations often exist with respect to the specific positions and the degree of turning permitted. Lower limb traction can be maintained when the patient is positioned in a modified side-lying position. Coordinating treatments with analgesia schedules reduces the patient's pain and fatigue, thereby improving tolerance to treatment and prolonging the treatment. These patients usually tolerate the head-down position well, provided head injury does not complicate the clinical picture.

The acute effects of mobilization that will benefit the patient with musculoskeletal trauma include augmentation of ventilation, perfusion, and ventilation and perfusion matching and promotion of mucociliary transport and cough effectiveness. General mobilization exercises and proprioceptive neuromuscular facilitation can be used to promote a mobilization stimulus. Cycle pedals can be attached to a chair or the end of the bed to provide a low-intensity exercise challenge for some patients. Maximal work output can be achieved within the patient's capacity using an interval training type schedule (i.e., schedule of work to rest periods). A mobilization program that promotes the long-term effects of exercise can be prescribed that involves as many large muscle groups as possible in rhythmic, dynamic exercise.

Frequent deep breathing and coughing are continued during and between treatments, depending on whether the patient requires mechanical ventilation. Body positioning is carried out within the limits of the patient's traction and casts. Impaired mucociliary transport is treated with body positioning and frequent position changes. Secretion accumulation may necessitate postural drainage. Modified positions may be indicated because of the positioning restrictions imposed by the fractures, traction, and fixation devices. If indicated, manual techniques may be coupled with postural drainage. Care must be taken to ensure that the addition of manual techniques is beneficial and is tolerated by the patient.

Relaxation interventions, both active and passive, should be integrated into the treatment regimen for the trauma patient to reduce excessive oxygen consumption and promote comfort.[16] *Active relaxation* refers to relaxing the patient through participation of the patient in relaxation procedures. *Passive relaxation* refers to relaxing the patient using passive procedures (e.g., body positioning, physical supports, talking slowly and calmly, and taking adequate time for conducting treatments). Taking time to implement mobilization is essential. First, mechanically moving and having patients who have multiple injuries move, requires a prolonged period of time. In addition, the cardiovascular and pulmonary systems of patients who are critically ill need time to adapt to new positions physiologically and to control discomfort. Prolonged periods of time may be required to turn a patient, dangle him or her over the bed, or transfer him or her to a chair with continuous monitoring. Every effort is made to maintain the patient's spirits, reduce stress, and encourage a positive attitude toward active participation early in the rehabilitation program that begins in the ICU.

Care must be taken to avoid undertreating or overtreating individuals with traumatic injury. A clear chest can rapidly regress because of general immobility and limitations to body positioning imposed by traction and pain. Treatments should always be coordinated with the patient's analgesics to optimize treatment response and for the patient's comfort. Whenever possible, the patient should be equipped with slings and pulleys and weights at bedside and a trapeze bar overhead for bed mobility and upper-extremity exercise. In addition to their cardiovascular and pulmonary benefits, all activities are taught in conjunction with breathing control exercises and coordination with the respiratory cycle.

Head Injury

Pathophysiology and Medical Management

Hypoxemia is observed in many patients with injury to the central nervous system. This may reflect primary damage to the cardiovascular and pulmonary centers of the brain or secondary effects of associated trauma. Arterial blood gases are therefore closely monitored in these patients.

Acute cerebral edema with sudden increase in intracranial pressure (ICP) and reduction in cerebral perfusion pressure rapidly affects central control of respiration. Advancing cerebral edema is evidenced by deterioration in level of consciousness, pupillary reflexes, ocular reflexes, and pattern of respiration and exaggerated muscle tone and posture. The sequence of these clinical signs corresponds to progressively increasing ICP from the cortex toward the medullopontine region. With involvement of the brainstem, respiration becomes variable and uncoordinated. With loss of central control and imminent cessation of breathing, respiration is shallow and ataxic. The appearance of the jaw and laryngeal jerk with each inspiratory effort suggests a poor prognosis.

Physical therapy and the patient's normal routine may have a dramatic effect on the ICP. ICP can be elevated indirectly by an increase in intrathoracic pressure as a result of physical therapy or suctioning. Turning and positioning may produce obstruction to cerebral venous outflow. Noxious stimuli, such as arterial and venous punctures or cleansing wounds, and relatively innocuous stimuli, such as noise or pupil checks, can elevate ICP. Whether these factors elevate ICP depend on cerebral blood volume and intracranial compliance. On cerebral stimulation, a chain reaction is initiated. Cerebral activity is increased, which in turn elevates metabolic rate, blood flow, and hence volume and ICP. Alternatively, increased cerebral blood volume secondary to gravitational effects increases ICP and reduces cerebral perfusion pressure.

The head of the bed is usually maintained at 30 to 40 degrees to promote venous drainage and thereby reduce ICP.

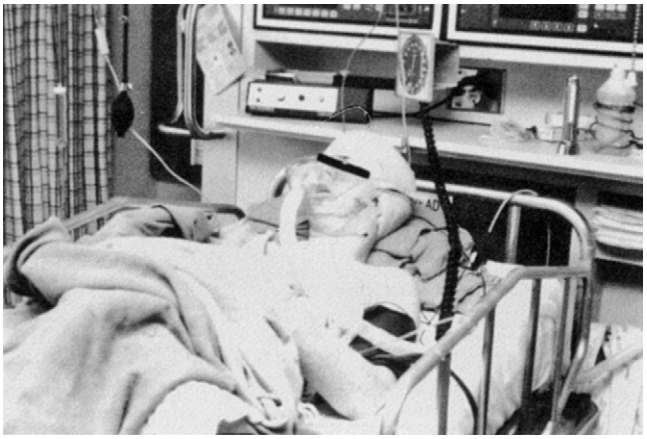

Fig. 35-1 Patient after neurosurgery procedure; head of bed elevated 20 degrees to help reduce intracranial pressure.

The patient's head and neck can be fixed in a neutral position by halo traction or by sandbags positioned on either side (Figure 35-1). Mechanical hyperventilation is used to maintain P_{CO_2} below normal limits but above 20 mm Hg. Arterial blood gases are checked during or immediately after hyperventilation. Prolonged hyperventilation is avoided.

Barbiturate coma may be induced to decrease the cerebral metabolic rate for oxygen and hence cerebral blood flow. The reduction in cerebral metabolic rate exceeds the reduction in blood flow, and thus oxygen supply exceeds demand, which is a desirable treatment outcome. Invasive hemodynamic monitoring is instituted in conjunction with barbiturate coma because barbiturates contribute to hemodynamic instability.

A complication of head injuries is acute lung injury, specifically neurogenic pulmonary edema (see Chapter 36). Autonomical nervous system dysfunction contributes to hypertension and neurogenic pulmonary edema. The endothelial tight junctions in the pulmonary capillaries leak protein into the interstitium along with fluid. Constriction of the lymphatic vessels may also contribute to fluid accumulation by impeding the removal of lung water. Increased fluid accumulation in the interstitium may progress to the alveoli, contributing further to impaired gas exchange and reduced lung compliance.

Principles of Physical Therapy Management

Physical therapy priorities in the management of the patient with cardiovascular and pulmonary dysfunction secondary to head injury are shown in Box 35-1. Body positioning, a mainstay of treatment for the patient with reduced consciousness, is based on a detailed assessment, consideration of multisystem status, and serial monitoring of the patient's response.[17]

ICP may increase with treatment and in particular with turning or suctioning. An ICP of up to 30 mm Hg may be acceptable provided the pressure returns to normal immediately after the removal of the pressure-potentiating stimulus. Specific guidelines with respect to the maximum ICP for a given patient need to be obtained in consultation with the medical team. Prolonged elevation of ICP suggests low cerebral compliance and the possibility of potential brain damage unless pressure is reduced. Thus all interventions must be performed guardedly with due consideration given to corresponding changes in ICP. Typically, management of patients with central nervous system trauma includes judicious tracheal suctioning, a stringent turning regimen, lung hyperinflation with the manual breathing bag in the nonventilated patient, or deep breathing with occasionally increased tidal volumes or sighs in the ventilated patient.

If the ICP is unstable and a risk of brain damage exists, physical therapy should follow sedation. Ideally treatments should be performed when the ICP is low and intracranial compliance is satisfactory. Patients whose cerebral compliance is compromised need monitoring during position changes.[18] The head-down position is contraindicated. Noise and noxious stimulation that increases ICP should be kept to a minimum.

If the ICP is elevated, all noxious stimuli should be removed. In severe conditions a decision may have to be made by the team to limit or withdraw interventions that lead to an excessive ICP increase that does not remit instantly (e.g., physical therapy, positioning, suctioning, or neurological assessment).

Movement of the limbs is performed gently and in a relaxed manner. Patients in a comatose state may experience passive limb movement noxiously. ICP may be elevated as a result. Passive movements, however, may have the added benefit of promoting improved tidal ventilation in the nonventilated patient by providing afferent stimulation to the respiratory center via peripheral muscle and joint receptors.

Severe head injury may produce flexor or extensor posturing. These synergies may be inhibited by appropriately

Box 35-1 Physical Therapy Priorities in the Management of the Patient with Cardiovascular and Pulmonary Dysfunction Secondary to Head Injury

1. Prevent cerebral hypoxia by maintaining a patent airway
2. Reduce intracranial pressure and optimal cerebral perfusion pressure
3. Position the patient within the limits of fracture stabilization and elevated intracranial pressure to promote alveolar ventilation and ventilation and perfusion matching
4. Position the patient to reduce pathological patterns of muscle synergy and thereby promote ventilation and reduce oxygen consumption
5. Position the patient to reduce myocardial stress
6. Avoid activities and stimuli that increase intracranial pressure
7. Reduce atelectasis and its risk
8. Shift lung fluid accumulations and areas of atelectasis
9. Promote lymphatic drainage
10. Promote mucociliary transport and reduce pooling of secretions and risk of chest infection
11. Reduce the work of breathing and improve the efficiency of the muscles of respiration, particularly if long-term disability is a risk
12. Perform active, active-assisted, or passive movements as soon as possible to enhance cardiovascular and pulmonary function and secondarily to preserve musculoskeletal and neuromuscular function and reduce the risk of thromboemboli

positioning the patient. Judicious body positioning, in turn, reduces oxygen consumption and the patient's overall energy requirements.

Although arousing the patient and increasing oxygen consumption occur with cardiovascular and pulmonary physical therapy, arousal and oxygen consumption are generally minimized to reduce hemodynamic and metabolic demands in the patient with a head injury.

Spinal Cord Injury

Pathophysiology and Medical Management

The principal cause of death in the early stages of acute spinal cord injury, particularly for the high lesions, is cardiovascular and pulmonary complications. Lung volumes are reduced with the exception of residual volume, which increases. Vital capacity increases in the supine compared with the sitting position in quadriplegic patients. This does not, however, counter the negative effects of reduced functional residual capacity (FRC) and increased airway closure in this position and reduced flow rates.

Spinal cord injuries above C3 result in loss of phrenic nerve innervation, necessitating a tracheostomy and mechanical ventilation. The lower the level of the spinal cord lesion, the lower the cardiovascular and pulmonary risk. All patients with spinal cord injuries are at risk for developing atelectasis and pneumonia. The coughing mechanics of patients with quadriplegia are abnormal and contribute to ineffective airway clearance.[19] In addition, the quadriplegic patient is at risk for developing pulmonary emboli. Prophylactic low-dose heparin is used routinely unless the presence of pulmonary emboli is suspected and higher doses are indicated.

Patients with suspected spinal cord injuries usually undergo immediate spinal fixation on admission. Depending on the level of injury determined by clinical signs and radiographs, traction and fixation may be localized to the head and neck, or spinal support and casting may be required in the thoracic or lumbar regions.

Principles of Physical Therapy Management

Because of the need to maintain relative immobility in the acute stabilization period of suspected spinal cord injury, therapeutic body positioning rather than mobilization is a primary intervention for optimizing oxygen transport. Although modified body positioning can be achieved, the provision of optimal care under these restricted conditions is a singularly important challenge to the physical therapist, particularly with respect to the management of adequate oxygen transport while the patient is in the ICU. Patients with high spinal cord lesions can be positioned in all positions within the limits of the cervical traction device being used, barring head injury. Both head- and foot-tipped positions, however, are introduced cautiously and with hemodynamic monitoring because both positions can have significant cardiovascular and pulmonary and hemodynamic consequences secondary to spinal nerve loss and hence sympathetic nerve loss to the peripheral blood vessels. Turning frames such as the Stryker frame facilitate turning and tipping of these hemodynamically labile patients in the supine and prone positions.[20]

Effective body positioning, despite the need in some cases for extensive modification, may be sufficient to optimize oxygen transport secondary to improved regional ventilation and perfusion to all lung fields. In the spontaneously breathing patient, deep breathing and coughing maneuvers need to be coupled with position changes to optimize mucociliary transport. Some patients may not tolerate numerous positions and position changes and thus have impaired mucociliary transport. If secretion accumulation and stasis develop, postural drainage can be instituted; however, tipping must be attempted very cautiously. Patients should be monitored closely during and after treatment. Because of the hemodynamic lability of acute quadriplegic patients and the well-documented side effects of percussion and vibration,[8] these procedures must be applied cautiously, should they be indicated, depending on the severity of any complicating fracture-dislocation(s), the stability of fixation, the condition of the lungs, the presence of chest wall injuries, and hemodynamic lability.

The high-frequency oscillating ventilator may have some benefit in the management of multiple trauma patients with spinal injuries who require ventilation. The advantages of the high-frequency oscillating ventilator include improved spontaneous mucociliary clearance and reduced incidence of atelectasis. Weaning patients with high spinal cord lesions off the ventilator requires special skill because of the impaired function of the respiratory muscles. For these patients, weaning can be particularly fatiguing, frightening, and frustrating. Patients are weaned lying supine when they are alert and able to cooperate. Short periods off the ventilator on the T-piece are used initially. Use of the accessory muscles of respiration and any other muscular reserves is encouraged to compensate for the loss of function of the respiratory muscles. In some centers, patients are started in the weaning period on respiratory muscle training. The physical therapist must be well versed and practiced in this procedure before using it in conjunction with weaning the quadriplegic patient off the ventilator. Because of the potential risk of inappropriate application and of danger to the patient, respiratory muscle training must be effected knowledgeably to optimize its benefits for each individual patient.

Respiratory muscle weakness and fatigue, two physiologically distinct entities, are probably much more common in patients in the ICU than appreciated. These states need to be recognized and detected early because both are well known to cause respiratory muscle failure.[21] The distinction between the two conditions is that weakened muscles respond to resistive muscle training, whereas fatigued muscles do not. Exposing fatigued respiratory muscles to resistive loads can accentuate respiratory failure. The indication for respiratory muscle training, therefore, is weak rather than fatigued respiratory muscles. Rest is indicated for fatigued respiratory muscles. Whether the respiratory muscles are weak or fatigued must be established before respiratory muscle training is prescribed. Patients with quadriplegia with weak respiratory muscles, even if ventilated for a prolonged period, potentially may be weaned (low-level injury) or minimally may breathe independently for brief periods after a course of inspiratory muscle training.[22] For further detail on respiratory muscle training refer to Chapter 26.

The combination of immobilization and cardiovascular and pulmonary involvement secondary to multiple trauma may result in disuse atrophy and weakness of the diaphragm similar to that observed in other skeletal muscles. Respiratory muscle weakness and fatigue can be components of both obstructive and restrictive patterns of lung disease. Patients with spinal cord injuries do not have the same advantage of performing coordinated general body activity and relaxation maneuvers to help reduce the work of breathing. This contributes to a marked decrease in respiratory muscle strength and endurance, resulting in reduced vital capacity, rib cage mobility, and ability to cough. For these reasons, patients with paralysis and demonstrated respiratory muscle weakness are particularly well suited for respiratory muscle training. The quadriplegic patient has lost the function of the intercostal muscles, which are important muscles of inspiration and responsible for thoracic cage expansion. In addition, the absence of the abdominal muscles, which are the primary expiratory muscles, drastically reduces the ability to cough effectively and perform a forced expiration. The diaphragm and the accessory muscles of inspiration, namely the scalene and sternocleidomastoid muscles, then become the quadriplegic patient's respiratory muscles. These factors as well as the effects of heat, humidity, and the vertical position, all predispose the individual with quadriplegia to the development of respiratory muscle weakness and failure.

Maximum inspiratory mouth pressure and vital capacity can be measured routinely to monitor change in diaphragmatic function. The level of inspiratory resistance and the duration for which the patient can use each resistor are indications of the endurance of the inspiratory muscles. Measurement of vital capacity and maximum inspiratory and expiratory mouth pressures provide an index of the strength of the inspiratory muscles.

Certain precautions must be observed with respiratory muscle training. Each time a new resistance is tried, the physical therapist should be with the patient. The patient selects his or her own rate and pattern of breathing. The inspiratory rate is usually constant. Breathing that is too shallow is inefficient, and breathing that is too slow and deep may result in accumulation of carbon dioxide. The patient is cautioned about avoiding hyperventilation. The physical therapist, or the patient when he or she is capable, should check the valving system on the respiratory muscle trainer before each training session to ensure it is functioning properly.

Burns

Pathophysiology and Medical Management

Cardiovascular and pulmonary complications are common in patients with smoke inhalation with or without severe burns and are a major cause of death. Smoke and chemical inhalation produce edema, bronchospasm, cough, mucosal sloughing, hemorrhage, hoarseness, stridor, and profuse carbonaceous secretions. Irritation of the alveoli and acute pulmonary edema can result in a condition resembling ARDS (see Chapter 36).

On admission of the patient with burns to the hospital, the patency of the airway is assessed immediately. Inhalation injuries are common in burn patients, resulting from smoke inhalation, heat trauma, and chemical and gas inhalation. Oxygen and humidification are usually administered immediately. Heat may cause laryngeal and bronchial edema. If airway occlusion from impending edema threatens, intubation is performed. If indicated early, intubation may prevent respiratory distress within the critical 24-hour period after admission. Particular care is given to children and older adults with inhalation injury because these patients have a higher risk of developing secondary cardiovascular and pulmonary complications.

Carbon monoxide poisoning may complicate the clinical picture further and seriously threaten tissue oxygenation. Hemoglobin has a higher affinity for binding with carbon monoxide than oxygen. A carboxyhemoglobin level greater than 20% denotes carbon monoxide poisoning. Levels in excess of 50% may produce irreversible neurological damage. The principal danger of carbon monoxide poisoning is that arterial Pa_{O_2} can be adequate and tissue oxygen tension inadequate. Administration of high levels of oxygen is an initial priority to reduce the half-life of carbon monoxide from several hours to 1 hour.

Depending on the severity and extent of the burns, treatment ranges from conservative medical interventions to multiple surgeries related to progressive debridement and skin grafting. Both second- and third-degree burns can result in severe disfigurement and disability. Second-degree burns are partial thickness burns and tend to be painful. Third-degree burns are full thickness burns; these tend to be anesthetic in that the nerves themselves have been destroyed.

Treatment is directed at improving arterial saturation, maintaining fluid balance, and preventing infection. Hypoxemia is effectively treated with the administration of oxygen and maintenance of clear airways. If the patient is breathing spontaneously, oxygen is given via nasal cannulas or mask at flows of 1 to 5 L/min, depending on the arterial oxygen saturation. Moisture can be administered through a face tent with a heated nebulizer. Fluid balance is particularly challenging in the patient with burns because of the loss of skin, which is essential to the retention and compartmentalization of body fluids and in the regulation of fluid and electrolyte loss from the body. In addition, these patients may lose blood because of injury at the time of the accident. There is also a period without fluid replacement from before the injury to the time medical attention is available and intravenous fluid resuscitation commenced. Because of the nature of burns, even when fluid resuscitation has begun, fluid and electrolyte balance remains a challenge until considerable healing and repair have occurred. Fluid and electrolyte imbalances have considerable implications for hemodynamics and cardiovascular and pulmonary function (see Chapter 16) and contribute to hemodynamic instability, which necessitates modification of the physical therapy management.

An airway may be inserted initially with burns to the face, airway, and lungs in anticipation of progressive edema, which would make the insertion of the airway considerably more difficult hours or days later. Ventilatory assistance is indicated with evidence of respiratory insufficiency secondary to smoke inhalation and with burns of the nose, face, throat, airway, lungs, and chest wall. A nasotracheal tube is preferred to a tracheostomy tube because complications with a tracheostomy tube are greater in patients with burns.

Cardiovascular and pulmonary complications are generally related to sepsis or fluid overload in the initial stage. Acute pulmonary edema and congestion are largely preventable with careful fluid therapy. Central venous pressure can be misleading in the burn patient because of severe fluid loss and may remain at low values despite pulmonary edema. Pulmonary artery pressure more accurately reflects the status of the pulmonary circulation in these patients. Treatment of pulmonary edema consists typically of digitalis, diuretics, and mechanical ventilation. PEEP is usually indicated in the ventilated burn patient. Mist or aerosol inhalation is also used to reduce the thickness of pulmonary secretions.

Complications must be anticipated and prevented in the burn patient. These include impaired thermoregulation, hypermetabolism and increased energy expenditure, ileus and gastric distension, pain, and infection. Eschar formation associated with circumferential burns of the chest wall mechanically restricts chest wall movement and can lead to respiratory failure. Tissue edema that can continue for a few days after the burn contributes to increased tissue pressure and impaired tissue perfusion, potentiating tissue ischemia and necrosis. Late complications include gastrointestinal bleeding secondary to stress ulceration and the continued high risk of infection.

Principles of Physical Therapy Management

Cardiovascular and pulmonary physical therapy is often required immediately for the patient with inhalation damage to maintain the patency of the airways, prevent atelectasis and retention of secretions, and improve or maintain gas exchange. Pulmonary function may be severely impaired as the net result of inhalation damage, burns and trauma to the chest wall, pain, and fluid imbalance.

Cardiovascular and pulmonary physical therapy often has to be modified in the patient with burns. Mobilization to enhance oxygen transport is exploited as much as possible; however, because of blood volume and hemodynamic problems, orthostatic intolerance may limit mobilization and positioning alternatives. With more severe burns and more extensive burn distribution, body positioning is the primary intervention. Positioning for an optimal therapeutic effect on oxygen transport is challenging because of the significant physical limitations that may exist. Given that body positioning profoundly influences ventilation and perfusion matching,[23] the reduced number of positioning alternatives will contribute to shunt, ventilation and perfusion mismatch, and hypoxemia. This effect will be accentuated if the patient is mechanically ventilated (see Chapter 33).

Body positioning to optimize oxygen transport is life-preserving; however, positioning and limb splinting must also be considered from the outset to minimize deformity and restore optimal neuromuscular and musculoskeletal status. Positioning priorities in burn patients must address both these aspects of management.

Patients who have skin grafts require particular care during moving or positioning because of the danger of shearing forces on the graft, which can disrupt the circulation, nutrition, and healing of the new skin. Sterile procedures must be observed at all times. The physical therapist is usually required to cap, gown, mask, and glove before treating the patient with extensive exposed areas and to cover the chest with a sterile drape. Facilitating mucociliary transport is a priority if the patient has significant mobility and positioning restrictions because of the burn severity. Wherever possible, mobilization in conjunction with multiple body positions and position changes is attempted to maximize mucociliary clearance.[24] If secretions have accumulated, positioning for postural drainage requires the same consideration as positioning for improved alveolar ventilation and ventilation and perfusion matching. In the spontaneously breathing patient, postural drainage positions can be used selectively to increase alveolar volume in the superior lung fields and alveolar ventilation to inferior lung fields, in addition to facilitating drainage of the superior bronchopulmonary segments. If the patient is mechanically ventilated, however, the superior lung fields are preferentially ventilated (see Chapter 33). Should the addition of manual techniques be indicated, percussion may not be comfortably tolerated in the presence of first- and second-degree burns. Manual vibration may be substituted. Manual techniques are contraindicated over freshly grafted skin; however, manual vibration may be transmitted from a more distal site to a lung field that cannot be vibrated directly.

Risk of aspiration is increased if tube feedings are not discontinued for at least 1 hour before treatment. A nasogastric tube is often used and should be correctly positioned, particularly during treatment.

Stimulating exercise and gravitational stress may initially consist of being in the upright position, preferably with the legs dependent, performing selected limb movements and dangling over the edge of the bed for a few minutes if this can be tolerated. In patients with severe burns and fluid imbalance, however, active and active-assisted moments in an upright position that can be tolerated may be substituted. As the patient's tolerance increases, free, unsupported sitting can progress to standing and walking. Ambulation during ventilator-assisted breathing should always be considered for any patient for whom this activity is not contraindicated. The upright position and physical activity in the upright position are likely to markedly enhance the patient's cardiovascular and pulmonary and neuromuscular function and improve the patient's strength and endurance in preparation for long-term rehabilitation. If sitting up and ambulation are not imminent, appropriate limb movements, preferably active, can help provide an exercise stimulus that can enhance oxygen transport. Aggressive passive full range-of-motion exercises and positioning, in addition, are required to maximize joint range (a distinct goal from that of enhancing oxygen transport) wherever possible.

Positioning to minimize deformity is a priority given the potential consequences for cardiovascular and pulmonary function and oxygen transport, as well as musculoskeletal and biomechanical reasons. Positioning a burn patient, regardless of the goal, should take into consideration alignment, pressure points, muscle balance, and effect on healing and grafted skin.

Certain precautions have to be observed in the management of the burn patient. First, skin loss contributes to substantial fluid loss, often resulting in labile fluid and electrolyte imbalance. This situation enhances myocardial irritability and the risk of dysrhythmia. Hemodynamic and electrocardiogram monitoring is performed routinely during physical

therapy treatment. Second, large areas of skin loss increase the risk of infection; therefore the physical therapist must be familiar with sterile technique.

Organ Transplantation

An increasing number of patients have received organ transplantation with excellent results in terms of survival because of improved surgical techniques and new immunosuppressive drugs. Organ transplantation is a surgical procedure that can save and prolong the lives of patients with end-stage heart, lung, liver, kidney, pancreas, and small bowel diseases.

Optimal nutrition and exercise have been advocated as means of improving outcomes before and after transplantation.[25] The benefits of regular physical exercise have been well documented for patients who have had transplants. The benefits, however, begin in the ICU, where mobilization is prescribed to reap similar benefits including improved oxygen transport and physical conditioning and to potentially reduce or attenuate the side effects of immunosuppression.[26,27] In addition, the progression from mobilization in the ICU and hospital to the community can also help to address conditions that are often seen in these patients, including hypertension, type 2 diabetes mellitus, hyperlipidemia, and other cardiovascular risks. Once discharged, patients may attain a similar or even higher level of health and conditioning than their peers who have not undergone transplantation surgery.

As with other highly invasive surgeries, the degree to which a patient thrives long term versus merely survives has become a focus of interest. The quality of life is usually measured in terms of a patient's ability to function, from both physical and psychosocial standpoints, and his or her perceived sense of well-being. Physical therapists play a pivotal role in helping patients regain their highest levels of function after organ transplantation and minimizing postoperative complications.

Summary

This chapter has described the principles and practice of physical therapy in the management of people with cardiovascular and pulmonary dysfunction secondary to neuromuscular and musculoskeletal conditions that can lead to cardiovascular and pulmonary failure. Conditions included were neuromuscular conditions, musculoskeletal conditions, morbid obesity, head injury, spinal cord injury, burns, and organ transplantation. A detailed understanding of the underlying pathophysiology of these conditions and their medical management provides a basis for defining the physical therapy goals and prescribing treatments and their parameters. The principles of management described in this chapter cannot be interpreted as complete treatment prescriptions because each patient is an individual whose condition reflects multiple factors contributing to impaired oxygen transport or threat to it (i.e., the effects of recumbency, restricted mobility, extrinsic factors related to the patient's care, and intrinsic factors related to the patient in addition to the underlying pathophysiology). Special considerations with respect to physical therapy management with attention to body positioning and mobilization have been emphasized.

Review Questions

1. With respect to patients who are critically ill, describe the pathophysiology of cardiovascular and pulmonary dysfunction secondary to the following conditions: neuromuscular dysfunction, morbid obesity, musculoskeletal trauma, head injury, spinal cord injury, burns, and organ transplantation.
2. Relate cardiovascular and pulmonary physical therapy treatment interventions to the underlying pathophysiology of each of the conditions listed in question 1 in the patient who is critically ill, and provide the rationale for your choice.

Summary 595
Review Questions 595
References 595

The purpose of this chapter is to describe some common complications seen in patients who are critically ill that have implications for physical therapists practicing in the intensive care unit (ICU). Complications arising from the following conditions are included: respiratory failure, surgery, acute lung injury and ARDS, shock, sepsis, and multiorgan system failure (MOSF). Furthermore, the implications for cardiovascular and pulmonary physical therapy are presented. Complications add further complexity to the diagnosis of the multiple factors contributing to impaired oxygen transport and to the challenge of prescribing treatment parameters effectively. Understanding the pathophysiological deficits in these complex conditions is the basis for delivering effective management, reducing the risk of an untoward treatment response, and preventing worsening of the patient's condition. In addition, risks such as age, comorbidity, severity of trauma, extent of surgery, obesity, deconditioning, smoking, and Fi_{O_2} greater than 0.5 have been reported.[1] Compared with nonsurvivors, survivors of these conditions have increased right ventricular ejection fraction, Pa_{O_2}, Fi_{O_2}, and oxygen consumption ($\dot{V}_{O_2}$).[2] With respect to vasoactive substances, atrial natriuretic peptide, catecholamines, renin, and vasopressin are lower in survivors. Cardiac index is not different between survivors and nonsurvivors, and there is no correlation between hemodynamics and circulating vasoactive substances. Impending life threat is associated with global energetic failure secondary to cellular oxygen deficits. Despite the severity of illness of patients in the ICU, physical therapy has a well defined role in this setting.[3] More recently, the integration of physical therapy has been included in a quality control model of ICU care.[4] Although treatment options may be more restricted in patients with complications and greater

severity of illness, judiciously prescribed physical therapy can have an important role in reducing further complications, enhancing weaning from mechanical ventilation, and reducing ICU stay.[5]

Common Complications of Medical and Surgical Etiologies

Complications that arise in the ICU either directly or indirectly relate to threat or dysfunction of oxygen transport. Medical and surgical complications often coexist. Medical complications include metabolic dysfunction, pulmonary dysfunction related largely to mechanical ventilation, acid-base abnormalities, fluid and electrolyte disturbance, cardiac dysrhythmias, thromboembolism, myocardial dysfunction, gastrointestinal dysfunction, neurological dysfunction, and renal dysfunction. Surgical complications include hypoxemia, pain, deep vein thrombosis, and pulmonary embolism. The implications of these complications for physical therapy assessment and management are presented.

In severe cases of heart and lung failure, extracorporeal life support with artificial heart and lung, commonly called extracorporeal membrane oxygenation (ECMO), may be indicated. Rather than being a treatment, ECMO is a temporary means of providing partial or total life support. ECMO stabilizes the patient by regulating gas exchange and perfusion and facilitates recovery from the primary problem.[6] The major limitations to widespread applications are the need for anticoagulation and bleeding complications. Advances in ECMO have minimized the risk of bleeding and need for anticoagulants. They hold promise for prolonged extracorporeal circulation in patients with severe respiratory and cardiac failure.

Metabolic Dysfunction

Complications associated with respiratory failure that can further impair tissue oxygenation are described in Box 36-1. The metabolic consequences of these complications and impairment of oxygen transport are life-threatening for the patient. Thus prevention of their development is a priority. Should complications develop, however, early detection and definitive management become the priorities if the patient is to survive.

Box 36-1 Complications of Respiratory Failure

- Life-threatening impairment of oxygen transport and tissue oxygenation
- Fluid and electrolyte imbalances
- Cardiac dysrhythmias and hemodynamic instability
- Myocardial dysfunction
- Metabolic dysfunction
- Thromboembolism
- Neurological dysfunction
- Gastrointestinal dysfunction
- Renal dysfunction
- Metabolic and blood sugar irregularities
- Infection
- Nutritional deficits
- Complications of intubation and mechanical ventilation, including increased risk of infection
- Complications of oxygen therapy

A hallmark of these complications is the impairment of multiple steps in the oxygen transport pathway, which adds to the complexity of management.[7] The three major components of oxygen transport (i.e., oxygen delivery, consumption, and extraction) can be affected individually or in combination.[8,9]

In healthy individuals, the ratio of oxygen consumption to delivery is low (i.e., 23%, which ensures an oversupply of oxygen as a safety margin) (see Chapter 2). This safety margin also ensures that most patients are able to recover from insults to the oxygen transport system. If the insult is extreme, however, such as that resulting from complications of respiratory failure, surgery, acute lung injury and acute respiratory distress syndrome, shock, sepsis, and MOSF, metabolic dysfunction secondary to tissue hypoxia can result.

The relationship between oxygen consumption and delivery has elucidated our understanding of hemodynamic and metabolic changes observed in critical illness.[10] The phenomenon of oxygen-delivery dependence of oxygen consumption occurs when a patient's oxygen transport system is unable to supply sufficient oxygen to meet basal oxygen demand.[11] Oxygen delivery below 300 mL/min/m^2 limits the oxygen diffusion gradient and reduces oxygen extraction and usage at the cellular level. This is termed the *critical level of oxygen delivery.* When oxygen delivery exceeds 300 mL/min/m^2, $\dot{V}O_2$ does not depend on delivery. Thus the greater the delivery in relation to $\dot{V}O_2$, the greater the safety margin. When oxygen transport is so severely compromised that oxygen delivery falls below the critical level, anaerobic metabolism is triggered. Anaerobic metabolism, however, may also be triggered at levels of oxygen delivery that exceed the normal critical threshold for anaerobic metabolism.[12] This so-called "pathological dependence" of oxygen consumption on oxygen delivery occurs when the cells are inadequately extracting and using oxygen even in the presence of supranormal oxygen delivery levels. This phenomenon is observed in patients with ARDS and shock (discussed later this chapter).

Given that physical therapy is one of the most metabolically demanding ICU interventions,[13,14] the physical therapist needs to be able to calculate this safety margin to prescribe the type of treatment and its parameters (i.e., intensity, duration, and frequency) such that treatment is maximally beneficial and associated with the least risk to the patient.

The ultimate treatment outcome measures are markers of oxygen tissue metabolism.[8,15,16] In addition, continuous assessment of oxygen delivery, consumption, and extraction provide the basis for directing management of oxygen transport deficits.

Pulmonary Dysfunction

Complications of the cardiovascular and pulmonary systems can lead to respiratory failure (see Box 36-1).[17,18] Some of these, such as ventilator-associated pneumonia, relate to being mechanically ventilated. Certain technical problems related to the cuffs used in conjunction with artificial airways may occur (e.g., overinflation, distortion, and herniation of the orifice of the tube). Mucus plugs can occlude the endotracheal tube or tracheostomy and impede ventilation. The common

complications can be reduced if the tube is changed frequently and if minimal amounts of air are used for cuff inflation.

Prolonged endotracheal intubation can result in laryngeal edema, ulceration, and fibrosis. Mechanical ventilation may also rupture a bleb on the surface of the lung and produce a pneumothorax with rapid tension development. Chest tubes are inserted immediately to relieve the tension. Blebs occur when alveoli rupture, causing air to track to subpleural sites.

Mechanical ventilators can be a source of infection. The physical therapist can help minimize this risk by not directly handling the ventilator attachments that communicate with the airflow channels. Condensation from the hose should not be drained toward the ventilator or toward the patient. The physical therapist should be masked and gloved when connecting and disconnecting the patient to and from the ventilator.

Oxygen toxicity is a significant clinical complication of mechanical ventilation. Mechanical ventilators have precise oxygen controls to deliver the lowest possible inspired oxygen concentration needed to maintain arterial oxygen tensions. Because of the iatrogenic complications of high F_{IO_2} levels (i.e., denitrogen atelectasis and oxygen toxicity), oxygen above the patient's needs is never indicated other than for short periods of hyperoxygenation before suctioning or in preparation for, during, and immediately after mobilization.

Acid-Base Abnormalities

Any combination of acid-base imbalance may occur either acutely or chronically during respiratory failure. Severe alkalemia associated with potassium and chloride losses may occur after mechanical ventilation and can precipitate serious cardiovascular and neurological complications (see Chapter 16). Significantly impaired oxygen delivery to peripheral tissue may contribute to increased anaerobic metabolism and metabolic acidosis.[12]

Fluid and Electrolyte Abnormalities

Fluid retention can occur with prolonged mechanical ventilation in a patient with no evidence of cardiac failure. Pulmonary edema, weight gain, decreased pulmonary compliance, and reduced oxygen transport are common signs. Fluid overload is a common cause of this fluid retention. Individuals who are mechanically ventilated are therefore usually maintained underhydrated. Because of a tendency for sodium retention and hence fluid retention, intravenous saline solution is kept to a minimum. Humidifiers attached to mechanical ventilators are responsible for adding a considerable amount of water by absorption through the lungs.

Cardiac Dysfunction

When the heart fails to the point of cardiac output being compromised, intracardiac volumes and pressures can be monitored. Flow-directed pulmonary artery catheters (i.e., Swan-Ganz catheters) are commonly used in the ICU for monitoring patients who develop such hemodynamic complications. Although inserted through the venous side of the circulation through the right atrium and ventricle to lodge in a branch of the pulmonary artery, they provide useful measures and indices of right-sided and left-sided heart function and the adequacy of fluid resuscitation and pharmacological support. These catheters are also associated with some complications (see Chapter 16). Infection may lead to bacteremia and septicemia. Judicious selection and application of any invasive procedure is warranted to minimize undue hazard. The presence of these catheters limits head and neck positions and requires mobilization be carried out cautiously within the patient's hemodynamic tolerance.

Cardiac dysrhythmias are a common complication of respiratory failure. In addition, patients in respiratory failure tend to be older adults who as a group have a greater incidence of dysrhythmias secondary to cardiac disease. Electrocardiographic monitoring is therefore essential for all patients requiring ventilatory assistance in addition to patients with overt or suspected heart disease. Both atrial and ventricular tachydysrhythmias are seen in acute respiratory failure. Sinus tachycardia and premature ventricular contractions, however, are particularly common. Ventricular fibrillation or death may occur with rapid lowering of arterial P_{CO_2}.

In the presence of respiratory failure and absence of cardiac disease, the management of cardiac dysrhythmias lies predominantly in the correction of blood-gas abnormalities. Effective supportive management can usually be achieved with pharmaceutical agents. Electrolyte replacement may also be required.

A thorough understanding of the clinical presentation, diagnosis, and correct management of cardiac dysrhythmias is fundamental to the optimization of physical therapy treatments in the ICU and minimization of any risk to the patient. Cardiac dysrhythmias resulting from any cause necessarily require ongoing evaluation and therapy.

The physical therapist must be able to treat the patient with any dysrhythmia optimally and safely when associated with other medical or surgical conditions. The implications of the dysrhythmia for the patient's clinical presentation as well as treatment selection and response must be recognized by the physical therapist and considered in designing the treatment plan.

Thromboembolism

A high incidence of pulmonary thrombosis or embolism exists in patients in acute respiratory failure. Early diagnosis and management of pulmonary thromboembolism have been greatly facilitated by the use of serial ultrasound procedures and scans. Physical therapy has a key role in preventing the development of thromboemboli by promoting frequent changes in position; specific bed exercises, particularly of the lower limbs; and passive range-of-motion exercises if indicated. It is essential that movement and repositioning be performed regularly to maximize their cardiovascular and pulmonary protective benefits. Pneumatic extremity cuffs apply pressure intermittently over the lower legs to minimize venous pooling and assist venous return (see Chapter 33). Compression stockings also may be applied over the feet and legs to increase circulatory transit time in the dependent areas and reduce circulatory stasis.

Myocardial Dysfunction

As in any clinical situation, acute myocardial infarction can occur during the management of acute respiratory failure. The risks are increased because patients in respiratory failure tend

to be older and more susceptible to positional hypoxemia. The probability of heart failure and associated dysrhythmias is increased and compounds the problems of the patient in respiratory failure.

Gastrointestinal Dysfunction

Stress ulceration leading to peptic ulcers is commonly associated with chronic airway obstruction. The stress of respiratory failure predisposes the patient to peptic ulceration. Profound hemorrhage may occur and blood replacement is necessitated.

Gastric dilation may occur in patients who are receiving mechanical ventilation. Gastric dilation is best managed by a nasogastric tube and intermittent suction. Care must be exercised to avoid hypokalemia and hypochloremia caused by excessive gastric suctioning. Special care is also taken to avoid fecal impaction, particularly in the patient who is paralyzed. This risk can be reduced with suitable fluid balance, mobilization, and frequent turning in conjunction with appropriate trunk and lower-limb movements.

Muscular and Neurological Dysfunction

A close correlation exists between state of consciousness and arterial P_{O_2} and P_{CO_2}. In addition, alteration in blood gases causes changes in alertness, personality, memory, and orientation. Motor changes include generalized or localized weakness, tremors, twitching, myoclonic jerks, gross clonic movements, convulsions, and flaccidity. Neurological complications of respiratory failure must be differentiated from those of nonpulmonary origin. The physical therapist must be aware of the spectrum of neurological complications that can result from respiratory failure and recognize that apparent improvement of neurological signs may reflect improved cardiovascular and pulmonary status.

Critical illness neuropathy and critical illness myopathy are serious complications of critical illness and are associated with metabolic disturbance during illness, paralysis, neuromuscular blockade, recumbency, and restricted mobility.[19,20] Prevention is a primary goal and includes early detection. Detection of risk factors is an important component of the physical therapy assessment. Additional risk factors include ICU stays over 7 days, sepsis and systemic inflammatory response syndrome (SIRS), multiorgan system dysfunction, a high Acute Physiology and Chronic Health Evaluation III (APACHE III) score, the use of high-dose steroids, and patients who have had organ transplantation, patients with severe neurological or muscle disease, and those with hyperglycemia.[21]

Periodic nerve electrical stimulation has been one means of establishing nerve conduction integrity during an assault of critical illness requiring neuromuscular blockade and sedation. Medical management is focused on addressing its causes and reversing them. Because rehabilitation potential is threatened in the presence of critical illness neuropathy and critical illness myopathy, physical therapy goals focus not only on reducing the possibility of neuropathy and myopathy and their functional sequelae but also on facilitating weaning and improving clinical outcomes overall including functional independence.[21]

Renal Dysfunction

Lung and kidney dysfunction are closely related.[22] The development of renal failure greatly compromises the chances of the patient's survival. Renal failure can result from gastrointestinal bleeding, sepsis associated with shock, drug-induced nephrotoxicity, and hypotension. Urinary outputs are maintained with adequate fluid and diuretics, with care not to induce pulmonary edema. Dialysis may need to be instituted if more conservative management fails.[23] If dialysis is anticipated, the physical therapist should review existing treatment goals to modify treatment accordingly.

Systemic Inflammatory Response Syndrome

Localized inflammation is a physiological protective response. Typically this response is controlled by the body at the site of injury.[24] Loss of local control or an overly active response results in an exaggerated systemic response that is known as *systemic inflammatory response syndrome* (SIRS). Compensatory mechanisms and outcome (such as resolution, or potentially multiple organ dysfunction syndrome or death) depend on the balance of SIRS and the effectiveness of the compensatory mechanisms. The effectiveness of therapies to date remains equivocal.

Common Complications of Surgical Etiology

Respiratory failure in a patient postoperatively is usually associated with a low Pa_{O_2} and a high Pa_{CO_2}. This situation is likely to be more common than generally appreciated. If the patient is in good general health and is free from underlying cardiovascular and pulmonary conditions, recovery is usually rapid. Otherwise, more severe complications and cardiovascular and pulmonary failure may result and progress to a life-threatening situation. The effects of surgery on oxygen transport and on the various organ systems are described in Chapter 23. Common perioperative complications and their causes are listed in Boxes 36-2 and 36-3. With severely reduced arterial oxygen content, hence oxygen delivery, oxygen extraction increases.[25]

Hypoxemia

The most common postoperative complication is hypoxemia secondary to alveolar hypoventilation, reduced functional residual capacity (FRC), airway closure, and postsurgical atelectasis.[26,27] Adequate oxygenation, however, can be present despite hypoventilation when oxygen is being administered. The presence or absence of cyanosis may be an unreliable sign because peripheral cyanosis can occur despite adequate arterial P_{O_2}. Morbidity and mortality have been reported to be reduced in patients with severe respiratory failure and system involvement when supranormal levels of oxygen delivery are achieved.[21,28]

Box 36-2 Common Postoperative Complications

- Hypoxemia
- Hypercapnia
- Increased work of breathing
- Increased work of the heart
- Fluid shifts and third spacing
- Fluid and electrolyte imbalances
- Metabolic and blood sugar abnormalities
- Reduced blood volume
- Cardiac dysrhythmias
- Reduced cardiac output
- Reduced tissue perfusion and oxygenation
- Anemia
- Pain
- Alveolar hypoventilation
- Airway collapse
- Atelectasis
- Physiological shunting
- Ventilation and perfusion mismatching
- Impaired mucociliary transport
- Accumulation of mucus and stasis
- Pneumonia
- Thromboemboli
- Pulmonary embolus
- Coagulopathies
- Sepsis
- Shock
- Multiorgan system failure

Box 36-3 Factors Contributing to Perioperative Complications that Affect Oxygen Transport

- Premorbid cardiovascular and pulmonary status
- Premorbid oxygen transport (aerobic) capacity
- Premorbid systemic disease
- Premorbid general health and immune status
- Smoking history
- Age and sex
- Lifestyle factors: nutritional status, stress, work situation, family situation, psychosocial support system, and substance abuse
- Obesity
- Pregnancy
- Pain and anxiety
- Reduced arousal
- Reduced mobility
- Recumbency
- Medications (e.g., narcotics)
- Nutritional deprivation
- Reduction in normal sleep quality and quantity
- Type of surgery
- Extent of physical manipulation and compression of lung parenchyma, phrenic nerves, diaphragm, and the heart
- Fever and increased oxygen consumption
- Duration of surgery
- Position assumed during surgery
- Duration of static positioning during surgery
- Type, depth, and duration of anesthesia and sedation
- Use of an airway
- Use of mechanical ventilation
- Oxygen therapy
- Neuromuscular blockade
- Fluid loss and chest tube drainage
- Fluid accumulation and third spacing
- Infusion of blood products
- Site, number, and extent of incisions
- Dressings and binders
- Traction and splinting devices
- Placement of lines, leads, catheters, and monitoring devices
- Invasive monitoring equipment (e.g., Swan-Ganz catheter, Foley catheter, intracranial pressure monitor, central venous line, arterial lines, intravenous lines, and intraaortic balloon counter pulsation pump)
- Need for cardiopulmonary bypass machine
- Duration of cardiopulmonary bypass machine use
- Infection

Pain

Pain, in addition to the effects of anesthesia, frequently contributes to alveolar hypoventilation and atelectasis after abdominal or thoracic surgery. Rapid, shallow, and monotonous breathing may be spontaneously adopted by the patient to avoid pain and coughing. Although minute ventilation is favored, alveolar ventilation is compromised by the increased ratio of dead space to tidal volume. Furthermore, in the absence of deep breaths, coughs, and sighs, atelectasis may develop in the underventilated portions of the lungs. The ventilation-perfusion ratio is disturbed because blood flow to underventilated lung segments is ineffective, physiological shunting occurs, and arterial P_{O_2} tends to drop although P_{CO_2} may be unchanged. An abnormally high transpulmonary pressure is then needed to reinflate these atelectatic alveoli. The physical therapist ensures good pain control before intervention, including mobilization. Patient-controlled analgesia is used if the patient is able to cooperate sufficiently, as well as conventionally administered analgesia, as required.

Pulmonary Embolism and Deep Vein Thrombosis

Pulmonary embolism is a life-threatening complication. Pulmonary embolism usually results from a thrombus forming in the veins of the lower limbs, in the pelvis, in the right atrium, or in the right ventricle. Patients may be at risk if they have varicose veins, chronic heart failure, or cancer or if they are obese, pregnant, or taking oral contraceptives.

The patient with a pulmonary thromboembolism usually has a sudden onset of tachypnea, radiating chest pain, and apparent anxiety. Occasionally, right-sided heart failure follows. Enzymes are often elevated. Right-sided heart strain may be evidenced on an echocardiogram or electrocardiogram (ECG). Right bundle branch block, peaked P waves, and inverted T waves may be seen. There may be no abnormality noted on chest radiographs.

Treatment consists of primary ventilatory and circulatory support, with adequate oxygenation of peripheral tissues. Anticoagulants, such as heparin, are infused intravenously to minimize further formation of thromboembolic substrates.

Principles of Physical Therapy Management

Impairments in lung volume, mechanics, and gas exchange uniformly occur after anesthesia and tissue dissection. The extent and duration of these changes increase with the magnitude of the operative procedure, the degree of anesthesia required, and the patient's premorbid risk factors. These abnormalities observed in the postoperative period are characterized by gradual and progressive alveolar collapse. Total lung capacity, FRC, and residual volume are decreased in patients who develop complications. Because of the decrease in FRC (30% or more), lung compliance is decreased, and therefore the work of breathing is increased. Hypoxemia secondary to transpulmonary shunting usually becomes maximal within 72 hours after surgery and often is completely resolved with conservative management within 7 days. The Fi_{O_2} will depend on the mode of supplemental oxygen administration. Low oxygen flows and low amounts of Fi_{O_2} tend to be delivered via nasal cannulas. Higher flows can deliver higher amounts of Fi_{O_2} via oxygen masks and masks with reservoir bags. The Fi_{O_2} must always be taken into account in interpreting arterial blood gases. The Fi_{O_2} is selected to provide adequate oxygenation with the lowest oxygen concentration possible.

On the basis of patient assessment, arterial blood gases, fluid and electrolyte balance, hemodynamic status, and radiographs, a decision is made as to which treatments on the physiological hierarchy will optimize oxygen transport and what parameters will be used for each treatment. Positioning these patients upright and mobilizing them whenever possible will maximize FRC and reduce closing volumes and hence enhance gas exchange and oxygenation. What precludes mobilizing these patients even minimally is their lack of alertness, which must be explained. If the patient is unable to respond to treatment because of narcotics, for example, this can be discussed at rounds, and other medications should be considered so that the patient is able to cooperate more. Thus even extreme body positioning will achieve more favorable results.[29-31]

Endotracheal intubation and mechanical ventilation may be indicated if blood gases fail to improve with conservative management. The treatment priorities for the ventilated patient before and during weaning are presented in Chapter 33. Special attention in the postoperative patient is given to the pulmonary complications associated with diminished ability to move spontaneously, surgical pain, restrictions imposed by dressings and binders, and diminished ability to cooperate and to periodically hyperventilate the lungs.

Facilitating mucociliary transport is a primary goal in these patients. Impaired mucociliary transport can be precipitated by alveolar hypoventilation, perhaps the most common cause of postoperative complications. Sufficient impairment can lead to mucus stasis, airway obstruction, atelectasis, and infection. Multiple positions, including upright positions and 360-degree axial turns, and multiple position changes facilitate mucociliary transport. In the event of accumulation of mucus and difficulty in removing pulmonary secretions, specific body positions are selected to optimize postural drainage of the affected bronchopulmonary segments and to maximize alveolar volume and ventilation. The addition of manual techniques can be detrimental in severely ill patients; thus their use needs to be considered carefully.

Suctioning may be most effective immediately before and after position changes. The appropriate oxygen transport variables are monitored to assess treatment outcome and minimally to ensure that the condition of the patient, which may be unstable, is not deteriorating. If the patient's condition begins to deteriorate, treatment is discontinued until the condition stabilizes. Why the patient's condition deteriorated is determined so that a decision can be made as to whether treatment can be reintroduced and, if so, what modifications are indicated.

Pain management is integral to the management of the surgical patient. Noninvasive and nonpharmacological pain control strategies need to be exploited for all surgical patients to augment or reduce the need for potent analgesics, especially narcotics. Chapter 30 describes some physical therapy pain-control strategies for surgical patients that can be applied with modification to the patient with surgical complications. Of these, use of electrotherapy modalities, such as transcutaneous electrical nerve stimulation, may be limited in the ICU because of electrical interference with monitoring devices.

Rest is prescribed as judiciously as treatment interventions to enable the patient to physiologically restore between and within treatments. This is particularly important for ICU patients who are hypermetabolic and have increased oxygen demands. Particular care must be observed in prescribing treatment threshold parameters for these patients. Suprathreshold states can be associated with an inappropriate balance between oxygen delivery and oxygen consumption such that the patient becomes compromised (e.g., patient becomes hemodynamically unstable, cardiovascular and pulmonary distress is precipitated, or both). A greater volume of a mobilization stimulus, however, may be delivered to these patients with an intermittent mobilization regimen than with a single prolonged course of mobilization. Thus the benefits that would be accrued would be correspondingly increased.

Prevention of thromboemboli is a major treatment objective and is best achieved with mobilization, body positioning, passive movements, and physical devices, such as pneumatic cuff devices and stockings, to augment low-dose anticoagulants in patients at risk. Patients who develop pulmonary emboli are treated medically, and physical therapy must be correspondingly modified to minimize oxygen consumption until the patient is in no imminent danger.

Complications Resulting in Secondary Cardiovascular and Pulmonary Dysfunction

Acute Lung Injury and Acute Respiratory Distress Syndrome

Acute lung injury results from damage to the alveolar epithelium.[32] The extent of the damage reflects damage to the type I and type II alveolar cells. Damage to the type I cells results in alveolar edema, atelectasis, and loss of lung compliance

secondary to loss of structural integrity of the alveoli provided by the type I alveolar cells. Damage to the type II cells also contributes to atelectasis and loss of lung compliance, but the mechanism relates to impairment of the production of surfactant and pulmonary fluid that covers the alveolar epithelium.

Pulmonary edema refers to the accumulation of vascular fluid in the interstitial spaces and alveoli. In acute lung injury the mechanism of pulmonary edema involves increased water movement across the pulmonary endothelial cells and increased permeability of the endothelium to protein. This type of pulmonary edema is referred to as *noncardiogenic pulmonary edema.* Pulmonary edema that is cardiogenic in origin results from left ventricular failure. An increase in hydrostatic pressure damages the interstitial tight spaces, which normally provide an effective barrier between the pulmonary circulation and alveoli. The critical distinction between the two types of pulmonary edema is that cardiogenic pulmonary edema primarily involves the movement of water across the alveolar capillary membrane, whereas noncardiogenic pulmonary edema involves the movement of protein and water into the interstitial and alveolar spaces. The clinical consequences reflect the location of the edema (i.e., interstitial, alveolar, or both) and the amount of fluid accumulation.

Acute lung injury is characterized as a clinical spectrum of parenchymal cell dysfunction. Mild injury reflects predominantly endothelial cell dysfunction and noncardiogenic edema. Severe injury reflects a progression to both endothelial and epithelial cell dysfunction and ARDS. The clinical spectrum of acute lung injury and the clinical manifestations of mild and severe injury are shown in Figure 36-1. The clinical presentation of moderate injury falls between these two extremes.

ARDS results from major insult to the lung and injury to the alveolar-capillary membrane. Some of the causes of ARDS include shock, severe trauma or infection, overwhelming pneumonia, and inhaled toxins. Increased vascular permeability resembling that of the inflammatory response is a common feature. Fluid seeps into the interstitial spaces and overwhelms the alveoli, leading to pulmonary edema. Lung compliance and gas exchange are severely compromised. Thus the patient manifests severe dyspnea and hypoxemia. Diffuse pulmonary infiltrates appear on radiographs. Arterial hypoxemia results primarily from underventilated but perfused lung units and right-to-left shunt. In this situation, hypoxemia is relatively refractory to increases in Fio_2.

Fibrinogen in the fluids leaking into the alveoli contributes to fibrosis and reduction of lung compliance associated with ARDS. Increased lung surface tension and alveolar collapse tend to result from an inactivation of surfactant with the accumulation of fluid in the alveolar spaces. Thus, reduced lung compliance produces a decrease in FRC in the patient with ARDS.

The signs and symptoms of ARDS may take up to 48 hours to fully manifest. Survival rate has increased over the past decade from 50% to 80%.[33] The explanation for this improvement is unclear; however, the shift to an integrated management approach may be responsible.[34,35] Hypoxemia is a principal feature of the syndrome, resulting from ventilation-perfusion mismatch and from a right-to-left shunt, whereby fluid-filled alveoli are ineffectively ventilated.[36] Hyperventilation and labored respiration can be expected in conjunction with hypoxemia. Oxygen therapy has little effect in the

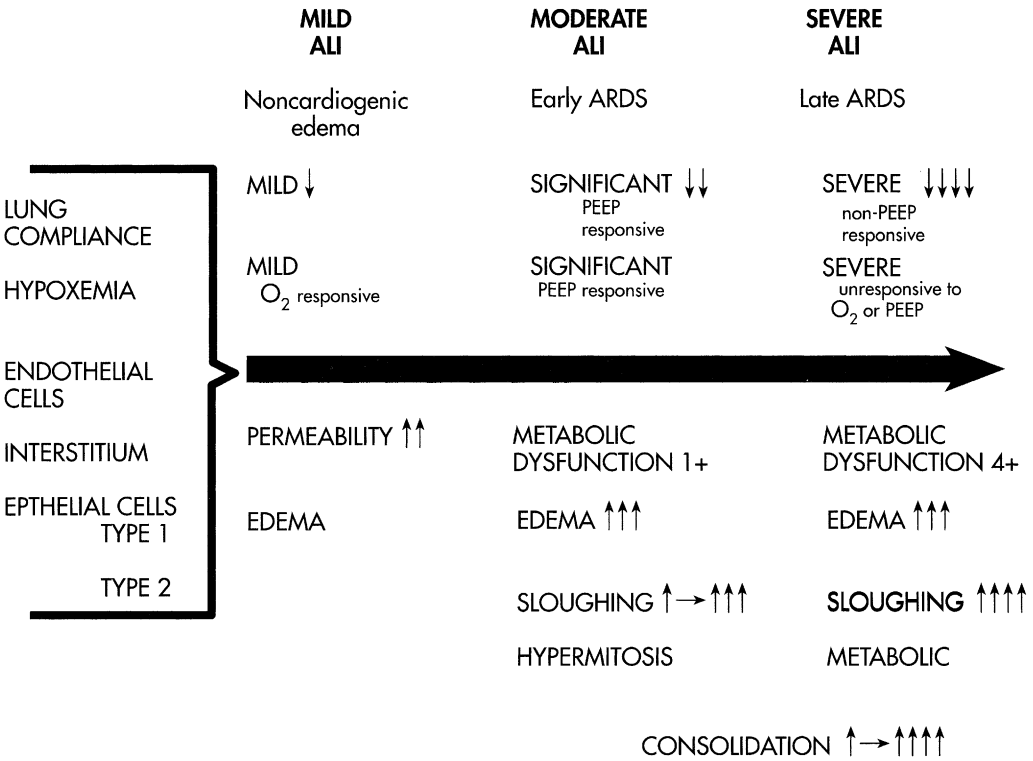

Fig. 36-1 Major pathophysiological manifestations composing the spectrum of acute lung injury from mild to severe disease. *(From Shapiro BA, Peruzzi WT: Changing practices in ventilator management: a review of the literature and suggest clinical correlates,* Surgery *117:121–133, 1991.)*

presence of shunting. Hypercapnia is not usually a major problem in the patient with ARDS.

The metabolic perturbations that can result include problems with oxygen delivery, consumption, and extraction, as discussed previously. When oxygen delivery falls below the critical level, anaerobic metabolism is triggered, resulting in increased lactate production. Elevated serum lactates are associated with a poor prognosis. Changes in oxygenation may not be reflected in $S\bar{v}O_2$ because of the abnormal dependence of oxygen consumption and delivery. Positive end-expiratory pressure (PEEP) can worsen DO_2 in patients with ARDS who are mechanically ventilated and sedated. In turn, $\dot{V}O_2$ may become oxygen supply dependent; thus peripheral extraction may be increased.

Recent advances in the medical management of ARDS include the use of partial liquid ventilation. Although not widely adopted, this form of ventilation may be more effective in recruiting dependent alveoli than conventional mechanical ventilation and may augment the benefits of exogenous surfactant replacement, inhaled nitric oxide, and prone positioning.[37] In addition to improving oxygenation and respiratory mechanics, partial liquid ventilation may reduce ventilator-induced lung damage.[38]

Over the past decade there has been greater interest in long-term outcomes of patients after a course of ICU care, with evidence to support poor long-term functional outcomes. Herridge and colleagues,[39] for example, followed 109 survivors of ARDS at 3, 6, and 12 months after hospital discharge. The patient characteristics were mean age 45 (36 to 58 years); mean APACHE II score 23 (17 to 27); mean ventilator days, 21 (12 to 40); and mean ICU stay, 25 days (15 to 45). All patients reported poor function and attributed this to the loss of muscle bulk, proximal weakness, and fatigue. Only 49% reported working at 12 months. Thus survivors of ARDS may have persistent functional disability 1 year after discharge from the ICU. Furthermore, extrapulmonary conditions such as muscle wasting and weakness were common.

Principles of Physical Therapy Management

As in the management of other conditions, physical therapists need to address the immediate short-term needs of the patient related to maximizing oxygen transport as well as long-term functional outcomes, including aerobic capacity and general physical conditioning, that meet the needs of daily living.

With respect to the short-term goals of maximizing oxygen transport in patients with ARDS (comparable to others with severe respiratory distress), patients will be intubated and mechanically ventilated. Intubation and ventilatory support are implemented if arterial blood gases are severely affected and respiratory distress worsened. An endotracheal tube can be placed through the nose or mouth or a tracheostomy can be performed in cases in which prolonged ventilatory support is anticipated. A high level of PEEP maintains the alveoli open and thereby optimizes gas transfer at end expiration. Arterial oxygenation is usually improved with PEEP because the effect of shunting is reduced and a given FiO_2 tends to be more effective. Although the FiO_2 may be reduced, which reduces the possibility of oxygen toxicity, supranormal oxygen delivery can be beneficial in these patients. Survival may be improved and frequency of MOSF reduced.

Further monitoring of respiratory status in conjunction with arterial blood gases is essential for following the progress of the syndrome. In addition to the oxygen transport variables, the principal parameters monitored in ARDS are reduced lung compliance, tachypnea, and the concentration of inspired oxygen needed to maintain acceptable levels of the arterial blood gases.

ARDS is characterized by a major pathophysiological restrictive component; hence the principles of management of restrictive lung disease are applied. Changes in lung compliance and FiO_2 requirements provide guidelines to treatment required, treatment response, and course of the syndrome. Patients with ARDS require close monitoring and often treatments aimed at promoting optimal gas exchange because of the severity of the syndrome and high incidence of mortality associated with it.

Initially, if the patient is sedated, body positioning is exploited to maintain blood gases, and optimal range of motion and skin care are the focus of management. In severe ARDS the patient usually requires a high degree of ventilatory support with high FiO_2, and sedation. Severely affected patients may require neuromuscular blockade to reduce their oxygen demand and enable them to respond to ventilatory assistance more effectively. Handling and positioning patients on neuromuscular blockade requires particular care because these patients lack muscle tone to protect their muscles and joints. Rotating beds can be extremely beneficial for patients who are either too hemodynamically unstable or difficult to turn manually. These mechanical beds slowly rotate side to side through an arc, thus changing the patient's body position continuously.[40,41] When the effects of continuous axial rotation on a kinetic bed are compared with the effects in prone position, they have been shown to be comparable.[42]

The prone position can have immediate benefit in remediating hypoxemia in patients with ARDS,[43,44] and oxygenation can be significantly improved over supine.[45] This position and semirecumbent positions can augment the effects of mechanical ventilation.[46] The prescriptive parameters of the prone position in patients with ARDS, however, need to be based on a careful analysis of the pros and cons for each patient, and no single position will be maximally beneficial all the time. There are other physiological benefits to shifting the patient's position rather than maintaining a single position (see Chapter 20), provided that oxygenation is not compromised. With improvement of ARDS (e.g., less ventilator support, reduced FiO_2, and satisfactory gases), the patient may be able to be mobilized with careful monitoring of vital signs, ECG, saturation, and subjective tolerance. Body positioning is initiated as soon as patients can tolerate it without significant desaturation. Special attention is given to body positioning to promote ventilation and perfusion matching and mucociliary transport and to minimize the effect of restriction of diaphragmatic and chest wall excursion. Some patients, for example, benefit from side-lying positions in which excursion of the inferior hemidiaphragm is favored. Other patients, however, seem to deteriorate from apparent restriction of the inferior lung in side-lying positions.

The underlying pathophysiology associated with ARDS is primarily related to respiratory mechanics, which could explain why improvements in oxygenation have not been associated with secretion clearance.[47] Each patient's condition and specific areas of lung involvement must be taken into

consideration when a turning regimen is prescribed. The effect of the patient's body position on blood gases helps to establish a suitable regimen on a rational basis. Optimal positioning can result in reduced supplemental oxygen needs.[48] The sitting position optimizes lung capacity even when a patient is intubated and mechanically ventilated. The airway can dislodge, however, so caution must be observed and the artificial airway properly secured before any mobility activity. The use of a reclining chair at the bedside should be considered in the management of patients with acute lung injury. Theoretically, the potential function of all lung fields will be benefited with the lungs in a more upright position. Patients who are too unstable to tolerate upright positions and whose oxygenation is compromised in this position[49] may respond favorably to extreme body positions and the prone position.[50,51] The clinical benefits of the prone position in the management of the majority of patients with ARDS have been well documented over the past 20 years; thus physical therapists need to consider positioning these patients prone as a common practice barring contraindications.

Improvements in oxygenation in patients with acute lung injury and ARDS with the prone position, including prone abdomen free, have been well documented in adult and pediatric populations.[33,52-55] The benefits can persist when the patient is returned to the supine position, and furthermore, the prone position does not adversely affect hemodynamics.[56] The use of the prone position in the management of ARDS has been reported to be independently associated with survival.[57] The literature is inconsistent, however, regarding whether patients respond differently depending on the underlying ARDS pathophysiology (pulmonary or nonpulmonary). Some investigators report no differences,[58] whereas others have reported marked differences with respect to radiographic changes, respiratory mechanics, and time course of oxygenation.[54] These differences may be explained by pathophysiological differences in the primary disease insult responsible for ARDS, stage and severity, and comorbidity.

The mechanisms for improved gas exchange in prone positions in these severely ill patients have been the subject of much interest. Hypotheses have included improved alveolar recruitment and lung volumes; homogeneous distributions of ventilation and perfusion[59]; increased static lung compliance[60]; and reduced compressive forces compared with the supine position.[61,62] In the posterior lung fields in the prone position, in the areas where atelectasis, shunt, and ventilation-perfusion mismatch are most prevalent, transpulmonary pressure exceeds airway opening pressure without apparently compromising anterior lung fields.[63] A decrease in $PaCO_2$ with prone positioning predicts survival.[64]

Problems with positioning patients in prone have been reported to be rare. Studies have been focusing on the differences between patients who respond favorably and those who do not (i.e., responders versus nonresponders). Patients may respond better in the early stages in which pulmonary edema is present versus the later stages in the presence of pulmonary fibrosis.[65] Alveolar recruitment procedures are more effective in improving PaO_2 in the prone position, and lower PEEP levels are needed to sustain improved PaO_2 compared with the supine position.[66] In addition, positive inspiratory pressure, hence barotrauma, and FiO_2 can be reduced.[59] The effects of mechanical ventilation including PEEP,[67] airway pressure release ventilation,[68] and certain pharmacological agents (inhaled nitric oxide) may be augmented in the prone position.[69] Other studies have reported a particular beneficial effect of the prone position. One study reported that the prone position rather than PEEP improved oxygenation.[70] Another study reported that prone positioning improves oxygenation more than inhaled nitric oxide in patients with severe ARDS.[71]

Although considerable evidence supports the clinical effectiveness of the prone position to improve oxygenation, this position should be considered for the management of hypoxemia associated with other conditions as a means of simulating the normal effects of gravity on cardiovascular and pulmonary function. Favorable results have been reported in the management of hypoxemia associated with acute respiratory failure in acute myeloid leukemia,[72] pulmonary hemorrhage,[73] and subarachnoid hemorrhage.[74]

Few complications have been reported with the use of body positioning, and in particular the prone position. Normal precautions are taken to ensure that ventilator tubing and lines and leads are not compromised. Despite beneficial effects of oxygenation in patients with ARDS related to trauma,[75] complications associated with prone positioning have been reported for such patients, including facial and chest wall skin necrosis, wound dehiscence, and cardiac arrest.[76] Special precautions are necessary in this subgroup. Brachial plexopathy has also been reported when positioning patients prone in the ICU.[19] In addition to frequent body position changes, the semiprone position may help to avoid the adverse effects of prone positioning in some patients.[77]

Shock

Common causes of shock include hypovolemia, septicemia, heart failure, and direct insult to the central nervous system. Some of the classical features of shock are hypotension, reduced cardiac output, tachycardia, hyperventilation, diaphoresis, pallor, confusion, nausea, and incontinence. Inadequate tissue perfusion results in extracellular acidemia and loss of potassium ions from the cells. The pulmonary blood vessels constrict in response to hypoxemia, which tends to increase pulmonary artery pressures.

Failure of cellular function secondary to shock can result from a deficiency of substrate for energy production, a reduced ability to use the nutrients for energy production, or both. The pathophysiological mechanisms responsible include hypoperfusion of the tissues, hormonal and metabolic cellular changes, and the toxic effects of the metabolic changes. Collectively, these produce cellular damage. With hypoperfusion and decreased oxygen delivery and other nutrients, the production of adenosine triphosphate is reduced. The maintenance and repair of cell membranes is disrupted, resulting in swelling of the endoplasmic reticulum and eventually the mitochondria. Persisting cellular hypoxia contributes to rupture of the lysosomes, which releases enzymes that contribute to intracellular digestion and calcium deposition. Once the lysosomes have ruptured and intracellular digestion has been triggered, irreversible cell damage ensues, impairing oxygen extraction and uptake.[9]

The dependence between oxygen consumption and delivery is a marker for septic shock and thus provides justification for increasing oxygen delivery (see Chapter 2).[78] The relationship of oxygen consumption and delivery has been used to evaluate

patients who are critically ill with SIRS and predict metabolic stress on this basis.[79]

The pathology of shock and the effect on the respiratory membranes of the mitochondria follow a similar course regardless of cause. Swelling of the interstitial tissue disrupts the perfusion of the pulmonary capillaries. Congestive atelectasis and pulmonary edema ensue. In the advanced stages, hyaline membrane changes and pneumonitis may occur.

When shock is associated with heart failure, ventricular assist devices or an intraaortic balloon pump may be indicated. These devices reduce the degree to which the patient can be positioned and moved; therefore consultation with the team is essential in progressing such a patient.

Septic shock is a serious condition; patients manifest hypotension despite intensive medical treatment. Persistent hypotension leads to decreased blood flow to vital organs and can result in acute MOSF. Poulsen and colleagues (2009)[80] followed 174 patients in the ICU to evaluate the physical outcomes of survivors 1 year after septic shock. Survivors were interviewed about their physical function and socioeconomic status. Seventy-eight patients were invited to participate, and 70 replied. After 12 months, two thirds of the patients reported that they had not regained their preadmission physical status, and 81% attributed this to loss of muscle mass. Physical function is substantially reduced in survivors of septic shock 1 year after discharge; thus recovery of physical function warrants being identified as a long-term goal.

Principles of Physical Therapy Management

Foremost, the physical therapist must be knowledgeable about the relationship of oxygen delivery and consumption in patients with shock, as well as the implications of the pathophysiological processes on oxygen extraction. The type of treatments and their parameters are based on a careful analysis of oxygen transport variables. Treatments are prescribed within the patient's safety margin. Physical therapists in the ICU must also be knowledgeable about the signs and symptoms associated with impending and frank shock. By recognizing and understanding the components of the different types of shock and the effect on the cardiovascular and pulmonary systems, the physical therapist can better prescribe a rational treatment plan for the short- and long-term management of the patient.

Although physical therapy may be limited in reversing the signs and symptoms of shock, physical therapy can help to restore and maintain optimal cardiovascular and pulmonary function, reduce the risk of complications associated with restricted mobility and recumbency, and maintain physical status at an optimal level during the episode and in anticipation of the patient's recovery. The primary objective, however, is to minimize oxygen demand. A minimal objective is not to worsen the patient's condition by imposing excessive metabolic demand. This is the case in patients whose oxygen delivery is approaching the critical level with respect to oxygen consumption dependence. Excessive demands in these patients can be life-threatening.

Patients in shock are usually unresponsive. The course of the shock episode is often complicated by the sequelae of restricted mobility and recumbency. The specific goals related to optimization of cardiovascular, pulmonary, and musculoskeletal function and prevention of further complications associated with cardiovascular and pulmonary function in particular are priorities.

Treatment goals are therefore critically appraised and prioritized throughout each day to target physical therapy treatment only to the very immediate and essential needs of the patient, avoiding unnecessary fatigue. Prudent patient positioning is a priority because of the relative immobility and reduced spontaneous movement observed in these patients, and recumbency. Approximations to the upright position (i.e., head of bed up and foot of bed down) can augment sympathetic stimulation and improve hemodynamic status and reduce sympathomimetic medications. In addition, this position simulates the upright sitting position (although not perfectly) with respect to its beneficial effects on pulmonary and cardiac function.

Late stages of refractory shock leading to renal failure may necessitate dialysis. If hemodialysis is indicated, the patient is connected to a unit that dialyzes the blood externally. This process takes several hours and is usually repeated every few days.

Comparable to the management of other patients who are unstable and severely ill, physical therapy may consist of primarily supportive care and comprehensive monitoring in the patient with severe effects of shock regardless of whether he or she is in an acute or chronic stage.

Sepsis and Multiorgan System Failure

Sepsis is the response to bacteremia or other byproducts of bacteria in the blood. The clinical features of sepsis include fever, tachycardia, tachypnea, and respiratory alkalemia. Metabolic abnormalities are also a common feature of sepsis. Sepsis is the most common predisposing factor contributing to MOSF, which typically involves failure of more than two organ systems.[81,82] Table 36-1 shows the major organs affected and their clinical manifestations (i.e., pulmonary, gastrointestinal, hepatic, renal, cardiovascular, hematological, and central nervous systems). The cascade of pathophysiological features of MOSF is precipitated by multiple mediator systems. The release of these mediators impairs oxygen delivery and usage of oxygen by the cells. Inadequate tissue oxygenation may be a mechanism underlying MOSF. Thus, the supply of the major energy source to the cell, adenosine triphosphate, is reduced, which leads to structural and functional damage of the various organ systems. The mortality rate ranges from 60% to 80%.

Conditions that predispose a patient to MOSF include sepsis, overwhelming infection, multiple trauma and tissue injury, inflammation, and tissue perfusion deficits. Patients who are older, have chronic conditions, are immunosuppressed, or have a severe initial presentation have an increased risk of failure and mortality.

Sepsis causes damage to peripheral nerves and muscles as well as organs and is termed critical illness polyneuropathy (CIP).[83] Although the pathogenesis is not understood, these effects must be detected early and addressed to avoid clinical manifestations including muscle weakness, prolonged recovery, and delayed weaning. The systemic inflammatory response and MOSF have been implicated, and neuromuscular blockers and steroids can exacerbate these manifestations. The use of steroids and muscle relaxants should be minimized. Stabilizing the underlying critical condition and avoiding sepsis are of major importance in preventing CIP.

Table 36-1 Presentation of Multiorgan System Failure

Organ	Clinical Presentation	Syndrome
Lungs	Hypoxemia, lung compliance, diffuse infiltrates	Acute lung injury, ARDS
Kidneys	Creatine >2 mg/dL Urine output <500 mL/24 h Urine output >500 mL/24 h	 Oliguric ARF Nonoliguric ARF
Liver	Bilirubin 2 mg/dL, SGOT and LDH Intractable hyperglycemia or hypoglycemia Cholecystitis	Jaundice Hepatocyte failure Acalculous cholecystitis
Gut	Upper gastrointestinal bleed	Stress ulceration
Coagulation	Thrombocytopenia, prolonged PT and PTT	Hypofibrinogenemia, DIC
Heart	Hypotension, CI	Heart failure
CNS	Response only to painful stimuli	Obtundation

Modified from Kirby RR, Taylor RW, Civetta JM: Critical care, *ed 2, Philadelphia, 1996, Lippincott Williams & Wilkins.*

ARDS, Acute respiratory distress syndrome; ARF, acute renal failure; CNS, central nervous system; CI, cardiac index; DIC, disseminating intravascular coagulation; LDH, lactate, dehydrogenase; PT, prothrombin time; PTT, partial thromboplastin time; SGOT, serum glutamic-oxaloacetic transaminase.

Fig. 36-2 Patient in the intensive care unit with multiorgan system failure. Note the ventilator, continuous dialysis, intraaortic balloon pump, and multiple intravenous drips.

General guidelines for current medical strategies for sepsis and septic shock have been documented.[84] These include life support measures including fluid resuscitation, blood product administration, vasopressor and inotropic support, bicarbonate therapy, and hemodynamic stabilization. To control the sepsis process requires identification and management of the source of sepsis, as well as antibiotic and steroid administration. Sedation, analgesia, neuromuscular blockade, and glucose control are instituted to reduce excess metabolic demand. In the event of renal dysfunction, hemofiltration may be required, along with intermittent hemodialysis. The management of acute renal failure in patients who are hemodynamically unstable with fluid overloaded may include continuous renal replacement therapy (CRRT). CRRT is a dialysis treatment provided as a continuous 24-hour-per-day therapy. Intermittent dialysis treatments are treatments that are provided for brief intervals, usually every day or every 2 or 3 days as needed.

Preventive strategies are implemented to avoid the sequelae of recumbency and restricted mobility, which include risk of deep vein thrombosis and embolism. Like other patients who are critically ill, they are at risk of stress ulceration, thus, stress ulceration prophylaxis is a component of routine medical management.

Principles of Physical Therapy Management

The patient with sepsis and MOSF, like the patient in shock, is gravely ill and unlikely to be able to cooperate with treatment (Figure 36-2). The principles of management are comparable to those for managing the patient in shock; however, oxygen delivery is likely to be consistently compromised in these patients. If oxygen delivery is critically low, $\dot{V}O_2$ depends on oxygen delivery and the patient is in a state of metabolic acidosis (see Chapter 2). In this situation—when oxygen delivery is compromised to the point of not meeting tissue oxygen demands—the goal of treatment is to maximize oxygen delivery[85] and minimize oxygen demand so that oxygenation of vital organs is threatened to the least extent. Thus the physical therapist must estimate the oxygen reserve capacity (i.e., the balance between oxygen demand and oxygen supply) in every assessment to select optimal treatment that is associated with the least risk. Treatments are selected to improve the efficiency of oxygen transport and usage and thereby reduce the work of the heart and of breathing. Above all, treatment should not worsen the patient's oxygen transport status. Selective body positioning, including the prone position, can augment oxygen transport and maximize the effective FiO_2.[86] Even though the patient will likely benefit more from some positions than others, frequent body position changes, preferably a 360-degree turning regimen, are still necessary to avoid the sequelae of static body positioning. Semiprone positions can substitute well for full prone positions if the patient is too hemodynamically unstable. Semiprone positions may be tolerated better by the patient and may be safer. Even though hourly position changes may not be feasible in these severely ill patients, prolonged periods in a static position (more than 2 hours) are deleterious. Thus a balance between these two concerns must be achieved.

Promoting optimal mucociliary transport remains a priority even in the absence of secretion accumulation. Frequent position changes and numerous positions ensure that pulmonary secretions are continually being redistributed to prevent accumulation and enhance removal. Should postural drainage be indicated, these positions may need to be modified.

Fig. 36-3 Mobilizing a patient with critical illness polyneuropathy in the intensive care unit. Note the presence of marked muscle atrophy on both lower extremities.

Head-down positions in particular may not be tolerated well. The relative benefits of superimposing manual techniques must be established on the basis of careful assessment because these procedures are associated with an increased metabolic demand to which the patient is not readily able to adapt. Increasing the oxygen demand of these patients may worsen their condition.

The assessment of neuromuscular function is challenging and inaccurate in patients who are severely ill. Patients may have marked weakness related to CIP and myopathy[87,88] and from interventions themselves (e.g., resting of the respiratory muscles with mechanical ventilation; pharmacological agents including glucocorticoids, some antibiotics, and neuromuscular blockers) (Figure 36-3). Thus these interventions may be risk factors, and their use needs to be assessed.

Summary

This chapter presents several major complications that can develop in a patient secondary to various conditions in the ICU. These have implications for physical therapy management. Complications add to the complexity of the physical therapy diagnoses of the patient's underlying problems with respect to oxygen transport and cardiovascular and pulmonary management. The complications highlighted in this chapter include those that impair multiple steps in the oxygen transport pathway and hence jeopardize metabolism at the cellular level. This sequence of events is most frequently associated with the complications of respiratory failure, surgery, ARDS, shock, sepsis, and MOSF.

Physical therapy treatments in critical care areas are typically short and frequent and should always be effective. Patients with complications however, are usually severely compromised and often less able to cooperate with treatment, which necessitates particularly short and frequent sessions. Because of the severity of illness, patients with the complications described may require treatments that are more passive (i.e., stress to the oxygen transport system must be minimal, thus the treatments are lower on the physiological treatment hierarchy). These patients require frequent and comprehensive monitoring (often several times daily) of their oxygen transport capacity (i.e., the relationship between oxygen delivery and consumption, and oxygen extraction, to establish if and when treatment is indicated and the specific parameters of treatment). If a patient is thought to be too unstable for treatment at a given time, continued monitoring of her or his status is essential so that small windows of opportunity can be exploited during stable periods. During periods of monitoring (as opposed to periods of active treatment intervention), the physical therapist continues to have an important role in recommending body positions and frequency of body position changes so that these can yield the greatest benefit to oxygen transport. Treatment continues to progress in preparation for discharge to the ward. Physical therapy assessment and evaluation are ongoing to determine the precise moment when intervention can commence or needs to be modified or withdrawn until the patient has stabilized again. Physical therapy care is imperative throughout a patient's stay in the ICU because patients remain at risk of turns for the worse, which may occur suddenly. Prevention remains the overriding goal until the patient is discharged from the unit.

Review Questions

1. Describe the complications associated with respiratory failure.
2. Describe the implications for cardiovascular and pulmonary physical therapy (assessment and management) of respiratory failure, surgical complications, acute lung injury, ARDS, shock, sepsis, and MOSF.
3. Few longitudinal studies have examined the long-term prognosis for survivors of complications in the ICU. Identify some research questions related to long-term physical therapy outcomes (consistent with the International Classification of Functioning, Disability and Health), and design some studies to address these.
4. Describe some methodological challenges related to physical therapy research in the ICU and how these might be addressed.

Pediatrics entails a special application of cardiovascular and pulmonary physical therapy. This chapter stresses that cardiovascular and pulmonary development and its related vulnerabilities form the basis for neonatal and pediatric practice in this area.

The objectives of this chapter are to review cardiovascular and pulmonary development and related vulnerabilities; relate developmental pathologies to issues of adequate ventilation and oxygen transport; identify cardiovascular and pulmonary co-morbidities associated with reduced physical activity and obesity; present principles and precautions of direct respiratory care; and incorporate these principles into suggestions for practice.

This chapter begins with a brief description of critical events and important characteristics of cardiac and pulmonary development. Relevant pediatric conditions are then presented to build on to this developmental perspective and stress that cardiovascular and pulmonary pathology and ventilatory compromise are often related to developmental vulnerabilities. Obesity is presented as a complicating factor in the cardiovascular and pulmonary health of children with and without clinical diagnoses. Finally, treatment approaches are described, including pediatric cardiac rehabilitation, pulmonary care for neonates, infants and children, pediatric pulmonary rehabilitation, and developmental therapeutic handling used to improve trunk alignment and ventilatory muscle function.

Knowledge of cardiovascular and pulmonary development, congenital and developmental cardiovascular and pulmonary

pathology, and appropriate pediatric interventions is essential for any pediatric therapist. Most children require ongoing attention to respiratory function, whether as a primary focus of physical therapy or as an inherent aspect of motor development. This chapter is relevant to therapists who perform direct cardiovascular and pulmonary care and to those who incorporate a cardiovascular and pulmonary awareness into developmental motor therapy and the promotion of wellness in children.

Cardiovascular and Pulmonary Development

The application of cardiovascular and pulmonary physical therapy to infants and children requires a special understanding of developmental anatomy and physiology. Knowledge of normal development and its inherent points of vulnerability will help the reader understand some of what is known about cardiovascular and pulmonary pathology in pediatric populations.

Cardiac Development

Differences in fetal and neonatal gas exchange account for differences in the anatomy and physiology of fetal and neonatal circulation. A basic review of developmental circulation is essential for the discussion of congenital heart defects and the role of pediatric cardiovascular and pulmonary physical therapy.

Fetal Circulation

Placental oxygenation is a major characteristic of fetal circulation. Additionally, in fetal circulation, blood flow through the right and left sides of the heart occurs in parallel, and therefore cardiac output is actually combined ventricular output (CVO).[1] This is possible as a result of shunts present in fetal circulation.[2]

Three points of shunting during fetal circulation are at the ductus venosus, foramen ovale, and ductus arteriosus. The oxygenated blood from the umbilical vein passes through the ductus venosus to the foramen ovale.[1] The foramen ovale allows right-to-left blood flow through the atria, bypassing the lungs.[1,2,3] Left ventricular output (LVO) enters the ascending aorta and flows to the brain and upper body. The ductus arteriosus similarly allows the lungs to be bypassed, as most of the right ventricular output (RVO) flows to the descending aorta and from there to the lower body.[1,4]

RVO is larger than LVO (59% and 41%, respectively).[5] Fetal blood flow to the lungs from the right ventricle is low because of high pulmonary vascular resistance during fetal circulation. Only 10% to 12% of CVO goes to the lungs,[5-7] and its function is to nourish the developing lung tissue rather than to provide gas exchange.

Neonatal Circulation

Adult-like circulation occurs at or shortly after birth, with separation from the placenta and ventilation of the lungs resulting in closure of the ductus venosus, foramen ovale, and ductus arteriosus.[1,8] This process, referred to as transitional circulation, occurs early in neonatal life and increases the efficiency of oxygen uptake and transport.[2,4,9]

The initiation of breathing and removal of lung fluid increase pulmonary blood flow. Whereas fetal circulation is characterized by high pulmonary vascular resistance and low systemic resistance, separation from the placenta causes a rise in systemic resistance and a decrease in pulmonary vascular resistance. As this shift in relative pulmonary and systemic resistances occurs, the shunts close and the ventricles shift from working in parallel to working in series.[9,10]

CLOSURE OF FORAMEN OVALE

The increase in left atrial pressure that occurs during transitional circulation results in apposition of the valve of foramen ovale against the interatrial septum, functionally closing this site of fetal circulatory shunting.[10,11] The anatomical closure occurs several weeks to several months later.[11]

CLOSURE OF DUCTUS ARTERIOSUS

Functional closure or constriction of the ductus arteriosus occurs within the first 24 to 48 hours after birth in response to increased arterial oxygen saturation. Anatomical closure of ductus arteriosus occurs by 2 to 3 weeks in most term neonates.[4] The responsiveness of the ductal smooth muscle to arterial oxygen tension and to endogenous prostaglandins is affected by gestational age at birth.[4,12]

Pulmonary Development

Structural and functional characteristics of pulmonary development in infants and children are significant because they may contribute to specific aspects of respiratory vulnerability.[10]

Newborn Respiration

The pulmonary anatomy of the term infant is markedly different from the adult but also different from the child. An infant's airways are narrower from the nares to the terminal bronchioles. This presents a point of pulmonary vulnerability because a smaller-diameter airway is more easily obstructed by mucus, edema, foreign objects, and enlarged lymphatic tissue. The infant also has a higher larynx.[10] Although this position of the larynx enables the newborn to breathe and swallow simultaneously, it may also contribute to predominant patterns of infant nasal breathing, which may result in increased work to breathe during any compromise of the nasal airway.

Even without airway compromise, the work of breathing is increased during the neonatal period. The initial low compliance of the newborn's lungs requires increased effort for ventilation, which results in a high respiratory rate and increased oxygen consumption.

Although the process of transitional circulation allows more efficient oxygen transport in the neonate than in the fetus, gas exchange in the newborn is still somewhat inefficient because of immature alveolar structure and function, with significantly lower number of alveoli present in the lungs of a newborn as compared to an adult.[3] The surface area for gas exchange in a newborn is one-twentieth that of an adult,[13] and

the diffusion distance across the alveoli-capillary membrane is increased because of thick alveolar walls.[14] Functional characteristics of infant pulmonary development are also significant in terms of understanding possible contributions to pulmonary distress in infants. The diaphragm of a newborn has fewer type I (fatigue-resistant) muscle fibers (20% compared with 50% in an adult).[10] This difference predisposes an infant to earlier diaphragmatic fatigue when stressed.

A biomechanical difference between the infant and child is the circular and horizontal alignment of the ribs and the concomitant horizontal angle at which the diaphragm inserts on the ribs during newborn and early infant chest development.[8,10,15] This, along with the more cartilaginous nature of the ribcage, results in less efficient chest wall mechanics, leading to increased work of breathing (see Chapter 39 for a more complete discussion of chest development).

Respiration in the Child

Two residual structural differences exist beyond the newborn period and have potential implications for pulmonary vulnerability in the child. First, the somewhat horizontal angulation of the ribs persists until approximately 10 years of age and results in less efficient chest wall mechanics.[16] Second, although lymphatic tissues, including tonsils and adenoids, grow in proportion to skeletal growth from 1 to 11 years of age,[17] they may be a potential source of upper airway obstruction in some children.

As infants and children grow and develop, however, most structural and functional disadvantages disappear. An aspect of growth and development that can be protective for infants and younger children is alveolar multiplication. This begins in the first year of life and continues until approximately 8 years of age.[3,8]

Cardiovascular and Pulmonary Considerations in the Preterm Infant

All of the cardiovascular and pulmonary structural and functional characteristics of neonates that have been previously discussed apply to the premature infant. Additionally, there are significant gestational aspects of cardiovascular and pulmonary vulnerability that are more pronounced and create more problems in premature infants (Table 37-1).

Recall that the transitional circulation of a term newborn includes a decrease in pulmonary vascular resistance over the first day. In preterm infants, however, lung immaturity and abnormal surfactant function[18] may result in retained high pulmonary resistance (poor lung compliance), hypoperfusion, and respiratory distress syndrome.[3,19,20] Persistent pulmonary hypertension will reinforce persistent right-to-left shunting through the ductus arteriosus.[21] Respiratory distress syndrome (RDS) has been identified as the best predictor of prolonged patency of ductus arteriosus.[22]

As the respiratory distress of the premature infant improves with neonatal intensive care, cardiovascular and pulmonary vulnerabilities can then occur in the opposite circulatory direction. Given the gestationally related responsiveness of ductus arteriosus to oxygen, some preterm infants retain patency of the ductus even when pulmonary vascular resistance falls.[23] The result is left-to-right shunting that leads to excessive pulmonary blood flow and the need for supplemental oxygen and mechanical ventilation,[24] which increases the risk for bronchopulmonary dysplasia.[25,26] Therefore the immature status of cardiovascular and pulmonary anatomy in preterm infants predisposes them to hypoxia under any conditions that require increased oxygen.[14,18] Cardiovascular and pulmonary pathophysiology and the stressors inherent to medical care often present challenges beyond the adaptive capacities of these fragile little systems.

Table 37-1 Factors Contributing to Cardiovascular and Pulmonary Dysfunction in the Premature Infant

Anatomical	Physiological
Capillary beds not well developed before 26 weeks of gestation	Increased pulmonary vascular resistance leading to right-to-left shunting
Type II alveolar cells and surfactant production not mature until 35 weeks of gestation; elastic properties of lung not well developed; lung space decreased by relative size of the heart and abdominal distention	Decreased lung compliance
Decreased responsiveness of ductus arteriosus to oxygen tensions; delayed ductal closure	Left-to-right shunting
Type I, high-oxidative fibers compose only 10% to 20% of diaphragm muscle	Diaphragmatic fatigue: respiratory failure
Highly vascular subependymal germinal matrix not resorbed until 35 weeks of gestation, increasing the vulnerability of the infant to hemorrhage	Decreased or absent cough and gag reflexes; apnea
Lack of fatty insulation and high surface area to body/weight ratio	Hypothermia and increased oxygen consumption

Modified from Crane LD: Physical therapy for the neonate with respiratory disease. In Irwin S, Tecklin JS, editors: *Cardiopulmonary physical therapy,* St Louis, 1995, Mosby.

Common Pediatric Diagnoses

The sections that follow present and discuss specific cardiac and pulmonary conditions. Common neuromuscular or developmental diagnoses that carry an inherent risk for compromised respiration or associated cardiovascular and pulmonary disease are also discussed. This list is not all-inclusive but merely represents an attempt to provide a preliminary knowledge of underlying pathologies and medical management of children with conditions commonly encountered in the practice of pediatric cardiovascular and pulmonary physical therapy.

Cardiac Diagnoses

Patent ductus arteriosus, endocardial cushion defects, and tetralogy of Fallot are the cardiac defects discussed within the limits of this chapter. Additionally, Table 37-2 provides a

Table 37-2 Common Pediatric Diagnoses and Associated Heart Defects and Conditions

Diagnosis	Heart Defect/Condition
Duchenne's muscular dystrophy[27]	Cardiomyopathy (adolescence)
Fetal alcohol syndrome[28]	Atrial septal defect Ventricular septal defect Tetralogy of Fallot Pulmonary valve stenosis Patent ductus arteriosus
Friedreich's ataxia[29,30]	Cardiomyopathy Ventricular hypertrophy Congestive heart failure

Turner syndrome[41]	Aortic abnormalities
Williams syndrome[42]	Supravalvular aortic stenosis Supravalvular pulmonary stenosis

summary of common developmental diagnoses and their associated cardiac defects and conditions.

Patent Ductus Arteriosus

Patent ductus arteriosus (PDA), already introduced as a cardiopulmonary complication in preterm infants, is the most common heart defect during the neonatal period.[24,36] In term newborns, however, PDA incidence is 1 in 2000 births (5% to 10% of infants with congenital heart disease).[4]

Gestational age, the presence of lung disease, the size of the ductus, and the direction of the shunt mediate the clinical features of PDA.[24,36,43] The preterm infant with very low birth weight will have the most extreme clinical picture. An infant or child with a large ductus will also have an obvious clinical presentation. Tachycardia, an ejection systolic murmur, bounding peripheral pulses, increased respiratory distress, and poor feeding or poor weight gain are the classical signs of PDA.[4,23,36] In the term infant, PDA may be more clinically subtle, especially when the ductus is small.[4]

Depending on the extent of the PDA, medical management includes nonsurgical (intravenous) use of indomethacin or direct, minimally invasive surgical closure.[24,36,44-46]

Endocardial Cushion Defects and Atrioventricular Septal Defects

Endocardial cushion defects (ECD) or atrioventricular septal defects (AVSD) represent a spectrum of defects characterized by malformation of the atrial septum, the mitral and tricuspid valves, and/or the ventricular septum.[47] Combinations of these defects are categorized as complete, transitional/intermediate, and partial, depending on degree of ventricular septal deficiency.[48-50] In the complete form, all of the structures are deficient. In the partial form of ECD, only an atrial septal defect with a cleft mitral valve is present.[47-49]

There is marked variation in the underlying anatomy of this class of cardiac defects, such that clinical features are equally varied and difficult to summarize inclusively. In neonates with a complete defect, heart failure may manifest in infancy. Children with milder forms of this defect, however, may not be symptomatic until much later in life, and sometimes, not until adulthood.[49] Additionally, it is common for ECD to be associated with other cardiac defects.[47]

Although the total incidence of endocardial cushion defects in infancy is 1% to 4%, the incidence in infants and children with Down syndrome is 40% to 50%.[51,52] A complete AVSD is associated with this genetic disorder.[50] Operative management of infants and children with ECD depends on the morphology of the defect, the degree of pulmonary hypertension, and the extent of mitral valve regurgitation.[48] For infants with complete AVSD, early surgical repairs are indicated.[52,53,50]

Tetralogy of Fallot

Tetralogy of Fallot (TOF) is named for its tetrad of defects: ventricular septal defect, right ventricular outflow obstruction, right ventricular hypertrophy, and aortic override.[54,55] A neonate with TOF will have symptoms dependent on the extent of right ventricular tract obstruction, which results in decreased pulmonary blood flow and the presence of right-to-left shunting.[54] The classical picture is one of cyanosis, especially with crying or agitation.[47,55] Although most infants have sufficient pulmonary blood flow at birth, the cyanosis usually increases within a few weeks or months after that.[54]

In neonates, initial medical management may include treatment of hypoxemia by pharmacologically maintaining patency or reopening the ductus arteriosus for additional pulmonary blood flow.[55,56] The elimination of conditions that produce hypoxemia may also include pharmacological agents to increase systemic vascular resistance and decrease myocardial contractility.[54] Surgical repairs are generally performed between 3 and 6 months of age.[54,55]

Pulmonary Diagnoses

The section that follows provides a brief discussion of common pulmonary disorders for which chest physical therapy is indicated. Additional physical therapy intervention and interactions of select diagnoses with obesity are described later in this chapter.

Respiratory Distress Syndrome

The most common respiratory disorder in infants born prematurely is respiratory distress syndrome (RDS), or hyaline membrane disease. The higher incidence of RDS has been linked to lower birth weights, and this condition has been described as the primary cause of mortality and morbidity in this population.[3,18,20] A correlation between RDS and increased morbidity, including apnea, bradycardia, and pneumonia, has been reported.[57]

RDS results from lung immaturity, insufficient number of alveoli, and an inadequate amount of surfactant.[3,7,20] Surfactant decreases alveolar surface tension and prevents alveoli collapse during expiration. The surfactant deficiency results in alveolar collapse and increased work of breathing.[20] Antenatal corticosteroids[20,58] and surfactant replacement are standard care for prematurely born neonates to reduce symptoms and sequelae of RDS.[3,59,60] Respiratory failure is common in these infants and necessitates oxygen therapy and assisted ventilation, which, in turn, may lead to further respiratory problems, lung injury, and bronchopulmonary dysplasia.[3,61,62]

Chest physical therapy (CPT) has been commonly advocated for airway clearance and to decrease postintubation atelectasis in infants with RDS.[63-66] However, concerns have been raised about possible brain damage associated with CPT in infants with extreme prematurity and very low birth weight.[65,67] Evidence supporting the application of this intervention with preterm infants has been insufficient and, at times, contradictory.[66,67,68] The results of a Cochrane review of effects of percussion and vibration on the pulmonary system in mechanically ventilated infants were also inconclusive but showed no increase in risk for intraventricular hemorrhage associated with these CPT techniques.[66]

Bronchopulmonary Dysplasia

As more preterm newborns survive neonatal respiratory distress, the prevalence of chronic lung disease, or bronchopulmonary dysplasia (BPD), has increased.[62,69] Although in the past the etiology of BPD was strongly linked to high-pressure positive pressure ventilation and oxygen therapy in the treatment of respiratory distress during the neonatal period,[18,70] this condition is now also seen in infants who initially may need only low-pressure ventilation and minimal oxygen supplementation but whose respiratory function deteriorates over time, with an increased demand for oxygen and ventilatory support seen later, after prolonged mechanical ventilation.[62] Oxygen toxicity, combined with damage to the alveoli caused by mechanical ventilation, leads to inflammation, pulmonary edema, and fibrosis.[61,62,71]

The risk for BPD is highest in infants born at 32 weeks of gestation or earlier, with a birth weight ≤1200 grams, and in those who have more severe RDS.[3,62,71] Table 37-3 displays the definition and diagnostic criteria for BPD.[71]

Medical management of BPD is primarily supportive. Long-term oxygen therapy is often necessary for infants who exhibit persistent severe hypoxemia. The target oxygen saturation levels administered via several different strategies is 90% to 95%.[72] The most promising reported ventilatory strategies include avoiding intubation whenever possible, administering surfactant early if the infant has to be intubated, and using noninvasive ventilation, such as nasal continuous positive airway pressure (CPAP) or synchronized nasal intermittent positive pressure ventilation (SNIPPV).[72,73] Such sequelae of BPD as congestive heart failure, cor pulmonale, and pulmonary edema warrant diuretic therapy for these infants.[18]

Many infants with BPD require rehospitalization before 1 year of age, with respiratory symptoms persisting beyond infancy and into childhood, adolescence, and even adulthood. Decreased lung function in these children[3] has been linked to the duration of oxygen supplementation.[72] Because BPD survivors demonstrate decreased growth and increased incidence of neurodevelopmental sequelae, including cerebral palsy, impairments in gross and fine motor skills, cognition and language development, many of them require developmental interventions, such as physical, occupational, and speech therapies.[18,72,74] Evidence related to CPT application for airway clearance with infants born preterm has been discussed earlier in this chapter.

Table 37-3 Definition of Bronchopulmonary Dysplasia: Diagnostic Criteria

Gestational Age	<32 wk	≥32 wk
Time point of assessment	36 wk PMA or discharge to home, whichever comes first	>28 d but <56 d postnatal age or discharge to home, whichever comes first
Treatment with oxygen >21% for at least 28 d **plus:**		
Mild BPD	Breathing room air at 36 wk PMA or discharge, whichever comes first	Breathing room air by 56 d postnatal age or discharge, whichever comes first
Moderate BPD	Need* for <30% oxygen at 36 wk PMA or discharge, whichever comes first	Need for <30% oxygen at 56 d postnatal age or discharge, whichever comes first
Severe BPD	Need* for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 36 wk PMA or discharge, whichever comes first	Need for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 56 d postnatal age or discharge, whichever comes first

BPD, Bronchopulmonary dysplasia; *NCPAP*, nasal continuous positive airway pressure; *PMA*, postmenstrual age; *PPV*, positive-pressure ventilation.

*A physiologic test confirming that the oxygen requirement at the assessment time point remains to be defined. This assessment may include a pulse oximetry saturation range. BPD usually develops in neonates being treated with oxygen and positive pressure ventilation for respiratory failure, most commonly respiratory distress syndrome. Persistence of clinical features of respiratory disease (tachypnea, retractions, rales) are considered common to the broad description of BPD and have not been included in the diagnostic criteria describing the severity of BPD. Infants treated with oxygen >21% and/or positive pressure for nonrespiratory disease (e.g., central apnea or diaphragmatic paralysis) do not have BPD unless they also develop parenchymal lung disease and exhibit clinical features of respiratory distress. A day of treatment with oxygen >21% means that the infant received oxygen >21% for more than 12 h on that day. Treatment with oxygen >21% and/or positive pressure at 36 wk PMA, or at 56 d postnatal age or discharge, should not reflect an "acute" event, but should rather reflect the infant's usual daily therapy for several days preceding and following 36 wk PMA, 56 d postnatal age, or discharge.Reproduced with permission from Jobe AH, Banclari E: Bronchopulmonary dysplasia, *Am J Respir Crit Care Med* 163:1723-1729, 2001.

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTNB) is another neonatal problem considered in the differential diagnosis of RDS. It is associated with delayed clearance of amniotic fluid from the lungs, and is the most common cause of respiratory distress in neonates.[47,75] It is a self-limiting condition that usually resolves spontaneously, with symptoms lasting from 2 hours to 2 days. Risk factors for TTNB include cesarean section delivery, macrosomia (birth weight of greater than 4000 grams), male sex, and maternal asthma or diabetes.[75]

Meconium Aspiration Syndrome

Meconium is the content of fetal and newborn bowels. Meconium aspiration syndrome (MAS) is respiratory distress in a full-term or post-term neonate born through meconium-stained amniotic fluid (MSAF). This diagnosis is made in absence of any other explanation.[76,77] Meconium aspiration may occur with the first postnatal breaths or with gasping in utero just before delivery.[76,78,79] Although in the past, it was suggested that MAS could be prevented if the upper and lower airways were suctioned immediately after birth,[80] more recent research showed no benefit from routine intrapartum oronasopharyngeal suctioning and yielded varied recommendations regarding endotracheal intubation and lower airway suctioning performed immediately after delivery.[77,81,82] Generally, intubation is recommended for "depressed" but not "vigorous" infants born through MSAF. A systems approach to prevention of MAS has been proposed, including careful monitoring of the delivery by a well-trained interdisciplinary rapid response team and an evidence-based decision-making process regarding the need for endotracheal intubation and suctioning.[81]

Aspiration of meconium may result in serious and devastating pathophysiology. Most commonly, the meconium will partially or completely block the peripheral airways.[76-79] Atelectasis is the classical finding, but with partial obstruction, hyperexpanded areas will also be observed as the result of air trapping in distal, small airways after inspiration. Common complications of MAS include tension pneumothorax, persistent pulmonary hypertension, bronchiolitis, and meconium-induced chemical pneumonitis.[76-79] Additionally, long-term pulmonary sequelae, such as BPD, and neurological and neurodevelopmental disorders, such as seizures, cerebral palsy and global delays, have been reported in these infants.[76,83,84]

Medical management of MAS includes respiratory support via supplemental oxygen and, if necessary, mechanical ventilation; extracorporeal membrane oxygenation (ECMO); and surfactant administration.[82] CPT has been advocated for infants with MAS,[85,86] but more research is needed to confirm its benefits for this patient population.

Pneumonia

NEONATAL PNEUMONIA

The most common organisms producing neonatal septicemia associated with pneumonia in neonates are group B streptococcus and *Haemophilus influenzae*.[47] Neonatal pneumonia mimics RDS in clinical presentation and chest radiographs.

ASPIRATION PNEUMONIA

Aspiration is an unfortunate result of small children's "indiscreet curiosity"[87] in exploring their environment and relying on their mouths for sensory learning. Aspiration can also result from gastroesophageal reflux[88] and decreased upper airway neuromuscular control.[89]

Bronchial drainage techniques are often indicated as part of the medical management of infants and children after aspiration to aid with airway clearance and reduce the possibility of bacterial superinfection.

PNEUMOCYSTIS JIROVECI PNEUMONIA IN CHILDREN INFECTED WITH HIV

In infants with perinatally acquired HIV, *Pneumocystis jiroveci* pneumonia (PCP) frequently occurs within the first 12 months of life, with the peak incidence reported at 3-6 months of age. Although in the United States there has been a decline in the rate of PCP infection, it remains the leading cause of death in children with HIV/AIDS in Africa.[90]

The clinical presentation of PCP includes failure to thrive, cough, dyspnea, tachypnea, fever, hypoxemia, and chest radiograph evidence of diffuse parenchymal infiltrates of reticulogranular quality.[90,91] PCP is most definitively diagnosed after bronchoalveolar lavage studies. Chemoprophylaxis is recommended to prevent the first episode of this disease. Treatment includes antibiotic therapy, antiretroviral therapy, nutritional support, short courses of corticosteroids, and surfactant administration in severe cases.[90]

Asthma

Although asthma is described in detail in Chapter 5, a discussion of pediatric pulmonary problems would not be complete without mentioning this common cause of childhood lung disease. Currently, approximately 22% of school children in the United States have asthma, with this disease prevalence ranging from 15.5% to 28.3% among different states.[92]

Childhood asthma can begin at any age, and its clinical etiology and clinical course are variable. Children with early medical histories that include very low birth weight, bronchopulmonary dysplasia, and respiratory syncytial virus (RSV) infection may be at increased risk for developing asthma.[93-95] Common triggers for asthma symptoms and exacerbations are allergens, respiratory viral infections, tobacco smoke, air pollutants and irritants, extreme temperatures and high humidity, excessive weight gain and low physical fitness, stress, and exercise leading to bronchospasm.[96]

Medical management usually includes avoidance of known precipitants, bronchodilator drugs, and corticosteroids (in chronic, severe cases). Other measures include immunotherapy and child, parent, and health-care provider education, as well as monitored exercise to maintain healthy weight and fitness.[96,97]

Asthma is underdiagnosed and undertracked among minority groups and children from families with low socioeconomic status (SES).[98] Some studies suggest that detection and treatment in schools may be part of the solution.[98,99] Similarly, education regarding asthma management of children from minority or low SES families may be effectively

implemented in schools by positioning the school nurse as the case manager.[98-101] In a school district that does not have a full-time nurse in each school, the physical therapist may need to track and be aware of asthma in the child before he or she engages in physical exertion.

Cystic Fibrosis

Cystic fibrosis (CF) is a complex, autosomal-recessive disorder that occurs at a frequency of one in 3500 live births.[102] A defect in a single gene, the CF transmembrane conductance regulator (CFTR), leads to pathological changes in exocrine glands, including airways, sweat glands, pancreas, biliary tract, and gut.[103,104]

The Cystic Fibrosis Foundation Consensus Statement on the Diagnosis of CF[102] includes recommendations for newborn screening (NBS) to identify infants at risk for CF and for the sweat chloride test as the primary method used to confirm the diagnosis. The diagnostic pathway for screened newborn babies differs from that used for patients who present with clinical symptoms of CF. Positive results of NBS warrant a sweat chloride test, which, if also positive, is followed by genetic testing. In patients with signs and symptoms of CF and a family history of the disease, a sweat chloride test is performed, followed by a clinical evaluation, genetic testing, pancreatic function tests, and tests for specific pathogens, such as *Staphylococcus aureus* or *Pseudomonas aeruginosa,* present in the respiratory tract. Clinical symptoms of CF are chronic productive cough, respiratory infections with CF pathogens, abnormal chest radiographs, airway obstruction, nasal polyps, and clubbing of the digits. Other symptoms include gastrointestinal and nutritional problems, systemic loss of salt, and male genital abnormality.[102] The disease progression is one of chronic lung infection that results in fibrosis and bronchiectasis that lead to respiratory insufficiency, the primary factor in morbidity by the second or third decade of life.[103,104] Chronic nocturnal hypoxia becomes a stimulus for the development of pulmonary hypertension and right ventricular failure and is associated with poor prognosis.[105]

The chronic pulmonary disease in CF is related to increased secretion of abnormally viscous mucus, impaired mucociliary transport, airway obstruction, bronchiectasis, overinflation, and infection.[102] Early detection and early treatment are key to the management of CF. The major marker of pulmonary disease in this population is forced expiratory volume in 1 second (FEV_1).[106] However, one study that used high resolution computed tomography (HRCT) to examine the lungs of children 6 through 10 years of age who had no abnormality of FEV_1 revealed air trapping and bronchiectasis.[107] Similarly, when $FEV_{0.5}$ was used as a marker, airway function was noted to be diminished soon after diagnosis in infants with CF.[108] These results support the importance of early intervention in children for whom detection occurs during infancy.[106] Further development of genetic diagnostics and gene therapy may enhance early identification and address effective, if not preventive, early treatment.[109,110]

Medical management includes early nutritional support, treatment of pancreatic dysfunction, judicious use of antibiotics, and preventive infection control measures.[111] The early institution of prophylactic pulmonary physical therapy, such as airway clearance techniques, helps to control or decrease the effects of bronchiolar and bronchial obstruction. Involvement of the child and family in pulmonary care is particularly important. Family understanding of the nature of the disease and the purpose of each therapeutic measure promotes successful intervention. An individualized home program of CPT should be established, taking into consideration the child's ongoing pulmonary needs and the family's unique contributions and constraints.

Bronchial drainage is an aspect of conventional treatment for CF with several options that allow both efficacy and patient independence.[112] Airway clearance techniques (ACT) are described in detail in Chapter 21, but alternatives to traditional percussion and postural drainage warrant mention within the context of CPT for children with CF. Specifically, the forced-expiration technique (FET) as part of the active cycle of breathing (ACB) technique, the use of a positive expiratory pressure (PEP) mask, autogenic drainage (AD), the use of the flutter device, and the application of high-frequency chest compression (HFCC) through an inflatable vibrating vest have been shown to be effective in assisting sputum expectoration, often in greater amounts and in less time per treatment compared with other interventions.[113-119] The efficacy of PEP in this population remains equivocal.[120,121]

Although postural drainage, percussion, and vibration are the treatment of choice for infants and children who are unable to be instructed in techniques that use specific patterns of voluntary breathing, other techniques are available for children who can follow breathing instructions and who can perform a reliable pulmonary function test. Children as young as 2 to 3 years of age can be taught to "huff" as part of FET;[113] the PEP mask has been used with children as young as three years;[115] and AD can reportedly be taught to children at 4 to 6 years of age.[116] The Cystic Fibrosis Foundation CF Pulmonary Guidelines[119] recommend ACT for patients with CF to maintain lung function, clear sputum, and improve their quality of life. Because none of these techniques have been shown to be superior to others, it is recommended to base their prescription on the child's age, specific technique preference, and incidence of adverse events associated with the use of ACT.[119] In patients diagnosed with CF, an airway clearance program should be initiated in early infancy.[111] The benefits of each technique should be carefully considered relative to each child's cognitive, respiratory, and motor planning abilities when choosing or modifying the airway clearance program, and the child's response to any technique must be carefully monitored. The head-down position should not be used for infants and toddlers younger than 2 years of age because it may exacerbate gastroesophageal reflux and affect oxygen saturation in infants with CF who have gastroesophageal reflux disease.[111,119,122]

Ventilatory muscle training is an important aspect of pulmonary treatment in older children with CF. Studies have demonstrated that training to improve the endurance of ventilatory muscles decreases dyspnea and increases general exercise tolerance in patients with CF.[123,124] The role of general exercise in the cardiovascular and pulmonary management of children with CF is discussed within the context of pulmonary rehabilitation later in this chapter. It is important to mention that the use of aerobic exercise for patients with CF is recommended for general health and fitness benefits, as well as a component of the airway clearance program.[104,119]

Special Respiratory Problems Associated with Intubation and Tracheostomy

Once an infant or child develops respiratory failure, intubation and mechanical ventilation are usually required.[3,125] The goals of medical management are then to treat the cause of the respiratory failure as aggressively as possible and to wean the child from mechanical ventilation as quickly as possible. If a child's condition necessitates long-term mechanical ventilation, if an artificial airway is needed to bypass an upper airway obstruction, or if there is a risk for aspiration, a tracheostomy is usually performed.[126]

Infants and children who have a tracheostomy and are intubated for long periods of time require vigorous prophylactic airway management, such as bronchial drainage and airway suctioning. Several studies showed that CPT, including postural drainage and vibration emphasizing right upper lobe segments, significantly decreased the incidence of postextubation atelectasis in infants intubated for more than 24 hours.[64,127] However, as discussed in the RDS section of this chapter, there is insufficient current research evidence to support or refute the use of CPT with infants with extreme prematurity and low birth weight.[66]

Pulmonary Considerations in Children with Movement Disorders

Although cardiovascular and pulmonary symptoms may not be the primary reason for referral to physical therapy in children with neurological, neuromuscular, and other developmental movement disorders, these children do have motor involvement that can result in respiratory and postural muscle weakness, chest immobility, and hypoventilation. Furthermore, many of these children have medical histories remarkable for cardiovascular and pulmonary complications or have progressive disorders that will result in cardiovascular and pulmonary compromise.

Table 37-4 provides an extensive summary of the interactions between trunk musculature and ventilation in children with atypical development. Although the biomechanical deviations noted are frequently seen in children with abnormal muscle tone, they are also common in children with scoliosis, sternal deformity, or general immobility of the thorax. These deviations and other aspects of ventilatory compromise are discussed with regard to motor diagnoses common to pediatric practice.

Cerebral Palsy

Children with cerebral palsy (CP) generally have weak trunk and postural muscles, related to muscle tone abnormalities. A combination of atypical neural mechanisms and muscle weakness produces atypical movement patterns and deviations in functional alignment, leading to decreased chest expansion and lung function.[128] The trunk control and respiration relationships described in Table 37-4 are consistent with the clinical picture of external pulmonary development in children with CP.

Although the extent of mobility impairment is variable among children with CP, hypoventilation, increased work of breathing, inefficient cough, increased risk for aspiration, and poor breath support for vocalization can occur.[129] These children demonstrate decreased movement variability,[130] which contributes to thoracic stiffness. A high chest, flattened anteriorly, with excessive rib flaring is common in these children (Figure 37-1).

Table 37-4 Functional Relationship of Trunk Control and Respiration

Biomechanical Component	Postural/Trunk Control Consequences	Respiratory Consequences
Weak abdominal obliques	Passive lumbar lordosis Protruding tummy Lower rib flaring Decreased trunk rotation Unable to weight shift Dependence on rectus abdominis	Ineffective cough High chest Retained horizontal rib alignment Tight rectus abdominis may lead to pectus excavatum Child may use diaphragm for trunk control, limiting its function as a primary muscle of respiration Decreased support of abdominal contents under diaphragm
Tight pectoralis minor	Forward shoulders Scapula pulled laterally and anteriorly, away from the thoracic wall Upper thoracic flexion	Anterior upper chest cannot adequately expand
Weak serratus anterior	Weak upper fibers—medial edge of scapula leaves the thoracic wall	Decreased structural reinforcement of the posterior chest wall Interdigitation of the lower fibers of serratus anterior with the external abdominal oblique will interact to affect the dynamic stability of the ribcage
Decreased active upper thoracic extension	Kyphotic upper trunk Passive overlengthening of the scapular retractors	Approximation of upper ribs → decreased upper chest mobility → decreased oxygenation of the upper lobe → abdominal breathing
Decreased ribcage stability	Serratus anterior will elevate the ribs rather than stabilize the scapula against the thoracic wall	Decreased structural support for the respiratory muscles to work from

Fig. 37-1 Flattened anterior chest with marked rib flaring in a child with cerebral palsy.

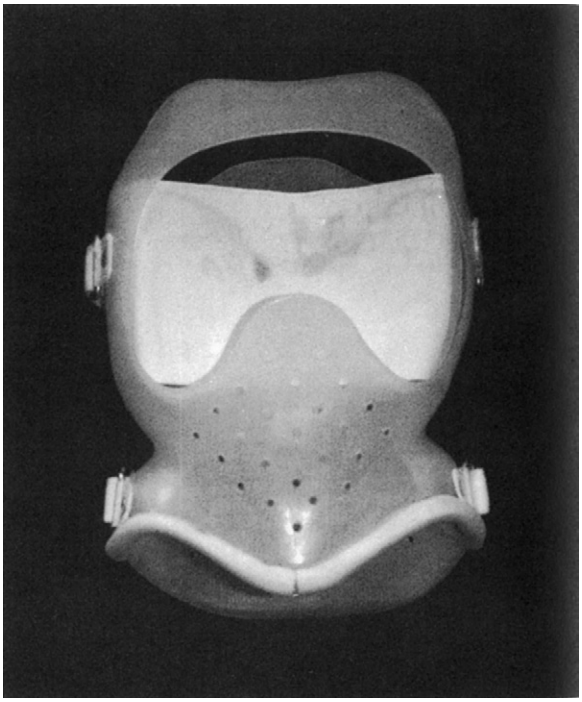

Fig. 37-2 An anterior cut-out and elastic support in a body jacket/spinal orthosis aids diaphragm function.

Therapeutic attention to respiration should first identify possible aspiration[131] and suggest modifications for positioning during feeding. Additionally, certain postures for sleep and play may be less restrictive for chest excursion and should be incorporated into a home program.[131,132]

CPT, including postural drainage, percussion and vibration techniques, may be indicated if the child develops a primary pulmonary complication. Because gastroesophageal reflux is a common comorbidity observed in children with CP, head-down positioning should not be used for postural drainage.[131,133] Prophylactic postural drainage can also be integrated into many sensory stimulation programs for more severely involved children. Additional "handling" to address ventilatory function will be discussed in a subsequent section on motor approaches to respiratory treatment.

Myelomeningocele

Myelomeningocele, or spina bifida, is a diagnosis that physical therapists generally equate with issues of ambulation and mobility; however, central ventilatory dysfunction is prevalent in infants, children, and adolescents who also have an associated Arnold-Chiari type II malformation.[134-137]

The Arnold-Chiari type II malformation, which occurs in 57% to 76% of infants with myelomeningocele, is a hindbrain malformation consisting of a caudal herniation of the cerebellum and brainstem into the cervical canal.[138] Ventilatory problems associated with a symptomatic Arnold-Chiari type II malformation include inspiratory stridor (vocal cord paralysis), central apnea, and respiratory distress.[134,137,139] Abnormal ventilatory patterns, however, have also been observed in asymptomatic infants[136] and adolescents.[135] Ventriculoperitoneal shunting for management of hydrocephalus and, if necessary, cervical decompression are the surgical approaches to treatment of life-threatening ventilatory complications in this population.[137,138,140]

Other pulmonary issues in children with myelomeningocele warrant discussion. Trunk weakness and hypotonia are observed early in the motor development of infants and toddlers with this condition.[140] In children with thoracic and high lumbar level lesions, abdominal muscle support for diaphragm function may be insufficient. The use of abdominal binders and spinal orthoses/body jackets with anterior (diaphragm) cut-outs and an elastic insert are indicated to aid in diaphragm function (Figure 37-2).

Spinal deformities, such as congenital or acquired scoliosis, kyphosis, lordosis, or their combinations limit chest expansion and decrease ventilatory function in these children. In addition, sudden progression of scoliosis may be indicative of unstable neurology (tethered cord).[140] Therefore close attention to ventilatory ability is necessary both for general monitoring and for possible preoperative evaluation.

Down Syndrome

Respiratory complications are the most common cause of hospitalization in children with Down syndrome.[141-143] These complications are related to structural airway abnormalities and pulmonary hypoplasia, such as tracheomalacia, subglottic stenosis, decreased number of alveoli, increased alveoli size, and widened alveoli ducts. Frequent respiratory infections, pneumonia, sleep-disordered breathing, and interstitial lung disease have been reported in these children.[143]

Impaired pulmonary function in children with Down syndrome is also related to generalized weakness of trunk musculature.[144] The postural deviations common in these children (Figure 37-3) reflect inefficient muscle function for both ventilation and movement.[145] The trunk control-ventilation relationships delineated in Table 37-4 summarize the clinical presentation of external pulmonary development in these

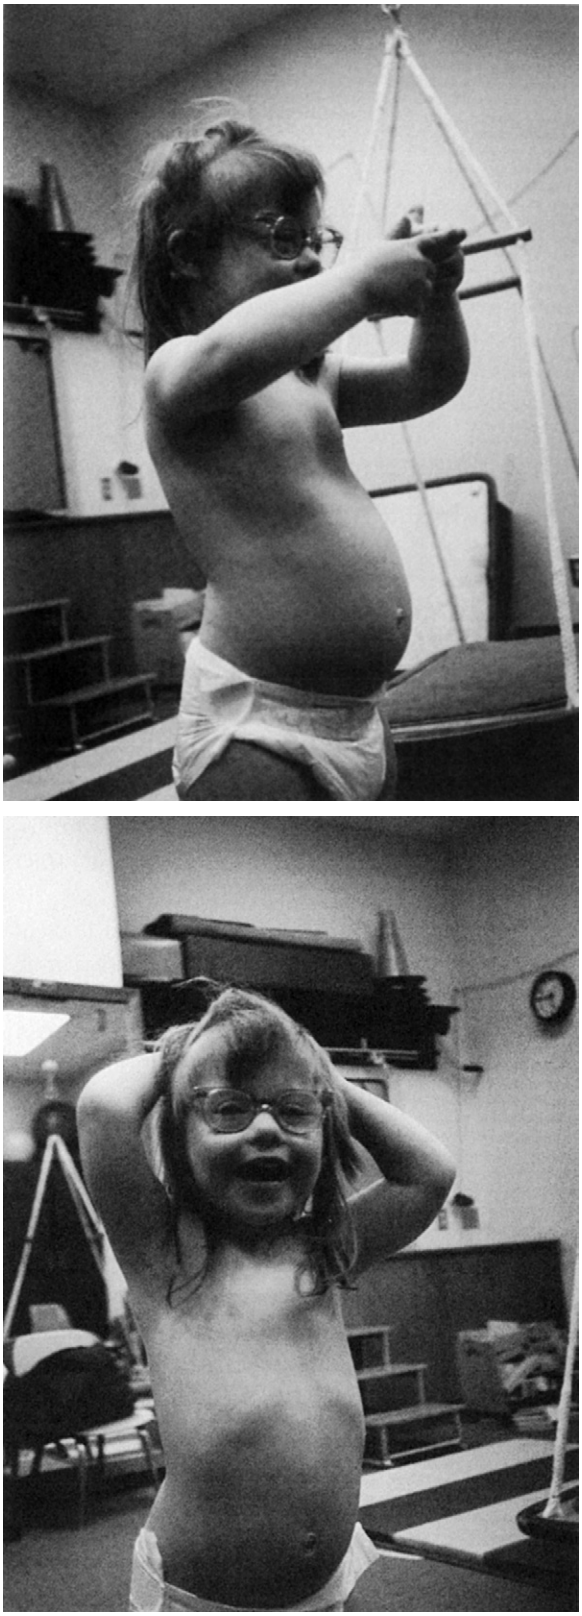

Fig. 37-3 A, Characteristic posture of a child with Down syndrome/hypotonia. Note the abdominal protrusion and sternal retraction. **B,** Rib flaring with upper extremity movement; the abdominal obliques are not stabilizing the lower ribs. *(Photos from Moerchen VA: Respiration and motor development: a systems perspective,* Neurology Report *18:8-10, 1994. Reprinted with the permission of the Neurology Section, APTA.)*

children. Too often, physical therapists who are treating children with Down syndrome address only motor development. Respiration needs to be considered if therapy goals include increased vocalization or improved exercise tolerance.

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is an example of a diagnosis in which the neuromotor and chest wall impairments together lead to ventilatory failure. End-stage respiratory failure in this disease results from progressive respiratory muscle weakness, thoracic deformity, reduced lung compliance, retained secretions, ventilation-perfusion imbalance, and hypoxemia.[146-148] In 70% to 90% of these patients, death is directly related to restrictive respiratory complications. In addition to ventilatory failure, cardiac function also deteriorates in DMD. Dilated cardiomyopathy or congestive heart failure develops during or after puberty.[27,149]

Physical therapists are typically involved in treatment of these patients for preservation of motor function. Early attention to ventilation, however, is warranted. Spinal fusion to prevent scoliosis-related compromise of ventilation in these patients considers both the progression of the spinal curvature and vital capacity (VC).[148,150]

CPT should be a component of the overall physical therapy management of children with muscular dystrophy. Deep breathing, coughing, and activities to address endurance are recommended but will require ongoing modification as the disease progresses.[148] Research has demonstrated positive effects of inspiratory muscle training on ventilatory muscle strength and endurance in these children[151-153] and suggested that these effects are dose dependent.[151,153] Significant correlation between these variables was found in children with VC decline of less than 10% per year before training, but not in children with a greater rate of the disease progression.[151]

Respiratory dependence does occur as the disease progresses. Close monitoring of VC and nocturnal hypoventilation can allow respiratory support to be implemented before the onset of acute respiratory failure.[146,148,154,155] The speed of progression of the disease is significant to the timing of noninvasive positive pressure ventilation (NPPV). Symptoms of nocturnal hypoventilation may be treated initially with continuous positive airway pressure (CPAP), especially if obstructive sleep apnea is noted.[156,157] Transitioning to NPPV is typically required when diurnal hypercapnia is noted,[158] unless severe bulbar weakness is present.[159] Furthermore, when NPPV in combination with insufflation/exsufflation is used to treat adolescents with end-stage DMD, pulmonary complications requiring hospitalization have been reduced.[154] Peak cough flow is greater with in/exsufflation than with manual cough techniques.[160] Progressing to tracheostomy (invasive) ventilation is elective and may be avoidable with combined noninvasive methods initiated earlier in the disease process.

Miscellaneous Conditions

Children with many other diagnoses and musculoskeletal conditions may present with clinical signs (decreased strength, atypical alignment, and limited mobility) that should cue the

therapist's attention to pulmonary function. Genetic disorders that involve chest wall deformity, such as Marfan syndrome, Poland syndrome, or osteogenesis imperfecta,[161] may entail ventilatory compromise. Children with juvenile rheumatoid arthritis (JRA) may have inflammation of thoracic joints or may splint through their trunks when they try to move painful extremities. Decreased respiratory muscle strength and lung function have been reported in children with polyarticular and systemic JRA.[162] With these children, breathing exercises will have a role both in pulmonary care and in pain management.

Pain, weakness, or chest wall deformity may lead to the development of compensatory movement patterns that limit the mechanics of the child's thorax. Conversely, inadequate oxygenation may lead to the development of compensatory movement patterns that support ventilation. Therefore attention to ventilation should be an inherent aspect of observing motor development and quality of movement in all children.

Obesity as a Cardiovascular and Pulmonary Comorbidity

The childhood obesity epidemic that is occurring worldwide, across cultures and socioeconomic groups, cannot go unmentioned as a comorbity associated with cardiovascular and pulmonary disorders.[163,164] In addition, overeating and immobility (either elective or secondary to motor impairments) create an additional set of risk factors for the development of cardiovascular and pulmonary disease.[164-166] A brief review of these comorbidities is provided.

Obesity and Asthma

Asthma and obesity present an interaction of factors that are somewhat cyclical in their effects. Children with asthma may be less active, especially if their asthma is exercise induced and they have not been instructed in how to prepare for physical activity. Inactivity superimposed on excessive energy intake (overeating) leads to an overweight status. Among children with asthma, children with obesity wheeze more, use their inhalers more frequently, and have higher bronchial hyperreactivity than do children with normal body mass index (BMI).[167] It has been debated whether high BMI is a risk factor for asthma or whether chest symptoms related to obesity mimic asthma.[166,168,169] A systematic review of the literature has pointed to a strong association between childhood obesity and the development of asthma in adolescents.[170]

Obesity and Obstructive Sleep Apnea

The incidence of obstructive sleep apnea (OSA) related to obesity in clinical as well as nonclinical populations of children is alarming. In typically developing children, the severity of OSA is positively related to degree of obesity.[171-173] Additionally, obesity and obstructive sleep apnea in children are associated with elevated blood pressures and other cardiovascular comorbidities.[172-174]

In clinical populations with known low neuromotor tone of the upper airways, such as children with Down syndrome and Prader Willi syndrome, obesity is associated with higher incidence of obstructive sleep apnea.[175-178]

Physical Therapy Intervention Approaches

Postoperative Pediatric Cardiac Rehabilitation

Postoperative physical therapy consists largely of techniques to increase respiration, mobilize secretions, and progress physical mobility.[179] Positional rotation for pulmonary care is possible if the child has a stabilized sternum. Breathing exercises and coughing will need to be modified based on the patient's age and cognitive level. Huckabay and Daderian (1990)[180] reported improved postoperative cooperation in children 3 to 10 years of age when choice making was incorporated into a breathing program. Another study showed significant reduction in risk for postsurgical pulmonary complications in children who underwent preoperative and postoperative cardiovascular and pulmonary physical therapy as compared with postoperative physical therapy alone.[179]

Immobilization after cardiac surgery is to be avoided as much as medically possible.[179,181] Passive range of motion may be initiated immediately, taking care to avoid compromising arterial lines. Ambulation is generally initiated once the child is extubated and has had atrial and groin lines removed.[181]

Child and family education as part of pediatric cardiac rehabilitation has been observed to reduce parent and child anxiety related to safe levels of physical activity.[182-184] Although studies of pediatric cardiac rehabilitation have focused on children older than 6 years, monitored exercise has been shown to produce such effects as a safe increase in peak oxygen consumption and a decrease in resting heart rate.[182-184]

Exercise prescription for cardiovascular and pulmonary rehabilitation of older children who have undergone cardiac repairs at an early age will require careful monitoring. Lower exercise $\dot{V}O_2$ values, lower cardiac output, and lower values of diffusion capacity of the lung for carbon monoxide have been observed in response to exercise in children who have undergone cardiac surgery compared to healthy peers.[185-187] In addition, lower functional health status has been reported in these children.[188] Exercise recommendations for this clinical population include submaximal performance[186,189] and technique training to increase the biomechanical efficiency of movement while decreasing the associated metabolic costs.[185]

CPT for Neonates and Infants

The primary goal of CPT for neonates and infants is to improve airway clearance. If techniques of bronchial drainage can increase the diameter of the airways through secretion mobilization, then ventilation may also be improved and the work of breathing reduced. These techniques should be judiciously applied for prophylaxis and treatment in infants who have or are at risk for developing airway clearance problems. Applying bronchial drainage techniques to infants requires a thorough understanding of each infant's condition and the precautions and considerations inherent to any technique or combination of techniques.

Positional Rotation

Frequent changing of position will prevent prolonged dependency of any one portion of the lung so that pooling of secretions can be limited or avoided and improved ventilation can

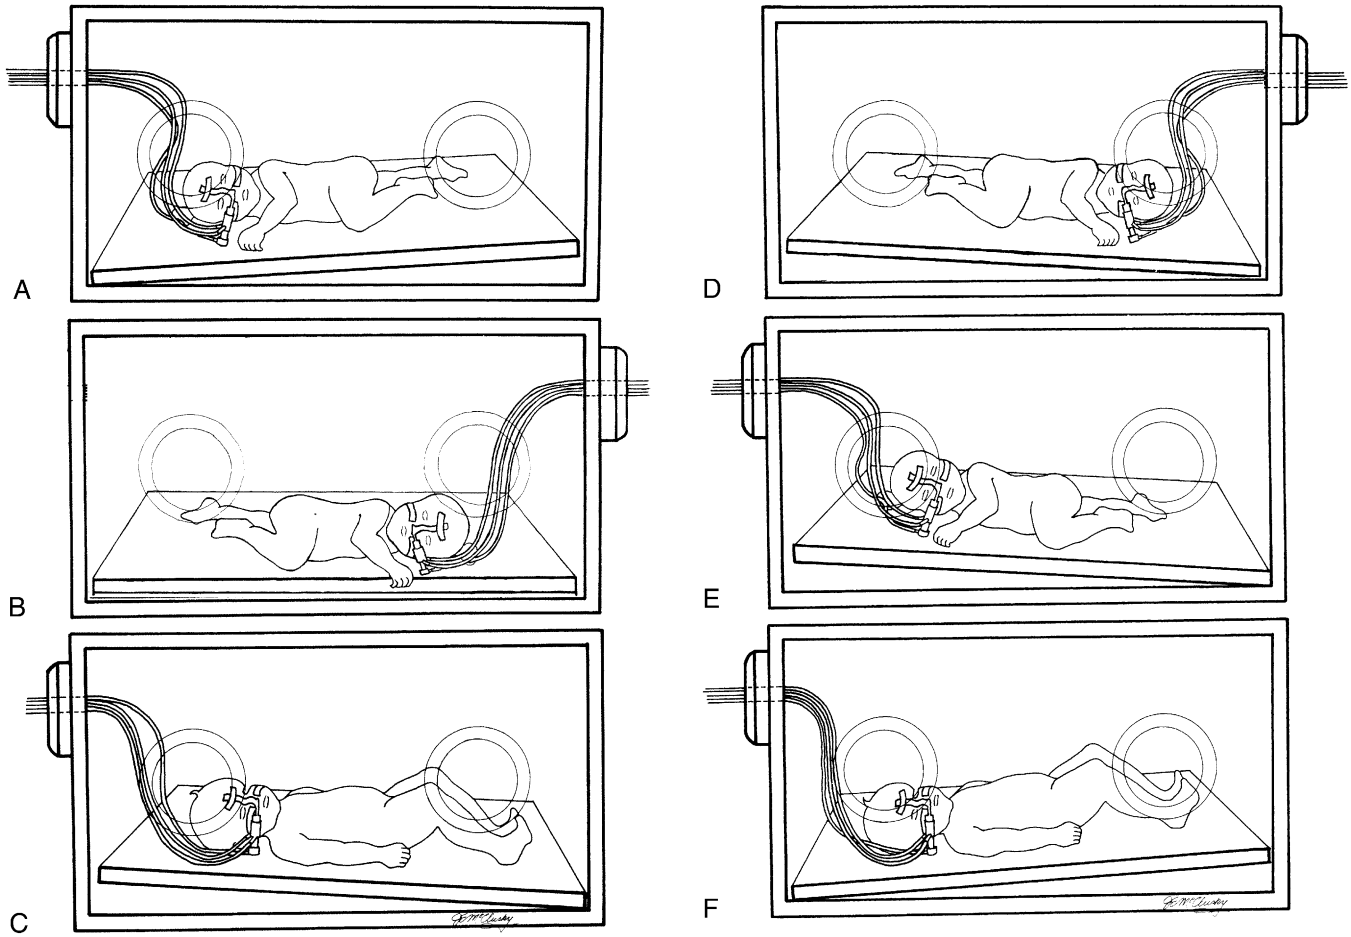

Fig. 37-4 Sequence for positional rotation. *Position 1:* Segments that come off the left lower bronchus posteriorly are drained by positioning the infant on his or her right side, three-fourths prone with a head-down angle. *Position 2:* The posterior segment of the right upper lobe is drained by positioning on the left side, three-fourths prone with the bed flat. *Position 3:* The anterior segments of the upper lobes are drained by positioning supine with the head of the bed elevated or flat. *Position 4:* Segments that come off the right lower lobe bronchus posteriorly are drained by positioning on the left side, three-fourths prone with a head-down angle. *Position 5:* The posterior segment of the left upper lobe is drained by positioning on the right side, three-fourths prone with the head of the bed elevated. *Position 6:* Segments that come off the tracheobronchial tree anteriorly are drained by positioning supine with a head-down angle. *Positions 7 and 8:* Segments such as the right middle lobe or lingula that come off the tracheobronchial tree anterolaterally will be drained in a three-fourths supine position, slightly head down (see Figure 37-5). Babies on ventilators may also be positioned prone. This is usually done by the therapist rather than in a routine positional rotation (see Figure 37-6).

be achieved.[190] Whereas positional rotation programs for adults emphasize the lower lobes, positional programs for infants must emphasize all lung areas (Figure 37-4). The upper lobes and right middle lobe (Figure 37-5) are common sites of airway collapse and atelectasis in infants, and the right middle lobe bronchus is surrounded by a collar of lymph nodes, making it vulnerable to extrinsic compression. Important considerations and essentials of a positional rotation program for infants are outlined in Box 37-1.

Infants born preterm do tolerate and benefit from prone positioning (Figure 37-6). Studies have demonstrated improved oxygenation, tidal volume, dynamic lung compliance, and synchrony of chest wall movement when preterm neonates are placed in prone positions.[191-194] Additionally, nested prone and side-lying positioning, with boundaries provided for comfort, has been shown to decrease stress behaviors in these infants.[3,195] However, when healthy infants born

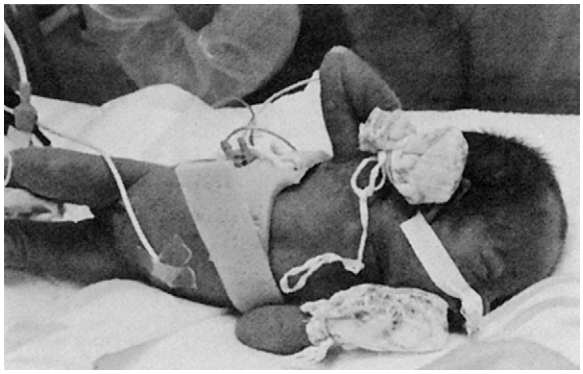

Fig. 37-5 Three-fourths supine position for right middle lobe. Lingula is the same three-fourths supine position with the patient lying on his or her right side.

prematurely approach their discharge to home, the benefits of prone over supine positioning in decreasing their work of breathing are no longer observed.[194]

Positional rotation is generally performed manually every 2 hours, and although this provides pulmonary benefit, it may also contribute to the disruption of homeostasis that has been documented to occur in the course of neonatal intensive care.[3,195,196] Murai and Grant (1994)[197] demonstrated that the use of continuous positional oscillation nursery beds as compared with manual repositioning decreased the duration of oxygen supplementation without adversely affecting the cardiovascular and pulmonary status of the neonates.

Box 37-1 Essentials of a Positional Rotation Program

1. Care should be taken to coordinate any change in the infant's position with other nursing procedures to avoid unnecessary stimulation.
2. Infants should never be left unattended when in a head-down position.
3. Vital signs should be monitored closely by respiration and heart rate monitors. The alarms should be turned on.
4. The infant's chest should be auscultated for adventitious breath sounds after positioning.
5. While the infant is in a drainage position, secretions will be more easily mobilized. The infant's trachea or endotracheal tube should be suctioned as needed.
6. Avoid placing the infant in a head-down position for approximately one hour after eating to avoid aspiration of regurgitated food.
7. Any change in the infant's position should be done slowly to minimize stress on the cardiovascular system.
8. Infants with umbilical arterial lines can be placed on their abdomens; however, one should always check that the line has not been kinked.
9. Some infants might require modified drainage positions. Infants with CF, as well as infants with severe cardiovascular instability and infants with or at risk for intracranial bleeding should not be placed in a head-down position.

Postural Drainage

Postural drainage positions to promote gravity-assisted drainage of specific segmental airways can be safely applied to infants and children. In the acute care setting, however, many of the head-down positions are modified according to tolerance and precautions or contraindications (Table 37-5). The rule for modification of any position for postural drainage is that the position used should be as close to the classical (anatomically correct) position for that segment as safely possible. Examples of the classical postural drainage positions for each bronchopulmonary segment are pictured in Figure 37-7.

Tiny infants (especially those weighing less than 800 grams) usually require and benefit from modification of the head-down position. Horizontal to slightly elevated positioning of the head may be best.[198] This modification is primarily due to changes in oxygenation[198] and the high incidence of intraventricular hemorrhage in infants born preterm.[199-201] In addition, Trendelenburg positioning is contraindicated for infants with cystic fibrosis and cerebral palsy because of high incidence of gastroesophageal reflux disease observed in this patient population.[111,119,122,131,133]

Fig. 37-6 Infants born prematurely (even those on ventilators with numerous catheters) may be placed prone when care is taken.

Table 37-5 Precautions and Contraindications for Postural Drainage in a Neonate

Position	Precaution	Contraindication
Prone	Umbilical arterial catheter Continuous positive airway pressure in nose Excessive abdominal distention Abdominal incision Anterior chest tube	Untreated tension pneumothorax
Trendelenburg position (head down)	Distended abdomen SEH/IVH* (grades I and II) Chronic congestive heart failure or cor pulmonale Persistent fetal circulation Cardiac dysrhythmias Apnea and bradycardia Infant exhibiting signs of acute respiratory distress Hydrocephalus Less than 28 weeks' gestational age	Untreated tension pneumothorax Recent tracheoesophageal fistula repair Recent eye or intracranial surgery Intraventricular hemorrhage (grades III and IV) Acute congestive heart failure or cor pulmonale

**SEH/IVH*, Subependymal hemorrhage/intraventricular hemorrhage.

Chest Percussion and Vibration

Percussion and vibration are used in conjunction with postural drainage to augment the effect of gravity in the removal of secretions.[63,66] There are several ways to perform percussion on infants. For a larger infant, it is possible to use a cupped hand in a manner similar to percussing an adult's chest. For a smaller infant, some modification of this technique is needed. Chest percussion for a smaller infant is accomplished by tenting three or four fingers or using any of the commercially available percussion devices made for neonates (Figure 37-8). A small anesthesia mask or "palm cup" can also be used effectively.[63,66]

Precautions for chest percussion in the infant include, but are not limited to, unstable cardiovascular or oxygenation status (although percussion may be provided safely if continuous transcutaneous monitoring is available), coagulopathy, subcutaneous emphysema, or intraventricular hemorrhage.

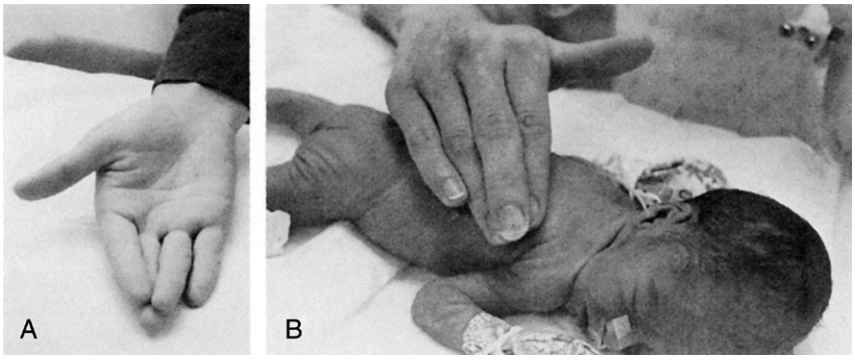

Fig. 37-8 "Tenting" of the fingers for percussion of premature infants or small children.

Fig. 37-9 Manual chest wall vibration of an infant born preterm.

Additionally, percussion is generally contraindicated over a healing thoracotomy incision or if the child displays irritability and signs of respiratory distress with the treatment.

Vibration is accomplished either through manual vibratory motion of the therapist's fingers on the infant's chest wall (Figure 37-9) or through the use of a mechanical vibrator. An electric toothbrush can be adapted by padding the bristle portion with foam.[63,66] Vibration has been observed to occasionally increase irritability and may be less well tolerated than percussion. The most common precaution for vibration is increased irritability with the development of bradycardia and respiratory distress.

The decision to use chest percussion and vibration will depend on the reviewed principles and precautions, the medical condition of the infant, and the infant's tolerance to handling. Continuation of percussion and vibration will depend on the day-to-day medical status of the infant and his or her response to treatment.

Airway Suctioning

Sterile airway suctioning is discussed in detail in Chapter 44; however, some special considerations for suctioning the airway of an infant must be highlighted.[202-205]

1. If possible, suction with a transcutaneous oxygen monitor in place. These monitors give continuous feedback regarding the infant's oxygenation status.
2. Bagging should be done only with a bag attached to a pressure manometer to ensure that sufficient pressures are being used without exceeding the maximum safe levels (these limits should be similar to the ventilator settings).
3. Suction for no more than 5 seconds with each catheter withdrawal.
4. Infants should be carefully hyperoxygenated when hyperventilated so as to minimize hyperoxia and hypoxia. Bagging usually does not need to continue for more than 5 to 10 seconds to maintain adequate oxygen levels.
5. Monitor the blood pressure of preterm infants before, during, and after suctioning. Change in blood pressure may indicate increased intracranial pressure and risk for intracranial hemorrhage.

In intubated infants, the need for endotracheal tube (ETT) suctioning should be carefully assessed. Clinical indications for ETT suctioning include respiratory pattern and rate changes, presence of secretions in the ETT (observed visually or heard during respiration), abnormal breath sounds audible upon chest auscultation, decrease in oxygen saturation and PaO_2, increase in $PaCO_2$, bradycardia, ventilator waveform changes related to proximal airway pressure, and agitated behavior.[205]

CPT for Children

The goals for CPT in children (2 years of age and older) include more than improving airway clearance. Children are capable of following directions and imitating a therapist's demonstration of deep breathing, coughing, and active exercise. CPT in children is focused on improving ventilation and efficiency of breathing;[179] increasing general strength and endurance with an emphasis on muscles of respiration; improving posture; and addressing relaxation, breathing control, and pacing.[206]

The application of CPT with children often requires patience and creative adaptation. The challenge is to make it seem less like a treatment and more like a game. It is important, however, to be honest in your explanations and to speak to children with respect and at a level appropriate for their age and development.

Involving the family in CPT treatment of a child can be invaluable.[179,207,208] In some cases, the parent may do most of the "hands-on" and repeat instructions to the child under the direct guidance of the therapist. This arrangement will also help reinforce parent and family education for carry-over of home therapy.

Positional Rotation

The goal of positional rotation and postural drainage is to prevent the accumulation of secretions and to aid in their removal. Any child who is immobile, receiving artificial ventilation, or not expanding his or her chest adequately should have his or her position changed at least every 2 hours. Recall that positional changes will enhance oxygen transport and promote pulmonary drainage.[190] If the child is reluctant to have his or her position changed, changing the location of the television may be helpful. Be creative!

YOUNG CHILDREN

In younger children (18 months to 3 years of age), deep breathing is usually encouraged by blowing bubbles, tissue paper, mobiles, or simple horns. To achieve maximal chest expansion, the child should be positioned on each side while playing blowing games or singing. The theory behind the side-lying position is that the downside lung ventilates more effectively (see Chapter 19). Additionally, if the poorly ventilated lung is uppermost, stretch techniques can facilitate deeper breathing (see Chapter 23).

Spontaneous coughing in younger children often occurs with a change in position or with crying. For the child who does not cough spontaneously or whose cough is inadequate to clear secretions, nasopharyngeal suctioning may be necessary.

OLDER CHILDREN

School-age children can be more specifically instructed in various breathing exercises, such as diaphragmatic breathing, pursed-lips breathing, and segmental lateral costal breathing. They may also be candidates for using relaxed deep breathing for control and pacing of activity. Cooperation with this age group, however, still remains higher if some aspect of therapy is fun. Elaborate whistles are available that encourage deep breathing; they make therapy fun by challenging the patient to make the whistle components move. Additionally, pediatric incentive spirometers are available with cheerful, "cool" pictures to make respiratory exercises seem more like a game.

Older children (not infants) can be stimulated to cough by applying a firm pressure over the trachea in the suprasternal notch. Be aware that coughing, whether spontaneous or stimulated, may elicit gagging and vomiting, especially if airway clearance is scheduled too soon after a child has eaten.

Preoperative and Postoperative Care

The efficacy of postoperative CPT is highly related to preoperative care.[179] The appropriate application of preoperative assessment, instruction, and direct therapeutic intervention helps to decrease the incidence of postoperative complications.

Preoperative teaching is extremely important for both the child and the family. Parents may often be more anxious than the child, so patient and family education is important. The level of preoperative training with the child will depend on his or her age.

If the child is very young (under two years of age), the therapist needs to meet with the parents and explain the purpose of bronchial drainage treatments, potential airway clearance problems, and possible complications. The preventive nature of these interventions should be stressed, and procedures that can be done with the child after surgery should be demonstrated and discussed. These may include positioning, chest percussion, vibration, and airway suctioning. In addition, the physical therapist should always allow time for the parents to ask questions.

If the child is able to understand simple concepts, the therapist can, in addition to parent education, instruct the child in various breathing games, use of an incentive spirometer, coughing, and general upper and lower extremity exercises.

Postoperative procedures can be effectively explained and demonstrated to children starting at approximately 8 years of age and older. The importance of bronchial hygiene should be stressed during demonstration of deep breathing and coughing. The child can be shown how to splint the incision using a pillow or a stuffed animal to assist with comfort while coughing. Do not tell the child that coughing will not hurt; be honest but reinforce that splinting will help. Teach the child diaphragmatic and pursed-lips breathing with an inspiratory-hold maneuver, and, if appropriate, teach the child how to use an incentive spirometer.

Postoperative pulmonary complications may not be as prevalent in the pediatric age group as in adults, but they still occur. The most common complications are atelectasis, infection secondary to pooling of secretions, and airway obstruction. Infants and children with the following characteristics will be at risk for developing postoperative pulmonary complications: preexisting lung disease, thoracic or upper abdominal location of incision, prolonged postoperative bed rest or restricted mobility, and neuromuscular involvement that affects the ability to move, cough, and breathe deeply.

Postoperative interventions generally focus on increasing ventilation, coughing, and active mobility.[179,181] Specific bronchial drainage is used only if the child is unable to clear his or her airway or is at risk because of chronic lung disease.

After high abdominal or thoracic surgery, there may be a tendency for the child to splint on the side of the incision. Arm, shoulder, and trunk movement should be encouraged to prevent any postoperative complications. For the younger child, chest mobility can be encouraged by clapping the hands overhead or by dramatizing songs such as "The Itsy Bitsy Spider." More conventional exercises may be taught to the older child.

Children tend to mobilize very quickly (unless their movement is limited by motor involvement or a specific surgical procedure). In general, once the child is out of bed and moving about, with clear lungs and an effective cough, postoperative CPT can be discontinued.

Pediatric Pulmonary Rehabilitation

Rehabilitation programs for children with chronic lung disease include the same components and have essentially the same goals as adult pulmonary rehabilitation. However, the specific diagnoses most prevalent in children differ from those in adults. Asthma and CF are the most common conditions among children who may benefit from pulmonary rehabilitation.

Exercise and Asthma

Exercise and conditioning are very important interventions for children with asthma. Improved chest and trunk mobility, control of breathing, strength, posture, increased exercise capacity, and improved quality of life are all goals that can be addressed in the design of exercise programs for these children.[209-211]

The transient airflow obstruction associated with physical exertion may render children (and their parents) wary of exercise. Several approaches may be beneficial at promoting and maintaining exercise in this population. First, aerobic conditioning will reduce the ventilation requirement for activity, thus reducing the increased rate of ventilation with exertion. Second, wearing a face mask and inhaling through the nose will warm up and humidify the inhaled air before it moves to the intrathoracic region, thus raising the threshold for exercise-induced bronchospasm.[212-214] Third, because many younger children perform bursts of activity at unpredictable times of day and may not be allowed to carry their inhalers with them in school or during sports events, the physical therapist may be influential in communicating with the child's physician to identify longer-acting medications that might be given at home.[213] Finally, exercise-induced symptoms may be reduced in some children with the use of 10- to 15-minute warm-up and warm-down exercise periods.[212,214] Recommendations for warm-up exercise include submaximal activity performed at up to 60% maximal heart rate[214] and repeated activity that varies in intensity and includes high burst periods.[212]

Part of a pulmonary rehabilitation program may involve providing recommendations for the child's participation in physical education (PE).[209] Certain aspects of exercise relative to pulmonary function in children with asthma need to be communicated to the PE teacher. Running is the form of exercise most likely to aggravate exercise-induced asthma, especially if performed in a cool, dry environment. Swimming, by contrast, is an excellent activity.[104,209,211] Strenuous or continuous exercise may induce bronchospasm, whereas short periods of exercise (less than 5 continuous minutes) may be beneficial for conditioning without bronchial aggravation.[209,214] PE teachers should also be aware that the child may need to use a pre-exercise inhaler to participate in PE without pulmonary consequence.[209,214]

Exercise and CF

Physical activity designed to improve exercise tolerance helps children with CF to mobilize secretions and improve body image. In terms of preventing opportunistic infections in these children, exercise is also associated with an increased immune responsiveness.[215] Furthermore, quality-of-life measures and subjective reports also indicate improvement when exercise is part of the overall management program of children with CF.[216-218]

An individualized exercise program should be developed for each child with CF. A pre-exercise examination and evaluation should include the following components:

1. Evaluation of the range of motion, strength, and posture
2. Complete chest evaluation
3. Evaluation of neuromuscular control, including muscle recruitment patterns during breathing and arm and trunk movements
4. Evaluation of ADL tolerance and limitations
5. Inspiratory muscle strength (maximal inspiratory negative pressure at the mouth) and endurance testing (The inspiratory endurance testing can be done with an inspiratory muscle training device by having the child breathe for a predetermined length of time at progressively increased resistances until tolerance is reached.)
6. Cardiovascular and pulmonary exercise testing performed with electrocardiogram, blood pressure, and oxygen monitoring, to assess exercise capacity by determining the peak oxygen uptake or VO_{2peak}

A basic exercise program for children with CF should include activities to elongate tight musculature; retrain and strengthen weak musculature; transfer postural, range of motion, and strength gains to preferred functional physical activities; and address overall endurance.[216-218] Vigorous exercise and fitness training in these children requires careful monitoring of pulmonary response. Considerable research exists to support aerobic and anaerobic training in children with CF.[104,216,217] Physical therapists should pay special attention to promotion of enjoyment of exercise by offering a variety of different activities and supporting the child's self-esteem, with a goal of improving the overall exercise compliance.[219]

Among hospitalized children with CF, those who followed either aerobic or resistance training protocols had better aerobic and strength outcomes, respectively, than children in a standard CPT program, with no significant differences between the exercise and nonexercise groups in disease severity or length of hospital stay.[217] Attention to nutritional status in these children is paramount to prevent decreased activity and promote exercise tolerance and quality of life.[220-222] The evidence base suggests that the benefits of exercise will likely outweigh the risks in this population when other aspects of health are optimized.[104]

Therapeutic Handling to Maximize Trunk and Ventilatory Function

Attention to pulmonary function is easily accomplished within any "handling" approach to motor therapy for children with trunk weakness, tightness, alterations in tone, or general immobility. Most handling consistent with a neurodevelopmental treatment (NDT) approach lends itself readily to a dual focus on movement quality and ventilation. Extrinsic pulmonary development is clearly interrelated with musculoskeletal and motor development of the trunk.[223]

After an observational assessment of chest mobility, trunk posture and muscle recruitment strategies during breathing and functional activities, intervention should begin with initial handling for functional range of motion through the trunk. This will typically require elongation of the pectoral, sternocleidomastoid, upper trapezius, and rectus abdominis muscles. Manual lowering of the rib cage will also be necessary to work toward maximizing chest mobility (Figure 37-10).

Passive elongation of muscles must always be followed by active elongation. Controlled prone extension on a large inflated ball is both fun for the child and effective for the therapist (Figure 37-11). Manual guidance for upper extremity abduction and external rotation will facilitate active elongation of the pectoral muscles via active firing of the scapular

Fig. 37-10 Manual lowering of the rib cage. *Arrows* indicate direction of therapist's hand movement (caudal and medial).

Fig. 37-11 Handling to facilitate active upper thoracic extension as a means of opening the anterior chest and lengthening the rectus abdominis muscle while supporting the lower ribcage on the ball.

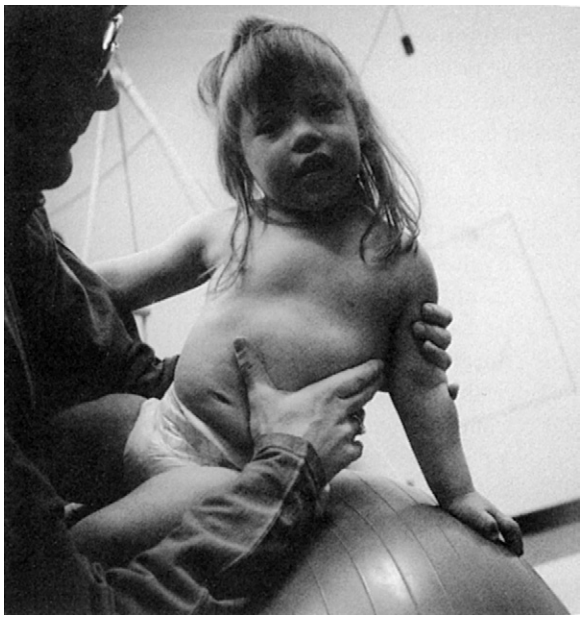

Fig. 37-12 Handling to reinforce upper chest expansion and abdominal oblique stabilization of the lower ribs.

retractors.[224] The ball can be used to impart movement and support the lower rib cage. This elongates the anterior trunk (rectus abdominis), lengthens intercostal muscles, and facilitates increased upper chest expansion.

Handling to achieve proprioceptive input of the scapulae on the posterior thorax will help to reinforce active thoracic extension and anterior chest expansion.[223,224] The therapist's hands can stabilize the rib cage to reinforce the abdominal oblique muscle function during movement (Figure 37-12). Activities requiring alternating extension-rotation and flexion-rotation will recruit control of the abdominal obliques and maintain active upper trunk extension. Bubble blowing, using whistle toys, and singing are excellent means of monitoring the ventilatory changes that occur with active use of increased upper chest expansion. As tidal volume increases, vocalizations should increase in frequency, sound higher, and become louder.

The concept of functional carryover is central to the treatment approach presented here. Addressing ventilation and trunk control simultaneously has intuitive appeal based not only on shared musculoskeletal relationships but also on the necessity of pulmonary tolerance for motor activity.

Summary

Cardiovascular and pulmonary physical therapy with infants and children begins with an understanding of the issues

related to development and developmental vulnerabilities. In this chapter, specific cardiovascular and pulmonary conditions in pediatrics are described and treatment recommendations provided. Cardiovascular and pulmonary development and function are the basis for indications and precautions for treatment of neonates, infants, children, and adolescents.

The link between pulmonary and motor functions is also important. Many children with motor involvement are at risk for or have medical histories remarkable for cardiovascular and pulmonary dysfunction. Motor approaches that maximize ventilatory function are critical, because efficient oxygenation is a priority not only for children with primary cardiovascular and pulmonary diagnoses but also for children with motor disorders.

Review Questions

1. Discuss the importance of changes in pulmonary blood flow during transitional circulation, and relate these changes to closure of foramen ovale and ductus arteriosus.
2. Describe six characteristics of an infant's pulmonary anatomy that contribute to the increased work of breathing and potential for pulmonary distress in this age group.
3. Identify and discuss two aspects of cardiovascular and pulmonary vulnerability in the preterm infant.
4. Compare pulmonary disorders commonly seen in preterm neonates with those seen in full-term neonates.
5. Compare the goals of chest physical therapy for infants and older children. What are the similarities and differences?
6. When the therapist treats infants to improve airway clearance, what are the precautions for and/or considerations of each of the following?
   - Positional rotation
   - Postural drainage
   - Percussion
   - Vibration
   - Airway suctioning
7. How might neuromotor (neuromuscular) dysfunction affect pulmonary development?
8. Identify two cardiovascular and pulmonary comorbidities of obesity in typically developing children.
9. Describe goals, precautions, and suggested monitoring for exercise in children who have the following:
   - A history of cardiac surgery
   - Asthma
   - Cystic fibrosis

Cardiovascular, pulmonary, and autonomic nervous system functions are dynamic and undergo changes as people age. It is important for physical therapists to be aware of changes that occur with normal aging to better understand the impact of pathological conditions and impairment on these systems' functions. In addition, a clear understanding of how these systems respond to exercise training will assist the clinician in prescribing and evaluating exercise interventions in older adults.

Understanding aging is more complicated than simply taking into account chronological age. As people age, greater variability occurs among individuals, making predictions about any one individual challenging. The trends of some changes are probably not linear but curvilinear, with changes accelerating after the age of 65. Thus many of the physiological studies that have been done with 60-year-olds may not apply to individuals who are 80, 90, or 100 years of age. Many of the studies that are available on exercise in older individuals have been conducted with people who are less than 65 years of age. The vast majority of these studies used only men as subjects or had a small number of women in the sample. Sex may be an important variable in relation to exercise and aging, but the data available on this issue are limited.

Another consideration is the composition of study populations. With increasing age there is a greater incidence of pathology and co-morbidities. Latent cardiovascular disease and histories of chronic illnesses are common in older populations. Co-morbidities are frequently encountered in older adults. It may be more common for a person over 75 years of age to have health problems than to be healthy. The physical therapist may be more interested in the responses of a frail 85- or 90-year-old woman who has a history of hypertension, coronary artery disease, and diabetes than someone who is healthy at this age because this reflects the population most often referred to physical therapy. The occurrence of pathological states in study populations may affect the cardiovascular and pulmonary responses to exercise. Furthermore, the study of the physiological aspects of exercise and aging is still evolving. The literature can be confusing and contradictory, making conclusions and generalizations difficult. An attempt is made in this chapter to provide some direction in this confusing maze of information.

An additional issue is a model of aging that might sort out some of the determinants of aging (Figure 38-1). The model identifies biological factors, disuse, pathology, and psychosocial concerns as determinants of aging. Biological factors address genetics, sex, cellular mechanisms, and metabolic and physiological responses that influence aging. Disuse is implicated in the more sedentary lifestyle led by many older adults, which results in loss of exercise capacity.[1] With exercise training, it should be possible to reverse or attenuate capacities that decline as a result of disuse. This chapter focuses on the biological and disuse characteristics of aging. The impact of various pathological conditions is discussed in other chapters.

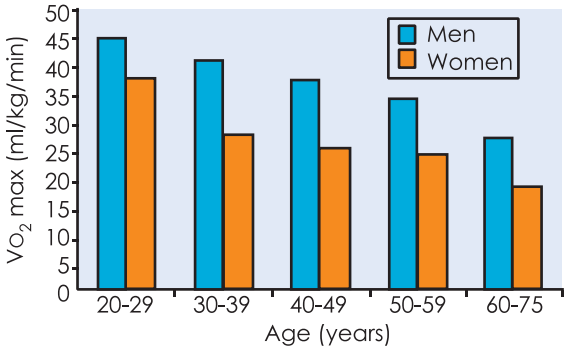

Fig. 38-2 Decline in $\dot{V}O_{2max}$ from 20 to 75 years of age in both men and women. *(From Hossack KF, Bruce RA: Maximal cardiac function in sedentary normal men and women: Comparison of age-related changes,* Journal of Applied Physiology *53:799-804, 1982.)*

Psychosocial issues related to exercise and aging are not addressed.

Cardiac Changes with Aging

Aerobic Capacity

Aerobic capacity is the maximum ability to perform exercise with large muscle groups. This ability is produced by interaction of the lungs, heart, and peripheral tissues. The most common indirect measure of aerobic capacity is maximum oxygen consumption ($\dot{V}O_{2max}$), or the maximum amount of oxygen used during exercise. $\dot{V}O_{2max}$ is directly related to cardiac output (the amount of blood pumped by the heart) and the arteriovenous oxygen content difference (the amount of oxygen extracted in the periphery). Cardiac output is the product of heart rate and stroke volume. Aerobic capacity reflects the central cardiac function and the efficiency of the peripheral tissues to extract and use oxygen.

$\dot{V}O_{2max}$ declines with age[2,3] at a rate of 0.40 to 0.50 mL/kg/min per year for men and between 0.20 to 0.35 mL/kg/min per year for women (Figure 38-2).[4] The reduction is approximately 10% per decade. The decline is faster and greater in men than women; however, men have a larger aerobic capacity overall than women.[5,6] $\dot{V}O_{2max}$ is related to body size, which is generally smaller in women than men. $\dot{V}O_{2max}$ is associated with peripheral vascular reserve in older men but not in women.[7] Increases in body weight along with aging result in reduced $\dot{V}O_{2max}$, even if aerobic capacity remains the same, because relative oxygen consumption is related to body weight. Reduced physical activity with aging also contributes to a loss of $\dot{V}O_{2max}$.

Considerable disagreement exists regarding the mechanisms that contribute to the decline in $\dot{V}O_{2max}$ with age. Both cardiac and peripheral changes contribute to this loss. Maximum cardiac output declines with age similarly in men and women.[7] A reduction in maximum cardiac output may account for 50% to 100% of the total reduction in $\dot{V}O_{2max}$.[8-10] McGuire and colleagues (2001)[2], however, suggested that reductions in peripheral oxygen extraction were the dominant mechanism responsible for reduced $\dot{V}O_{2max}$ with age. A major component to the decline in maximum cardiac output is decreased maximum heart rate.[3,9,11] The decline in heart rate is linearly related to age and occurs in both sedentary and active people.[5,12] Discrepancies in the age-related response of maximum stroke volume also exist; studies have reported reduced, preserved, and increased maximum stroke volume with age.[2,3,9,13] The decline in $\dot{V}O_{2max}$ associated with aging is most likely attributable to decreased maximum heart rate, stroke volume, and arteriovenous oxygen content difference, although each component's contribution varies.[8,14]

Cardiac Mechanics

Age-related changes in cardiac structure occur in the form of left ventricular wall thickness[13,15] and are attributed to an increase in size of cardiac myocytes[16] and increased collagen.[13] Additional cardiac structural changes include increases in vascular intimal thickness, vascular stiffness, and left arterial dimension.[13,17]

The diastolic properties (cardiac filling) of the heart alter with age. Diastole requires relaxation of the myocardial fibers, sufficient venous return to rapidly fill the heart, and timing of the atrial contraction to contribute to the end-diastolic volume. Relaxation may be hampered by increased ventricular stiffness, although there is limited evidence of this in humans.[14] The period of the isovolumetric myocardial relaxation (the time between aortic valve closing and mitral valve opening) is prolonged with aging.[15] Likewise, the peak rate of left ventricular filling during early diastole is progressively reduced so that between the ages of 20 and 80 years, the average rate can be reduced up to 50%.[13] Despite the changes in early diastole, the resting left ventricular end-diastolic volume remains the same because of an enhanced left atrial contribution to ventricular filling.[13] This is accompanied by an enlarged left atrium and an audible fourth heart sound in most older adults.[13,18]

Considerable disagreement exists regarding what happens to diastolic function during exercise. End-diastolic volume index (end-diastolic volume normalized for body surface) increases similarly in both young and older men during submaximal exercise; however, only older men remain at these elevated levels during exhaustive exercise.[13] Filling pressures during exercise in men increase with age.[19] In addition, peak left ventricular diastolic filling rate during submaximal and maximal exercise decreases with aging.[20,21] Decreased filling rate is associated with increased ventricular stiffness and prolonged relaxation time.[22]

Resting measures of systolic and cardiac pump function do not change with aging. The resting end-systolic volume and

stroke volume do not change with age. Likewise, ejection fraction at rest (end-diastolic volume – [end-systolic volume/end-diastolic volume]) is similar in healthy older and younger individuals.[13]

Unlike resting systolic function, the pumping function of the heart changes considerably in response to exercise. Myocardial contractility as measured by the ratio of end-systolic volume to systolic arterial pressure declines during exercise as people age.[14] The end-systolic volume index increases, whereas the ejection fraction decreases during exercise.[13] Reduced contractile performance is related to decreased response to beta-adrenergic stimulation, changes in the myocardium, increased systolic blood pressure, and ventricular wall abnormalities.[8]

Exercise Training

For older people who remain active, the rate of decline in $\dot{V}O_{2max}$ is reduced to 5% per decade, compared with an anticipated decline of 10% per decade in sedentary adults.[11] A meta-analysis of 29 studies on endurance training, which included 1030 men and 466 women between the ages of 61 and 78 years, concluded that endurance training increases functional capacity in young older adults.[23] Less improvement was seen with increasing age, a shorter length of training, low $\dot{V}O_{2max}$ before training, and short duration of exercise sessions. The analysis suggests that a healthy 68-year-old individual who exercises for 30 minutes three times per week for 4 to 6 months can improve $\dot{V}O_{2max}$ by 14%.[23] Similar improvements occur in both men and women.[24,25]

The mechanisms underlying improvements in $\dot{V}O_{2max}$ in older adults who engage in endurance training are not clear. One consistent finding, however, is greater extraction of oxygen in the exercising skeletal muscle, which produces a wider arteriovenous oxygen content difference in both older men and women.[9,22,26] This implies that adaptations in the peripheral skeletal muscles account for some of the increase in $\dot{V}O_{2max}$ in older adults. The impact of exercise training on maximum cardiac output is uncertain.[22] Maximum cardiac output can either remain the same or increase after exercise training, depending on the effect of training on maximum stroke volume and maximum heart rate. Maximum heart rate remains the same in older men regardless of activity level, suggesting that the decline in maximal heart rate depends on factors other than exercise and physical fitness.[27] A decrease in response to circulating catecholamines is most often cited as the reason for changes in maximum heart rate with aging.[28] Relatively intense endurance training for a year or more can increase peak stroke volume in men.[29-31] Adaptations to exercise training in older women have been attributed predominantly to peripheral changes in arteriovenous oxygen content difference rather than central changes in cardiac function.[32,33] This apparently occurs despite intensive endurance training over a year-long period. In contrast, a relatively recent study that compared men and women who were masters athletes with healthy sedentary older adults, healthy young persons, and sedentary controls reported that stroke volume for any given filling pressure was greater for masters athletes compared with age-matched sedentary older adults.[34]

A recent study followed a small group of competitive distance-running men for 10 years with measures of the cardiovascular, pulmonary, and metabolic systems.[35] The 5-kilometer race time slowed over the 10 years, along with decreased training mileage, intensity, and frequency. Consistent with this, the peak exercise heart rate and oxygen consumption declined. Another intriguing study indicates that telomere length, a measure of the ability of cells to replicate, is preserved in healthy, older adults who engage in vigorous aerobic exercise.[36] The preservation of telomere length is positively related to maximum oxygen consumption, suggesting that exercise reduces cell senescence with aging. Further studies examining the outcomes of prolonged, sustained endurance training in older men and women are needed to characterize the adaptations that occur in women.

The diastolic changes that occur with aging can be reversed with exercise training.[20] Levy and colleagues intensively endurance trained 13 rigorously screened older men aged 60 to 82 years (mean age 68 years) and 11 younger men in their 20s, for 6 months. The training produced increased resting, submaximal, and peak filling rates for the older group comparable to the changes observed in the younger group.[20] End-diastolic peak volume at rest and exercise also increase after lengthy endurance training.[30] Thus training may reduce the age-associated diastolic changes. In contrast, endurance athletes who were followed for 10 years after age 65 showed deterioration in diastolic left ventricular function indices consistent with decreased cardiovascular diastolic function.[35] Another study demonstrated that 1 year of vigorous exercise training in sedentary seniors did not improve cardiac stiffening, but improved left ventricular mass and reduced arterial elastance.[37] The mechanisms of these responses are uncertain in humans. Studies in rats have shown that exercise training increases calcium uptake in cardiac sarcoplasmic reticulum, decreases relaxation time, reduces the decline of left ventricular pressure, enhances fatty acid oxidation, and increases cytochrome c oxidase levels.[20,38,39] All these changes have been associated with reduced diastolic function with aging.

Exercise training can also improve systolic performance in older men as reflected by the increase in exercise stroke volume. Increased peak stroke volume occurs with an increased exercise ejection fraction, a decrease in end-systolic volume, and greater left ventricular wall mass.[3,30,31] These changes apparently do not occur in older, estrogen-deficient women.[33] Table 38-1 summarizes these changes.

Vascular and Autonomic Changes with Aging

Aging increases arterial stiffness because of a loss of elastin, elastin fractures, and an increase in collagen and calcification.[17,40] Sex may influence some of these changes. Some evidence suggests that aortic stiffness may be greater in women after menopause than men.[41] Arterial wall thickness and diameter and resting systolic pressure also increase (Figure 38-3).[14,17] It is unclear whether peripheral vascular resistance increases in normotensive older adults. Changes in the structure, size, and reactivity of the arteries increase the work of the left ventricle and have been directly implicated in the increase in cardiac myocyte size.

Complaints of dizziness when an older patient moves from supine to standing are frequently encountered by the physical therapist. Postural hypotension, or orthostatic intolerance, generally does not occur in healthy community-dwelling older adults but is common in individuals over 70 years of age who

are debilitated and in hospitals or nursing homes.[42,43] Orthostatic intolerance is associated with decreased resting diastolic function, possibly decreased stroke volume, extreme inactivity, and, in individuals with hypertension, high systolic blood pressure.[44]

There are decreases in baroreceptor and cardiopulmonary reflexes with aging.[14,45] Arterial and venous dilation are reduced, but vasoconstriction is relatively spared. The heart demonstrates an overall decrease in responsiveness to autonomic stimulation. Older individuals experience higher central venous and mean arterial pressures, but lower forearm blood flow and forearm vascular resistance in response to passive leg raising.[45]

Response to Exercise

During submaximal and maximal exercise, arterial blood pressure is either unchanged or increased when younger subjects are compared with older subjects.[46] There also appears to be impaired peripheral vasodilation in skeletal muscle in response to exercise.[9] Redistribution of blood flow during exercise normally involves the shunting of blood from inactive limbs and viscera. There seems to be an enhanced vasoconstriction in inactive muscles during dynamic exercise in healthy older men.[47]

Exercise Training

Exercise training improves peripheral blood flow in skeletal muscle in 60-year-old men and women.[3,48] Exercise training, specifically aerobic training, has been reported to decrease blood pressure.[49] Meta-analysis revealed that 4 or more weeks of aerobic training can decrease systolic and diastolic blood pressure[50] and mean arterial blood pressure responses in older individuals when compared with sedentary individuals.[48] Adults who regularly exercise compared with sedentary individuals have smaller or no age-associated stiffness of the large arteries and have improved vascular endothelial function.[51] Aerobic training also reduces the age-related decline in cardiovagal baroreflex sensitivity and partially restores diminished cardiovagal baroreflex sensitivity in older men.[52] Aerobic training alters the autonomic nervous system and its control over resting heart rate by enhancing parasympathetic activity and attenuating sympathetic activity.[53] During vigorous exercise, the predominant activity of the autonomic nervous system is to increase sympathetic nerve activity, producing an increase in norepinephrine concentrations and increasing blood flow via dilation of the large arteries and constriction of the veins (Table 38-2).[13,54] Long-term aerobic training, however, reduces sympathetic nerve activity for a given work rate, thereby lowering exercise heart rate at a given work rate.[53] In summary, habitual exercise can improve characteristics of arterial aging, preserve vascular function, and possibly reduce the risk for cardiovascular disease.[51]

Pulmonary Changes with Aging

Structure and Function

Two major changes to the pulmonary system associated with aging are decreased elastic recoil and stiffening of the chest wall.[8,55] Elastic recoil of the lungs depends on the composition of the connective tissue, the structure of the connective tissue, and alveolar surface tension produced by surfactant.[8] Limited evidence suggests that the structure of the connective tissue may be the primary mechanism for age-associated change in

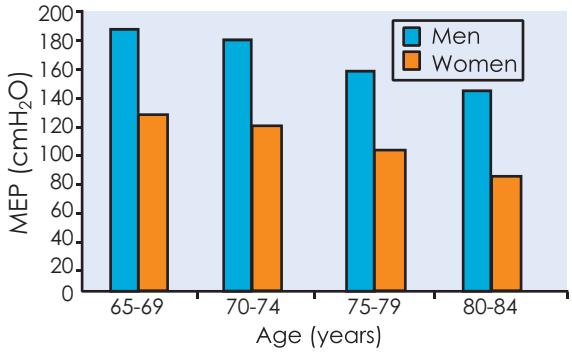

Fig. 38-4 Decrease in maximum expiratory pressures between 65 and 84 years of age for both men and women. This is a measure of respiratory muscle strength. *(From Enright PL, Kronmal RA, Monlio TA, et al: Respiratory muscle strength in the elderly,* American Journal of Respiratory Critical Care Medicine *149:430-438, 1994.)*

elastic recoil. Chest wall stiffness is accompanied by an increase in chest anterioposterior diameter, costal cartilage calcification, narrowing of the intervertebral disks, and changes in the rib to vertebrae articulations.[55-57] Postural changes such as kyphosis from osteoporosis limit expansion of the thoracic cage during inspiration and place the diaphragm at a mechanical disadvantage.[56]

Decreases occur with the alveolar-capillary surface area, the alveolar septal surface area, and the total surface area of lung parenchyma.[58] This reduces the alveolar surface area available for gas exchange and increases the amount of physiological dead space.[55]

Loss of elastic recoil with aging is directly associated with reduced forced expiratory flow.[59] Limitations in exhalation are caused by airway narrowing and closure at all lung volumes, thus reducing forced expiratory volume in 1 second (FEV_1).[8] Additionally, early airway closure also produces an early closing volume and a relative increase in the total residual volume. The combination of reduced elastic recoil and increased chest wall stiffness further increases residual volume and leads to a decrease in forced vital capacity in older individuals.[60,61] Flow rates are also lower in women and African-Americans than in white men at any age.[8]

Respiratory muscle strength, as reflected by the ability to create pressure over a range of lung volumes and flow rates, is similar when comparing healthy 30- and 70-year-olds.[62] This suggests that respiratory muscle strength does not change with aging; however, transdiaphragmatic pressure is reduced in older compared with younger individuals, suggesting reduced diaphragmatic strength.[56] Decline in diaphragmatic strength can contribute to diaphragmatic fatigue and ventilator weaning failure in older individuals.[56] Maximal inspiratory and expiratory pressures have been reported to decrease 15% between the sixth and eighth decades (Figure 38-4).[63] Perhaps these observed differences are similar to the differences observed with submaximal and maximal cardiac responses with the dynamic pressure measures over a range of volumes and flows considered submaximal.

Changes in the surface area result in a decrease in the diffusion capacity of the lung.[60,64] Both the loss of surface area and a decrease in pulmonary capillary blood volume contribute to reduced and uneven ventilation-to-perfusion matching in older adults. The resting partial arterial pressure of oxygen declines 5 to 10 mm Hg between the ages of 25 and 75 years.[8] These changes do not affect the arterial oxymyoglobin saturation or oxygen content. Parallel changes in the peripheral vasculature, pulmonary vascular resistance, and pulmonary arterial pressure at rest increase (Table 38-3).

Responses to Exercise

In addition to the structural and functional changes at rest, several changes occur in breathing during acute exercise. Expiratory flow limitations occur at lower exercise intensities as people age. A normal, healthy 69-year-old will begin to experience flow limitations even in response to moderate exercise.[8] Practically, the individual may experience this by having greater difficulty catching his or her breath during exercise.

Normally as people exercise, the tidal volume increases directly with increasing exercise intensity up to about 50% to 60% of the vital capacity. This remains unchanged as people age, although the vital capacity for older adults is reduced.[65] Likewise, as exercise and the tidal volume increase, there is a slight drop in the ratio of dead space to tidal volume. This drop is not affected by aging, although the older person will breathe more (have a higher minute ventilation) in response to submaximal exercise.[66] Of interest, the short-term modulation of the exercise ventilatory response does not change in healthy older men compared with healthy younger men, despite changes in ventilatory capacity with aging.[67]

The work of breathing is increased during exercise as people age as a result of several factors. Older adults require an increased ventilatory response to exercise to attain the same alveolar ventilation and $PaCO_2$.[66] Combined with the loss of elastic recoil, which causes airway closure at higher lung volumes, expiratory flow limitation occurs at moderate exercise intensities (an expiratory volume of 70 to 100 $L \cdot min^{-1}$), producing a hyperinflation, a noticeable increase in elastic and flow-resistive work of breathing, and shortness of breath.[66] In addition, an increase in the end-expiratory lung volume with increasing exercise results in breathing that occurs at a stiffer point in the lung-volume relationship. The increased stiffness imposes a higher elastic recoil on the ventilatory muscles, requiring greater pressure generated by the inspiratory muscles. The increase in expiratory flow resistance likewise requires greater pressure development by the expiratory

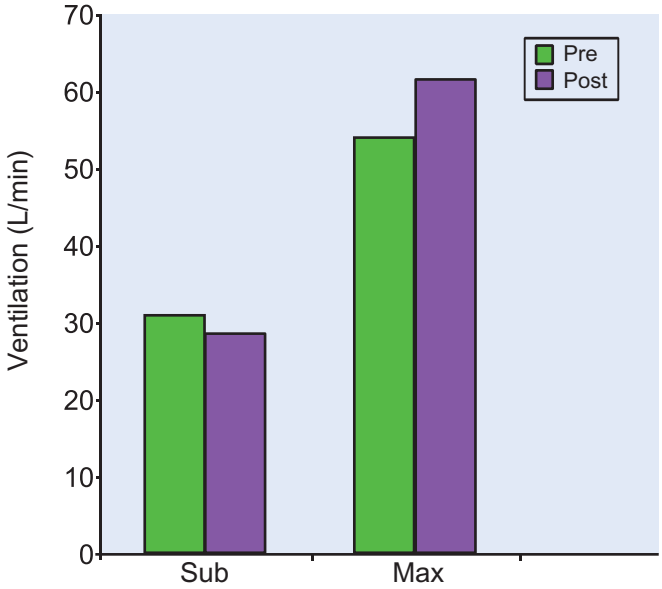

Fig. 38-5 Submaximum and maximum minute ventilation preexercise and postexercise training with a 12-week walking program in women whose mean age was 72.5 years. *(From Warren BJ, Nieman DC, Dotson RG, et al: Cardiorespiratory responses to exercise training in septuagenarian women,* International Journal of Sports Medicine *14:60-65, 1993.)*

muscles. Both the inspiratory and expiratory changes increase the work of breathing. The increase in the work of breathing increases the respiratory muscle oxygen consumption so that the respiratory muscles alone may require 10% to 12% of the total body oxygen consumption during maximal exercise in a sedentary 70-year-old man.[8]

What is also apparent is that the reserves used to respond to exercise represent a greater percentage of the available capacity. An older individual can exceed 50% of inspiratory muscle capacity even during moderate exercise. This is in contrast to the younger individual who rarely exceeds 50% of the inspiratory muscle capacity with exercise.[8] Thus the reserve capacity to generate pleural pressure is reduced in older adults because greater capacity is needed for even moderate exercise.

The variability characteristic of exercise responses in older individuals is particularly evident when considering gas exchange and pulmonary-vascular hemodynamics. In general, most individuals demonstrate only slight changes in arterial blood-gas homeostasis, but some individuals demonstrate arterial hypoxemia with exercise.[8] This response may be a factor of fitness. More fit older individuals appear to exhibit progressive arterial hypoxemia and carbon dioxide retention during mild-to-moderate exercise.[68,69]

Pulmonary artery pressure increases with age at any oxygen consumption or cardiac output during exercise.[70] In addition, the maximum pulmonary artery pressure at maximal exercise is reached at substantially lower oxygen consumption and cardiac output levels in older individuals compared with younger people. Pulmonary wedge pressure also increases with age and can exceed 25 mm Hg during peak supine exercise.[8] Limited data suggest that these high pressures may in turn induce pulmonary edema during intense exercise in older adults. Pulmonary edema would limit diffusion and may contribute to ventilation-perfusion maldistribution.[8]

Exercise Training

Aerobic training in older adults may offset some of the changes that have been described. Studies that address some of these changes, such as chest wall compliance or pulmonary artery pressure, are limited or nonexistent. The studies that are available deal with relatively young subjects who are 60 to 70 years of age, which does not provide insight into what exercise might do for individuals in their 70s and 80s, or beyond.

Aerobic training can decrease submaximal minute ventilation.[25,71] One study used a walking program with 70-year-old women over a 12-week period and demonstrated a 7.7% drop in submaximal minute ventilation (Figure 38-5).[25] Decreased minute ventilation is accompanied by a decrease in carbon dioxide production, respiratory exchange ratio (carbon dioxide production/oxygen consumption), and blood lactate level for any given level of submaximal exercise.[25,71] Thus the improved ventilatory efficiency after training may have more to do with improved efficiency in the periphery rather than an impact on the pulmonary system directly. Improved

peripheral metabolic efficiency results in the production of less carbon dioxide; therefore the lungs do not have to work as hard to eliminate carbon dioxide. The important functional results of these changes are that the older adults who engage in exercise training will feel less breathlessness, experience a lower perceived exertion, and use a lower proportion of their maximal ventilatory capacity during exercise.[72]

Exercise training also increases maximum ventilatory responses during maximal exercise.[25,72] The 12-week walking program referred to above increased maximum minute ventilation by 14% in 70-year-old women (see Figure 38-5).[72] These women walked five days per week at an intensity of 78% of the maximal treadmill heart rate, or 118 beats per minute on average, so even though the program was not very strenuous, it produced substantial changes in maximum ventilation. Exercise training can improve submaximal ventilatory efficiency and increase maximum ventilation in older adults. Table 38-3 summarizes the pulmonary changes seen with aging and exercise.

Summary

As people age, profound changes occur at rest and in response to submaximal and maximal exercise. Many of these changes can be reduced or reversed as a result of exercise training. The implication is that many of these changes may have more to do with disuse than aging per se. Sedentary individuals tend to show these changes to a greater extent than more active seniors. Prevailing evidence suggests that older adults at any age can derive benefits from exercise training. Even very modest, short-term interventions can be effective. Older individuals should be encouraged to engage in regular physical activity to improve their exercise capacity and health overall.

Review Questions

1. What are the major changes that occur with aging in the cardiovascular system?
2. What outcomes will exercise training produce in an older adult's cardiovascular system?
3. What are the major changes that occur with aging in the autonomic nervous system in response to exercise, and which of these changes can be influenced by exercise training?
4. What are the major changes that occur in the pulmonary system with aging and in response to exercise?
5. Describe the possible impact of exercise training on the aging pulmonary system.

The cardiovascular and pulmonary systems provide both physiological support (oxygen delivery) (see Chapters 2 and 4) as well as a mechanical support (respiratory and trunk muscle control) for movement. This chapter focuses on breathing mechanics and their interactions with other organ systems in both health and dysfunction. Its three main premises are:

1. Breathing is a three-dimensional motor task that is influenced by gravity in the three planes of motion.
2. Breathing is influenced by multisystem interactions that simultaneously support respiratory and postural control during motor tasks.
3. The mechanics of breathing influence both health and motor performance outcomes related to participation.

The four motor impairment categories identified in the *Guide to Physical Therapist Practice*, second edition, are incorporated into this chapter.[1] A fifth category, the internal organs, has been added (Box 39-1). In addition to addressing the impact of these impairment categories on health and motor performance from a ventilatory perspective, we present a method to cross-reference impairment-based findings with functional limitations. Six common functional tasks that require the integration of breathing and movement are shown in Box 39-2. Children and adults with multiple physical challenges are patients in whom the interaction between respiratory control and postural control is particularly relevant.

The role of multisystem interaction in effective breathing and postural control is an emerging field; hence it lacks rigorous evidence from experimental evaluation. Nonetheless, the physiologic evidence supporting the interactions among systems and their impact on breathing and posture (see Chapter 6) is compelling and sufficient to inform contemporary approaches to patient care in physical therapy practice. As an area of research, multisystem interaction represents a relatively new frontier that could have far-reaching implications for research in other physical therapy areas with respect to assessment, intervention, and evaluation.

Breathing: A Three-Dimensional Gravity-Dependent Activity

Planes of Ventilation and Gravitational Influence

Ventilation is a three-dimensional activity. With each breath, the chest wall expands in the anterior-posterior plane, the inferior-superior plane, and the medial-lateral plane (Figure 39-1). The muscles that support breathing are resisted by gravity in one direction, assisted by gravity in another direction, and relatively unaffected in other directions. When a person is upright, superior expansion of the chest wall is resisted by gravity while inferior expansion is assisted, and other movements of the chest wall (anterior, posterior, and lateral expansion) are relatively unaffected by gravity. The adverse effects of gravity are counteracted by muscles that can function effectively in the presence of gravitational force. If the respiratory muscles become dysfunctional due to weakness, paralysis, or fatigue; or pathological conditions, the patient may no longer breathe effectively within gravity's influence.[2,3] Further, the impact of posture on breathing mechanics, as well as on cardiovascular function, has been well documented (see Chapter 20).[4] Therefore, when physical therapists are positioning patients with impaired breathing mechanics or posture, they need to consider how gravity can affect the muscles that support breathing and posture in each body position, as well as how it affects oxygen transport overall.

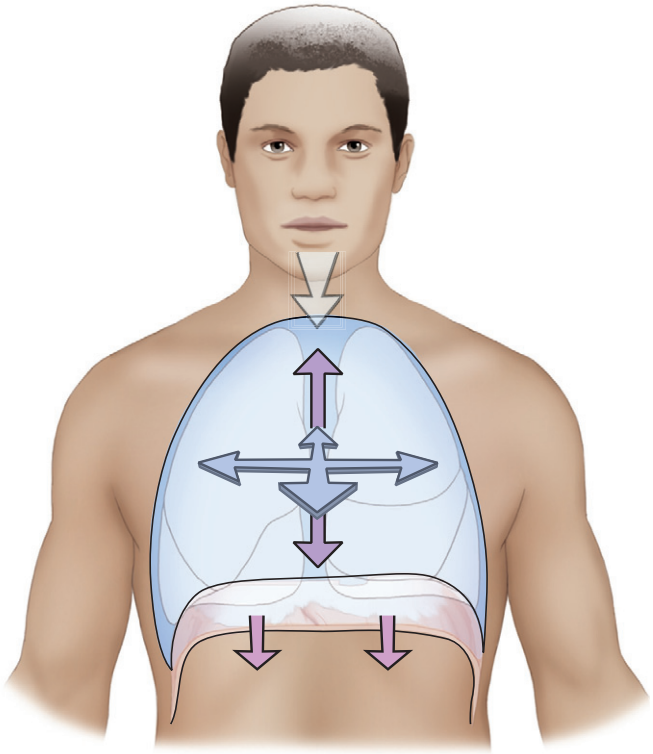

Fig. 39-1 Planes of respiration: anterior-posterior, inferior-superior, and lateral.

Effects of Gravity on Normal and Abnormal Chest Wall Development

Gravitational force is crucial in the normal development of the skeleton. Typically developing infants move freely in and out of a range of body positions (prone, hands and knees, and standing), allowing gravity to alternately assist or resist their movements. Moving through these positions, the infant strengthens muscle groups and learns to interact with the gravitational force in his or her physical environment and compensate as needed.[5] The development of the bones, muscles, and joints that constitute the trunk is influenced by genetic factors and movements performed in a gravitational field. Infants with limited ability to move and counteract gravity develop malaligned joints and impaired muscle support that, in turn, impair breathing mechanics, or vice versa.[6-8] Cerebral palsy, spinal muscle atrophy, stroke, head trauma, and spinal cord injury are conditions that can cause such muscle imbalance in children.[3] Weakness or fatigue of the trunk muscles can result from conditions outside the neuromuscular system[9] (for example, oxygen transport deficits from bronchopulmonary dysplasia and congenital heart defects and nutrition-related deficits such as gastroesophageal reflux and malabsorption; see Chapters 6 and 32). Such symptoms can impair breathing mechanics, as well as muscle tone

Fig. 39-2 A, Caitlin, six months of age. Caitlin has spinal muscle atrophy, type I. Note persistent immature triangular shaping of chest wall secondary to pronounced muscle weakness and an inability to counteract gravity effectively. **B,** Melissa, three-and-a-half years of age. Melissa has a C5 complete spinal cord injury due to birth trauma. Melissa's chest wall has become more deformed than Caitlin's chest wall due to the prolonged exposure to the severe muscle imbalance of the respiratory muscles within gravity's constant influence. Note the marked pectus excavatum and anteriorly flared ribs in supine. **C,** Carlos, 5 years of age and **D,** Kevin, 17 years of age. Both have spastic cerebral palsy. Note the lateral flaring of the lower ribcage, the asymmetry of the trunk, and the flattening of the entire anterior ribcage, all of which are more noticeable in the older child.

(as in hypertonicity or hypotonicity), and can contribute to deficits in motor planning and learning.[10]

Children who have impaired breathing mechanics and are recumbent for prolonged periods are exposed to abnormal gravitational stress. Over time, this leads to pathological changes and deformities such as retention of the primitive triangular shape of the newborn chest wall (Figure 39-2, *A*). In some cases, the child's diaphragm remains functional in the presence of weak or paralyzed abdominal and intercostal muscles. In turn, this can affect skeletal development (Figure 39-2, *B*). Pronounced imbalance of the thoracic muscles can result in chest wall deformity, compromising the child's ability to meet his or her ventilatory needs. Musculoskeletal abnormalities include anteriorly flared lower ribs, dynamic pectus deformity (most often, pectus excavatum; less often, pectus carinatum), laterally flared ribs, and chest wall asymmetry

Fig. 39-3 A and **B,** Chest wall of a newborn. Note triangular shape, short neck, narrow and flat upper thorax, round barreled lower thorax. Muscle tone is primarily flexion and breathing is primarily diaphragmatic and in one plane: inferior.

(Figure 39-2, *B, C, D*).[6,8,11] These deformities have varying impact on ventilation depending on the gravitational consequences of each position.

Understanding chest wall development in typically healthy children is essential for the physical therapist to assess chest wall deformities and their impact on oxygen transport.[11] Chapter 37 describes normal growth and development of the cardiovascular and pulmonary systems during infancy and childhood. The present chapter takes this information a step further, and considers the impact of musculoskeletal and neuromuscular impairments on typical childhood development. Initially the newborn's chest wall is triangular: narrow and flat in the upper portion and wider and rounded in the lower portion (Figure 39-3). The infant's short neck reduces the effectiveness of the upper accessory muscles as ventilatory muscles. The infant's arms tend to be flexed and adducted across the chest wall, hampering lateral or anterior movement of the chest wall. The infant, largely a diaphragmatic breather, shows disproportionate development of the lower chest wall, which promotes a triangular shape of the ribcage. Newborns breathe primarily in a single plane (inferior), rather than in three planes apparent in adults.

From 3 to 6 months of age, the infant develops more trunk extension tone and spends more time on his or her elbows in prone. The baby begins to reach with the arms into the environment. This facilitates development of the anterior upper chest wall. Continuous stretching and upper extremity weight bearing helps to expand the anterior upper chest wall both anteriorly and laterally, while increasing posterior stabilization.[5] An increase in the strength of the intercostal muscles and pectoralis muscles improves the infant's ability to counteract gravity exerted on the anterior upper chest wall in the supine position, leading to the development of a slight convex configuration of the area and a rectangular shaping of the thorax from the frontal plane (Figure 39-4). The baby begins to breathe more effectively in multiple planes as the muscles' length-tension relationships become more efficient.

The next step in development occurs when the child assumes erect body positions independently (i.e., sitting, kneeling, and standing). Until this time, the ribs are aligned relatively horizontally, with narrow intercostal spacing (Figure 39-3). The newborn's chest wall accounts for about one-third of the trunk cavity. As the child progressively moves against gravity, the ribs, with the aid of the abdominal muscles, rotate downward (more so in the longer lower ribs), creating the sharp angle of the ribs (Figure 39-5). This elongates the ribcage until it eventually occupies over half of the trunk cavity (Figure 39-6). Chest x-rays of newborns and adults, as

Fig. 39-4 Infant chest wall at 3 to 6 months of age. Increased upper thorax width. More convex shaping of entire chest wall occurs as antigravity movements are becoming possible. Note the short neck and two functionally separate chambers: thorax and abdomen.

Fig. 39-5 Infant chest wall at 6 to 12 months of age. The infant spends more time upright. The activation of abdominal muscles, gravity's influence, and increased postural demands result in a more elongated chest wall, wider rib spacing, and increased intercostal muscle activation, as well as a functional interface of the ribcage onto the abdomen with the abdominal and intercostal muscles. This improves both the respiratory dynamics by giving more external support to the diaphragm at the mid-trunk level and the postural stabilization potential needed for more complex motor tasks. Note that the base of the ribcage is no longer barrel-shaped as it is in the newborn.

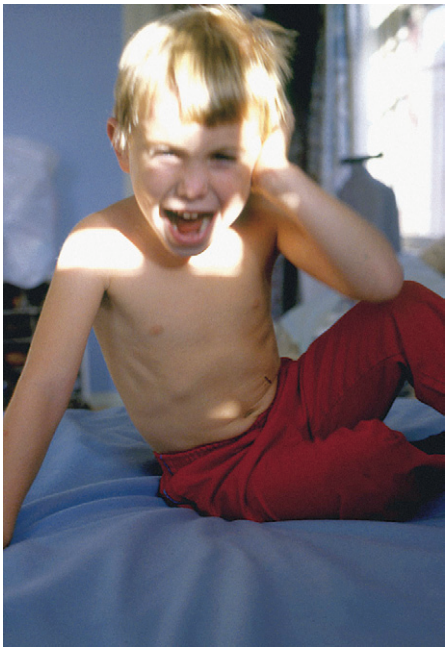

Fig. 39-6 A 4-year-old boy. Note the elongated chest wall, which occupies more than half of the trunk space, the wide intercostal spacing, the effective muscle stabilization of the lower ribcage with the abdominal muscles, the rectangular shaping of the chest wall from a frontal view, and the elliptical shaping of the chest wall from a transverse view.

Table 39-1 Typical Chest Wall Development from Infant to Adulthood

Chest Wall Components	Infant	Adult
Size	Thorax occupies one third thoracic cavity	Thorax occupies more than half thoracic cavity
Shape	Triangular frontal plane, circular anterior-posterior plane	Rectangular frontal plane, elliptical anterior-posterior plane
Upper thoracic	Narrow, flat apex	Wide, convex apex
Lower thoracic	Circular, flared lower ribs	Elliptical, lower ribs integrated with abdominals
Ribs	Evenly horizontal	Rotated downward, especially inferiorly
Intercostal spacing	Narrow, limits movement of thoracic spine and cavity	Wide, allows for individual movement of ribs and spine
Diaphragm	Adequate, minimal dome shape	Adequate, large dome shape
Accessory muscles	Nonfunctional	Functional

well as pictures of infants, illustrate these developmental trends (Figure 39-7, *A, B*); details are further summarized in Table 39-1.

Optimum respiratory function cannot be expected in a person with an underdeveloped or deformed chest wall, spine, or both.[3] As long as the condition that caused the trunk muscle imbalance persists, regardless of whether that deficit was a neuromuscular disorder or an impairment in another motor impairment category (see Box 39-1), the chest wall and spine will likely develop atypically.

Strategies to optimize trunk development include:

- Frequent body position changes
- Management of adverse neuromuscular tone
- Facilitation of weakened chest wall muscles
- Promotion of optimal breathing patterns
- Incorporation of ventilatory strategies with movement
- The alignment of physical therapy goals with the child's development and medical program

Influence of Multisystem Interactions on Motor Performance: Relationship Between Respiratory and Postural Control

Normal human movement reflects the interactions of multiple organ systems. If these interactions are atypical or inadequately compensated when impaired, motor impairments can result. Thus it is recommended that every physical therapy examination and evaluation include multisystem screening of the five impairment categories (Box 39-1) in order to determine the impact of each organ system on total motor performance. The following Soda Can Model of respiratory and

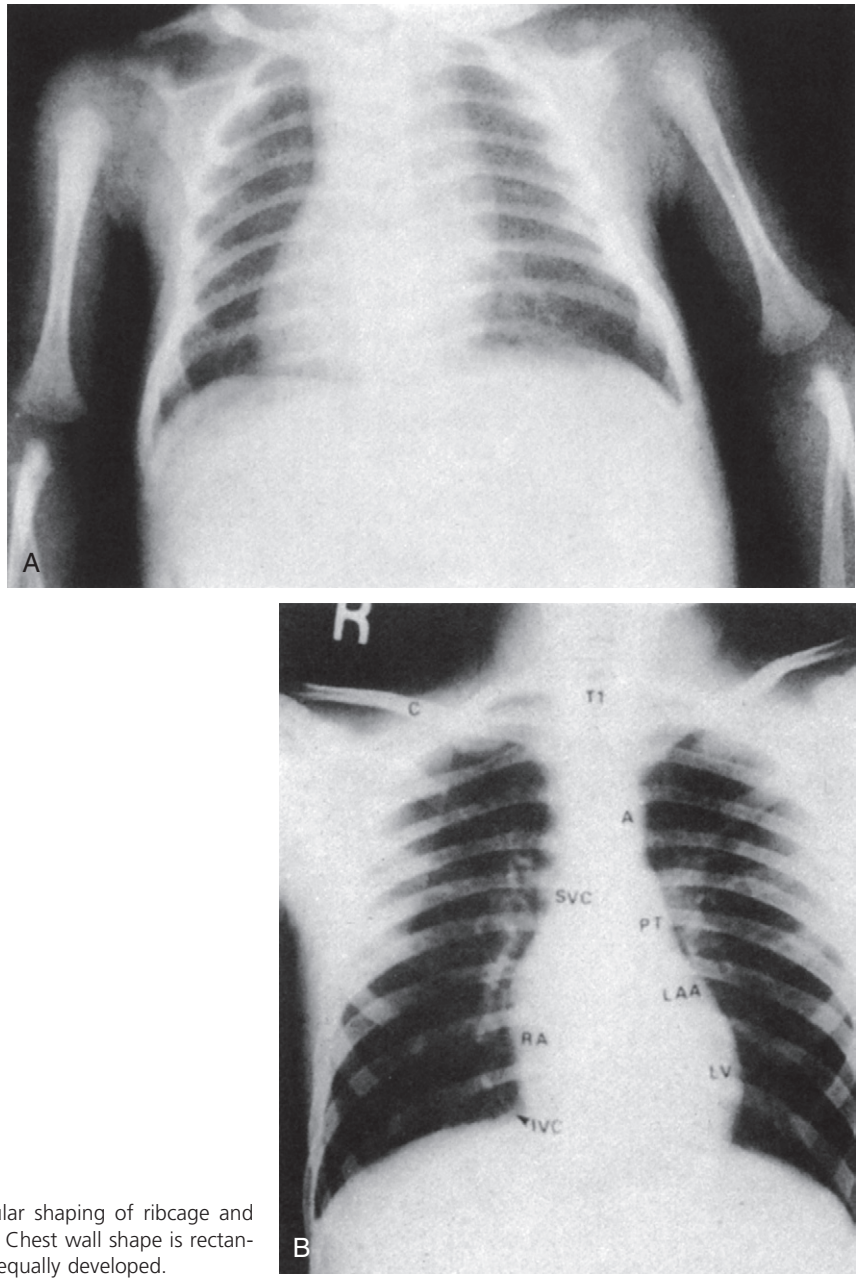

Fig. 39-7 **A,** Chest x-ray of a newborn. Note triangular shaping of ribcage and narrow intercostal spacing. **B,** Typical adult chest x-ray. Chest wall shape is rectangular, ribs angled downward, upper and lower thorax equally developed.

postural control was developed to facilitate the clinician's understanding of the multisystem interactions between the mechanics of breathing and the simultaneous needs of postural control

Soda Can Model of Respiratory and Postural Control

The muscles of respiration are muscles of postural support and vice versa.[14] Each muscle that originates from or inserts onto the trunk is both a respiratory muscle and a postural muscle. This duality of function means that respiratory and postural control should not be evaluated separately. External and internal forces that affect the function of the respiratory muscles also affect postural responses. The Soda Can Model illustrates this dual function.

Structurally Weak, Yet Functionally Strong

The shell of a soda or soft drink can is made of thin aluminum that is easily compressed when the can is open and empty. This same can, however, unopened and full, is almost impossible to compress or deform without puncturing the exterior shell. The strength of the can is derived from the positive pressure it exerts against atmospheric pressure and gravity through its closed (unopened) system (Figure 39-8, *A*). As soon as the closed system is compromised by either opening or puncturing the can, it loses its functional strength. It is no longer capable of counteracting the positive pressure forces acting on it. Once the can is opened, it is possible to compress it completely (Figure 39-8, *B*).

The structural integrity of the trunk of the body is similar to that of the soda can described in the Soda Can Model. The

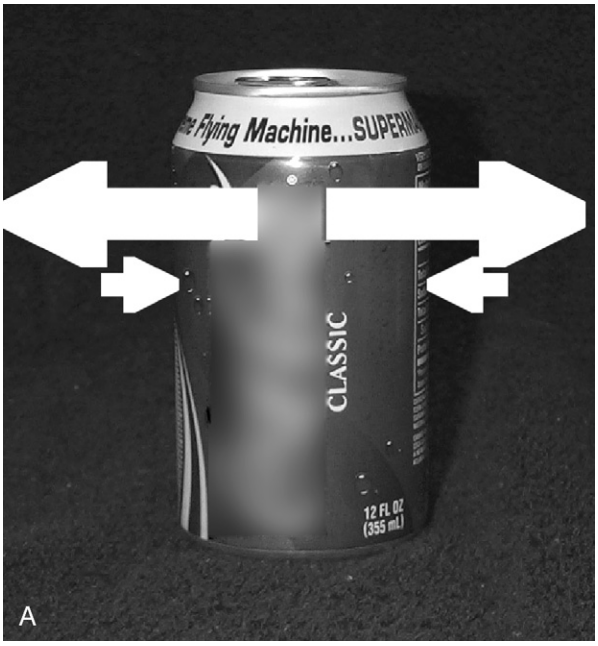

Fig. 39-8 Soda Can Model of respiratory and postural control. **A,** A soda can derives its functional strength because the internal pressure of the carbonated drink is higher than the atmospheric pressure acting on it, not because of its thin aluminum shell. **B,** Without the internal pressure support, the aluminum can is easily deformed and compressed.

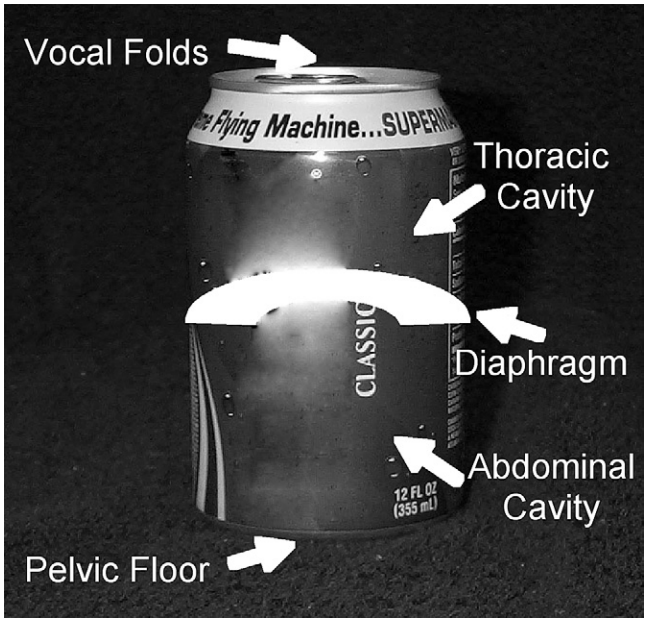

Fig. 39-9 A soda can as a three-dimensional model for trunk muscle support for breathing and postural control. Note that the control of pressure begins at the level of the vocal folds and extends down to the pelvic floor. A breach in pressure anywhere along the cylinder impairs the total function of the can (or, in the human analogy, the function of the patient's trunk).

skeletal support of the trunk is not inherently strong. The spine and ribcage alone cannot maintain their alignment against gravity without muscular support that enables them to generate pressure that is capable of countering gravitational pull. This is commonly observed in patients in intensive care. Weakened from prolonged illnesses and medical procedures, patients in the intensive care unit (ICU) typically slump into a forward, flexed posture when they sit up initially. This is associated with less ability to generate pressure through muscle activation to support alignment of the pelvis, spine, and ribcage in an upright position. In pediatric patients, the effects can be particularly alarming. Melissa provides such an example. She incurred a C5 spinal cord lesion from a vaginal birth injury and experienced marked collapse of the pelvis, ribcage, and spine when sitting upright. Melissa was incapable of making an effective inspiratory effort in this position, which explained her intolerance to upright activities. Figuratively, her "soda can" was compressed, and correspondingly, her breathing mechanics were severely compromised (Figure 39-8, *C*).

Positive Pressure Support Instead of More Skeletal Support

The aluminum can is a chamber. Once the chamber is filled with carbonated fluid and sealed, carbonated gases are released, leading to positive pressure pushing outward, which lends dynamic support to the metal. Likewise, the trunk of the body is composed of thoracic and abdominal chambers that are dynamically supported by muscle activity that generates the positive pressure in both chambers needed to support both respiration and posture.

The thoracic and abdominal chambers are separated by the diaphragm (Figure 39-9). The chambers are "sealed" at the top by the vocal folds, at the bottom by the pelvic floor, and circumferentially by the trunk muscles. Muscle support allows these chambers to match or exceed the positive pressure exerted on them by external forces to support the "flimsy" skeletal shell. The primary muscles involved in this support are the (1) intercostal muscles, which generate and maintain transthoracic pressure[15]; (2) the abdominal muscles, especially the transverse abdominus, which generate and maintain

transabdominal pressure[16,17]; (3) the diaphragm, which regulates and uses the pressure in both chambers[18,19]; (4) the back muscles, which stabilize the spine to optimize its alignment and articulation with the ribcage[20]; (5) the pelvic floor muscles, which work synchronously with the diaphragm to support breathing and urinary control[21,22]; and (6) the vocal folds, which regulate intrathoracic pressure to stabilize the diaphragm and upper extremities.[23] These muscles work synergistically to adjust the pressure in both chambers so that the demands of ventilation and posture are met simultaneously.[24]

The following synopsis of the biomechanics of breathing describes the interactions among the diaphragm, intercostals muscles, and abdominal muscles within the construct of a positive pressure chamber.[24-27] The diaphragm is the primary muscle of respiration, but its function as a pressure regulating muscle may be less well recognized. The diaphragm separates the thoracic and abdominal cavities, thus creating and using the difference in pressure between the two chambers to support the simultaneous needs of respiration and trunk stabilization. The interactions among the diaphragm, intercostal muscles, and abdominal muscles, along with support from other trunk muscles, work synergistically to generate, regulate, and maintain thoracic and abdominal pressures necessary for the concurrent needs of breathing and motor control of the trunk.[28] In summary, the diaphragm depends on the intercostal and abdominal muscles for effective and efficient breathing, and likewise, the trunk depends on the diaphragm for muscular support and pressure support during activities, particularly those with high postural demands.[20,28-30]

When the diaphragm contracts to effect inhalation, its central tendon descends inferiorly, creating negative pressure in the thoracic cavity. This draws air into the lungs due to the pressure difference with atmospheric pressure. Simultaneously, the intercostal muscles are activated to counter the negative pressure that draws them inward.[7,31-34] Inadequate intercostal muscle support tends to collapse the chest wall, which in the long-term can cause musculoskeletal deformity (e.g., pectus excavatum) and secondary loss of chest wall compliance (see Figure 39-2, *B*).[6,7,35,36] With descent of the diaphragm, positive pressure is created within the abdominal cavity and augmented by counterpressure exerted by the abdominal muscles, particularly the deepest muscle, the transverse abdominus.[37] This pressure equals the negative pressure created in the thorax, based on Newton's Law—that is, for every action, there is an equal and opposite reaction.[38] Further, positive abdominal pressure provides a fulcrum for the diaphragm to stabilize its central tendon. This central stability mechanically supports the contractions of the lateral (peripheral) fibers up and over the abdominal viscera (lateral and superior chest wall expansion).[24] That is, the coupling among the intercostals, abdominals, and diaphragm is greater than the sum of their parts for maximal respiratory function.[26,39]

The abdominal cavity has relatively higher pressure at rest than the thoracic cavity, as reflected by the position of the diaphragm within the trunk. Its dome is convex superiorly because the higher pressure from the abdominal cavity pushes it upward. In lung disease, the relationship between the abdominal and thoracic pressures may reverse and compromise the mechanics of breathing. For example, patients who have obstructive lung disease such as emphysema, trap air distally in the diseased lung segments.[40] Air trapping and other manifestations of the condition cause the thoracic cavity to become the higher-pressure chamber at rest, pushing the diaphragm inferiorly and flattening its dome. The diaphragm's mechanical support becomes compromised to the extent that it no longer functions well as an inspiratory muscle. To compensate, patients with end-stage emphysema tend to lean forward on extended arms, flex their trunks, and activate their abdominal muscles to increase abdominal pressure as a means of restoring the pressure relationship with the thoracic chamber. If successful, these patients are able to displace the dome of the diaphragm upward to enable it to function more effectively as an inspiratory muscle, thereby relieving dyspnea.[41]

Top and Bottom of the "Soda Can": The Vocal Folds and Pelvic Floor

VOCAL FOLDS AND VOCAL APPARATUS

Positive thoracic pressure is needed for both postural support of the upper trunk and expiratory maneuvers such as talking, coughing, and bowel and bladder evacuation.[42-44] The vocal apparatus, including the vocal folds, provides the superior valve for pressure regulation of the thoracic chamber. If the vocal folds are compromised because of an impairment of the upper airway or because they are bypassed with a tracheostomy or endotracheal tube, the patient is incapable of generating and sustaining positive thoracic pressure support. After the patient has inhaled and achieved higher pressure inside than outside the lungs, the air is simply expired. There is no valve at the top to hold the pressure within the chest. Activities of the trunk that require positive thoracic pressure will be compromised. Without functioning vocal folds to regulate the controlled release of thoracic pressure during exhalation, the patient has no means of slowly, or eccentrically, releasing the air for speaking or performing eccentric trunk or extremity activities. The therapist may observe impairments such as dysfunctional speech and eccentric motor activity. The same is true for concentric contractions. Without the vocal folds being able to serve as the pressure valve, the patient is unable to generate intrathoracic pressure to elicit an effective cough.[45] Similarly, if the patient is unable to close the glottis and direct thoracic positive pressure toward the pelvic floor, bowel and bladder evacuation may be compromised.[46-49] Patients with tracheostomies often experience constipation. Bowel motility usually improves with decannulation when the vocal folds are restored as an active component of thoracic pressure regulation. The patient with compromised vocal folds can briefly generate positive expiratory pressure for activities such as coughing and yelling by concentrically contracting the trunk flexors, primarily the abdominal muscles, pelvic floor muscles, pectoralis muscles, latissimus dorsi muscles, or some combination, at peak inspiratory lung volume. This positive thoracic expiratory pressure, however, cannot be sustained because the expiratory pathway (e.g., tracheostomy tube or paralyzed vocal folds) is wider than the opening of the vocal folds, resulting in a larger volume of air to be expelled per second. Unlike patients with obstructive lung disease who have an abnormally prolonged expiration, patients with impaired pressure regulation at the top of the chamber have no mechanism to prolong exhalation for either eccentric or concentric motor tasks.

In addition to regulating airflow from the lungs, the vocal folds have a role in generating increased thoracic pressure needed for stabilization associated with balance or activities such as lifting, pushing, and upper extremity weight-bearing activity.[23,50-52] This response is called the glottal effort closure reflex.[43] The vocal folds adduct and prevent air leakage while the chest wall, back, abdominal, and pelvic floor muscles contract to increase abdominal and thoracic pressures. Increased trunk pressure stabilizes the shoulder complex to enhance force production of the muscles of the upper extremities. For example, a tennis player with a strong serve often takes advantage of the glottal effort closure reflex. The server throws the ball up while taking a deep breath, then he or she closes the glottis at the peak of inspiration to trap the inspired air and activate the chest wall and abdominal muscles to increase thoracic pressure. When the tennis racket contacts the ball, the server explosively expels the air (usually with a grunt) to maximize the force production for the serve. This concept is used in every day life to perform tasks such as pushing open a heavy door, lifting a heavy box, or leaning on a table with one arm and reaching across to lift an object with the other arm. This mechanism is also used by infants to bear weight on their arms during activities such as crawling. These types of activities require full or partial glottal closure to increase the functional strength of the arms. This concept is consistent with that of the Soda Can Model, that is, providing a means of regulating pressure to augment functional strength and control.

The importance of the vocal folds as the superior (i.e., uppermost) pressure regulator of the trunk may be observed in a child with a tracheostomy necessitated because of an airway impairment or a paralyzed vocal fold, or in a child with poor vocal control due to other reasons. The physical therapist may observe that the infant crawls with elbow flexion rather than on extended arms, even though there is no muscle weakness in the arms. It is possible that the inability of the vocal folds to maintain adequate positive pressure within the thoracic cavity during weight bearing (glottal effort closure reflex) causes the elbows to flex (rather than weak triceps). In this case, strengthening the vocal folds, or adding a Passy Muir® valve (speaking valve) to a tracheostomy tube may improve the child's potential to generate the positive thoracic pressure needed for energetically demanding postural activities. In other words, restoring the trunk's pressure support system (analogous to the soda can) may lead to greater functional gain than focusing on exercises for the upper extremities.

Other types of vocal fold interactions can influence speech, breathing, and postural control through their effects on this pressurized system. For example, the function of the vocal folds may be improved as a speech valve if the abdominal pressure is improved with an abdominal binder in patients with spinal cord injury.[53,54] For children with upper airway obstruction such as laryngeal malacia, excessive inspiratory flow rates, which create excessive negative pressure in the upper airway, may decrease vocalization or elicit exercise-induced asthma.[55]

PELVIC FLOOR

The pelvic floor muscles provide support at the inferior end of the cylinder, that is, at the base of the abdominal cavity. Dysfunction of these muscles can impair the potential of the abdominal cavity to generate positive pressure.[23] For example, when abdominal pressure is intended to be directed toward the vocal folds for coughing, sneezing, yelling, and laughing, insufficient pelvic floor muscle strength or motor control may reduce positive pressure through the pelvic opening. This is often expressed as urinary stress incontinence, rendering the intended respiratory or postural maneuver less effective.[56,57] Numerous conditions compromise the integrity of the pelvic floor, but most common is the overstretching of pelvic floor muscles during childbirth leading to pelvic floor muscle weakness and inadvertent incontinence, especially during activities such as sneezing, coughing, and running. Women with this condition may cross their legs or perform other pressure-supporting compensatory behaviors to reduce urinary incontinence until their pelvic floor muscles heal. In other conditions, such as cystic fibrosis, women have a high incidence of urinary stress incontinence secondary to repetitive stress on the pelvic floor from the positive pressure associated with chronic coughing.[58,59] Incontinence is not restricted to patients with primary pulmonary disease. Women with low back pain and impaired postural responses also have been reported to have a higher incidence of incontinence.[56]

INTERNAL ORGANS

The organs of the thoracic and abdominal cavities generate or use pressure changes in the thorax and abdomen to augment their functions. The neuromuscular system, for example, creates pressure changes in the thorax and abdomen. The lungs and esophagus use this pressure change to effect efficient breathing and augment upper gastrointestinal motility. The cardiovascular system contributes to small changes in thoracic pressure. Using these changes and the changes from the respiratory mechanics, the heart and vasculature can optimize circulation, blood pressure, and tissue perfusion. The abdomen also uses pressure changes to optimize internal organ function. Rhythmic abdominal pressure is transmitted through the intestines to stabilize the lumbar spine, augment lower gastrointestinal motility, and optimize movement of body fluids including lymphatic drainage (Figure 39-10).[60]

Without pressure support, which includes the rhythmic change in the thorax from negative to positive pressure and the rhythmic change in the abdomen from neutral to positive pressure (making the abdomen the relatively higher pressure system), the function of the internal organs may be compromised. Dysfunction may be expressed as a decrement in blood pressure (hypotension), inefficient breathing, gastroesophageal reflux with or without abnormal posturing such as in Sandifer's syndrome, inadequate bladder emptying (increasing risk for urinary tract infections), and constipation.[61-64] Although these dysfunctions may not result solely from reduced pressure support, it is a major contributor.

Soda Can Model Summary

The Soda Can Model of respiratory and postural control provides a three-dimensional, dynamic illustration of how the trunk meets its concurrent needs for breathing, postural control, and function of the internal organs. When the patient has reduced ability to generate, regulate, and maintain pressure within the thoracic and abdominal chambers, the mechanics of breathing and other body functions may be

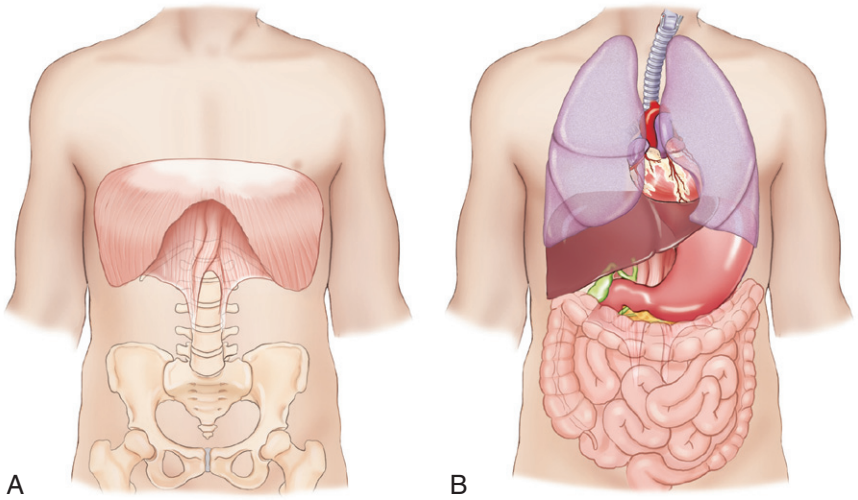

Fig. 39-10 A, Note the position of the diaphragm, which serves as the internal pressure regulator between the thoracic and abdominal cavities. The vocal folds and pelvic floor serve as the external pressure valves. **B,** Note the number and alignment of the internal organs within the thorax and abdomen that are affected by the changes in the diaphragm's position during respiration.

impaired. Inadequate pressure support may begin with an impairment of the mechanics of breathing, such as in a neuromuscular or musculoskeletal disorder. Alternatively, the problem may originate in conjunction with another impairment—for instance, an impairment of the cardiovascular, pulmonary, integumentary, or internal organ system—that nonetheless leads to impaired breathing mechanics. Breathing mechanics are best assessed from a multisystem perspective.

Compensatory Breathing Patterns Associated with Insufficient Muscular Support

As illustrated in the Soda Can Model, the trunk muscles provide the pressure changes necessary for breathing. What happens, however, if the muscles are weak, paralyzed, fatigued, or otherwise nonsupportive? What types of compensatory breathing patterns can be used? Six compensatory breathing patterns are described below and summarized in Table 39-2.

Paradoxical Breathing

Paradoxical breathing refers to opposite movements of the chest wall during normal breathing (occasionally termed belly breathing, see-saw breathing, or reverse breathing). The most common type of paradoxical breathing is caused by strong contraction of the diaphragm in the absence of adequate muscular support from the intercostal muscles and abdominal muscles. The diaphragm contracts, the abdomen rises excessively because weak or paralyzed abdominal muscles do not increase positive abdominal pressure, which limits the descent of the diaphragm. The upper chest wall collapses inward because of inadequate stabilization from the intercostal muscles (see Figure 39-2, *A*). Although not efficient, paradoxical breathing can be sufficient for breathing without mechanical ventilator support for patients with neuromuscular weakness.[7,11]

Another type of paradoxical breathing is observed when the diaphragm is weak or paralyzed and the upper accessory

Table 39-2 Compensatory Breathing Patterns Associated with Insufficient Muscular Support

Paradoxical breathing	a. Functioning diaphragm with paralyzed or weak intercostals and abdominal muscles b. Paralyzed or weak diaphragm with functional accessory muscles; may or may not have functioning abdominal muscles
Diaphragm and upper accessory breathing	a. Paralyzed or weak intercostals
Upper accessory muscles breathing	a. Paralyzed or weak diaphragm and intercostals; abdominal muscles may or may not be functional
Asymmetrical breathing	a. Paralyzed or weak thoracic muscles on one side b. Often associated with hemiparesis or scoliosis
Lateral or "gravity-eliminated" breathing	a. Generalized weakness, no paralysis b. Breathing takes place in the plane with the least resistance to gravity c. Often associated with weakness due to prolonged illness
Shallow breathing	a. Small tidal volumes b. Often associated with high neuromuscular tone or painful conditions

Fig. 39-11 Nicholas, 1 year of age. Nicholas was born with both hemidiaphragms paralyzed and requires full-time mechanical ventilation. When he is off the ventilator for brief periods of time to assess his independent breathing pattern, he demonstrates the second type of paradoxical breathing: a rising upper thorax and falling abdomen during inhalation.

Fig. 39-12 Justin, 9 years of age. Justin has a congenital pectus excavatum. No neurological impairment. His breathing pattern is primarily diaphragm and upper accessory muscles. Note the persistent elevation of the ribcage and the inward collapse of the lower sternum (pectus excavatum). Justin's sternum moved paradoxically with every inspiratory effort, especially during high respiratory and postural demand.

muscles remain intact. The abdominal muscles may or may not be functional. The inspiratory action is opposite to the motion that was described for the most common type of paradoxical breathing (Figure 39-11). The abdomen is drawn inward by the negative pressure in the thorax created by the upper accessory muscle during inhalation. The chest wall rises and the abdomen falls. Generally, this type of paradoxical breathing requires at least partial mechanical ventilatory support because the accessory muscles cannot adequately meet the needs of long-term independent ventilation. In addition, they are more likely to fatigue and lead to respiratory distress. The loss of the diaphragm as the primary respiratory muscle results in greater inspiratory volume deficits than the loss of just the accessory-muscles support observed in the prior paradoxical breathing pattern. Loss of the diaphragm as the primary pressure regulator for the trunk also contributes to deficits in postural control.

Diaphragm and Upper Accessory Muscles Only (Paralyzed or Nonfunctional Intercostal Muscles)

Another type of compensatory breathing pattern can be observed when the intercostal and abdominal muscles are paralyzed or weak but the diaphragm and upper accessory muscles continue to function (i.e., patients with tetraplegia, high paraplegia, some congenital pectus excavatum deformities, upper airway obstruction, and asthma). These patients counterbalance the strength of the diaphragmatic inferior pull by using their sternocleidomastoid muscles and possibly their scalene, trapezius, and pectoralis muscles. Allowing for superior and possibly some anterior and lateral expansion of the chest wall, this compensatory breathing pattern minimizes the collapse of the upper chest wall that is observed in paradoxical breathing. This must be cognitively coordinated with inspiration. This pattern can be an effective breathing pattern for patients with neuromuscular weakness but may be less efficient for patients with asthma. On assessment, these patients can present with shortened neck muscles. Intercostal retractions (the collapsing of the intercostal spaces on inspiration) may be observed, especially at the level of the xiphoid. Paralyzed or weak intercostal muscles will be sucked in toward the lungs during negative pressure generated within the thoracic cavity, which can lead to intercostal retractions and can develop into a pectus excavatum in the long-term (Figure 39-12).[6,65]

Upper Accessory Muscles Only

If the patient cannot recruit the diaphragm, intercostal, and abdominal muscles, then independent breathing can be achieved only by using the upper accessory muscles in the superior plane and limited anterior expansion. These patients often require mechanical ventilation to augment their breathing independently because the lung volumes they are able to generate are insufficient to support the oxygen needs of the body.

Asymmetrical Breathing

Asymmetrical movement of the chest wall in patients with stroke, scoliosis, or other conditions is often associated with an asymmetric breathing pattern. This pattern is generally sufficient for breathing without mechanical ventilation because the strong side compensates for the weak side.[66] This compensation, however, may lead to asymmetric alignment of the trunk that adversely affects postural control in upright body positions. In addition, the adverse effects on posture can lead to adverse musculoskeletal changes over time, especially in the pediatric patient whose musculoskeletal system is still maturing.[67] Prevention of these secondary changes is a clinical priority[68] (Figure 39-13).

Fig. 39-13 Charles. Right hemiparesis from a stroke. **A,** Note asymmetry of the trunk in sitting during breathing and postural control. **B,** Note the weakness in the right upper thorax. Charles' right upper thorax moved less during inhalation than the left, which accentuated his asymmetrical trunk alignment and may have been a contributing factor to his impaired posture and upper extremity function in stance and during gait.

Lateral or Gravity-Eliminated Breathing

Patients with generalized weakness such as that associated with benign hypotonia, prolonged illness, or incomplete spinal cord injury, may breathe wherever gravity provides the least resistance. For example, in a supine position, patients with weakened chest wall muscles cannot effectively oppose the force of gravity in the anterior plane; thus they alter their breathing patterns to expand their chest walls primarily in the lateral plane in which gravity is eliminated. In sitting, these patients tend to breathe inferiorly where gravity assists the movement. Likewise, in a side-lying position, they tend to breathe in the anterior plane. Because their muscles are weak rather than paralyzed, these patients have a positive prognosis with respect to breathing retraining methods.

Shallow Breathing

Shallow breathing can result from injuries to the central nervous system. Such impairments include high tone associated with Parkinson syndrome, head injuries, and cerebral palsy. Shallow breathing occurs secondary to high neuromuscular tone (e.g., spasticity, rigidity, and tremors), which severely limits chest wall expansion in any plane; cerebellar discoordination; and/or improper neuromotor sequencing because of lesions in the brain, most commonly associated with medullary lesions. Shallow breathing may also occur secondary to pain, including low back pain. In such cases, breathing patterns are altered less from muscle weakness and more from the patient limiting his or her thoracic movement, thereby changing thoracic pressure. The breathing pattern is usually symmetrical, shallow, sometimes asynchronous, and frequently tachypneic (respiratory rates over 25 breaths/min for adults). Initiation and follow-through of a volitional maximal inspiration can be difficult or impossible for patients. This will markedly curtail the ability to produce an effective cough, maintain bronchial hygiene, or yell.[29]

Application of the Soda Can Model to a Clinical Example

Inherent in the Soda Can Model of respiratory and postural control is the concept that impaired pressure regulation of the trunk may result from an impairment in any organ system that generates or uses this pressure. Organ systems therefore need to be screened for their role in the motor dysfunction of breathing, postural control or both. Five impairment categories were identified at the beginning of this chapter (see Box 39-1) as well as six functional activities that require the effective coordination of the mechanics of breathing and the postural demands of motor tasks (see Box 39-2). A clinical case illustrating these points follows.

Multisystem Evaluation, Examination, and Intervention

Case History

Katie is a 9-year-old girl (Figure 39-14, *A*) diagnosed with congenital idiopathic scoliosis (infantile scoliosis) that required surgical stabilization of two upper thoracic vertebrae when she was 3 years old. After surgery, several ribs became fused on the concave side of the scoliosis and contributed to progressive kyphoscoliosis as Katie matured. Spinal fusion from T1 to S1 was planned when she was 9½ years old, when the scoliosis reached 98° despite conservative bracing from 3 years of age and close monitoring by the orthopedic surgeon.

The presurgical work-up revealed that Katie's lungs were severely restricted by her musculoskeletal impairment; the pulmonologist was unsure she would survive surgery. Figuratively speaking, Katie's soda can was crushed, resulting in dysfunction of multiple organ systems, even though the original impairment was in a single system, the musculoskeletal system. Katie was referred to physical therapy with the goal of improving her restrictive lung pathology so that she could become a viable surgical candidate. Katie had not been referred to physical therapy previously.

Fig. 39-14 A, Katie, 9 years of age; diagnosis of infantile scoliosis. Presurgical workup showed her FVC at 33% of predicted value. **B,** Katie, age 10 years old. 1 year later. Her surgeon believed that the improvements in lung volumes and a slight reduction in the scoliosis would allow him to postpone the surgery, giving Katie more time to grow before the surgery blunted her adult height. Katie's loose shirt partially occludes the severity of the spinal deformity. **C,** Katie, age 13 years old. 6 months after back surgery. Scoliosis was reduced as much as possible given her fused ribs (from surgery as a toddler) and other joint limitations.

IMPAIRMENT CATEGORIES

Based on a multisystem examination and evaluation based on the Soda Can Model, Katie's pathology was no longer regarded as motor dysfunction resulting from one system. The progression of her impairments, starting with the original insult to the musculoskeletal system, is described in Table 39-3.

1. Katie's pathology originated in the musculoskeletal system, specifically her spine. Her skeletal support, the "aluminum can," had collapsed over her growing years. Katie's muscle support matured around those deformities and did not develop optimal length tension relationships. Her weakness primarily involved the muscles of the trunk and proximal joints. Her distal extremity muscles showed less weakness. In particular, her intercostal muscles were so weak from disuse that the negative pressure of inhalation caused her chest wall to be drawn inward (paradoxical breathing). She was unable to generate sufficient muscle force to counteract the internal negative pressure associated with normal inspiratory lung volumes. Although the paradoxical movement had not led to a pectus excavatum, this possibility remained. Her hips and shoulders matured around her malaligned spine, which resulted in additional joint dysfunction. Katie's mother reported that her daughter had never been a physically active child, which was expected given her multiple joint limitations.
2. Katie's musculoskeletal weakness resulted in a secondary neuromuscular problem. Her muscle recruitment and balance strategies developed to compensate for atypical musculoskeletal alignment that neither supported the symmetrical development of her body nor effectively supported the concurrent demands of thoracic pressure support for the control of respiration and posture. As a result, Katie's breathing pattern was atypical (paradoxical) and this likely contributed to reduced lung volumes.
3. Reduced lung volumes and limited physical activity could explain Katie's marked endurance and mechanical impairments related to the cardiovascular and pulmonary systems. Her breathing mechanics and potential lung space were compressed to the extent that she developed severe restrictive lung pathology. No heart or vascular problems were reported by her physician based on her initial evaluation. Right heart failure, however, which can develop secondary to chronic pulmonary dysfunction, was a risk for Katie as she matured.
4. The shape of the scoliosis severely compressed Katie's stomach, causing internal organ impairment and, in turn, undernutrition and dehydration. Katie ate less than 200 calories at each meal due to premature satiety. Fluids made her feel full faster, which further compromised her hydration and capacity to consume sufficient calories. Fortunately, she did not develop gastroesophageal reflux from the abnormal thoracic and abdominal pressures and musculoskeletal malalignment.
5. Katie's integumentary system appeared to have adapted to her deformities. Her surgical scars had healed and had not adhered to underlying structures. Despite severe spinal deformity, the connective tissue around Katie's trunk and extremities was easily moved. This permitted maximum mobility of the underlying skeletal structures. Adhered integument and connective tissue were possibilities.

Table 39-3 Identifying Katie's Motor Impairments from a Multisystem Model and Planning a Targeted Intervention Strategy

Impairment Categories	Musculoskeletal	Neuromuscular	Cardiovascular/ Pulmonary	Integumentary	Internal Organs
Identify primary pathology	Scoliosis				
Identify the progression of impairments	Musculoskeletal→	Neuromuscular→	Cardiovascular/ Pulmonary→	Internal organs→	(Integumentary)
List current impairment problems	**Musculoskeletal**: Abnormal joint alignment, proximal worse than distal; abnormal length tension relationship of all muscles affected by joint malalignment resulting in weakness proximal > distal **Neuromuscular**: Trunk muscle weakness and malalignment resulting in the development of inadequate postural control strategies and a constant conflict between breathing and postural needs **Cardiovascular/pulmonary**: severe restrictive lung condition resulting in significant endurance impairments; impaired breathing mechanics, including paradoxical breathing (weak intercostal muscles); RR 32 breaths/min (tachypneic); forced exhalations even at rest; weak cough; chronic nocturnal hypoventilation; inadequate respiratory reserves for inhalation or exhalation demands; 3-5 syllables/breath (normal 8-10); sustained phonation 2-3 sec (normal 10 seconds); no cardiac symptoms (yet) **Integumentary**: No connective tissue limitations around scars from previous surgeries or around her shoulders or pelvis **Internal organs**: Malnutrition; dehydration; no reflux;				
Functional limitations and impact on participation	Functional limitations were noted in all activities that required greater oxygen or caloric fuel than Katie's restricted body could provide or that required effective coordination of breathing with movement. This resulted in limitations from the most basic motor activity of breathing to limitations in coughing, sleeping, talking, eating, and moving, thus causing severe limitations in Katie's ability to participate in normal childhood activities such as running, walking, biking, etc.				
Prioritize the current problems by categories	Internal organs→	Musculoskeletal→	Neuromuscular→	Cardiovascular/ Pulmonary→	(Integumentary)
Diagnosis	Nine-year-old girl with congenital idiopathic progressive kyphoscoliosis with severe secondary restrictions to her breathing mechanics and lung growth, nutritional health, strength and alignment of the entire musculoskeletal frame, resulting in pain, endurance impairments, significant health risks, and overall limitations in the child's physical capabilities and participation.				
Prognosis	Marked compromises of the musculoskeletal and neuromuscular support for breathing and movement, combined with Katie's poor nutritional status, limit the pulmonary status she needs immediately for surgical clearance. I believe that Katie can improve the alignment, mobility, strength, and control of her ribcage and respiratory mechanics necessary to meet the pulmonary demands of surgery if given enough time to achieve a true change in the muscle function (minimum of 4-6 weeks of training). After surgery, Katie will need an aggressive physical therapy program to develop new neuromuscular strategies that effectively utilize her new musculoskeletal alignment to maximize breath support and postural control in order to reduce her long-term cardiopulmonary, nutritional, and musculoskeletal health risks, as well as to increase her potential to participate in normal childhood activities.				
Pre- and postsurgical goals	**Presurgery**: Improve nutritional status, hydration, skeletal alignment of the trunk, and strength and control of the thoracic musculature in order to improve Katie's breathing mechanics and cough effectiveness so that she can survive the scoliotic reduction surgery and the recovery phase. **Postsurgery**: Use Katie's improved breathing mechanics to initiate an effective airway clearance program and to develop neuromuscular strategies to utilize and maintain her new spine alignment in order to reduce the risk for postsurgical pulmonary complications and to maximize breath support and postural control long term in order to reduce her ongoing cardiopulmonary, nutritional, and musculoskeletal health risks and to increase her potential to participate in normal childhood activities.				
Interventions specific to Katie's short-term goal of surgical readiness	**Musculoskeletal**: Rib mobilization to maximize inspiratory lung volumes; other ROM of joints as needed. **Neuromuscular**: Neuromuscular reeducation to increase intercostal activation for inspiratory lung volumes and chest wall stabilization; neuromuscular reeducation to reduce recruitment of abdominal muscles for forced exhalation strategies; incorporation of new breathing pattern into postural demanding tasks starting with low level activities such as walking. **Cardiovascular/pulmonary**: Endurance training—ventilator muscle training, including both resistive inspiratory and expiratory devices to increase respiratory endurance and low level power production; power training—using peak flow meter and incentive spirometers for visual feedback for maximal effort breathing; coughing strategies for improved airway clearance. **Integumentary**: No short-term interventions needed. **Internal organs**: Devised plan for increasing overall hydration and caloric intake through multiple small meals/snacks and constant sipping of water throughout the day, including school hours; school approval was critical to carryover.				

FUNCTIONAL LIMITATIONS

A functional assessment was conducted to cross-reference the evaluation from both perspectives: impairments and functional limitations. The functional findings were consistent with the impairment findings: Katie had marked functional limitations due to impaired breathing mechanics that were impacting her quality of life.

1. Katie's breathing pattern at rest showed excessive diaphragmatic excursion, underuse of the intercostal muscles (especially on the left, concave side of her chest wall), and paradoxical breathing. Her respiratory rate (RR) was 32 breaths per minute with forced exhalations (normal RR is 10 to 20 breaths/minute). With minor increased physical workload, such as walking fast, she responded by breathing faster rather than deeper. Consistently, Katie had limited physical endurance compared with her peers. Her forced vital capacity (FVC) was 33% of predicted for her sex, age, and height, indicating severe restrictive lung pathology.
2. Her cough neuromotor sequence was normal, but the small lung volume impaired her expiratory force. Her peak expiratory flow rate (PEFR) was 59% of predicted. Clinically, less than 60% of predicted PEFR has been associated with an ineffective cough and increased risk of secondary pulmonary complications.
3. Katie's teachers reported that she fell asleep most afternoons in school and often complained of headaches. Given her severe restrictive lung pathology and weak thoracic muscles, nocturnal hypoventilation was suspected. A sleep study 3 years earlier showed no abnormalities. Hypoventilation due to fatigue can contribute to poor lung function during the day and could account, in part, for her limited growth. Her pulmonologist concurred and ordered another sleep study. Chronic hypoventilation was confirmed.
4. According to her mother, Katie had always been a quiet child. The question was whether she was naturally quiet or whether she was conserving energy. Her speech consisted of three to five syllables per breath. Normal speech consists of 8 to 10 syllables per breath.[43] Katie's sustained phonation of a vowel was 2.4 to 3.1 seconds (normal is 10 seconds).[43] Katie yelled on demand, but her mother reported that she rarely did so spontaneously. Her lack of breath support could explain her quiet speech, short answers, and apparent reserved style. It was not possible to establish whether Katie was quiet by nature or had become quiet as a result of a lifetime of poor breath support.
5. Katie's stomach was compromised by kyphoscoliosis, which contributed to her feeling full after consuming fewer than 200 calories. Not only did Katie have poor weight gain as she grew, but as she aged and needed more calories for vertical growth, she lost weight. Furthermore, she failed to achieve even conservative vertical height goals that had been anticipated by her orthopedic surgeon prior to scheduling Katie for a spinal fusion.
6. Katie had marked endurance limitations for age-appropriate physical activities. She fatigued when walking more than 1½ lengths of the school gym or riding her bike more than 1½ blocks. Katie's weak muscles and impaired breathing mechanics, combined with malnutrition, dehydration, and impaired oxygen delivery, meant that she had less physiological reserve capacity for activities beyond those for basic survival. Katie's body was unable to meet the needs of both breathing and high postural demands of childhood activities.[28,30] Katie preferred to engage in low energy cost activities such as playing the violin, reading, and playing quietly.

PRIORITIES OF INTERVENTIONS

Understanding Katie's progression of impairments streamlined the screening process. The status of Katie's pulmonary system precluded her having surgery. Her primary pathology, however, had not originated in the pulmonary system. This presented several questions: How had all five motor impairment categories contributed to her current pulmonary status? How could treatment interventions be prioritized to meet Katie's short-term respiratory and surgical goals? In the short term, the evaluation led to the several interventions that are described below. Katie's long-term health and participation goals were developed after surgery.

1. Katie's poor nutritional status meant she had minimal energy reserve to participate effectively in a conditioning program to strengthen her respiratory muscles in preparation for surgery. Likewise, her dehydrated state could reduce the mobility of pulmonary secretions, thus increasing her postsurgical risk for atelectasis and pneumonia. Thus, addressing Katie's nutritional and hydration needs was the first priority. Katie was instructed to eat at least six meals daily rather than three. She was permitted to use a water bottle in class. In school, she was encouraged to drink at the start of every new subject. Her nutritional intake was managed by her pediatrician.
2. Surgery was the recommended intervention to improve the alignment of Katie's spine and ribcage. In the short term, however, manual mobilization of her ribcage was a priority to gain movement to augment lung volumes.
3. After Katie's ribcage mobility was increased and a body position identified that gave her the best support for chest wall movement, specifically, sitting, a neuromuscular rehabilitation program was initiated to improve her respiratory mechanics. The goals of the program were:
   a. To increase recruitment, strength, and function of the intercostal muscles as inspiratory muscles (to increase lung volume) and as chest wall stabilizers (to minimize paradoxical breathing), while decreasing the use of forced abdominal muscle exhalations, thus reducing the energy cost of breathing (by manipulating thoracic pressure more effectively).
   b. To increase the power generated by both the inspiratory and expiratory muscles needed to increase lung volumes and cough effectiveness. This was achieved with the use of peak flow meters and incentive spirometers that provided Katie with visual feedback of specific targeted performance (large effort, low repetitions).
   c. To increase endurance and overall fitness of the respiratory muscles through use of an aggressive daily ventilatory muscle training program involving both the inspiratory and expiratory muscles (low resistance, high repetitions) (see Chapter 26). Ventilatory resistance muscle training was used instead of a traditional fitness training program such as treadmill walking because Katie's weakness, malalignment, and painful joints likely would have prevented her from exercising

sufficiently to elicit a favorable response and may have contributed to additional joint problems.

d. To improve Katie's ability to meet the conflicting needs of respiration and postural control required for functional endurance and motor performance, low-level activities (e.g., walking) were prescribed initially, with distance being increased over time (with increased endurance). Katie was instructed how to use the new breathing pattern during functional tasks designed to challenge her balance and breathing simultaneously.

4. In anticipation of orthopedic surgery, ensuring effective pulmonary hygiene was the goal. The contributions of her various body systems to the efficiency and effectiveness of her breathing mechanics, lung volumes, cough effectiveness, endurance, and posture were targeted through multiple interventions.
5. Katie's integumentary system did not show any impairment and was not a major contributor to her limited pulmonary status. After surgery, however, dehydration predisposed her to skin breakdown and poor tissue healing. She was monitored for residual problems.

DIAGNOSIS AND PROGNOSIS

Katie's musculoskeletal pathology impaired the structural support of her trunk and respiratory mechanics. Musculoskeletal restrictions contributed to dysfunction in other systems due to their various interactions. She was referred to physical therapy for one reason, to improve breathing mechanics so that she could undergo surgery to correct the initial pathology, the scoliosis. Based on the physical therapy examination, the pulmonologist was informed that Katie's condition showed potential for improvement. A minimum of 4 to 6 weeks was needed to achieve a training effect that would sustain her through the long surgery. Surgery was postponed for 8 weeks to allow Katie the maximum benefit of the physical therapy intervention. With respect to the long-term goals of health and participation in typical childhood activities, improving her breathing mechanics was only one goal. Other goals were to be addressed after surgery.

OUTCOMES

Katie and her mother understood the risks of surgery and were motivated to participate in an aggressive physical therapy program that relied heavily on home participation. Katie and her mother were instructed regarding the necessity of a home exercise program five days a week for 5 to 6 weeks in order to increase muscle strength and endurance. Katie was enthusiastic: exercising every day. Pulmonary function improvements are shown below, along with their influence on her surgical status.

1. Katie's pulmonary function baseline for FVC was 0.45 L (33% of predicted, or 1.36 L), and her PEFR was 1.64 L/s (59% of predicted).
   a. Three weeks later, Katie's FVC improved to 0.57 L (42% of predicted).
   b. Five months later, FVC had increased to and stabilized at 0.63 L (45% of predicted).
   c. Three months after initiating her program, Katie's PEFR improved to 2.31 L/s (81% of predicted), which is within a normal range for effective coughing.
   d. Two years later, after a sleep study confirmed chronic hypoventilation and after successful initiation of noninvasive mechanical ventilatory support at night, that is, bi-level positive airway pressure (BiPAP), Katie's FVC had improved to 0.71 L, but this value was now only 40% of predicted for her sex, age, and height (1.78 L). Pulmonary function progressively increases with age until adulthood, but Katie's lungs did not keep pace with expectations for a typically developing child. A predicted FVC of 60% is often used as the clinical index of adequate lung volume necessary for normal pulmonary maneuvers such as coughing, sighing, and sneezing. With an FVC of 40% of predicted, she was still at long-term risk for secondary respiratory problems due to impaired lung volumes.
2. At 4 months, the orthopedic surgeon recommended postponing surgery because her scoliosis was reduced progressively from 98° to 91°. He believed that her improved pulmonary status had a positive effect on her skeletal frame and that as long as she remained stable, it was worth postponing surgery to give her every chance to grow and continue making respiratory gains before undergoing a spinal fusion (Figure 39-14, *B*).
   a. Katie's surgery was postponed for over 3 years, until she was 12 years old, allowing her to achieve more vertical growth before surgery. The orthopedic surgeon expressed surprise that surgery had not been indicated before Katie reached 10 years of age.
   b. Katie continued to do her exercises three to four days a week over the course of intervention. She had no postoperative respiratory complications. Her scoliosis was markedly reduced (Figure 39-14, *C*). Additional surgeries may eventually be required for her shoulders, hips, and fused ribs.

Katie's ongoing care included interventions such as gastric surgery for placement of a gastrostomy tube that was needed to improve her nutrition, growth hormone administration, BiPAP nocturnal support to reverse chronic hypoventilation and its effects on her physical endurance and growth, and a comprehensive physical therapy program focusing on her growth and postural maturation. This case history focused on the initial physical therapy intervention to illustrate how a multisystem assessment can be used to develop a differential diagnosis regarding her physical and pulmonary limitations. Katie's scoliosis and muscle development made her incapable of generating, maintaining, and regulating adequate pressures in her thoracic and abdominal cavities to support normal respiration, postural control, and internal organ function. The Soda Can Model helped explain why the impairment of her musculoskeletal system had major implications for her health and the function of other systems.

QUALITY OF LIFE

In addition to Katie's medical improvement, her mother reported that the respiratory and multisystem approach to her daughter's physical therapy program "absolutely saved her life." Katie appeared increasingly confident in her abilities, which was noted at the second physical therapy visit, during which she appreciated the positive results of her diligent adherence to the home program. Within 6 months of the initiation of the physical therapy program, Katie's paradoxical

breathing was eliminated, she no longer used forced abdominal exhalations, her chest wall expansion improved, and her sustained phonation improved 50% (from 3.1 seconds to 4.7 seconds); all of which appeared to contribute to her increased physical activity. She began swimming lessons, joined recreational softball, and generally reported that she "likes this new feeling; it's easier to move and breathe." Her mother reported that Katie smiled more often.

CLINICAL RELEVANCE OF THIS CASE REGARDING IMPAIRED RESPIRATORY MECHANICS AND POSTURAL CONTROL

The cardiovascular and pulmonary systems are systems that create and use pressure support within the trunk's cavities to maximize performance; thus they should not be assessed or treated in isolation. Rather, they need to be assessed in conjunction with other organ systems. The body functions as a whole with individual systems interacting and supporting one another. In particular, postural control and mechanical support for breathing are interdependent; yet breathing necessarily takes precedence over postural requirements. Therefore mechanical support for breathing needs to be assessed and treated within the context of the mechanical support for postural control because both activities use the same muscles.

Although Katie's initial pathology originated in the musculoskeletal system, her more important problems, clinically, involved the neuromuscular system (motor planning and strength), the cardiovascular and pulmonary systems (severely impaired respiratory mechanics, inadequate respiratory endurance, and the risk for cardiac impairments), and the internal organs (persistent undernutrition and dehydration). If Katie had been treated based on an impairment of one system, she may not have achieved comparable clinical and functional outcomes that allowed her surgeon to delay her surgery for 3 years and allowed her to achieve other health and functional outcomes.

Application

Pathologies stemming from any motor impairment category may result in impaired breathing mechanics, a conflict in postural control and breathing that interferes with motor performance, or both. For example, a patient with a neuromuscular condition such as a spinal cord injury (SCI), cerebral palsy, stroke, or head injury will have impaired breathing mechanics and impaired postural control due to paralysis, weakness, or impaired motor planning or execution. The physical therapist needs to assess such a patient from a neuromotor perspective, as well as from that system's interaction with the musculoskeletal, cardiovascular, pulmonary, integumentary systems and the internal organs. This helps ensure that the major limitations affecting motor performance and health are identified and prioritized for intervention. Improvements in chest wall and thoracic alignment can be achieved in the long term from a multisystem approach. See Melissa's changes from 3 to 12 years of age after an SCI incurred at birth (compare Figures 39-15 and 39-16 with Figures 39-2, *B,* and 39-8, *C*). Melissa's chest wall and spinal deformities were almost completely reversed after years of interventions from a multiprofessional team approach to her multisystem impairments.[11] Melissa was

Fig. 39-15 Melissa, 6 years of age. Note the use of the thoracic-lumbar-sacral orthosis with an abdominal cutout supported by an abdominal binder. This provided support for her developing spine and trunk while still allowing for optimal support for breathing mechanics. Note that the TLSO provided ideal alignment of the proximal extremity joints (shoulders and hips), as well as ideal head alignment for normal functions such as talking and eating.

not assessed or treated by a physical therapist or other rehabilitation professional until she was 3½ years old. Key long-term interventions and outcomes follow.

1. Melissa used an abdominal binder whenever she was upright to provide the abdominal pressure needed for internal organ support, improved breathing mechanics, and lumbar stabilization. This is a lifelong intervention.
2. Melissa also needed a body jacket or thoracic-lumbar-sacral orthosis (TLSO) with an abdominal cutout and abdominal binder. An abdominal binder alone would not provide adequate support for her developing spine and proximal joints. She still developed a scoliosis, but she did not develop a kyphosis or axial rotation of the curve. The orthopedic surgeon stated that this made surgical correction easier, safer, and faster.
3. An aggressive neuromuscular reeducation program was implemented to teach Melissa how to engage her upper accessory muscles, especially her pectoralis muscles, as substitute chest wall stabilizers and how to use them as long-term inspiratory muscles to balance the excessive inward pressure generated by the isolated contractions of the diaphragm. She was also instructed on how to use her breath support (ventilatory strategies) to improve the efficiency of her mobility skills such as in rolling over and reaching.
4. An airway clearance program was developed to minimize the family's reliance on suctioning. Melissa and her family learned multiple manual assistive coughing techniques that effectively expectorated mucus. They reduced her suctioning from 24 to 36 times daily to one to three times

Fig. 39-16 Melissa, 12 years of age, after orthopedic surgery to reduce scoliosis. **A,** Note that the chest wall deformities that were prevalent at 3 years old are almost absent. The only apparent skeletal restriction is the slight reduction in mid-thoracic expansion around ribs 6 and 7, which looks like a high "waistline" just under her bra-strap line in supine position. The intercostal muscles, which were paralyzed, are the only muscles supporting the ribcage at that level. Melissa used her upper accessory muscles, especially her pectoralis muscles, to support breathing and chest wall alignment around ribs 1-5 and her diaphragm around ribs 8-10. **B,** Melissa continues to wear an abdominal binder in upright postures, but it was removed for this picture.

daily. She had multiple bouts of pneumonia in her first 3½ years of life, but none from age 3 to 12 years of age.

5. Melissa's nutrition and hydration needs were addressed by the health care team by increasing her caloric intake and improving her hydration. A picture taken when she was 12 years old shows that she had been consuming sufficient calories for growth. (A gastrostomy tube was not inserted because it had not yet been invented when Melissa was a young girl.)
6. Nocturnal positive pressure ventilatory support was initiated when Melissa was approximately 6 years of age because of nocturnal hypoventilation and the conflict between the use of calories for growth and breathing. The positive pressure support relieved her work of breathing and rested her muscles. In addition, it appeared to reverse forces that could contribute to pectus deformity of her anterior chest wall.

Fig. 39-17 Jonathan, 6 months of age. His severe gastroesophageal reflux required surgical support (gastrostomy tube and Nissen fundoplication procedures) at 5 months of age. His mother reports that his favorite posture when he is supine is extreme trunk extension and right head rotation. This is a typical compensatory strategy in response to the noxious stimulus of reflux and/or upper airway obstruction.

The same concept can be applied to other impairment categories. For example, in Katie's case, if her integumentary system showed connective tissue restrictions secondary to kyphoscoliosis, her integumentary system would be the primary limiting factor to improving pulmonary status rather than the neuromuscular system and internal organs. In other words, if Katie's ribcage could be mobilized but overlying taut skin disallowed movement, breathing strategies to increase her lung volumes would be ineffective. This is observed in patients who have connective tissue involvement such as in the case of scar formation, scleroderma, or severe burns. In these cases, the skin has insufficient mobility to allow the underlying muscles to move the chest wall. If the chest wall moves inadequately, lung volumes will not be sufficient to deliver sufficient oxygen to working muscle. The severity of the condition and damage to the integumentary and proximal underlying structures will determine the extent of impaired breathing mechanics.

Conditions related to the internal organs may have a subtle influence on postural control and breathing. Infants with severe gastroesophageal reflux, for example, may assume a posture of trunk hyperextension and right head rotation in supine (Sandifer's syndrome) (Figure 39-17).[63,69-72] Such posturing may be mistaken for a neuromuscular lesion. In fact, the infant may use this posturing to move away from the noxious stimulus of reflux experienced whenever he or she moves into a flexed trunk posture of head turning and lateral

trunk bending to the left. If the child is not assessed from a multisystem perspective, the physical therapist may focus on treating the excessive extensor tone and asymmetry of the trunk rather than the underlying cause of the motor behavior, which stems from the internal organs. If untreated, these infants may develop further spinal extension and upper thoracic breathing strategies to avoid exacerbating the reflux and increasing intraabdominal pressure. Reflux can be exacerbated with descent of the diaphragm onto an irritable stomach and by increased intraabdominal pressure. Over time, the infant may develop impairments in all motor systems, potentially affecting overall health and participation. For example, children with cystic fibrosis were traditionally tipped downward for postural drainage to improve lung function; however, this treatment predisposed many of these children to gastroesophageal reflux and a worsening of their pulmonary status.[73,74] The outline below describes how the motor systems could be affected by a pathology originating in the internal organs.

1. Internal organs: The pathology originates within these organs.
2. Neuromuscular system: Inadequate motor control of trunk flexors, necessary for balance, forced expiratory maneuvers, and lumbar stabilization, may develop. Pathology of the internal organs may predispose the child at a later stage to low back dysfunction and pain because normal positive pressure stabilization motor strategies, especially from the diaphragm and abdominal muscles, are not developed in childhood.
3. Musculoskeletal system: Sequelae of associated pathology may include (a) excessive ligamentous shortening of lumbar vertebrae secondary to the chronic lordotic posture and/or (b) elevated ribcage alignment, which results when the trunk flexors do not actively engage in pulling the ribcage inferiorly and the over-recruitment of upper accessory muscles continues to promote this position, which can contribute to (c) increased risk for low back pain secondary to poor lumbar stabilization strategies, weak abdominal muscles, and atypical vertebral alignment.
4. Cardiovascular and pulmonary systems: Limited overall endurance may result if the child develops an upper thoracic breathing pattern as his or her primary breathing pattern in response to the noxious feedback received in response to using the diaphragm as the primary respiratory muscle. This could also predispose the child to neck and shoulder dysfunction because the conflict between the respiratory recruitment of the upper accessory muscles and the dual role these muscles play in upper quadrant movement may contribute to overuse and later complaints of symptoms such as pain, fatigue, and headaches.
5. Integumentary system: This system is less commonly a contributor to motor impairments, but can be in cases such as surgical scars, where tight connective tissue in the skin restricts flexion of the trunk, shoulder, or hip.

Impaired breathing mechanics do not occur strictly because of a direct impairment of the lungs, airways, or chest wall muscles. Impaired breathing mechanics can occur from insults to any organ or system that influences motor performance. The cardiovascular and pulmonary systems should be seen as integral parts of motor assessment in order to determine whether the mechanics of breathing are facilitating or impairing the patient's overall motor performance. That is, breathing mechanics may be the cause or the consequence of motor dysfunction. A thorough multisystem evaluation helps the clinician distinguish the two. Respiratory muscle testing has a role in determining the degree to which impairments are respiratory or postural in origin.[75] With an analysis based on a Soda Can Model, the physical therapist can identify the sources of the underlying impairments and target interventions accordingly.

Summary

In this chapter, the role of respiratory mechanics as they relate to a range of body systems has been explored. Gravity was described as a major influence on both the potential movement of the chest wall and development of the chest wall, trunk, and thoracic structures. The dual role of the trunk to support both respiratory and postural control was introduced in the context of the Soda Can Model. Clinical cases based on multiple motor impairment categories were described to illustrate how trunk control, breathing, and internal organ function depend on the ability of the body to generate, maintain, and regulate pressure in the thoracic and abdominal cavities, the control of which extends from the vocal folds down to the pelvic floor. In the clinical examples, the five motor impairment categories—musculoskeletal, neuromuscular, cardiovascular and pulmonary, and integumentary systems and the internal organs—were screened with respect to their roles in motor performance and breathing mechanics; each system influences the performance of the others. Such analysis provided the basis for designing treatment plans that targeted the primary impairments. Anticipated motor outcomes involving the trunk and breathing were achieved.

Review Questions

1. Explain the role of gravity in normal chest wall development of infants.
2. Explain how the pressures in the thorax and abdomen provide postural support for the trunk and the role of the diaphragm in that process.
3. Explain the role of the vocal folds and the pelvic floor in normal respiration and in high postural demanding activities.
4. Explain the relationship between the gastrointestinal system and respiration.
5. Using one of your patients as a case study, apply the concepts of multisystem evaluation, examination, and intervention planning as discussed in this chapter.

The ability to transplant an organ from one individual to another is a relatively new phenomenon. New advances in surgical techniques and immunosuppressive drugs, ability to detect and treat rejection, and improved outcomes have made transplantation of solid organs a viable treatment option for patients with end-stage cardiac and pulmonary conditions. The increased life expectancy of transplant patients means that physical therapists have many opportunities for patient intervention both before and after transplant in various settings. Trends in patient demographics indicate that a physical therapist may see a transplant patient not only in a regional medical center setting but also in outpatient and rural clinics. This chapter contains guidelines for managing patients with heart or lung transplants.

Background

Transplantation of tissues and organs has been of interest to physicians and surgeons since the 18th century. Advances in our understanding of the immune system, development of immunosuppressive medications, and techniques such as cardiopulmonary bypass have provided the opportunity for successful organ transplants. In 1954, the first kidney was successfully transplanted. Other successful organ transplants include the first heart transplant in 1968, combined heart-lung transplant in 1981, and single-lung transplant in 1983.[1]

Organ transplantation has become a viable alternative to medical treatment of many conditions. Because of the success rates, many types of transplants are no longer considered experimental but are considered appropriate treatment for organ failure. As a result of improved survival, long-term outcomes are as important as short-term outcomes as a measure of successful transplantation. The number of Medicare-approved medical centers that perform lung and heart-lung transplants has grown to 50 in the United States, and there are 110 certified heart transplant centers.[2] Over 2000 heart transplants and 1000 lung transplants have been performed annually since 2000. The 5-year survival rates for heart transplants of all status levels are reported as 70.9%; for lung transplants, 43.1%. Other national data on median waiting time and survival rates are presented in Table 40-1.

Organ Donation

The major cause of limitation in the number of organ transplants is the lack of organ supply with an increasing demand for organ transplantation. The number of patients who could benefit from transplant significantly exceeds the number of organs available. The Organ Procurement and Transplantation Network (OPTN) is an organization whose primary goal is to increase the availability of donated organs available and improve organ sharing. OPTN was established by the National

Box 40-1 General Criteria for Transplant Waiting Lists

- Age (under 65)
- Terminal illness (expected life span less than 1 year)
- Nonsmoker
- Adequate social support system
- Disease free in other systems

Organ Transplant Act of the United States Congress in 1984 and is administered by the private, nonprofit organization United Network for Organ Sharing (UNOS), under contract with the U.S Department of Health and Human Services. An organ procurement organization (OPO) coordinates the management of the organ donor and family, the transplant center, and the recipient.[3]

The number of organs available for transplant remains well below the need for donor organs. Currently, there are over 110,000 individuals on the national waiting list for all organs, with over 3200 candidates waiting for heart transplant and approximately 1800 candidates waiting for lung transplant. A general list of criteria for patient selection for transplant is presented in Box 40-1. Names of patients on the waiting list are filed in the UNOS Organ Center, a centralized database that links transplant centers with OPOs. Once an organ donor has been identified, a computer-generated list of potential recipients is ranked, according to the criteria established for each organ. Criteria may include blood or tissue type, size of organ, medical status of the patient, and amount of time a patient has been on the waiting list. The organ procurement coordinator confers with the transplant surgeons until a potential recipient is identified. Surgical teams then travel to the donor hospital while the recipient is concurrently prepared for surgery. Heart, lung, and liver transplantation success is optimized when transplant occurs within 6 hours after removing the donated organ. Surgical methods that allow for longer travel times or changes in management of the donor organ have increased the number of available organs; however, the number of available organs still remains significantly below the need.

Policies were updated by the UNOS in 2006 to decrease the number of patients dying while waiting for transplant. These changes increased the number of transplants for the most severely ill patients awaiting heart transplant.[4]

Issues Associated with Transplantation

There are many ethical, psychological, and social concerns surrounding organ transplantation. Ethical issues relate to increasing potential donor sources and distributing available organs. Psychological issues include stress due to an unknown waiting time, the potential of moving from one's home to a location near a transplant center, and possible employment disruption. The transplant process affects not only the individual patient, but the patient's social support systems as well. This is highly significant because adequate social support is a factor in long-term transplant success and quality of life.[5]

Ethical Considerations

The ethical considerations of organ transplantation relate to increasing potential donor sources and distributing available organs. The bioethical issues involved in the selection of appropriate organ donors continue to generate considerable debate. For example, one important issue is whether the donor's family should be compensated monetarily for the organ donation. Currently, there can be no legally accepted monetary gain from organ donation in this country.

Other bioethical considerations include how to allocate the available organs to individuals waiting for transplant. All patients are screened for medical and psychological conditions that would adversely affect the outcome of transplantation. The specific acceptance criteria are different for each organ; lung transplant criteria differ from heart transplantation criteria. OPTN policies specify that each transplant center will create its own specific policies.[6] In general, waiting list time remains the primary factor that determines who is next in line to receive an available organ; however, other matching factors are considered for each available organ. Patients who are current smokers are not candidates for lung transplantation, although most centers allow former smokers to qualify for a lung transplant. Patients with documented alcohol abuse are not candidates for transplantation. Criteria are used so that individual preferences of team members are not given priority. In addition, ethnicity, gender, religion, and financial status are not part of the transplant criteria.

Psychological and Social Considerations

There are many psychological issues associated with organ transplantation, such as feelings of uncertainty, upheaval associated with moving, and issues of psychological adjustment. The time spent waiting for a transplant can vary considerably. During the waiting period, patients struggle with the need to carry on their lives, knowing that at any moment they may be called to the hospital for transplant. In addition, the patient is torn between wanting to remain hopeful that a

transplant will provide new life and the reality of knowing they have a terminal condition. Anxiety and depression have been identified as prevalent psychological issues related to transplant.[7]

The number of transplant centers in the United States is limited. Because donor organs are viable for only hours after removal from the donor, patients waiting for transplant are frequently required to live within a several-hour radius of the transplant center. Patients need information and logistics assistance for relocation to a transplant center. They may also require emotional and financial support for this transition.[8] The demands of waiting and relocation to the transplant city put considerable stress on the patient and their significant others. Those patients who relocate to transplant centers may have the most difficult time psychologically, especially when they leave family and significant others behind. The psychological stresses are somewhat different for spouses. Spouses speak of the struggle to remain hopeful, yet plan for a future that may not include their loved one. If the patient and spouse move together to a new city to wait for transplant, they may find themselves with more time together than previously. In this "forced retirement" situation, new stresses are added to relationships. Transplant teams usually include a psychologist or social worker to whom patients may be referred for individual or family counseling if needed.

Other concerns include psychological adjustment and the effect of social supports on mediating coping skills. Feelings of being useless are common because patients waiting in a new city are outside of their own environment and must find some meaningful activities. Coping strategies appear to strengthen psychological outcomes. After transplant, patients are often emotionally overwhelmed with a feeling of gratefulness that they are alive and feelings of guilt that someone else's grief has given them a chance to rejoice. A strong support system is considered an essential component of a successful transplant and improves psychosocial outcomes after transplantation.[9] Therapists can assist patients by listening to feelings, being supportive, and encouraging participation in support groups. Support groups that include patients waiting for transplants as well as posttransplant patients can offer significant psychosocial support. Spouses and significant others also benefit from group support.

Physical Therapy Considerations

As important members of the transplant team, physical therapists need an understanding of the physiological components of both the pretransplant disease and posttransplant state, as well as knowledge of the influence of surgery, medications, or rejection on musculoskeletal structure and function. In addition, physical function may be decreased due to the primary cardiopulmonary condition and overall deconditioning. Knowledge of medical management, including medications, ventilatory support, and hemodynamic monitoring, assists the therapist in determining whether modifications are needed during rehabilitation.

Physical therapists have a role in the management of the transplant patient in all stages of transplant: before transplant, during the acute postoperative phase, and throughout the rehabilitation phase. The purpose of physical therapy before transplant is to identify baseline function and to screen for impairments that may limit rehabilitation goals. The pretransplantation period offers an opportunity to address limitations in strength and range of motion or endurance and to improve physical function. Because of the surgical intervention, bed mobility, ventilation, secretion management, range of motion, and pain control are important areas to address in the immediate postoperative phase. In the posttransplantation rehabilitation phase, physical therapy goals are to return the patient to the highest functional level. Upper and lower extremity muscle strength and range of motion are addressed, as well as posture, shoulder and trunk mobility, breathing pattern, breath sounds, and functional mobility.

Oxygen Transport

Cardiac and pulmonary conditions leading to transplant produce limitations in the oxygen transport pathway. An understanding of the limitations in the oxygen transport pathway assists the therapist in designing a plan of care specific for each individual. Oxygen transport may be affected by the primary disease process, the surgical or medical intervention, or the medications used posttransplant. Cardiac conditions lead to impairments in myocardial function, leading to decreased oxygen availability for daily activities. Peripheral muscle dysfunction often occurs concurrently with the myocardial condition.

Pulmonary conditions lead to impairments in the mechanics of the lungs and chest wall, as well as diffusion abnormalities, producing a low blood oxygen content that is inadequate for daily activities. Myocardial function may be decreased secondary to increased vascular resistance in the lung. Likewise, peripheral utilization of oxygen may be decreased as a result of the pulmonary condition or inactivity.

Surgical and Medical Considerations

Physical therapists need to consider the effect of surgery, medication, or rejection on oxygen transport and functional ability. In patients who have undergone a surgical procedure, physical therapists must identify and manage problems related to anesthesia, pain control, hemodynamic instability, and alterations in muscle function, depending on the site of surgical incisions. The medication regimen for patients following organ transplant is complex and, in many cases, more cumbersome than the medical management of the underlying condition. Patients must take immunosuppressant medications for the rest of their lives. These medications, along with others used to manage the symptoms related to the immunosuppressants, have consequences for peripheral muscle function and energy production. Limitations in physical function may be due to the primary condition, the lack of physical activity, and the side effects of medications. Specifics will be covered later in this chapter.

The principal limitation to survival is graft rejection. Although advances in immune suppression have been successful, graft rejection remains a difficult medical problem. During the first year after transplant, the primary causes of morbidity and mortality relate to acute cellular rejection and infection. In the long term, chronic rejection is problematic. In heart transplant patients, cardiac allograft vasculopathy, an accelerated form of atherosclerosis, remains a primary limitation to long-term survival.

Rehabilitation of the Transplant Patient

To assist in management of the patient with transplant, rehabilitation is categorized into the following four phases: (1) pretransplant, (2) surgery and the postoperative acute phase, (3) postoperative outpatient phase, and (4) community- or home-based phase. Although the ultimate goal of transplant rehabilitation is to improve the patient's function and quality of life, each phase of rehabilitation has its own emphasis.

Pretransplant Rehabilitation

Heart Transplant and End-Stage Cardiac Disease

Patients are referred for heart transplantation for end-stage cardiac conditions. The primary diagnoses for adults requiring a heart transplant are severe coronary artery disease (38%) and end-stage cardiomyopathy/heart failure (53%). In children under 1 year, the primary diagnosis requiring transplant is congenital cardiac abnormalities; for ages 1-10, cardiomyopathy.[10]

Patients with heart failure report symptoms of fatigue, dyspnea, and orthopnea. Physical signs include the presence of a third heart sound, pulmonary rales that do not reverse with coughing, jugular venous distension, peripheral edema, and hepatomegaly. Compensatory mechanisms include increased sympathetic nervous system activity, increasing resting heart rate, and activation of the rennin-angiotensin system, increasing blood pressure.

Patients with heart failure generally meet the heart transplant selection criteria if they have New York Heart Association (NYHA) class III or IV heart failure that is unresponsive to medical management. Specific criteria for recipient status vary somewhat from center to center, although International Society for Heart and Lung Transplantation (ISHLT) criteria for listing are generally followed.[11] Exercise testing criteria can be used to guide transplantation. Patients who complete a maximum test may be eligible for a heart transplant if peak $\dot{V}O_2$ is ≤14 mL/kg/min, or ≤12 mL/kg/min if on a beta blocker.[11]

Recipients waiting for heart transplantation are classified based on severity of disease. Patients in the worst medical condition (Status IA) are placed higher on the transplant recipient list. Table 40-2 outlines the criteria for each level of heart transplant recipient status.

Pretransplant management of the patient with heart failure is designed to preserve cardiac output until the transplant can be completed. Outpatient medical management includes medications and supplemental oxygen. Hospitalization may be needed for inotropic medication support such as dobutamine. The increased use of left or right ventricular assist devices (LVAD or RVADs) augments cardiac output and allows the patient a bridge to transplantation.

The main rehabilitation goal in the preoperative period is to prevent losses of physical function. Maintenance of range of motion, soft tissue extensibility, and muscle strength are suggested goals. Although patients with severe disease may be unable to participate in therapy, cardiac rehabilitation is an effective treatment for improving functional status of patients with significant heart failure and those with LVADs, whether or not transplantation is anticipated.[12,13] Recent literature demonstrates that medically supervised exercise training is both safe and effective at improving aerobic capacity and physical function in patients with LVAD devices awaiting heart transplantation.

Table 40-2 Heart Transplant Recipient Status

Status Level	Status Criteria
Status IA	Mechanical circulatory support for acute hemodynamic decompensation Mechanical circulatory support with objective medical evidence of significant device-related complications Continuous mechanical ventilation Continuous infusion of a single high-dose intravenous inotrope
Status IB	Patients require at least one of either of the following: a. Left or right ventricular assist device b. Continuous infusion of intravenous inotropes
Status II	Those patients not meeting Status IA or IB criteria

Lung Transplant and End-Stage Pulmonary Disease

Patients are referred for lung transplantation for end-stage pulmonary conditions. The primary diagnoses for adults requiring a lung transplant are severe chronic obstructive pulmonary disease (COPD) (44%), idiopathic pulmonary fibrosis (IPF) (17%), and cystic fibrosis (CF) (15%). Other conditions include pulmonary arterial hypertension (PAH). The guidelines for selection of patients for the lung transplant waiting list were updated by the ISHLT in 2006 and include specific criteria for the most common pulmonary conditions.[14,15] Within the disease-specific listing criteria for COPD, the guidelines include a BODE (body mass index, airflow obstruction, dyspnea, and exercise capacity) score of 7-10. The BODE is more useful than measures of airflow obstruction in predicting mortality from COPD; higher scores are associated with increased mortality.[16] Before 2005, patients who had accrued the most time on the waiting list were given priority for lung transplants. The change to a lung allocation score now gives priority for transplants to those patients who have a greater medical urgency for transplant. The lung allocation score is based on "(i) waitlist urgency measure (expected number of days lived without a transplant during an additional year on the waitlist), (ii) posttransplant survival measure (expected number of days lived during the first year posttransplant), and (iii) transplant benefit measure (posttransplant survival measure minus waitlist urgency measure)."[17] The urgency and survival measures are based on factors that predict risk for death in patients with lung transplant and include functional status as well as physiological measures. This change has increased the number of transplants for patients with IPF and slowed the number of transplants for COPD.[14]

Table 40-3 **Preoperative Pulmonary Rehabilitation**

Activity	Time	Specific Activities	Targeted Area Exercise and Intensity
Warm-up (group)	10 minutes	Active range of motion	Upper body Lower body Trunk
Individualized endurance program	10 to 30 minutes (may be done as intervals)	Cycle ergometer	25 to 30 watts
		Treadmill	0.8 to 1.5 mph, 0% to 5% grade
		Arm ergometer	0 to 25 watts (forward or backward)
Individualized strength program	15 to 20 minutes	1 set of 8-12 repetitions	Pulleys Theraband
		Upper extremities	Latissimus pull-downs Rhomboids Shoulder extension/ rotation Shoulder flexion Pectoral Triceps
		Lower extremities	Quadriceps Hip extensors Hip abductors
Cool-down (group)	10 minutes	Stretching (full-body) Breathing retraining Relaxation	

Idiopathic pulmonary fibrosis is characterized by scarring of lung parenchyma leading to decreased lung volumes and decreased diffusing capacity. Risk factors for mortality include the lung pathology, pulmonary function results, physical function from the 6-minute walk test, and respiratory failure.[14] Criteria for listing of patients with IPF include a decrease in FVC of 10% or more during 6 months and pulse oximetry less than 88% during a 6-minute walk test.[15] Patients with IPF waiting for lung transplant who walked less than 679 feet had higher mortality than those who walked longer distances.[18]

Recent advances in vasodilator therapy for patients with pulmonary artery hypertension and poor survival of patients with PAH after transplant have reduced the number of patients with PAH who receive lung transplants. The criteria for listing patients with PAH include an NYHA class III or IV status on the maximal vasodilator therapy and 6-minute walk test of less than 350 meters.[15]

In patients with cystic fibrosis, the predictors of mortality include declining FEV_1 and chronic infection. The current criteria for transplant include FEV_1 less than 30% of predicted, as well as other markers of declining pulmonary function.[19]

Pulmonary rehabilitation is an essential component of management of patients with chronic lung conditions even without transplant, and it is becoming an accepted requirement for patients awaiting lung transplantation. Clinical data from pulmonary rehabilitation programs suggest that patients with better physical function before transplant have improved posttransplantation outcomes.

The causes of exercise limitation in people with chronic lung conditions are both ventilatory and musculoskeletal. Muscle changes in pulmonary conditions include decreased muscle oxidative capacity and muscle weakness.[20] Reasonable goals for pretransplant rehabilitation include improvement in muscle strength in lower extremity musculature, functional upper extremity muscle strength and endurance, functional shoulder and chest wall range of motion, demonstration of coordinated diaphragmatic breathing with exercise and activities, and improved cardiovascular endurance. Because of the significant effect of immunosuppressive medications on muscle strength, a greater emphasis is placed on resistance training in a patient awaiting lung transplantation than in most typical pulmonary rehabilitation programs. An example of a preoperative pulmonary rehabilitation program is outlined in Table 40-3.

Patient Education

The pretransplant waiting period provides an ideal opportunity for patient education. Nursing generally provides much of the education regarding preoperative procedures, postoperative course, and medication. Rehabilitation teaching includes breathing training, airway clearance techniques, and activity progression.

Other Transplants

Patients awaiting other organ transplants may also be referred to physical therapy for treatment of musculoskeletal problems. Because of the level of metabolic abnormality in patients awaiting liver and kidney transplants, endurance training is difficult to perform. Other physical therapy interventions, however, may be used as appropriate (i.e., muscle strengthening, range of motion).

Surgical Implications

Surgical procedures have implications for the physical therapist in the areas of pain, abnormal hemodynamic responses, and movement patterns. The surgical approach for transplant is chosen to provide the surgeon the optimal working area and visual field. The choice of incision may affect patient comfort and function after surgery. Patients may experience pain in the

area of the incision, and they may present with decreased muscle function and joint pain related to the muscles that were incised during surgery. The physical therapist should be familiar with the surgical incisions and their impact on rehabilitation. Other related complications from thoracic transplant include injury to the phrenic nerve, brachial plexus injury, and peroneal nerve injury secondary to prolonged positioning during surgery and recovery.

Heart transplants are usually performed through a median sternotomy incision and require cardiopulmonary bypass.[21] The native heart is excised, leaving a portion of the right atrium (atrial cuff), including the SA node. The left atrium of the donor heart is sutured to the recipient's atrial cuff and the major vessels reattached, starting with the pulmonary arterial vessels and followed by the aorta. Drainage tubes are placed in the pleural and mediastinal spaces and an epicardial pacing wire is placed before closure of the sternum. Total heart ischemic time is minimized, with less than 4 hours recommended. Finally, the two halves of the sternum are wired together, the new heart defibrillated, cardiopulmonary bypass discontinued, and the patient awakened.

Lung transplantation surgical incisions depend on whether a single- or double-lung transplant is to be performed. Single-lung transplants are performed through a standard posterolateral thoracotomy incision, made through the fifth rib. The latissimus dorsi and lower trapezius muscles are incised, as are the intercostal muscles at this level. If the rib at the surgical level fractures, it is resected so that the bone ends do not rub or puncture the lung. The serratus anterior muscle is preserved if at all possible, but the lateral portion of the rhomboid may be cut to allow more access for the surgeon. Postoperative pain and impaired upper quarter movement patterns may present significant problems for patients.

Double-lung transplants are performed as two single-lung transplants, in a technique referred to as bilateral sequential lung transplantation. The surgical incision extends from the midaxillary line under the submammary fold to the other midaxillary line and may or may not use a transverse sternotomy.[22] In this technique, called the clamshell incision, the pectoralis major is separated from the chest wall, and the serratus anterior may be incised.[23] Complications from this technique include sternal overlap if a transverse sternotomy is used.

Acute Phase Rehabilitation

The acute phase of rehabilitation begins in the intensive care unit and continues throughout the patient's hospital stay. Interventions are focused on facilitating normal cardiovascular and pulmonary function and increasing functional abilities in self-care and ambulation.

Heart Transplant Acute Management

Postoperative management of the patient following heart transplantation is similar to that of other cardiac surgeries. Patients experience hemodynamic instability, dysrhythmias, pulmonary hypertension, coagulopathies, and acute rejection. Factors that can lead to a complicated postoperative course include length of ischemic time and reperfusion injury. Prolonged ischemic time is associated with graft dysfunction.[24] Reperfusion injury is also associated with poor short-term outcomes.

Patients are weaned from mechanical ventilation within 24-36 hours, and chest tubes and pacing wires are removed after 2 days. During this time, there is a risk of acute cellular rejection. Acute cellular rejection is characterized by lymphocyte and myocyte infiltration into the cardiac muscle, resulting in dyspnea, fatigue, and heart failure. The symptoms of acute cellular rejection are often mild; therefore patients undergo cardiac biopsy at regular intervals to identify the presence of rejection. Biopsy specimens are obtained by inserting a catheter in the jugular or subclavian vein into the right atrium. Humoral rejection is observed in the first weeks or months after an organ transplant. Humoral rejection is considered an immune system response that results in inflammation and thickening of the endothelial lining of the cardiac vessels.

Current guidelines for management of patients with heart transplant include a recommendation for a multidisciplinary team that meets regularly.[25]

EXERCISE GUIDELINES

Goals of the acute phase of rehabilitation include the following: (1) regain normal postural cardiovascular responses (no postural hypotension) and (2) increase functional activities. The former is focused on the patient being able to tolerate changes in position, increase time in upright sitting, and transfer independently. Upper and lower extremity range of motion and strength need to be adequate to perform activities of daily living. An example of a cardiac rehabilitation program is presented in Table 40-4.

Specific issues for physical therapists include abnormal ECG and cardiovascular control. ECG readings may be normal because the donor heart has an intact conduction system, although the atrial cuff from the native heart may cause the ECG to have two P waves. Control of cardiovascular responses is altered because of cardiac denervation that occurs with surgery. When the donor heart is removed, the extrinsic nervous supply including vagus nerve and sympathetic trunk are severed. Consequently, there is no direct innervation to the heart to control heart rate response during change in position or exercise. Heart rate and stroke volume increase as a result of the effect of preload, as demonstrated by the Frank-Starling law, and through circulation of catecholamines. For the physical therapist, this means that heart rate and blood pressure respond more slowly to changes in position and exercise and require a longer time between position of activity changes. Other complications of heart transplant include sternum instability, infection, and pain.

In the rehabilitation process, median sternotomy precautions may need to be observed. Emerging evidence suggests that activity may be progressed more quickly than previously thought.[26] Principles of inpatient cardiac rehabilitation are followed in the postoperative period. Patient activity is progressed as long as a normal physiological response in achieved.

Lung Transplant Acute Management

Postoperative management of the patient following lung transplantation begins in the intensive care unit. After lung transplantation, patients are generally mechanically ventilated for 24 to 72 hours. Often, paralytic agents are used in this period so that ventilation can be optimized. Chest tubes are likely in place, and patients are medicated for pain. Infection

Table 40-4 University Hospital Cardiovascular Rehabilitation Supervised Exercise/Activity Plan for Surgical Patients

Step	METS	Exercise	Activity
1	1.5	Active/passive ROM, in bed for 5 reps Turn, cough, deep breathe, and use incentive spirometer q2-4 h	Partial self-care Feed self Use of bedside commode
2	1.5-2.0	Active ROM, sit on edge of bed for 5 reps Teach rating perceived exertion (RPE)	Partial/complete self-care Sitting bed bath Up in chair for meals
3	2.0	Walk 100 feet, slow pace Active ROM 10 reps	Complete self-care Incentive spirometer independently, TID
4	2.5	Walk 150 feet, average pace Teach pulse counting Warm-ups, standing for 10 reps	Use of bathroom with assistance May take warm shower after pacer wire removed
5	3.0-3.5	Walk 300 feet, average pace Walk down flight of stairs Instruct in home exercise	May stand at sink for ADLs Dressing independently
6	4.0	Walk up flight stairs Walk 500 feet, average pace Schedule submax ETT Enroll in phase II rehabilitation	All self-care independently

Guidelines for Exercise:
Patient HR to be 50 to 120 bpm
No significant arrhythmias
Exercise HR not more than 20 beats above rest
SBP <200, DBP <120 during exercise
No worsening ST changes
<10 to 15 DBP drop during exercise
RPE of 10 or less
No angina or other symptoms
Patient to complete entire step before advancing to next step

control is imperative; isolation rooms with negative-pressure ventilation are used, and respiratory isolation procedures are maintained.

Problems in the immediate lung transplantation period include ineffective airway clearance, poor gas exchange, and rejection. Hypotension and hypoxemia can lead to decreased blood flow at the site of anastomosis for the new lung, creating necrotic changes and impairment in airflow. Problems with airway clearance are related to the denervation of the transplanted lung, specifically the autonomic nervous system pathways. The lack of innervation leads to ineffective cough and ciliary clearance. Problems with gas exchange occur as a result of postoperative edema.

EXERCISE GUIDELINES

In the immediate postoperative period, the major goals are to prevent lung infection, optimize ventilation-perfusion ratio, increase time out of bed, and increase active range of motion on the surgical side. The primary goals are to mobilize the patient out of bed and increase daily activity. Patients are encouraged to be out of bed and walk in the hallway; in some cases, a stationary ergometer is used to increase endurance (ergometer can be brought to the room). Therapeutic interventions vary greatly. In general, an intervention may continue until an abnormal exercise response is reached. Abnormal responses include a decrease in heart rate or blood pressure with an increase in exercise, a decrease in oxygen saturation below recommended levels (88% to 90%), and/or symptoms of dizziness and diaphoresis.

Airway clearance is an essential component of acute care management. Many techniques are considered appropriate. Breathing training that targets diaphragm function is considered an essential component of acute management of the patient following lung transplantation. Suggested goals and interventions are shown in Table 40-5.

Posttransplant Outpatient Rehabilitation

Rejection

A common complication of organ transplantation is organ rejection. Acute rejection occurs within the first 6 months of transplantation, whereas chronic rejection remains a long-term problem. Rejection episodes are monitored closely, often with biopsy, and treated with a variety of immune suppressant medications.

Acute rejection is mediated by T cells. These T cells infiltrate the new organ allograft, and multiply, causing tissue destruction. Chronic rejection initially appears as hypertrophy of the intima in the transplanted organ and then progresses to fibrosis. In heart transplants, chronic rejection may also be seen as accelerated atherosclerosis. In lung transplants, chronic rejection appears in the airways as bronchiolitis obliterans. No effective treatment exists for chronic rejection.

Table 40-5 **Goals and Interventions for Acute Posttransplant Rehabilitation: Lung Transplant**

Problem	Goal	Interventions
Decreased secretion clearance	Independent secretion management Because the lungs are denervated, there is decreased sensation of secretions	Incentive spirometer Airway clearance techniques Assisted cough Positioning, single-lung: operative side up while side-lying to facilitate drainage; double-lung: avoid supine
Incisional pain	Pain management Postoperative pain related to surgical incision and decreased movement of muscles	Pain medication Active range of motion, shoulder girdle Positioning Mild heat Massage/soft tissue techniques
Abnormal postural hemodynamic responses	Normalize hemodynamic response (i.e., no postural hypotension, normal heart rate, respiratory rate, and blood pressure response to exercise)	Progressive mobilization from supine to sitting, sit in chair, walking in room Monitor HR, BP, RR, Sao_2
Increased oxygen/ventilatory requirements	Adequate oxygenation without supplemental (Sao_2 94%-96% on room air) Normal vital capacity Diaphragmatic breathing	Instruction of diaphragmatic breathing Facilitation of diaphragmatic breathing Lateral costal expansion techniques (surgery side) Incentive spirometry
Decreased functional mobility	Independent activities of daily living (dressing, hygiene, shower, toilet) Need adequate shoulder range of motion to perform these activities	Active and active-assisted range of motion, shoulder Wand exercises Encourage and assist with activities of daily living (hygiene, shower, toilet)
Decreased exercise tolerance	Independent transfers Independent ambulation 500 feet Out of bed most of day	Daily schedule Assisted ambulation (room progressing to hallway) Bicycle in room, 2 minutes initially; progress to 10 minutes
Compromised nutrition	No supplemental feedings (IV)	Schedule rehabilitation around meals Medical management of nausea

Heart Transplant

After heart transplant, patients continue to experience decreased aerobic capacity and endurance, muscle atrophy, and decreased physical function. In addition, immune suppression increases the risk for infection and leads to loss of muscle and bone. Rejection remains a significant risk, and heart transplant patients are likely to acquire premature atherosclerosis. Despite these problems, aerobic capacity and physical function are amenable to rehabilitation.[27] Common long-term impairments are chest wall soreness, abnormal upper quarter movement patterns, and low back and knee pain from overuse. Once the patient leaves the hospital, rehabilitation looks much like phase II cardiac rehabilitation. The overall objective is to increase functional activity to within normal limits.

CARDIAC AND RESPIRATORY PHYSIOLOGY IN HEART TRANSPLANT

After transplantation, functional capacity is about 50% of the capacity of control subjects; abnormalities in heart rate, blood pressure, and ventilatory abnormalities also exist during this period. In posttransplant patients, peak heart rate is lower than in controls (156 versus 168 beats/minute),[28] although heart rate kinetics are not different.[29] In regard to long-term effects of heart transplantation on heart rate, some children who have received heart transplantation do acquire a normal heart rate response to exercise.[30] The ventilatory response to exercise is abnormal, as demonstrated by a decreased diffusing capacity.[31] However, there may be some peripheral limitations that contribute to decreased functional capacity; these include decreased capillary density in muscle.[32] A summary of how cardiac variables are affected by heart transplant is shown in Table 40-6.

SIGNS OF REJECTION

The primary signs and symptoms of rejection are flu-like symptoms, including low-grade fever and muscle aches. Dysrhythmias and bradycardia below 60 or relative bradycardia (decreased compared with patient's normal resting heart rate) are significant and should be reported to the physician immediately. Rejection episodes are monitored by biopsy. Exercise can continue if the rejection episode is mild or moderate as determined by biopsy.

EXERCISE AND THE HEART TRANSPLANT PATIENT

Exercise training is important for reversing the physiological abnormalities observed after heart transplant, returning patients to improved functional status, and preventing disability incurred from the immunosuppressant regimen. The outpatient phase of rehabilitation resembles phase II cardiac rehabilitation, which generally continues for 8 to 12 weeks, at which time the patient is encouraged to continue exercise on his or her own or at a fitness facility. ISHLT guidelines for care address health-related issues for patients after heart transplant. Hypertension after heart transplant should be treated to achieve the same goals as the general population, and

Table 40-6 Effect of Heart Transplant on Selected Cardiovascular Variables As Compared with Normal Age-Predicted Values

	Heart Rate	Stroke Volume	Blood Pressure	$\dot{V}O_2$
Rest	Lower than normal	Lower than normal with little change when shifting positions	+	NA
Exercise	Lower (approximately 15 beats less)	Decreased and late onset	+	May approximate normal with exercise training program

Box 40-2 Summary Guidelines for Posttransplant Cardiac Rehabilitation

- Use cardiac rehabilitation phase II protocols
- Heart rate is not best indicator of exercise intensity
- Increase warm-up and cool-down to 10 to 15 minutes
- RPE in conjunction with other physiological monitoring (e.g. RPP)
- No exercise when patient is in acute rejection episode (biopsy needed)
- Continue exercise in mild rejection

lifestyle modifications are the same as for others with cardiac risk factors.[25]Aerobic exercise and resistance training are recommended. Guidelines for exercise for the posttransplant cardiac patient are shown in Box 40-2.

After heart transplantation, there is no direct innervation to the heart to control heart rate response during exercise. Heart rate and stroke volume increase due to the effect of increased preload and through circulation of catecholamines. There is evidence that some sympathetic re-innervation can occur 1-2 years after transplant.[33] For the patient in phase II cardiac rehabilitation, this means that the warm-up and cool-down portions of exercise should be *slowly* increased to 10 to 15 minutes. Exercise intensity should not be determined by heart rate alone, because of the effects of denervation. In addition, rating of perceived exertion (RPE) scales remain an unreliable method for determining exercise intensity after heart transplant, because large inter-individual variations occur in the relationship of RPE and maximal oxygen consumption.[34] Although there is no strong clinical consensus about the optimal method for prescribing and monitoring exercise intensity for patients following heart transplant, ventilatory threshold, rate-pressure product (RPP), or a combination of RPE and physiological monitoring is recommended. Evidence suggests that patients with heart transplants can exercise at high intensity and achieve better functional outcomes than sedentary individuals without transplant.[35] Intensity set at 10% below anaerobic threshold produced significant increases in aerobic capacity.[36] Endurance and strength exercise can be performed in this rehabilitation stage, although upper extremity strengthening should not be started until after the sternum has healed. Treadmill, bike, arm ergometry, and indoor cross-country ski equipment are all appropriate choices.[37]

Cardiac rehabilitation can result in substantial increases in aerobic capacity with patients able to improve 20% to 50% over prerehabilitation levels. The mechanisms that contribute to increased aerobic capacity include increased maximal heart rate, improved ventilatory capacity, and improved peripheral muscle function.[38] Supervised exercise programs lead to greater increases in aerobic capacity than do home exercise programs (49% versus 18% improvement, respectively).[27] Resistance training has been used in patients following heart transplantation as an essential component of cardiac rehabilitation to improve physical function and prevent losses of muscle strength associated with corticosteroid use. Resistance training does appear to increase bone mineral density to nearly pretransplant levels.[39] Resistance training increases oxidative capacity of muscles[40] and also prevents adverse effects of corticosteroids and immune therapy on skeletal muscle.

Despite the evidence that cardiac rehabilitation is beneficial in increasing aerobic capacity and exercise capacity, scant literature exists to suggest that exercise training prevents transplant atherosclerosis. Early studies of patients after renal transplant, however, show promising results of exercise in preventing atherosclerosis.[41]

Lung Transplant

Patients who have received a lung transplant may be referred to physical therapy as early as 10 to 14 days after transplantation occurs. In the early stages of this postoperative outpatient phase, patients are medically labile and need once- or twice-a-week monitoring of their medical status. Rehabilitation should progress in this phase, but close communication with medical personnel is recommended because of the many medication changes. Blood levels of immunosuppressive drugs are monitored, along with metabolic function (fluid and electrolyte levels, kidney and liver function).

CARDIAC AND RESPIRATORY PHYSIOLOGY IN LUNG TRANSPLANT

After lung transplant, patients continue to experience decreased aerobic capacity and endurance, muscle atrophy, and decreased physical function. In addition, immune suppression increases the risk for infection and leads to loss of muscle and bone. Rejection remains a significant risk. Despite these problems, aerobic capacity and physical function are amenable to rehabilitation. Patients in the outpatient phase of rehabilitation begin at low levels of function and progress to having few functional limitations. Therapists need to adapt and progress the rehabilitation program appropriately. Because of the debilitating side effects of immunosuppressive medications, rehabilitation needs to be aggressive and preventive in nature. Rehabilitation can occur in a group setting and/or on

Box 40-3 Summary Guidelines for Posttransplant Lung Rehabilitation

- Keep Sa_{O_2} above 90%
- Add supplemental oxygen, if necessary, during treated acute rejection episodes
- Patient should wear mask when with people
- Increase resistance exercise program during prednisone bursts
- Evaluate for musculoskeletal dysfunction

an individual basis. General guidelines for posttransplant lung rehabilitation are shown in Box 40-3.

After transplantation, functional capacity remains between 40% and 60% of predicted oxygen uptake, whether the patient received a single- or double-lung transplant.[42] Although there are mild ventilatory abnormalities, the decreased $\dot{V}_{O_2}$ is not well explained by the decrease in ventilation or by low oxygen saturation or anemia. Instead, several articles suggest that the main cause of decreased aerobic capacity is a peripheral muscle limitation. Problems in the periphery include decreased peripheral oxygen utilization, decreased mitochondrial capacity and decreased type I fibers, as well as decreased muscle power.[20,43]

SIGNS OF REJECTION

The primary symptoms of acute rejection are shortness of breath, exercise intolerance, and desaturation at rest or with exercise. Patients generally have a portable oximeter at home and may report episodes of desaturation. Rejection should be suspected and reported if a decrease in Sa_{O_2} of 4% to 5% for the same amount of activity is seen. Monitoring of ventilatory status should be the primary consideration of the therapist. Respiratory rate and oxygen saturation should be followed closely during exercise sessions.

EXERCISE AND THE LUNG TRANSPLANT PATIENT

Patients are generally excited about the improvement in shortness of breath and frequently surprised at the level of muscle weakness observed in the lower extremities. Once ventilation is no longer a limiting factor in function, other deficits emerge. In the initial stages of outpatient rehabilitation, patients may have multiple complaints about the side effects of medications and often generally do not feel well. Rehabilitation should continue through these periods of malaise. The overall objective of outpatient rehabilitation is to improve function to levels appropriate for the patient's age and interests. Usually, patients are closely followed by the medical staff for 2 to 3 months after transplant, and rehabilitation 2 to 3 times per week continues throughout this period. The most common impairments that limit function are decreased cardiopulmonary endurance, decreased muscle strength and endurance, range of motion limitations, and abnormal movement patterns of the shoulder or trunk. Impairments may be caused by the surgical procedure itself or as a result of years of abnormal muscle mechanics, posture, and decreased activity.

Aerobic exercise training for patients with lung transplantation provides substantial benefits in aerobic capacity. Frequency of exercise at least three times per week, intensity of 60% to 70% of heart rate maximum or RPE of 13 to 14, and duration of at least 30 minutes created significant increases in aerobic capacity.[42] Studies demonstrated an increase of aerobic capacity to 60% of prerehabilitation levels and decreased heart rate and ventilation for the same amount of submaximal exercise, indicating a training effect. After 6 to 12 weeks of training, $\dot{V}_{O_{2max}}$ and $\dot{V}_{O_{2peak}}$ increased as much as 14% over baseline testing and increased exercise time from 20 to 30 minutes.[42] The mechanisms by which aerobic capacity increases include decreased resting minute ventilation, suggesting increased efficiency of oxygen utilization. In addition, in two cohort studies, 6-MWD increased significantly.[20,44]

Peripheral muscle deconditioning contributes to decreased exercise ability and limited physical function. Lower extremity muscle strength can occur with resistance training. One study demonstrated a 35% increase in quadriceps force to almost 60% of that predicted after training, at 60% of 1-repetition maximum (1RM).[20] Lower extremity strengthening can begin early, but upper extremity resistive training should be delayed until wound and tissue healing is complete, generally about 6 weeks because of the delays in wound healing secondary to use of prednisone. Other important aspects of rehabilitation include posture reeducation, range of motion, and upper extremity movement patterns. Guidelines for outpatient physical therapy are provided in Table 40-7.

To improve physical function following lung transplantation, a pulmonary rehabilitation protocol may be used, or the therapist may creatively design a rehabilitation program. Except for delaying upper extremity strengthening for 6 weeks after surgery, no therapeutic interventions are contraindicated. For endurance training, stationary bicycles, treadmills, arm ergometers, indoor Nordic ski machines, rowers, and stair climbers may be used. Pulleys, weight equipment, free weights, resistive elastic bands, or gymnastic balls all may be appropriate for strengthening and facilitation of normal movement patterns. Because of the effects of prednisone, proximal muscle function must be addressed, and strengthening programs should be consistent with those designed to increase muscle force production, generally one set of 8 to 12 repetitions at 60% of 1RM. Once a patient has achieved a satisfactory level of function (determined by the therapist and patient), formal rehabilitation may be discontinued and the patient should participate in a community- or home-based rehabilitation program.

Community- or Home-Based Rehabilitation

Patients are generally followed at the transplant center until the medical staff is satisfied with patient progress. Return to home can occur at this point in time, whether or not rehabilitation goals have been met. For patients who have left their home community to wait for transplant, the transition to home frequently occurs at 3 months after transplant. The major goal of community-based rehabilitation is a return to normal function with minimal limitations. Therapists in rural settings and community hospitals may be involved with a transplant patient's plan of care in this phase. Therapists should be comfortable treating patients in many settings, skilled in addressing the common complications, and vigilant in watching for signs of rejection. In the initial stages of posttransplant rehabilitation, a supervised program is recommended. Hospital-based phase III cardiac rehabilitation

Table 40-7 Lung Transplant: Postoperative Outpatient Physical Therapy Management

Problem	Goal	Activity
Decreased aerobic capacity	Daily functional activities including leisure 30-minute aerobic exercise of moderate intensity (60%-70% $\dot{V}o_2$ max) at least 3 times/week Peak $\dot{V}o_2$ of 70%	Pulmonary rehabilitation Supervised aerobic exercise program with Sao_2 monitoring
Decreased lower extremity muscle strength Due to deconditioning and effects of prednisone	Functional muscle strength for sit to stand and stairs Leg press of 60% of body weight Manual muscle test, lower extremity muscle groups 5/5	Strength training program (1 set, 8-12 reps) Leg press Knee extension Hamstring curls
Abnormal upper extremity (shoulder girdle) mechanics for single-lung transplant due to thoracotomy incision	Able to perform all upper extremity activities in a normal fashion Range of motion to within functional limits muscle strength for function Muscle endurance for overhead activities	Strength training program (1 set 8-12 reps) Latissimus pull-down Shoulder retraction Fly Endurance training program (2-3 sets of 10 reps) Upper body ergometer
Abnormal coordination of breathing with activity or decreased diaphragm performance	Coordinate breathing with activity most of time Perform diaphragm breathing during exercise Demonstrate shortness of breath recovery techniques	Breathing training Breathing facilitation techniques

programs are appropriate, or patients may elect to exercise independently in a fitness facility. Some follow-up by the transplant center is important to encourage compliance in exercise programs. Once patients reach their desired level of fitness, a community-based program is appropriate for maintaining endurance, aerobic capacity, strength, and flexibility. Patients who participate in training can attain high levels of exercise performance, with an appropriate training regimen.[45]

Influence of Medications on Treatment

Rejection Issues

Although transplants prolong life, some health professionals believe that patients are merely exchanging one set of problems for another. For transplants to be successful, recipients must remain on powerful immunosuppressive drugs for the remainder of their lives. Some of these medications have crippling side effects. The effects of long-term prednisone are well known: osteoporosis, muscle weakness, and glucose intolerance. The long-term effects of cyclosporine and azathioprine affect the patient's ability to fight infection. Patients also need to manage medication side effects on a daily basis. It is these medications, however, that make for impressive survival rates.

Types of Medications

The drugs used to suppress the immune system are categorized as immunosuppressants. Each immunosuppressant targets a different component of the immune system, and multiple drugs are often required to prevent rejection of the transplanted organ. A side effect shared by all immunosuppressants is an increased risk for infection.

ANTILYMPHOCYTE ANTIBODIES

This class of medications includes the monoclonal or polyclonal antibodies to human lymphatic tissue. These antibodies have a powerful effect on decreasing T cell activity by causing cell death or movement of the T cells out of the vasculature. These drugs are most commonly used in treating acute rejection. Antithymocyte globulin (ATGAM [equine ATG] and Thymoglobulin [rabbit ATG]), muromonab-CD3 (Orthoclone OKT3), and daclizumab (Zenapax) are included in this category. Given intravenously, these drugs lead to flu-like symptoms and potentially unstable vital signs, mainly as a result of a significant increase in cytokine activity. Rehabilitation should not be provided during administration of these medications.

ANTIMETABOLITES

Medications in this class inhibit intracellular energy production and DNA synthesis pathways, preventing lymphocytes from proliferating. These drugs are most commonly used for long-term (maintenance) immune suppression. Azathioprine (Imuran) and mycophenolate mofetil (CellCept) are included in this category. Both of these drugs commonly cause gastrointestinal upset (nausea, vomiting, diarrhea, and abdominal pain). Intestinal absorption of these medications is easily affected by food intake or drug interactions (for example, antacids decrease absorption of CellCept). Aside from increasing a patient's risk for infection, these drugs may also cause bone marrow suppression (potentially resulting in anemia, thrombocytopenia, and leukopenia).

CORTICOSTEROIDS

Corticosteroids, such as prednisone and methylprednisolone, which are believed to block the production of interleukins and decrease the inflammatory response, have been a mainstay of organ transplant management for many years. Recently, however, corticosteroid-free immunosuppressive agent combinations have been tested; thus corticosteroids may have less of a role in maintenance immunosuppression in the future. Common adverse effects of corticosteroids include increased appetite, hypertension, diabetes, cataracts, delayed wound healing, muscle weakness, and osteoporosis. During the

Table 40-8 **Side Effects of Immunosuppressive Medications**

Medication Type	Trade Name	Action	Adverse effects
Antilymphocyte antibodies	ATGAM OKT3 Zenapax (daclizumab)	Mono- or polyclonal antibodies that cause T cell death or movement of T cells out of vasculature	Flu-like symptoms Unstable vital signs
Antimetabolites	Azathioprine (Imuran) Mycophenolate mofetil (CellCept)	Inhibits enzymes and prevents lymphocytes from proliferating	Blood: leukopenia, bone marrow suppression GI: pancreatitis Hepatic: toxicity
Corticosteroids	Prednisone	Block production of interleukins Stimulates protein breakdown	CNS: euphoria, insomnia Eyes: cataracts GI: hyperglycemia Skin: acne, delayed wound healing Muscle: weakness Bone: osteoporosis
Calcineurin inhibitors	Cyclosporine (Neoral) Tacrolimus (FK 506)	Decrease production of interleukins and T lymphocytes	Blood: leukopenia CNS: tremor, seizure Hepatic: toxicity Renal: toxicity

perioperative period, high doses of corticosteroids are initiated and then tapered to lower doses based on patient tolerance (with the goal of preventing acute rejection while minimizing side effects). Steroid therapy may be delayed until primary wound closure is certain (1 to 2 weeks), at which time the patient is begun on low-dose oral steroids. Acute rejection episodes are treated with high-dose oral or intravenous steroid pulses.

CALCINEURIN INHIBITORS

These drugs bind to proteins in the cells, decreasing the production of interleukin-2 or T lymphocytes. Cyclosporine (Neoral, Sandimmune) and tacrolimus (Prograf) are the most common of these drugs and are a main component of many immunosuppressant regimens. The main adverse effect is renal toxicity, which may be reversible if the dose is decreased. Cyclosporine is considered a nervous system irritant, leading to hand tremor and possible seizures. Therapists should be aware of these side effects. In addition, absorption of these drugs is affected by other medications and food intake. Serum concentrations of these drugs are increased with intake of grapefruit juice, as well as drugs such as erythromycin, diltiazem, and corticosteroids. Because of potential drug interactions, serum levels of these drugs are monitored closely. Table 40-8 summarizes the effects of common immunosuppressive medications.

Long-Term Complications of Transplant Management

Osteoporosis

Osteoporosis remains a prevalent and disabling problem for patients following organ transplantation surgery. Before transplant, the prevalence of osteoporosis is 37% in patients awaiting lung transplantation.[46] In the first year after transplant, a high incidence of vertebral and other atraumatic fractures occurs (between 8% and 65%), which can significantly limit physical function and complicate the posttransplantation rehabilitation course. Physical therapists have a role in identifying the physical limitations of osteoporosis and in prescribing appropriate exercise programs. Osteoporosis medications are considered essential components of care, and the addition of resistance exercise to a medication regimen does improve bone mineral density.[39]

Cardiac Allograft Vasculopathy

One of the most troubling long-term complications of heart transplantation is cardiac allograft vasculopathy, an accelerated form of coronary disease affecting cardiac arteries. Blockage of the arteries occurs, and the condition may be related to occurrences of acute rejection.[47] Physical therapists must continue to identify signs and symptoms of cardiac ischemia and refer patients for appropriate treatment. As preventive measures, patients may be on medications to lower cholesterol (statins) and to manage hypertension; these patients may be candidates for stenting or coronary artery bypass surgery as well. High-intensity exercise does appear to improve endothelial function and may decrease risk for cardiac events.[48]

Bronchiolitis Obliterans

Long-term chronic rejection of the transplanted lung results in a condition called bronchiolitis obliterans (BO). BO is the main problem seen in long-term survivors of lung transplantation. It results from lymphocyte infiltration into the basement membrane of the small airways, followed by migration through the intima into the respiratory mucosa. This process leads to epithelial damage and scarring, which may partially or fully occlude the small airways. As a complication of transplant, BO is usually irreversible. Because the primary pulmonary function affected is FEV_1, it is considered an obstructive lung condition. The diagnosis of BO is made through transbronchial biopsy.

Physical therapists working with long-term survivors of lung transplant may find that these patients demonstrate decreased lung function and symptoms of dyspnea with

Box 40-4 Long-Term Complications of Organ Transplant

- Accelerated atherosclerosis/hypertension/hypercholesterolemia
- Infections
- Cancers
- Osteoporosis
- Steroid myopathy with muscle weakness
- Glucose intolerance
- Nephrotoxicity
- Delayed wound healing

activity. The therapist, therefore, must continue to monitor ventilatory status and oxygen saturation in the lung transplant patient. Long-term complications of organ transplantation are summarized in Box 40-4.

Quality of Life

Although quality of life generally improves after heart and/or lung transplantation, many factors may influence that quality of life. Generally, patients report improved physical function, general health, and social functioning.[49] Despite these improvements, a decline in quality of life eventually occurs in long-term survivors. It is unclear whether this downturn is due to declines in physical condition or other social or psychological factors. Patients with lung transplantation generally have increased quality of life until the onset of bronchiolitis obliterans, which then causes a decline in quality of life.

Summary

Physical therapy has an important role in maintaining and improving functional levels of patients both before and after organ transplantation. Knowledge of cardiovascular and pulmonary physiology, along with the ability to analyze movement and function, allows rehabilitation professionals to maximize a patient's quality of life. The exciting field of organ transplant is growing quickly. New advances in long-term management of transplant recipients mean that rehabilitation professionals need to continue to develop and evaluate evolving approaches to care.

Review Questions

1. What are the psychological and social implications of organ transplant?
2. What is the role of pretransplant pulmonary rehabilitation?
3. How does the surgical incision affect the musculoskeletal function of a posttransplant patient?
4. What are the signs of organ rejection in the cardiac transplant patient? The lung transplant patient?
5. How is the rehabilitation of the heart transplant patient similar to and different from traditional cardiac rehabilitation?
6. How is the rehabilitation of the lung transplant patient different from other forms of pulmonary rehabilitation?
7. How do immunosuppressive drugs affect a patient's neuromuscular function? Muscle strength? Cardiopulmonary endurance?
8. What are the long-term complications of heart transplantation and of lung transplantation?

The role of the physical therapist in the community varies widely. Over the years, this role has changed in response to a range of factors, including epidemiological indicators of chronic conditions, advances in medical and surgical management, and policy changes. Lifestyle-related conditions and their associated comorbidity are health care priorities necessitating substantial community support, often for many years (Chapter 1). In addition, other chronic systemic conditions have well-documented cardiovascular and pulmonary consequences (Chapters 6 and 13). Policy changes during the 1980s resulted in the emergence of diagnostic-related groupings (DRGs), which led to patients being discharged from the hospital at more acute stages of illness. Further, the Balanced Budget Act of 1997[1] narrowed the criteria for those who qualified for prolonged inpatient postacute care, resulting in patients being transitioned home from extended care facilities sooner than they had been previously. The combination of these factors has changed the role of physical therapy in the community.

Physical therapy is provided in all inpatient care settings, including subacute hospitals, Medicare or another form of insured care skilled nursing settings, long-term acute care facilities, and rehabilitation facilities with transitional care units to facilitate functional progression so that patients are able to return home within days or weeks. Thus rehabilitation, by increasing the number of patients who return home, rather than remaining or being placed in facilities, is a way of reducing cost while maintaining care standards.[2] Changes in health care reimbursement from third-party payers affect patients' access to physical therapy services. Although such policy may be viewed as reducing physical therapy access, new paradigms of health care delivery and models of care for people with chronic conditions may emerge. Epidemiological indicators support patient-centered health care delivery systems and self-care and self-management approaches. The incorporation of self-management principles of practice can improve patients' quality of life and decrease hospitalization.[3-14] This chapter describes how physical therapists can facilitate the management of chronic conditions, particularly lifestyle-related conditions, when practicing in the community and home settings.

Because of dramatic increases in both patient longevity and prevalence of chronic illness, physical therapists see an

ever-widening range of diagnoses in their patients in the community. Global aging is occurring at an unprecedented pace. Worldwide, the number of people age 65 and older is expected to increase from 500 million to 1 billion by 2030.[15] Physical therapist interventions unique to aging populations need to be considered in relation to the available resources, as well as the challenges that present in the community practice setting more often now that patients are living longer (Chapter 38). Chronic conditions that were previously associated with later stages in life are now presenting earlier in life as a result of changing lifestyle behaviors (Chapter 1). Also, the medical community has improved its ability to quickly and effectively manage complicated acute medical situations—premature births, heart failure, cancer. More patients are surviving diseases once considered fatal and consequently requiring more services to safely and effectively manage the morbidity issues that result. Medical interventions in intensive care units have improved greatly, thus decreasing mortality, but morbidity related to myopathy of critical illness, cognitive impairments, and mental health sequelae has been found to have a significant impact on patients' ability to resume their prior level of independence (Chapters 33-36).[16-21] These patients return home more often and more quickly than in the past, but they often do so accompanied by unresolved cardiovascular and pulmonary impairments. For patients who are too medically fragile to return home or to obtain sufficient medical care at skilled nursing facilities, specialty hospitals have become necessary. These hospitals make it possible for ventilator-dependent or ventilator-assisted patients to receive physical therapy longer and at less cost than an acute care hospital.[22]

Practicing physical therapy in the community is distinct from practicing in acute care. When people with chronic conditions are living in the community, their focus is on health promotion and optimal health, rather than recovery from an acute episode of a condition or surgical procedure or trauma with frequent changes in their functional status, as is seen in acute care. In the community setting, the patient's goals are less focused on safety and more on optimal health. Patients' participation is vital in order to understand their definition of optimal health. Consistent with values of autonomy and independence, shared decision making should always be used—including the patient and family/caregiver in decisions regarding the patient's care with guidance from the health care team.[14,23] This model is at times challenging for health care team members who may feel more comfortable continuing to use a method in which they prescribe a task and tell the patient what to do, with little collaboration. However, the expected level of practice of every physical therapist is evidence-based practice (EBP) in decision making and treatment. The three aspects of EBP are weighted comparably: external clinical evidence, patient circumstances, and individual clinical expertise.[24] In this approach to practice, the patient's goals and his or her ability to carry out an effective plan are important. A patient cannot carry out an effective plan unless he or she is taught how to identify problems and manage or avoid them in daily situations when health care professionals are not present. Patients need a targeted and tailored education to understand how to make the best decisions about their health and to appreciate their responsibility in their own health management.

Given these practice settings, cardiovascular and pulmonary concerns are often the highest priority. From the young to the old, primary and secondary cardiovascular and pulmonary issues are often the limiting factors in a patient's rehabilitation progress, thus, need to be addressed in the patient's standard physical therapy care. The focus in home and long-term care settings is to enable individuals to achieve optimal health in the environment in which they live. This chapter focuses on considerations specific to patients with cardiovascular and pulmonary dysfunction (as either primary pathology or secondary to other impairments) who require physical therapy at home or in a long-term care setting, such as a nursing home, skilled nursing facility, transitional or assisted living facility, adult day program, or outpatient setting.

Chronic Conditions and Self-Management

Many people at home or in long-term care have chronic conditions, often related to lifestyle behaviors. Regardless of whether these conditions are the diagnoses for which they are receiving physical therapy, the related activity limitations and participation restrictions can limit their abilities to participate and progress in their therapy. Chronic conditions can affect the person's physical capabilities, as well as his or her emotions, attitude, and motivation. Many patients with chronic conditions or functional decline lead full and rewarding lives, but doing so requires the active participation of the patient and the physical therapist to maintain the fullest level of function despite the changes. The choices patients make about their health care, exercises, and methods of self-management will largely determine their health-related quality of life (Chapter 1).

Though people with chronic conditions have multiple impairments requiring adaptation of their lifestyles and schedules, the majority still accomplish what they want and need to do each day. The goal is to augment their knowledge about their symptoms and enable them to work within a collaborative, self-advocacy, and self-help model with their health care team to achieve optimal health. Positive self-management involves a combination of positive emotional outlook, active involvement in decision making, and maintenance of a lifestyle that is as optimal as possible. The interprofessional team needs to engage the patient in his or her care decisions. The physical therapist needs to be caring and fully present with the patient. Although the physical therapist can provide the initial stimulus for the process, effective self-management comes only from within the patient. The physical therapist can continue to be a resource and provide interventions as needed, but the goal is for the patient to be his or her own case manager and decision maker, whenever possible, regarding health care and optimal function (Chapter 1).[14,23]

In the home or community setting, the person with a chronic condition needs to make several choices. How does he or she decide what will promote optimal function and health? What resources must be employed to meet these needs (e.g., a maintenance program), or does the person have the potential to improve to the extent that he or she can benefit from further professional services? Many people are discharged from the hospital without referral to home care or outpatient physical therapy to manage their chronic conditions. If they are referred to a pulmonary rehabilitation program, for example, what determines when they have completed the

program? Financial support by private third-party payers and insurers is limited, influencing patients' decisions about which avenues to use to move further toward optimal health. Do they go to a health club or the local YMCA? Do they walk in a shopping mall or take yoga classes? Do they continue to pay privately for physical therapy, continue with a long-term pulmonary rehabilitation program, or simply exercise at home? The answers are as different as the people making the decision about what optimal health *is* in relationship to their personal circumstances. At times it may be a matter of trial and error; perhaps the patient's choice is not the same as that of a physician or other health care professional, but it is his or her decision and choice. A patient has the right to try, to succeed or fail, and make other decisions. He or she needs to know how to access the health care system if there are medical problems, and learning to do so must be an integral part of the patient education process.

Actively playing a role in decision making (i.e., self-management) empowers patients, making them more motivated, positive, active, and successful than passive patients who do only what the physical therapist and other health professionals advise.[23,25] A decrease in the number of visits allowed by third-party payers has forced a necessary change towards patient self-management and empowerment, which has led to improved efficiency and effectiveness in treatment. The promotion of positive self-management strategies for a more active, healthy lifestyle is one of the most important competencies of contemporary physical therapists.

The physical therapist facilitates this process by being caring, supportive, and respectful of patient goals and priorities. This has been referred to as a "healing presence," which may lead to a beneficial, therapeutic, positive experience for the patient.[26,27] The American Physical Therapy Association promoted this practice philosophy with the phrase "the science of healing, the art of caring."

Cardiovascular and Pulmonary Concerns in the Community

Patients with either chronic or acute conditions present with primary and/or secondary cardiovascular and pulmonary diagnoses at all levels of independence. Patients may have preexisting cardiovascular and pulmonary impairments such as asthma, hypertension, congestive heart failure, and comorbidities such as type 2 diabetes mellitus, obesity, and one or more types of cancer. Most patients will also have risk factors for one or more of these lifestyle-related conditions; thus risk factors need to be assessed and modified accordingly. Patients may have had problems such as hip fractures, joint replacements, CVAs, MIs, or some combination. The cardiovascular and pulmonary impairments related to the impairments and subsequent deconditioning associated with these conditions may be the limiting factor with respect to progression of physical therapy. These concerns need to be addressed so that the individual is able to reach his or her full rehabilitation potential.

One example is a patient with coronary artery disease, who is fully independent in his or her day-to-day activities but not at a maximal functional level because of limited education on how to further improve function. Another example is a patient who cannot resume his or her prior level of independent function after an acute bout of illness or hospitalization because of limits resulting from primary and/or secondary cardiovascular and pulmonary dysfunction. Both of these examples illustrate the resultant decrease in such patients' tolerance for, and ability to independently perform, activities of daily living. Because of these decreases, patients must acquire continued support to maintain their safety and improve their level of function. Those with the least ability to care for themselves after an acute bout of illness transfer into nursing homes or alternative long-term care, and those with higher levels of function move into assisted living facilities or return home with assistance and therapy. Such patients may present with decreased strength, endurance, and balance, leading to decreased independence, mobility, and activity level. Returning home with a decrease in independent functioning may be associated with negative emotions, which may further decrease appetite, activity level, motivation, and social/community interactions (Chapter 1).

Nursing homes, assisted living facilities, and senior housing offer residential services for those who can no longer care for themselves. Some facilities offer multiple levels of care within one system, ranging from independent living apartments to skilled-level care. For residents who live in independent apartments when they are well, the facility can offer temporary increased support from a skilled level of care with physical therapy and nursing support upon discharge from the hospital. The goal is for the patient to return to the least level of care with the highest level of independence. Physical therapy services can be utilized at all levels of care to improve independence and tolerance for daily activities to improve patient safety in the community. Patients living in residential facilities should be screened periodically to determine their readiness to benefit from further physical therapy intervention and enable them to live to their fullest capacity.

Functioning depends on the ability of the patient to maintain all of the components of oxygen transport to support activity. One example is a patient who fell in the parking lot of a hospital where she had been attending a pulmonary rehabilitation program. She was fitted with a long leg cast and discharged home. She reported being short of breath with sit-to-stand transfers, and soon she was hardly able to ambulate across the room with the standard walker she used before. When the physical therapist observed this patient using her bronchodilator metered-dose inhaler, she was using it improperly. After she was instructed on how to use the bronchodilator therapy effectively before activity, the patient's transfers and her walking ability improved markedly. She was able to coordinate her breathing with her activity, and her endurance further improved. Case reports and professional experiences such as this provide important information for the physical therapist to use in conjunction with the findings of research studies when planning and prescribing interventions for patients at home using evidence-based practice.[24]

Long-Term Care Facilities and Nursing Homes

Practicing in a long-term care facility as a physical therapist opens up an opportunity to work with an interprofessional health care team to carry out therapeutic goals during other tasks of the day. Aides, generalist and specialist nurses,

respiratory therapists, occupational therapists, speech therapists, dietitians, and on-call physicians all interact with patients each day and are able to remind and encourage patients to follow through on their exercise and activity goals. In order for this to happen, it is necessary to communicate the importance of the patient's active participation throughout the day.

Therapeutic goals and treatment plans for patients should be designed with solicited input from the patient and family or significant other. Clear and achievable goals must be developed and revisited as the patient progresses or regresses in therapy. If the patient's goal is to transition to a more independent living facility (i.e., home or an assisted living facility), then the plan would be more aggressive than if the goal were to maximize function within the current living facility. In order to achieve the patient's goals, a holistic approach to care that is mindful of cognitive, psychological, and pathophysiological impairments should be used. As goals and interventions are determined, quality-of-life issues need to be considered in order to comprehensively address each patient's needs. To increase patients' ability to achieve their therapy goals, therapy sessions may need to be scheduled based on the time that is thought to be most efficient in relation to the patient's medication schedule and other events of the day, rather than the most convenient time that fits into the therapy schedule.

The patient's ability to participate in therapy may be driven by multiple system impairments. Nutritional concerns are a priority. It is important to monitor whether the patient is losing or gaining weight. Poor denture fit and the impact of medications on taste and appetite can affect the patient's ability to eat. The patient may be depressed, also limiting appetite. The patient may not want to drink because of difficulty getting to the bathroom independently. Determine whether the patient is taking a diuretic and whether he or she has urinary incontinence. Patients who have difficulty managing urination because of frequency or urgency may be less likely to drink sufficient fluids, increasing the risk for hypovolemia, hypotension, decreased cerebral perfusion, and falls.[28]

Patients with severe breathing problems, such as those with heart failure or COPD, can become extremely short of breath doing even such simple tasks as eating. Nurses and aides, as well as family and friends, can make observations about these occurrences. As much as 30% of $\dot{V}O_{2max}$ can be attributed to labored breathing, which places considerable metabolic demand on the patient simply to breathe, let alone the challenge of pausing breathing to eat. A nutrition consult can be initiated to assess the patient's caloric intake and supplement this intake if indicated.

Ineffective sleep can be a problem after surgery, trauma, or CVA. Multiple factors may be involved, but sometimes the problem is simply the fact that the required positions for sleep are driven by joint precautions or the need for joint and skin protection, rather than what is comfortable for the patient. Nurses and care staff can help by being receptive to positioning options that may increase the patient's chance for effective sleep but that still meet the criteria for joint and skin protection. If the patient has difficulty waking in the morning or has headaches or difficulty following directions, sleep apnea or other sleep disturbances need to be considered. A wide range of issues—incontinence, anxiety, depression, chronic pain, a busy environment outside the patient's door—may contribute to sleep deprivation and should be addressed.

Functional gains may be achieved sooner when physical therapy is incorporated into the patient's daily living with the help of the nurses and aides. This can improve physical capabilities by aiding the learning process, as well as increasing the number of repetitions performed for motor planning. For example, if the patient is taught to use ventilatory strategies with movement, such as inspiring when extending the trunk (Chapter 23), this should be communicated to other caregivers and encouraged during movements that extend the trunk, such as dressing. If the goal is for the patient to walk to meals, the physical therapist and caretakers can have the patient transition from walking as far as he or she can toward the dining room for one meal each day, then walking to two meals each day, and finally, to all meals. The next progression would be to set more functional goals, such as walking to daily activities, to social settings, to the car, and so on; thus walking is no longer associated only with therapy. In-services for nurses and care staff that help reinforce physical therapy interventions can be conducted individually and in formal classes. Instruction can be incorporated into the staff competencies upon hire and annually. One-on-one therapist/aide education sessions should not be replaced by the competencies; rather, they should occur as needed when unique patient needs arise. Educational opportunities such as this can help to make patient education more consistent.

When all facility programs collaborate to follow through with therapeutic goals, the patient's progress can be realized sooner. It may be helpful to make the activity department aware, for example, of patients who need extra time or help with oxygen in order to participate in activity programs. Events such as an open house for staff in the physical therapy department would allow staff members to visit and ask questions about physical therapy and to better understand what role they can serve. Offering educational materials about the physical therapy profession and patient information pamphlets may help the staff to better understand what physical therapists do for patients.

In many long-term care facilities, not all patients are on the present physical therapy caseload. Other staff members of the facility may have helpful input and suggestions for additional patients who may benefit from physical therapy. In addition to chart reviews and discussing patients with the staff, it is also helpful to screen for patients in the dining rooms, activity sessions, and halls.

Monitoring Cardiovascular and Pulmonary Status in the Long-Term Care Facility

Because of short hospital stays, patients in long-term care facilities may be less medically stable than patients in the past. With this increase in patient acuity, it is particularly important to monitor each patient's response to activity. Many long-term care and subacute facilities now provide pulse oximeters and portable electrocardiogram monitors because of increased patient acuity. In addition, physical therapists need to be competent in monitoring blood pressure and heart rates. Auscultation is highly recommended as a clinical competency (Chapter 15). When patients present with acute changes in their status, it is important to utilize any methods of telemedicine available to communicate their medical status to their primary care

practitioner. Telemedicine can range from a formal program for AICD-pacer monitoring, for example, to using a secure Internet connection to send video or audio portions of a physical examination.[29,30]

During the initial evaluation, vital signs and oximetry are taken with the patient in supine or semi-Fowler's position for baseline, then in sitting and standing positions if orthostatic measurements are indicated. It is helpful to take the baseline resting blood pressure readings on both arms to ensure they are comparable. The arm with the higher reading should be used for recording and monitoring. If the two readings differ by more than 10 mm Hg on multiple recordings, cardiovascular pathology needs to be ruled out.

Vital signs and oximetry need to be evaluated before each physical therapy session and after intervention to assess the physiological response to exercise. Blood pressure and pulse should increase proportionally in relation to the activity (Chapter 18). An increase of 20% to 30% or 20 to 30 beats above resting heart rate would be within normal limits, with a recovery time of 5 to 10 minutes. These responses can be affected by medication; therefore it is vital to know what medications the patient is taking and to understand their impact on the vital sign response.

Many patients without primary cardiovascular and pulmonary diagnoses have abnormal responses to exercise, either as a result of a preexisting but undetected dysfunction or a more recent change. Each patient must be observed closely and measured objectively to be sure he or she is responding to exercise predictably. One example is a patient who was markedly deconditioned and obese prior to total knee arthroplasty. After the surgery, with short distance ambulation, she demonstrated a dramatic increase in HR without arrhythmias, an appropriate blood pressure response, and an increase in the work of breathing and accessory muscle use. If only the heart rate or the blood pressure had been used to determine therapeutic intervention limits, the exercise response may have been misinterpreted. Patients' response to exercise and intervention should be interpreted using their overall vital sign response. It is imperative to communicate the vital sign and exercise response to the primary care practitioner with as much information as possible to avoid inappropriate medication changes.

Physical Therapy in Home

Treating patients at home poses many challenges, one being the responsibility to help the patient return to the level of function before his or her illness. Gaining sufficient information from the prior level of care can expedite the care in the home. Some areas unique to home care are the need to continually assess and adapt treatment to the patient's living space, observing and anticipating safety concerns, and identifying creative ways to improve the patient's functional independence and quality of life.

Continuity of care is an essential component of quality health care, given the trend toward earlier and earlier hospital discharge. At minimum, acute care physical therapy addresses mobility, including safety, transfers, and household-distance ambulation as the patient recovers from an illness or procedure. Breathing exercises and positioning may be used in conjunction with functional mobility to facilitate movement and recovery. Patients are often unable to extrapolate their inpatient education to all of their home setting situations. Ideally, on discharge from acute care, patients should receive a home exercise program to help them with decision-making principles as well as exercises for them to perform. Decreased endurance due to recent insult/injury and bed rest during hospitalization and possible change in medication may compromise the potential of the patient to regain his or her premorbidity level of activity and function without appropriate follow-up care. A postacute exercise program designed for the specific needs of the patient and a complete review of the hospital stay should be communicated to the physical therapist in the community.

A patient's successful recovery from acute or long-term loss of independent function is often dependent on the availability of able caregivers. Patients who have a caregiver to help them can discharge home, rather than to a facility. Caregivers are often family, friends, or paid workers who provide this service. Caregivers should be educated to measure vital signs and monitor for changes in physical status, appetite, and behavior as part of their responsibility as the caregiver. Children with chronic illness whose parents can provide care, with or without nursing staff, often return home successfully. These children tend to integrate smoothly into the community, attend school, participate in recreation, function well, and report a high quality of life. Adult sons and daughters are often the caregivers of their parents. In such cases, these adult children may have children of their own, whose needs they are responsible for. This "sandwich generation" is often torn between caring for their aging parents and for their own children.[4] It is important for physical therapists to be sensitive to the needs of the patient and the limitations of the caregiver when determining the patient's safety at home. Many older adult patients remain independent at home, some of them amazing even the most seasoned clinicians with their inventiveness and the extent of their support systems. The physical therapist serves an integral role in teaching patients and families how to manage the impact of disease and elevate each patient's quality of life to the fullest extent.

Although a physical therapist makes numerous adaptations when treating patients at home, many physical therapy interventions performed in these settings are comparable to those prescribed for outpatients of similar ages and conditions. Activities to improve safety, strength, endurance, transfers, ambulation, and tolerance for activities of daily living (ADLs) are common, and often traditional methods such as supervised repetition of tasks (i.e., transfers and ADLs) are used as they would be elsewhere. Theraband products or nontraditional physical therapy equipment (e.g., water bottles as weights) may be indicated and prescribed based on the patient's needs and abilities. For patients whose activity tolerance waxes and wanes as a result of their chronic condition, water bottles or similar household objects can provide an inexpensive and readily adjustable tool to meet the patient's needs of any given day.

Education is especially important in home care. It can be directed to the patient, family, and caregivers and is especially important in ensuring the patient's safe and independent functioning when the physical therapist is not present. Safety and medical issues can arise unexpectedly. Patients and caregivers must be familiar with the signs and symptoms that indicate a change in their condition (e.g., weakness, discomfort/

pain, shortness of breath, changes in secretions, increased fatigue, inability to perform ADLs, depression, and loss of appetite). The physical therapist should gauge the patient's and/or caregiver's ability to interpret the medication schedule, understand the prescribed parameters for oxygen use, and recognize when to rest versus when to exercise. The therapist also needs to determine the patient's ability to self-monitor his or her sign and symptom response to activity (Chapters 17 and 18) both during therapy and during independent activities. Patients and their caregivers need to be able to monitor their cardiovascular and pulmonary status to prevent overexertion and accidents. Because of potential limits in learning, it is important to check the reliability and validity of each patient's self-assessments. Caregivers and family members can be taught how to monitor the patient's blood pressure, heart rate, and respiratory rate; they can also be taught to observe for changes in shortness of breath, amount and color of secretions, presence of dizziness or lightheadedness, color changes such as cyanosis or flushed skin, diaphoresis, changes in balance during ambulation, and changes in mental status—and to report such changes promptly to the physical therapist or physician. Patients and caregivers need to know how to manage signs and symptoms, as well as when to call 911 rather than simply calling the physician's office. If there are concerns about the patient's judgment and reasoning, which may cause gaps in the patient's learning, the physical therapist should adapt the education format accordingly.[14,31,32]

Monitoring Cardiovascular and Pulmonary Status at Home

Because patients discharge to home in more acute states than they did in the past, physical therapists need to have a high level of clinical reasoning and measurement competencies commensurate with the needs of patients now being managed at home. Patients who are postoperative or who have had a recent decline in function may experience difficulty with breathing or endurance when performing ADLs. Without home-based physical therapy, the patient's full return to their premorbidity status can be jeopardized.

In the home-care setting, the physical therapist tends to be independent without the advantage of the health care team close by, even though support is available through nursing and home-care agencies. The physical therapist needs to be prepared to evaluate patients and their progress with minimal consultation and information from the management team. This specialized practice area requires foremost that physical therapists have the ability to practice independently. They often need to handle emergencies and crisis situations. As in other areas of health care, home-care practice requires physical therapists to have annually renewed health provider CPR certification. Knowledge about policies and procedures for handling emergencies, infection control, and safety is essential. Home-care physical therapists evaluate the need for referrals to other health professionals such as social workers, nursing staff, and occupational therapy. Unfortunately, problems such as abuse and neglect are not uncommon, particularly in the older adult population; thus health professionals in home care must be alert for such evidence. If the patient's condition declines or new conditions have arisen (for instance, the patient shares that he or she has been falling), the physical therapist may need to do preliminary medical screening and decide the appropriate intervention, including notification of the patient's referring provider. The patient's status needs to be monitored in relation to changes in diet, bowel and bladder habits, and mental status; such findings need to be included in frequent updates and reports to the referring practitioner. Home care is a challenging practice setting that requires astute clinical reasoning and observation skills.

Fig. 41-1 Pulse oximeter.

By using equipment such as portable pulse oximeters (Figure 41-1) and blood pressure cuffs, along with physical examination (Chapters 6, 15, and 32), the physical therapist can do much to determine a patient's ability to safely perform exercise in the home setting, although there are limitations to the depth of such monitoring and examination. In rural and underserved areas, limited resources may restrict the use of 911 service to life-saving situations only. However, with advances in communication technology, patients and home therapists can gain access to care better than ever before. Advances in chronic disease management in relation to acute changes in status, maintenance care to avoid acute conditions, and research into chronic disease impact and management have come as greater bandwidth has improved the quality of visual and auditory communication.[29] According to the National Research Council Report in 2000,[33] the Internet is often used for health information websites but is only beginning to be explored for its potential value in clinical decision making, patient education, and clinical outcome improvement—all possible because of the sharing of resources by professionals, "immediate" access to specialists, and more timely adaptations in medication doses, among other advances.

Multiple articles have found limitations in health literacy can decrease a patient's ability to understand[14] prescription instructions, exercise programs, and appointment schedules. For example, in independent studies, Harmon and colleagues[13] and Sorensen and coworkers[32] noted that patients often do not adhere to their antihypertensive medication prescription regimen for a variety of reasons: a poor understanding of the importance of the medication, limited symptoms of hypertension, and a dislike of the side effects, complicated dosing rules, and financial constraints. This underscores the importance for physical therapists to clarify whether and how patients are taking their prescribed medication; only then can therapists determine whether their patients are sufficiently medicated to safely participate in an exercise program. Furthermore,

ongoing communication between patients and their prescribing clinician needs to be fostered on a more frequent basis than is available through office visits.

The use of webcams has great potential as a communication tool for monitoring home-based exercise. This emerging resource provides patients with access to specialists that physical distance may preclude while also allowing more frequent patient interviews than would be possible with only face-to-face meetings. Webcam interviews are more revealing than phone conversations because they convey the patient's nonverbal, as well as verbal, communication. In this way, the webcam interview is similar to an office visit—perhaps even better because the patient's level of attention, or *inattention*, to self-care can often be more evident when the patient is in his or her own home.[30,34,35] Webcams can be used by physical therapists to access patients for review and upgrade of their home exercise program. In one study, pulmonary rehabilitation programs performed in an outpatient setting were compared with home programs with telemedicine access, and no statistical difference in outcomes was found.[36] Because of the convenience of the webcams, few patients in the study disliked them, but concern was raised about the potential for increased isolation. This concern would need to be addressed if webcams are to be used as a primary means of communication instead of face-to-face meetings. However, the use of a webcam *in addition* to vital sign response as a way of communicating a patient's response to exercise can help the home physical therapist to advocate for the patient's need for medical examination or medication adjustment more clearly than a phone call.

For patients with heart failure, the use of AICDs and biventricular pacemakers is more common because of advances in morbidity and mortality (Chapter 32). Emerging technology is available in some areas to allow the cardiologist not only to monitor a patient's heart rate and rhythm, but also to measure discrete changes in fluid retention that are evident before activity-limiting symptoms.[37,38] Changes in a patient's clinical examination, combined with interview questions regarding diet and bowel and bladder function, can help a clinician monitor changes in fluid retention and lab values. In cases in which a patient often presents with such symptoms, more sensitive monitoring should be used to better control the patient's disease if possible. No data point stands alone, so even when advanced telemedicine options are available, the AICD-communicated data should be analyzed in relation to the physical examination and the patient's interpretation of his or her symptoms.[39]

Regardless of whether or not telemedicine resources are available, physical therapists must continue to use their clinical reasoning skills and their patient's vital sign measurements and convey the information accordingly to achieve best-practice principles and to be the best advocates for their patients. An example that illustrates the importance of this concept involves a patient who was being monitored for his primary diagnosis post-CVA in a home-care setting. The patient demonstrated a new-onset profound fatigue and reported that his knees felt as though they would buckle. The patient had been progressing in his exercise program in each prior session without symptoms, but he had not been monitored. Once the patient expressed the feeling of weakness, however, the physical therapist recorded his vital signs at rest without symptoms and then again after the next walk with symptoms. The patient's blood pressure and heart rate dropped during the exercise. The physician was informed of all signs and symptoms as they correlated to the activity and the new presentation of weakness, which prompted the physician to order a blood test. The results showed that the patient did not have an appropriate blood level of digitalis. Medication was adjusted and the patient's signs, symptoms, and functional level improved. Had the physical therapist not checked the vital signs and instead continued to challenge the patient to work past his symptoms, serious consequences may have resulted. As another possibility, if the physical therapist had called the physician without objectively recorded signs to support the patient's symptoms, the physician may have had insufficient information to determine the best course of action and the patient may have continued to be untreated.

Special Monitoring Considerations for Patients on Oxygen

Oxygen therapy is usually prescribed for hypoxemia (low levels of oxygen in the arterial blood) or to relieve myocardial work such as in cases of severe myocardial infarction.

Typically, arterial blood gases are drawn at rest with no patient activity (unless specifically noted, as in an exercise test with a blood gas), so it is not a likely resource to use in the home setting. Generally, Medicare guidelines specify that a patient with an Sp_{O_2} of 88% or less during activity or recovery be placed on home oxygen. This value is on the steep part of the oxyhemoglobin dissociation curve (Chapter 4). Because oxygen consumption increases proportionately with exercise, a patient may desaturate if oxygen transport is compromised to the extent that it is unable to compensate or respond appropriately to increased demand (Chapter 18). For example, if a patient is on oxygen at rest and the Sp_{O_2} is 90%, he or she may desaturate because the red blood cells need to give up more oxygen to supply the exercising muscle. The patient will be short of breath, and oxygen saturation recorded with an oximeter will be abnormal. A drop below 90% is of concern.

The pulse oximeter reading is an indirect measure of arterial oxygen saturation. For otherwise healthy people, this value is at least 97% at rest, and it is clinically acceptable to maintain oxygen saturation at 90% or higher. This saturation corresponds with maintaining Pa_{O_2} generally above 55 mm Hg; below 55 mm Hg, a dramatic drop in oxygen saturation is associated with a small drop in Pa_{O_2} (Chapter 4).

Best practice in physical therapy requires a pulse oximeter for patients at home or in other facilities. If the facility or home-care agency does not have an oximeter, the medical equipment supplier can provide one.

Patients on oxygen at rest need to have their arterial saturation assessed. Oxygen is a drug, and thus needs to be ordered and prescribed appropriately. The prescription should be written with sufficient flexibility so that it can be adjusted to the patient's needs. A prescription is written to account for a range of liters of oxygen that is estimated to maintain a level of acceptable saturation. For example, the prescription may state to titrate the patient's oxygen to 4 L/min to maintain Sp_{O_2} over 90%. This is true even for people who retain carbon dioxide and whose oxygen is carefully titrated to prevent a suppression of the hypoxic drive to breathe. Strategies are used to limit risk for CO_2 retention and increase ventilation, thereby

improving signs and symptoms and reducing risk for desaturation (Chapters 29, 30, and 43).

Though patients may have oxygen established by another professional before the therapy evaluation, it is important to review a few parameters with the patient and caregiver during the course of physical therapy. First, ask patients to tell you their actual oxygen use versus what was prescribed. Next, ask whether they were instructed to adjust the level of oxygen with activity and whether they know how to adjust the dose. If they *do* adjust the oxygen level, what criteria do they use to determine that they need to adjust the dose?[31] Gaps in health literacy and awareness of risk factors can make it difficult for patients to manage their home oxygen safely.

Safety Considerations in the Home Setting

Any evaluation of a patient in a home setting involves an assessment of the patient's home layout and safety concerns. The risk for injury is increased if a patient needs to perform household tasks that trigger signs and symptoms such as overexertion. Several questions can help establish ways of adapting a patient's activity intensity and the physical environment, while also engaging the patient in decision making (Box 41-1).

Box 41-1 Suggested Questions for the Patient

- If the patient is on oxygen, does he or she have a gas stove? Do close relatives, friends, or caretakers smoke? Signs need to be posted to warn about the danger of smoking and flames around oxygen. Patients who smoke need to have this reinforced.
- Does the layout of the home need to be altered to decrease the energy expenditure? Helping patients improve the efficiency of their home layout can improve their safety and independence.
- Patients with chronic primary and secondary cardiovascular and pulmonary conditions who live alone need to make provisions if they have medical emergencies. Does the patient have an alert necklace device or a cell phone that he or she can carry in a pocket? What procedure will be followed? Does the patient know how and when to contact 911 for help? Are there neighbors or family that can regularly check on the patient?
- Does the patient have a multi-level home? Is there a bathroom on all levels? If there is not a bathroom on each floor, can the patient ascend/descend the stairs safely and in a timely manner or does a commode need to be available on some levels?
- Does the patient have the proper adaptive equipment and assistive devices? The use of a rolling walker may improve a patient's walking endurance, allowing them to walk farther without activity-stopping symptoms. Grab bars in bathrooms and toilet seat risers may be needed to reduce energy cost.
- Has the patient modified the intensity and duration of instrumental ADLs, such as laundry and dishes, or is a caretaker available if the patient does not have sufficient endurance to perform such activities?
- Is the patient's bed and bedroom furniture designed to allow safe and efficient transfers into and out of bed?

Home-care agencies often provide the support of a social worker to help patients identify resources available to them. A physician's referral may be needed, and the service is generally covered under Medicare. Although these guiding questions are not exhaustive, they provide a basis for part of the assessment and evaluation.

Exercise and Activity at Home

For patients managed at home, the baseline tolerance for activity and exercise is often low, particularly in those with primary and secondary impairments of the cardiovascular and pulmonary systems. Establishing an exercise program with these patients can be challenging, especially when the patient is inactive or has attempted exercise before with unsuccessful or unpleasant results. Exercise is then less likely to be effective as a therapeutic intervention, and another approach may be necessary to address the patient's need for increased activity for functional and health reasons.

The physical therapist needs to consult with the patient so that exercise is incorporated into daily activities and interests that the patient enjoys, such as playing with grandchildren, gardening, walking, or visiting family and friends (which may involve walking to and from the car, as well as several transfers).

The frequency and intensity of these activities may be minimal initially and increase commensurate with improvement in conditioning. The patient's program is progressed accordingly in conjunction with feedback from the patient. Self-monitoring (perceived exertion and heart rate) and input from the patient should be encouraged. Some patients purchase their own oximeters and use them to monitor their saturation at rest and during activity.

The physical therapist ensures that patients can perform the exercises and ADLs safely and independently (with the appropriate device or caregiver support) while properly and accurately monitoring their own condition and modifying the intensity or distance appropriately with fewer and fewer prompts from the physical therapist. Once patients do this reliably, they or she can pursue activities of their choice, which hastens progression of therapy goals. Also, patients who actively participate in their own rehabilitation will more likely be effective in generalizing the skills learned to their daily life.

Home Oxygen

Home oxygen devices include oxygen concentrators, tanks, and liquid oxygen systems (Figure 41-2, *A*, and Chapter 43). Multiple extensions of oxygen tubing may be needed to enable patients to navigate throughout their homes—for instance, going to the bathroom, maneuvering in the kitchen, and walking to the living room (Figure 41-2, *B*). Although the presence of oxygen in the home is a safety concern that the home-care physical therapist needs to address, long tubing allows for proper oxygen delivery. Compensated flow meters measure the amount of oxygen that reaches the patient, and problems such as kinks are shown by a reduced flow reading. Some portable oxygen systems, particularly demand oxygen systems, may not deliver the amount expected (Figure 41-2, *C*). Thus a pulse oximeter is needed to ensure that the patient's

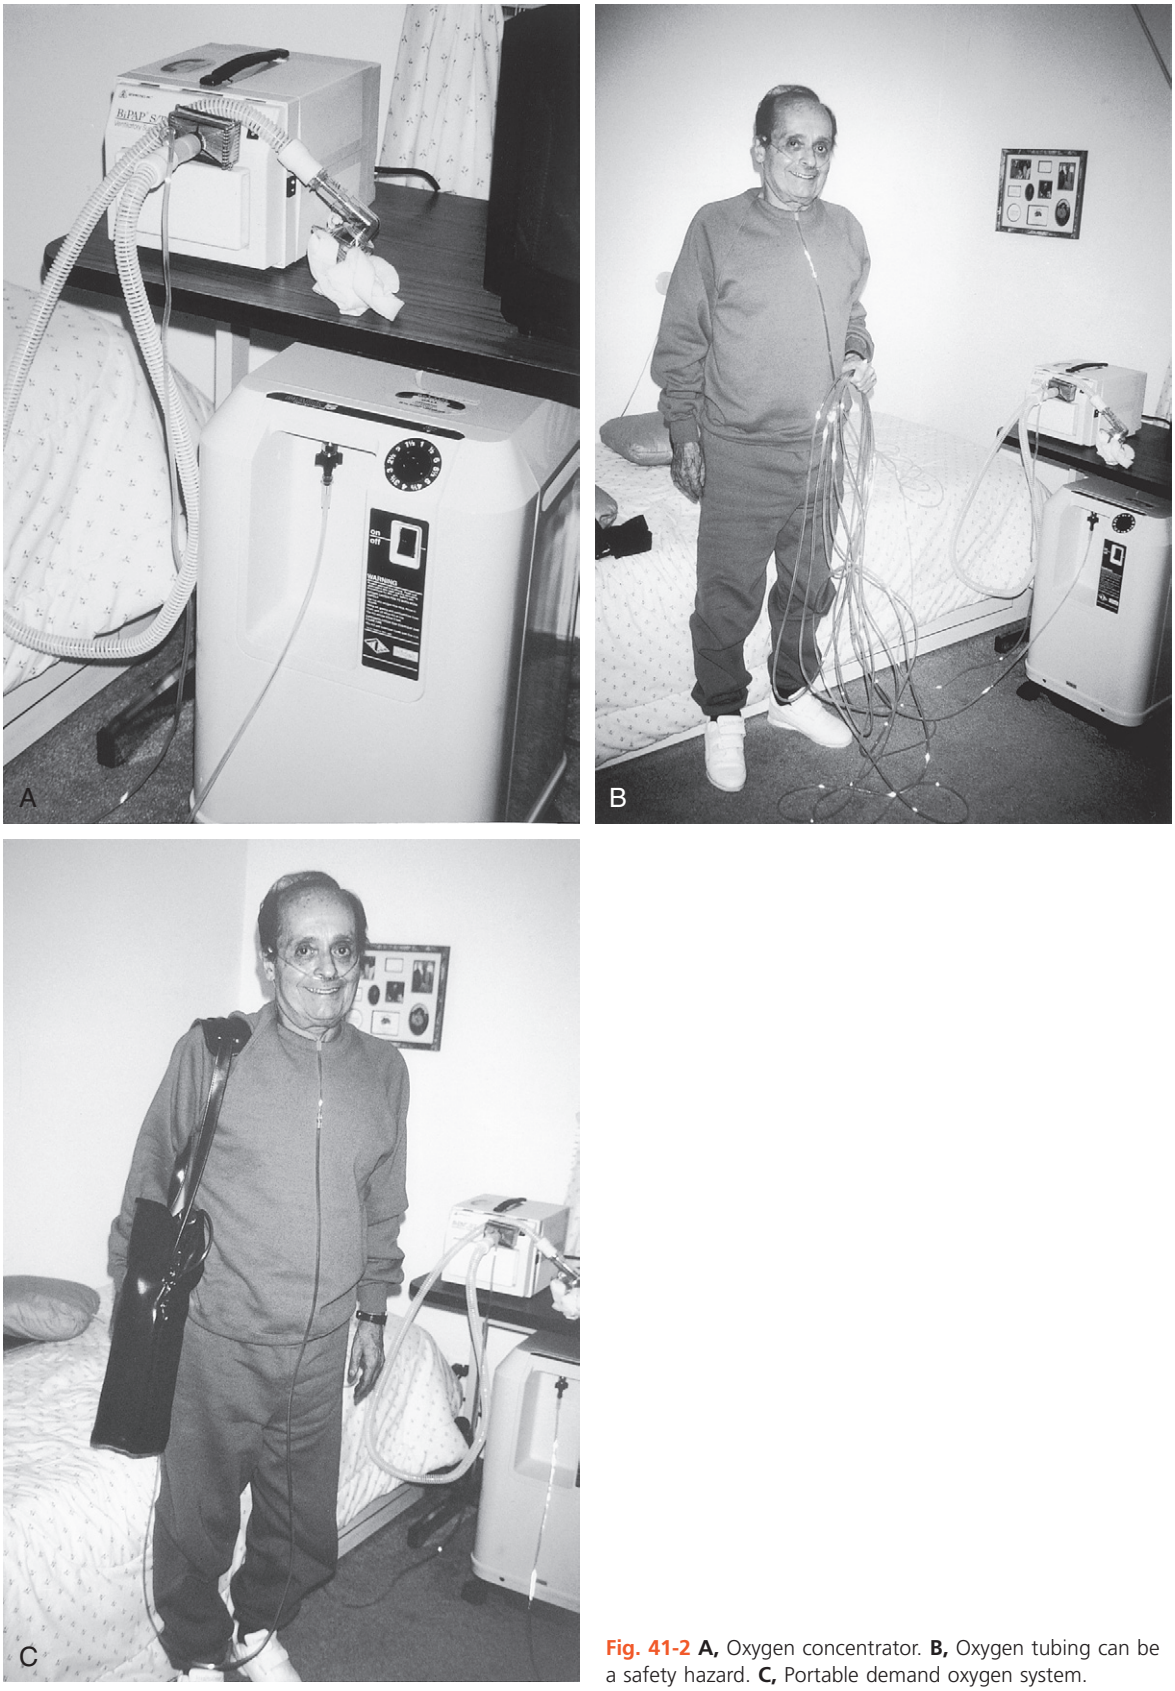

Fig. 41-2 A, Oxygen concentrator. **B,** Oxygen tubing can be a safety hazard. **C,** Portable demand oxygen system.

Fig. 41-3 Nasal CPAP machine.

arterial saturation is acceptable. Patients are taught to coil the tubing or use a similar strategy to minimize the risk for tripping. To minimize the need for long lengths of tubing, some patients use more than one tank or concentrator.

Patients with sleep apnea may use nocturnal nasal continuous positive airway pressure (CPAP) (Figure 41-3) or biphasic continuous positive airway pressure (Bi-PAP), which provides varying levels of ventilator assistance at night. A Bi-PAP machine allows the patient to rest and assists ventilation by providing pressure support on inspiration and exhalation. The patient is encouraged to use the machine at night in particular. Although the patient may have difficulty adjusting to the nasal CPAP, he or she will adapt to the assistance and appreciate its benefits.

Documentation

Functional outcomes consistent with the ICF have become as important as outcomes associated with limitation of function and structure (Chapters 7 and 17). Both short- and long-term goals are linked to functional outcomes that enable patients to be safe and as mobile, functional, and independent as possible in the care setting in which they live. The Guide to Physical Therapist Practice (published by the American Physical Therapy Association) defines practice patterns within the cardiovascular and pulmonary areas to use as a reference to establish goals and treatment plans.[40] Goals for patients with cardiovascular and pulmonary conditions, primary or secondary, are typically more detailed than, for example, being able to walk a specific number of feet with a particular device. Goals should also include quantifiable measures of quality—for example, rating of perceived exertion, dyspnea scores, and demonstration of symptom management during functional tasks.

Documentation needs to show progress toward the functional outcomes that the physical therapist has developed with the patient. The cardiovascular and pulmonary systems need to be optimized for the patient to reach maximal outcomes. When functional outcomes are met, the patient is reassessed to determine whether he or she can accomplish more or whether active therapies in the home or long-term care setting need to be replaced with a maintenance program. Patients with chronic conditions should be reexamined periodically to determine whether changes in their disease warrant further therapy. Patients may also progress to a higher level of function that could be managed at an outpatient level of care.

Documentation is the basis for reimbursement. Third-party payers read therapist documentation to determine the examination findings, evaluation, and plan of intervention for the patient. These notes are their primary means of determining a patient's overall status, including functional outcomes and quality of life. For patients who require long-term physical therapy, thorough and accurate documentation is vital to communication with third-party payers to increase the likelihood that patients will be able to receive the services they need. Teamwork that includes the patient in the decision making and goal planning has become a focus of optimal management in recent years.[23] Written and verbal communication is vital to the exchange of information and the targeted and timely progression of care to meet patients' ongoing and often-changing needs. One rule of thumb must always be remembered: "If it wasn't written, it wasn't done."

Support for People in the Home or Community

An important part of achieving optimal health upon returning home or settling into a new living facility is having the necessary social and emotional supports. Hospital stays or new functional limitations can often cause patients to think of themselves only as patients, solely defined by their medications, symptoms, and diagnoses. Family and friends can help prevent this. Close social ties help to keep patients connected to memories and situations that define them as individuals.

Support can also be found with people who have similar diagnoses or limitations. Support groups and networks are

often formed in the community and, increasingly, on the Internet. Such groups can be important resources for patients, regardless of the support they receive from family and friends. Peers in these groups may be the only people who fully understand what the patient is going through; support from these peers, as well as the opportunity for the patient to support others in return, can help inspire physical and emotional gains.

Peer groups, in person or over the Internet, can be valuable resources to help patients with chronic conditions make choices concerning their health and life situations.[41-46] Many websites and blogs offer free information or may request a nominal fee for membership for patients, health professionals, and supporters to receive newsletters and information in the mail. They host grassroots efforts such as conferences and informational sessions on self-care management and patient empowerment. These support groups publish newsletters that discusses research and provide tips from people living with chronic conditions to help share evidence-based information. These organizations inform people that they are not alone and steer them towards resources that can help with decision making as they strive for optimal health.

Many patient-friendly websites are available for people with COPD and other common chronic conditions, all of which are easily accessed through various search engines or by exploring the links sections of related websites. **Box 41-2** lists examples of websites that may be helpful to people with chronic conditions and their families or caregivers.

Therapeutic Goals for Home-Care Patients with Cardiovascular and Pulmonary Dysfunction

To be independent at home, patients with cardiovascular and pulmonary dysfunction should strive toward achieving all of the following:

- Understand the dysfunction or condition and how it results in the changes in signs and symptoms that affect daily functioning.
- Acquire the necessary adaptive equipment and assistive devices for use in the home and community.
- Acknowledge functional limitations (e.g., do not push limits without monitoring responses) to ensure safety.
- Adhere to medication regimens and the direction of physicians and other health professionals. Discuss what is working well—and what is not—and collaborate to find better solutions and interventions.[14,32]
- Arrange for caregivers to safely and consistently provide assistance as needed.
- Learn preventative care strategies (e.g., prevent pulmonary infections and do not increase salt/water intake if on cardiac precautions or taking steroids).
- Learn ventilatory strategies to increase comfort and function (Chapter 23).
- Learn to self-monitor for signs of impending difficulty (e.g., increased shortness of breath, swelling in ankles, productive cough, changes in mucus, decreased urine output, or rapid weight gain of 2-3 pounds per day).
- Pace activities and use energy conservation strategies and rest periods to accomplish more with less physiological demand.
- Optimize nutrition and hydration and notify health professionals about increases or decreases in weight.
- Seek referral to a dietitian as needed to understand the impact of food choice on health and function if knowledge deficits are affecting health promotion.
- Develop a social support network to provide emotional support when needed.
- Increase general exercise both in terms of a specific exercise program and in completing the necessary tasks of the day to continue functional gains.

Summary

The physical therapist can promote optimal health for patients with chronic and short-term illnesses who live in various community settings. A patient's path to optimal health involves patient education on effective methods of self-monitoring during activity, adherence to medication regimen, and use of multiple available resources to achieve a higher functional level. Education methods using shared decision making[23] can improve patient risk factor reduction, nutrition, and overall functional level more effectively and efficiently than methods in which the patient is not actively part of the solution. People living with chronic conditions can live more safely and independently at home if given sufficient education in a format in which they can understand the goals and expectations before them. As health professionals, physical therapists recommend modifications of patients' home environments and offer tools to use to best achieve their functional independence and fit their lifestyle based on the best available research. Patients' participation in such recommendations is vital to improve the degree and longevity of their progress toward optimal health. If patients are to be successful in living independently in the home setting, they need to be independent in their judgments and activities. Physical therapists must respect patients' choices and decisions, while sharing their own experience, therapeutic judgment, and expertise. The home setting can be a particularly rewarding practice experience, although at times it can be challenging. One thing is certain—if you ask a patient

where he or she wants to be, the answer is almost always the same: "There's no place like home!"

Review Questions

1. What are some common problems patients in the community may experience?
2. What role do preexisting cardiovascular and pulmonary conditions play in a new diagnosis or trauma (e.g., CVA or hip fracture)?
3. What are some common and unique situations or concerns particular to patient care delivery in (a) a nursing home, (b) an assisted living center, and (c) home care?
4. What role can a physical therapist play in optimizing the patient's self-management in each of the settings listed in the previous question?
5. Describe how cardiovascular and pulmonary function can be monitored in long-term care and in home care.
6. What instructions and considerations should be provided for a patient on oxygen?
7. How can caregivers and family members be incorporated into the management of patients with chronic conditions in the home and in a long-term care setting?

Body mechanics can be defined as the efficient use of one's body as a machine and locomotive entity. When working with critically ill or chronically dependent patients, physical therapists frequently change patients' body positioning before and during treatments to facilitate ventilatory potential and improve patient outcomes. Therapists and nurses attempting to position or move dependent patients need to understand and use proper body mechanics.[1-5] This knowledge is necessary to maximize treatment outcomes and to reduce biomechanical stress and trauma for the patient and for those working directly with the patient. Low back pain is the most common cause of work-related disability among employees younger than 46 years, and nurses and physical therapists account for over half of the annual prevalence of low back pain among health care personnel.[6,7] Positioning and moving dependent patients is an art that is quite different from working with a patient who can move independently and assume any given position with ease. In this chapter, the principles of body positioning and moving dependent patients are discussed.

Positioning for Optimal Ventilation

Because of the three-dimensional nature of breathing, one of the therapist's most important goals is to facilitate chest excursion in all three planes of ventilation: anterior-posterior, superior-inferior, and lateral.[8] This can be accomplished by improving the length-tension relationships of the muscles used in inspiration.[9,10] Massery[8] reasons that proper positioning to enhance inspiratory muscles will accomplish the following:

1. Improve the length-tension relationship of the accessory ventilatory muscles involved in that posture.
2. Incorporate a passive stretch of the chest wall.
3. Use the natural coordination of the trunk-chest wall movement with inspiration and exhalation patterns to maximize movement.

The following are some common improvements that can be incorporated into normal positioning.

Supine Position

All activity is performed within the field of gravity. Patients in a supine position may find breathing difficult because they must overcome gravity to move the chest wall with each breath. Using towel rolls or pillows to facilitate a better position may improve the patient's ventilation, both its ease and capacity. Positioning alternatives, however, need to be applied with each patient's comfort and tolerance in mind.

Upper chest expansion can be increased by removing pillows from under the patient's head to increase thoracic

extension. This will increase the length-tension relationship of the neck accessory muscles (scalene and sternocleidomastoid muscles). Increased movement will be noted in the upper chest in the superior and anterior planes.[8] Further anterior expansion may be achieved with a towel roll placed longitudinally at the vertebral spine to open the anterior chest of a patient who tends toward excessive flexion of the trunk (Figure 42-1, *A*).

If the patient needs support under the head to achieve a neutral chin tuck to protect swallowing ability, a thin pillow or horizontal towel roll under the occiput can be used (Figure 42-1, *B*).

External rotation of the shoulders with the scapulae in a neutral or retracted position will stretch the pectoralis and intercostal muscles. This may improve lateral and anterior chest wall movements.[10,11] If a patient has full range of motion (ROM) and is comfortable with the arms placed overhead or in full flexion/abduction/external rotation for maximal stretch, this is the optimal position for potential maximal excursion of the anterior chest wall (Figure 42-1, *C*). If there are major shoulder limitations, moderate shoulder abduction with forearm supination may be the best position available to facilitate chest excursion. Whenever significant limitations are found, the therapist should try to modify the position to accommodate the patient's needs and achieve optimal ventilation.

Side-Lying Position

Side-lying is an optimal position that may improve breathing patterns. At the same time, medical professionals should continue to heed the need for prescriptive rather than routine patient positioning. In side-lying, gravity is eliminated for anterior expansion and the diaphragm moves freely, particularly the upper hemi-diaphragm, which is not having to shift the abdominal contents as much as the lower hemi-diaphragm. Such a position may be optimal for preterm infants who, when placed in a side-lying or prone position, have been shown to have fewer stress behaviors, resulting in longer periods of sleep with less fussiness and crying.[12] However, side-lying positions can also result in decreased forced vital capacity and forced expiratory volume lung measurements and may not be optimal for patients with risks for cardiopulmonary compromise.[13] A specific example of the need for prescriptive rather than routine positioning of a patient in side-lying involves a patient with pneumonia or atelectasis. If a patient has right lower lobe pneumonia or atelectasis, side-lying on the unaffected left side will improve oxygenation. Conversely, side-lying with the affected side down will cause a decrease in oxygenation (differential shunt) because a patient with decreased ventilation receives more perfusion to the down lung with more shunting.

In side-lying, the patient's hips and knees should be flexed and supported for comfort. The upper extremities can be moved up and away from the body to allow for free movement of the upper chest wall. A pillow can be used to support the upper arm anteriorly, or the patient can be placed in a three-quarter supine position with a pillow behind the back to support the uppermost arm. If the patient has full ROM and is comfortable, a butterfly position of the arms can be used. This tends to expand the rib cage, lengthen the pectoral muscles, and facilitate inspiration.

Prone Position

Prone positioning can improve oxygenation with minimal untoward effects in several patient populations, including those who are critically ill and medically unstable, such as preterm infants, patients with acute respiratory distress syndrome (ARDS), and patients with hypoxemic acute respiratory failure.[12,14-23] Oxygenation is improved with prone positioning when compared with supine positioning via more homogenous lung inflation and alveolar ventilation,[24] but some cases with concomitant difficulties have been reported. One instance of severe hypotension was noted in a child with scoliosis, pectus excavatum, and neurofibromatosis who presented for a spinal fusion. It is recommended that sternal pressure be avoided in patients with chest wall deformities.[25] Early enteral nutrition is poorly tolerated in critically ill patients receiving invasive mechanical ventilation in the prone position. Medication can be given to enhance gastric emptying and prevent vomiting. Feeding the patient in the prone position becomes challenging if the patient is mechanically ventilated as well.[26]

When a patient is mechanically ventilated and has numerous tubes and monitors, turning him or her to the prone position takes planning and is staff intensive. Although turning a patient prone may be difficult, reviews of related studies report that prone positioning may reduce the absolute mortality of severely hypoxemic ARDS patients by approximately 10% in addition to improving their oxygenation by 27%-39%. However, the reviews also suggest that long-term prone positioning can expose patients with less severe ARDS to unnecessary increased risks for pressure ulcers, endotracheal tube obstruction, and chest tube dislodgement.[24,27] Thus body positioning requires careful prescription of not only the specific positions, but also the time the patient spends in those positions, which is largely response dependent.

Upright Postures

Upright postures create challenges to breathing by adding the components of balance and an unsupported spinal column. Many patients, however, spend prolonged periods of time in their wheelchairs or in other situations in which they are sitting or standing. Patients with poor trunk support may sit in a slumped position, which decreases tidal volume and minute ventilation. Approximating erect upright sitting postures may improve pulmonary function and better breathing support for functional activities.

Pelvic alignment is a key component to optimal posture. A relatively anterior tilted pelvis in healthy, flexible adults may reduce the kyphotic curve in the thoracic spine, adduct the scapulae toward a neutral position, produce a more neutral or externally rotated upper-extremity position, and pull the head back into a neutral chin tuck.[28,29] The anterior tilt of the pelvis may improve upper-extremity ROM and ventilation. Attending to this one consideration may be all that is needed to improve the breathing capacity of some patients, allowing them to continue to advance in their exercise programs or rehabilitation. Further benefit may be achieved with a lumbar roll.

Another simple means of attaining an anterior pelvic tilt in sitting is to have the patient lean forward over his or her legs, then slide a towel roll horizontally just behind the ischial

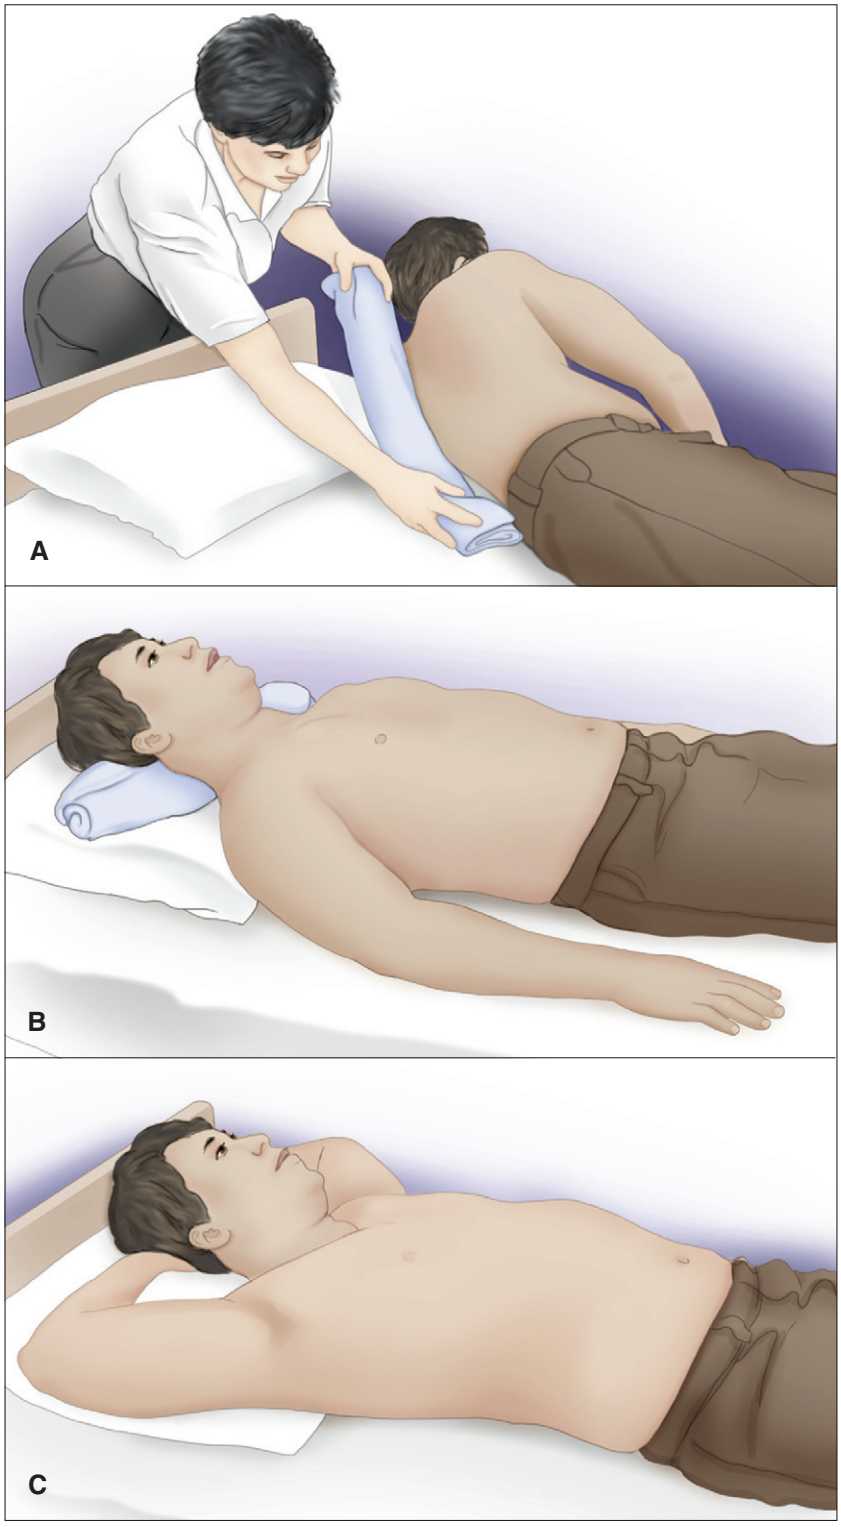

Fig. 42-1 A, Placement of a vertical towel roll. **B,** Increased openness of the anterior chest wall with the vertical thoracic towel roll and the occipital towel roll combined. **C,** Butterfly position with a thoracic towel roll to open the anterior chest.

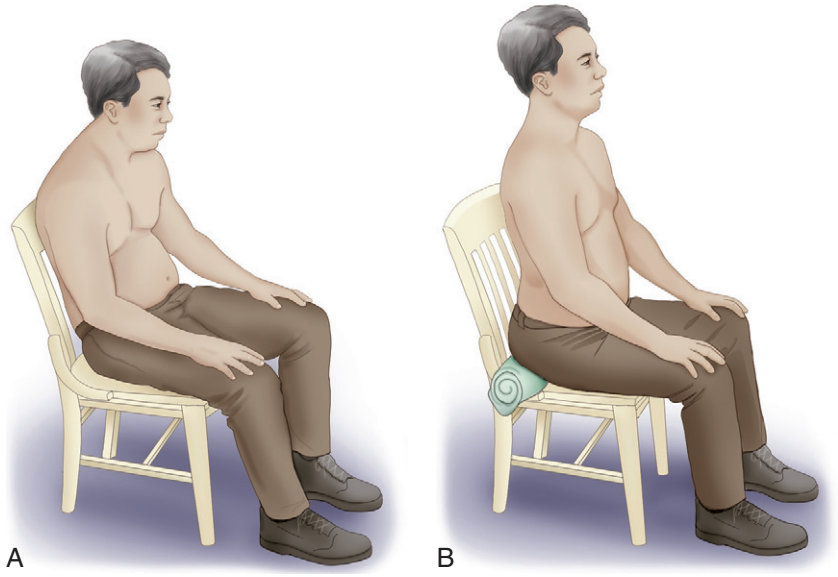

Fig. 42-2 A, Unsupported upright position of a patient with T1 paraplegia. Note the posterior pelvic tilt and excessive thoracic kyphosis with resulting collapse of the anterior chest wall. **B,** Ischial towel roll to support the pelvis in anterior tilt in a patient with T1 paraplegia. Note the changes in the thoracic spine and open anterior chest wall, as well as improved head and neck alignment.

tuberosities, which can prevent the pelvis from tilting posteriorly (Figure 42-2).[30] This can be well tolerated by patients with intact sensation and a pelvis that is at least minimally mobile. For patients with neurological impairment who have impaired sensation or less pelvic mobility, a wedge can be substituted; however, some sliding may occur.

In addition to a relatively anteriorly tilted pelvis, a posture of anterior trunk inclination (forward-lean) with arm bracing has been shown to increase ventilatory capacity.[31] Such positioning has resulted in higher values of maximal respiratory pressures and respiratory muscle endurance in patients with chronic obstructive pulmonary disease.[32] This forward-lean position with arm bracing posture (as in sitting with elbows on knees or a table) improves diaphragmatic function by reducing abdominal tension,[33] facilitating expiratory muscle action (such as that of the external oblique abdominis), and enabling arm and shoulder girdle muscles (such as the pectorals and serratus anterior) to act more effectively as accessory muscles of inspiration.[34]

Neutral Alignment of the Head and Shoulders

A vertical or horizontal towel roll may also be used with wheelchair positioning to better align the shoulders and head into neutral position. The anterior chest wall is also likely to be less compressed in this position.

A neutral head and neck position is important for patients with impaired speech volume or endurance and for patients with swallowing or aspiration impairments. A neutral chin tuck may optimize the length-tension relationship of the vocal folds, minimize vocal strain, and improve protective airway reflexes.[8] Vertical head alignment may also help to reduce airway resistance and maintain normal breathing rates, thereby helping to ensure optimal contribution from the diaphragm without compensation from chest wall inspiratory muscles.[35]

It is vital to evaluate the positioning of the patient's shoulders. Internal rotation of the shoulders and scapular protraction may restrict expansion of the upper chest. On the other hand, external rotation of the shoulders may increase upper chest wall movement and thoracic extension.[11] Clinically, lung volumes may improve when patient positioning is carefully considered. Often small, seemingly insignificant changes may augment the patient's clinical outcomes in conjunction with other therapeutic activities. If unattended, these small factors may impede patient outcomes. Body positioning is vital to improving ventilation as well as functional skills.

Lifting and Moving Dependent Patients

There have been changes in the concepts and principles of lifting. As discussed, the body was historically thought of in terms of a machine. Improper mechanics of lifting was thought to place disproportionate load on the discs. The key components of lifting were to "keep it close," "bend the knees," and "lift with the legs." Over 20 years ago, a shift in thought occurred, and since then spinal posture has been the focus of safe lifting.[36]

Lifting is a fundamental human activity. In practice, the therapist begins with slightly bent knees and the patient rears backward as the therapist extends his or her knees and starts to lift the patient's gluteal area first. Injuries seem to occur with the back in flexion. The rationale for a therapist having strong core muscles is to promote safe lifting. Abdominal strength is necessary to support the pelvis during lifting. Commercially available lumbar and abdominal elastic supports are widely used. These provide additional abdominal wall support, as well as serving as a reminder to the therapist to lift safely. Care needs to be taken to ensure these supports are worn properly and replaced when worn out. Another lifting

principle is maintaining the lordotic lumbar curve when lifting. This technique is used by weight lifters.

Lifting techniques may need to be modified because of factors such as limited space (e.g., small hospital rooms), clothing issues, or health conditions of the health care team members (e.g., degenerative knee joints).

A primary consideration when applying appropriate body mechanics during lifting is proper posture and balance (body stability), specifically with respect to the relationship between gravity, posture, and body stability (Figure 42-3). Gravitational force is exerted in a vertical direction down toward the earth's center. In addition, that point in a patient or object at which all of its mass is centered is called the center of gravity (the point at which the patient's maximum weight is concentrated). When standing, the body's center of gravity is located at approximately 55% of the body's total height from the ground: in the pelvic cavity, slightly anterior to the upper part of the sacrum. The lower a person's center of gravity, the greater his or her body stability. Consequently, when the body lifts a patient or an object, muscular effort needs to increase sufficiently to maintain stability and lift against the force of gravity because the lifter's center of gravity is displaced toward the object. Therefore the therapist can conserve energy and maintain stability by bearing the weight of the patient (or object) as close to his or her own center of gravity as possible. This allows the lifter maximum concentration of energy toward movement of the patient and minimal stress or injury. To facilitate a lift, the bed should be adjusted so that the lifter can reach the patient comfortably. Usually, adjusting the bed to the lifter's hip level is adequate. This places the patient close to the lifter's center of gravity.

Most lifting should be done with the legs (knees) as opposed to lifting with the arms and back to minimize biomechanical strain (Figure 42-4). Whenever there is a question about a single therapist's ability to lift a patient alone, assistance should be obtained either from another health care professional or by an assistive device such as a mechanical lift.[37]

Another consideration in lifting is the base of support of the lifter. The base of support is defined as the area between the feet, which provides the body's stability. The wider the base of support, the greater the body's stability. To expand on this point, it is necessary to define the line of gravity and its relationship to body stability. The line of gravity is an imaginary line passing through the center of gravity of an object and perpendicular to the surface on which the object (body) rests (see Figure 42-3). The closer the line of gravity passes to the center of the base of support, the greater the body's (object's) stability. Muscular effort is directly related to the distance that the line of gravity is shifted from the base of support.[38]

The guidelines for patient lifting are summarized below.

- The lower your center of gravity, the wider your base of support, and the nearer the line of gravity falls to

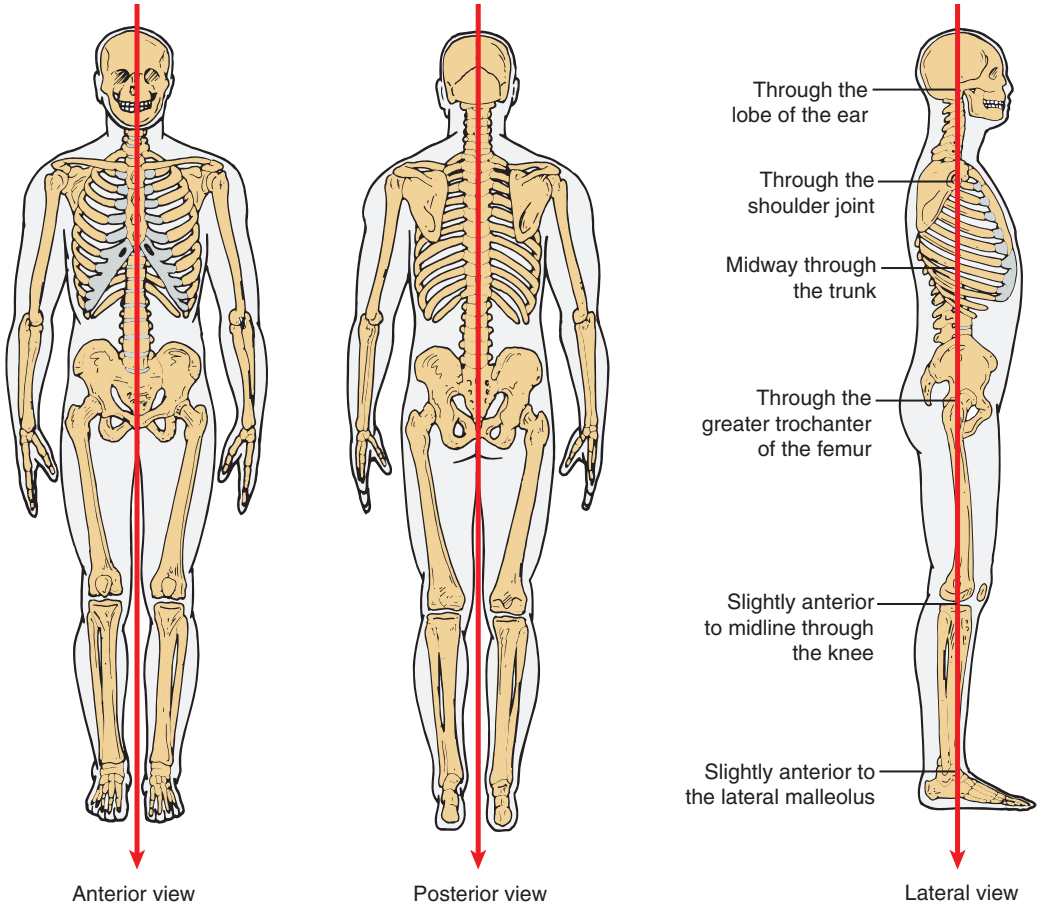

Fig. 42-3 The line of gravity passes through the center of gravity and the base of support to maintain body stability. *(From Cameron MH, Monroe LG: Physical rehabilitation: Evidence-based examination, evaluation, and intervention, St Louis, 2008, Saunders.)*

Fig. 42-4 Reach work level by bending the knees and hips rather than the back. Lift with the legs! This can also be done with a full double-knee squat similar to techniques by weightlifters.

Fig. 42-5 The patient should be prepared for a position change: knees bent, arms crossed over chest, and head lifted up to reduce friction between the patient's body and the bed.

the center of your base of support, the greater your body's stability. When lifting, stand with your feet apart, knees slightly flexed, and one foot forward. Keep your head and trunk aligned.

- When a body is used as a machine, the external weight on which it works displaces the body's center of gravity in the direction of the weight being lifted. To conserve energy and maintain stability, carry the weight as close to your center of gravity as possible. Lower your hips to the level of the surface supporting the weight you plan to lift by flexing your hips and knees. Adjust the bed as high or low as you need for comfortable and efficient work.
- The effort required to perform an activity depends on the weight of the object to be lifted. Know your limits. Do not attempt to lift alone if you have any doubt about your ability to do so.
- Other general tips for lifting are as follows (see Figure 42-4):
  - Lift with your legs. Keep legs in a position that permits them to supply most of the force for shifting your trunk.
  - Do not attempt to lift with your arms and back.
  - When lifting, avoid rotation of the spine. Shift your feet into a position that supports the patient's weight shift when moving or lifting the patient.
  - Stabilize your body against a stationary object whenever possible.
  - For efficiency, coordinate the move by using a synchronized verbal expression that is understood by therapists and patient—for instance, "one, two, three, lift."

One additional consideration must be noted—moving against the resistance of friction. Friction is defined as a force that opposes the movement of one object over the surface of another. Friction is reduced as the amount of surface-area contact between two objects is reduced.

When moving a patient side to side or up and down in bed, the therapist or nurse attempts to reduce the contact between the patient's body surface and the bed. The use of a turning sheet placed just above the patient's shoulders and extending to just below the patient's hips will help reduce such friction. Strategies for shifting a patient in bed include crossing the patient's arms over his or her chest or abdomen, having the patient flex the knees and hips, and asking the patient to flex the neck and raise the head as he or she is lifted (if the patient is unable to do this, the therapist or nurse can assist) (Figure 42-5).

Moving Dependent Patients

I. Moving the patient up or down.[39-40]
   A. Using a turning sheet (Figures 42-6).
      1. Sheet should cover the patient from shoulders to hips.
      2. Gather sheet material as close to the patient's body as possible.
      3. Hold at shoulders and hips with a flexion pattern (see Figure 42-6, *B*).
      4. Cross patient's arms over his or her chest; have the patient flex knees and hips.
      5. Ask the patient to raise his or her head if possible.
      6. Synchronize action by counting "one, two, three, lift."
      7. Shift weight from one leg to the other rather than lifting up and pulling on back.
   B. Without a turning sheet (up or down), more than one lifter may be needed.
      1. Follow basic procedure: cross patient's arms, ask patient to lift head, flex knees and hips.

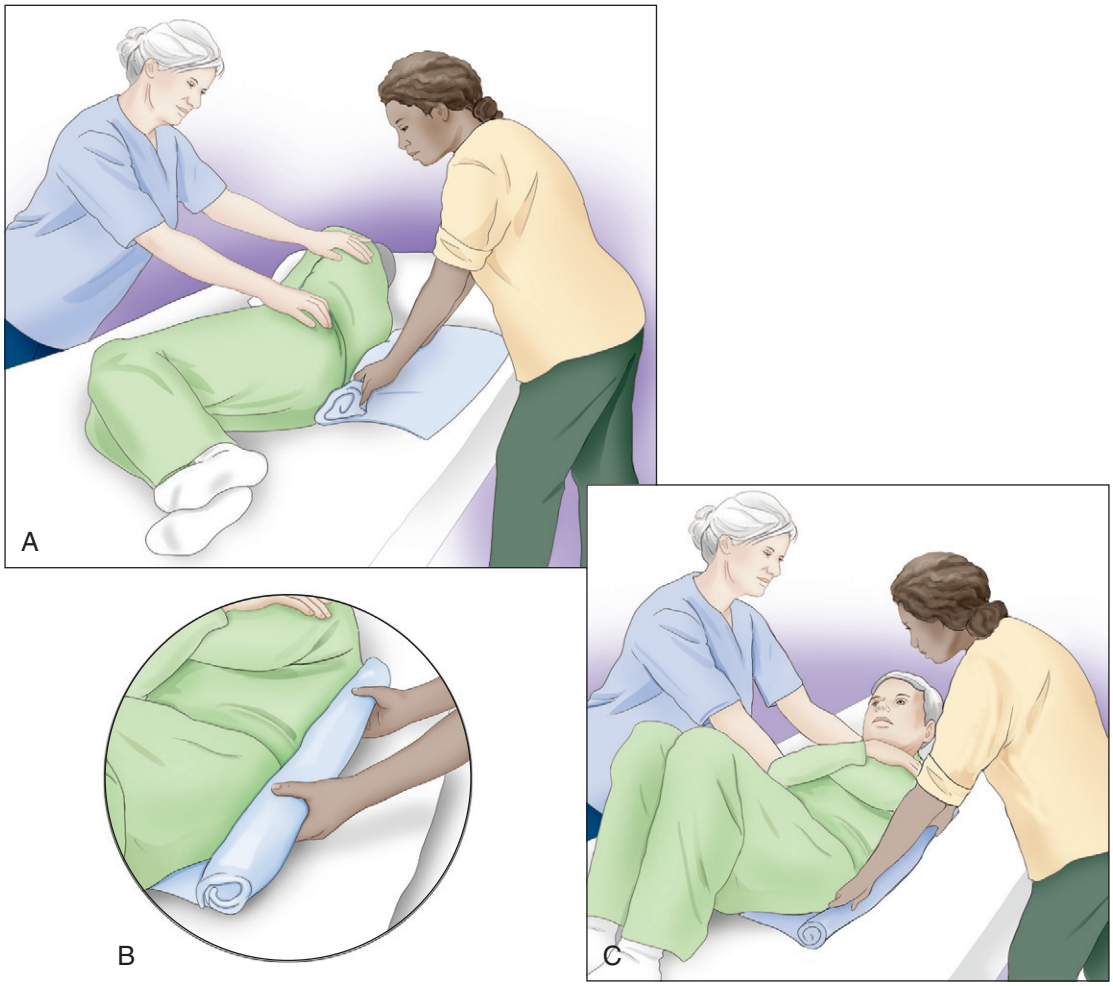

Fig. 42-6 A, To insert the draw sheet, the patient is turned onto his or her side and the half-rolled draw sheet is tucked under the patient (from just above the shoulders to just below the hips). The patient rolls over the draw sheet and it is pulled out behind him or her. **B,** The draw sheet should be rolled close to the patient's body. A flexion hand grip at the patient's shoulders and hip is most efficient. **C,** Moving the patient toward the head of the bed. The patient is prepared. The therapist is positioned to move toward the head of the bed in order to shift his or her body weight to move the patient.

2. The therapist places his or her hands and forearms under the patient's shoulders and hips.
3. If patient is extremely heavy or tall, another person can bend knees and assist.

II. Moving the patient to the side of the bed.
   A. With turning sheet.
      1. Cross patient's arms and other body parts toward the side to which the patient is to be moved.
      2. Therapist places his or her hands at the patient's hips and shoulder on material close to the patient's body.
      3. One therapist pushes, and the other pulls.
   B. Without turning sheet.
      1. Both therapists stand on the desired side.
      2. One therapist's forearms go under the patient's shoulder; the other's go under the patient's hips.
      3. Synchronize action by counting "one, two, three, pull."

III. Turning the patient onto his or her side.
   A. With turning sheet (to right side) (Figure 42-7).
      1. Move the patient supine to the opposite side of the turn (e.g., if turning onto right side, move the patient to the left side of the bed).
      2. Bring the patient's right arm to the side at a 90-degree angle up and away from the body.
      3. Place the patient's left arm across the chest.
      4. Place the patient's left leg over the right leg.
      5. Pull the sheet at the patient's back to turn.
   B. Without turning sheet (to right side).
      1. Move patient to opposite side (therapist's hands and forearms under patient's shoulders and hips).
      2. Use steps 2, 3, and 4 above.
      3. Roll patient to right side by pushing or pulling patient's left shoulder and left hip.

IV. Turning the patient prone (e.g., roll to right side) (Figure 42-8).
   A. With or without turning sheet.
      1. Move the patient to the opposite side of the bed from the side toward which he or she is turning.
      2. Cross the patient's left arm and left leg over the body.

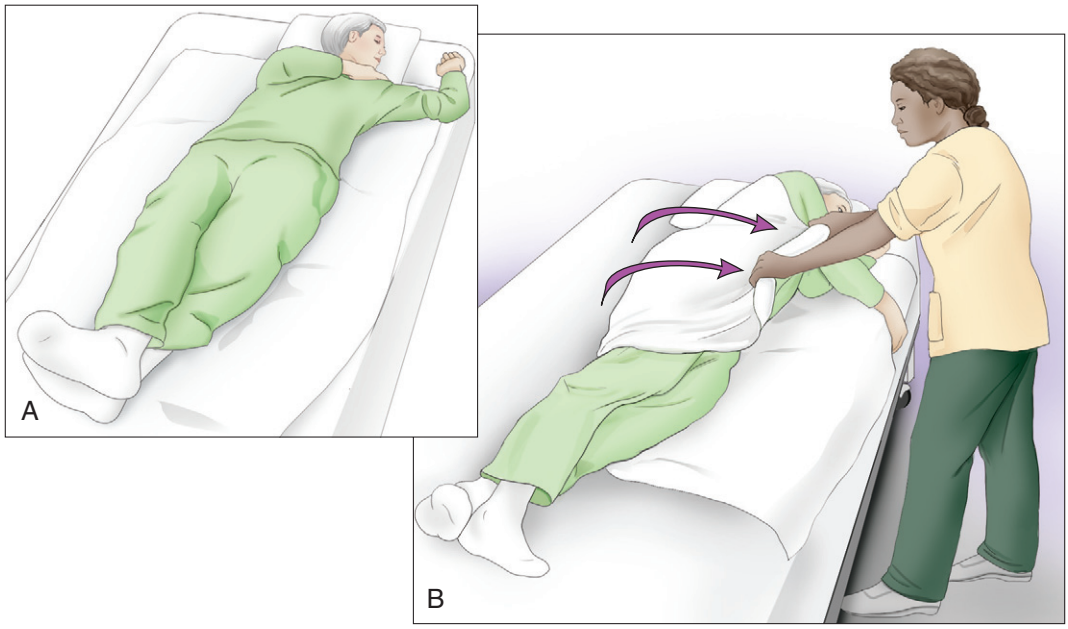

Fig. 42-7 **A,** Preparation for the patient to turn onto his or her left side: move the patient to the right side of the bed, position his or her left arm up to the side at a 90-degree angle, cross the right leg and arm over his or her body, and turn the patient's head to the left. **B,** A one-person turn to the right side using a draw sheet. The patient's body position is the same as for the turn to the side. The therapist is positioned with one foot forward, the other back. The therapist pulls the sheet with his or her hands positioned at the hips and shoulders of the patient.

Fig. 42-8 Positioning the patient prone (example: rolling to the right side). The patient's right arm is tucked in at his or her side with the left arm and leg crossed over.

3. Tuck in patient's right hand and arm at the body side as close as possible.
4. Push or pull on the patient's hips and shoulders to turn.
5. Free both arms; do not allow the patient to lie on the arm or hand.
6. A pillow may be placed under the patient's hips and lower legs to bend the knee and relieve strain of the patient's back at the lumbar spine.

Summary

Positioning and moving patients are integral functions of physical therapy. To be effective for the patient and safe for both the patient and practitioner, these functions need to be considered as clinical skills and performed systematically. Therapists and nurses need to analyze their physical activities in relation to the principles of efficient movement and the proper application of body mechanics before moving a patient. A "tube index," counting and identifying each technical attachment (e.g., IV, Foley catheter, arterial blood gas stent, or chest tubes), should be taken before moving a patient. Extra care needs to be taken to prevent dislodging important medical equipment—it could be a life-threatening situation if ventilator tubing in a patient were inadvertently extubated. The practical application of body mechanics has the potential not only to conserve energy and minimize strain to muscles and joints but also to enable the patient to be moved with the least discomfort or pain. Such strategies will help protect members of the health care team directly involved with positioning and moving the patient, as well as maximize patient safety.

Review Questions

1. What factors would determine the number of staff members needed to position a patient who is mechanically ventilated into a prone position?
2. How can changing a patient's position affect ventilation?
3. How can the therapist use towel rolls and easily accessible equipment to improve a patient's position and potential for improved ventilation?
4. What ventilation/perfusion changes occur when a patient is turned from the "affected" side down to the "unaffected" side down?
5. Can positioning be considered a clinical competency when it accomplishes a treatment goal? Discuss.
6. How could positioning to reach a therapeutic goal be documented?

Proper care of the pulmonary patient involves an interprofessional team approach for optimal patient outcomes. In order to maximize patient care, each team member should have a working knowledge of the scope of practice of every other professional on the team. As respiratory therapists, physical therapists, occupational therapists, speech therapists, physicians, and nurses apply their expertise in providing care for pulmonary patients, it becomes evident that coordinated teamwork is essential for patients to reach their full potential. The purpose of this chapter is to provide an overview of respiratory care principles and modalities frequently encountered in various settings for the other health care professionals who collaborate with physical therapists. Also discussed is the physical therapist's interaction with various modalities and pieces of equipment. A knowledge and comfort level with respiratory care modalities and equipment will relieve anxiety and promote effective and safe interventions. Physical therapists focus on patient interventions routinely; however, they need to know exactly why each patient is receiving respiratory treatment, why particular monitoring systems are chosen, and why patients respond to various interventions that are utilized.

Oxygen Therapy

The atmosphere contains 20.95% oxygen, the most essential element needed to sustain human life. Oxygen exerts a partial pressure of 159.6 mm Hg at sea level (dry air) and approximately 97 mm Hg (Torr) in arterial blood. The normal range,

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

as measured by arterial blood gas (ABG) analysis, is 80 to 100 mm Hg (Torr). Under normal circumstances, oxygen molecules travel from the atmosphere to the mitochondria at the cellular level, where it is used to produce ATP in a process called aerobic metabolism (oxygen transport mechanisms). The oxygen transport pathway involves the airways and lungs, heart and peripheral vasculature, and the muscle tissue in which the mitochondria reside. Any process that inhibits the transport of oxygen from the atmosphere to the cellular level can cause hypoxemia, decreased patient function, and, ultimately, death.

When oxygen is prescribed, it should be considered a drug. A particular dosage must be ordered by a set prescription. In general, physical therapists do not instruct patients to increase or decrease medication they are taking without a physician's order. Some practices have standing orders that allow the health care team to change oxygen settings by following a standardized protocol. For example, a prescription may be for 1 L/min of oxygen by nasal cannula at rest titrated up to 6 L/min to keep oxygen saturation above 90%. Although higher-flow oxygen cannulas can deliver increased liter flow, it is more standard in practice to increase titration according to a prescribed protocol.

Patients with cardiovascular and pulmonary impairments frequently need oxygen supplementation.[1] Respiratory care practitioners and the nursing staff are generally responsible for administration of this drug under a physician's order. Therapists have a variety of methods from which to choose to deliver oxygen in the most effective way (individual methods are discussed later in this chapter). Long-term oxygen therapy for patients with chronic obstructive pulmonary disease (COPD) who are hypoxemic has been reported to improve quality of life and life expectancy.[2-5] However, even though the benefits of long-term oxygen therapy have been established, U.S. congressional mandates for competitive bidding and caps in rental agreement programs have led to cutbacks. As a consequence, the dose of oxygen and its mode of delivery may need to be modified at rest and during activity.[6] This is an issue of significant concern. As practitioners working with patients requiring oxygen, physical therapists need to advocate for their patients to ensure that they receive appropriate oxygen therapy.

The purpose of oxygen therapy is to treat and prevent hypoxemia, excessive work of breathing, and excessive myocardial work.[7] Although individual oxygen appliances offer suggested guidelines regarding oxygen administration, the only way to ensure effective delivery from a given device is by blood gas monitoring of Pa_{O_2} (partial pressure of oxygen in the arterial blood) or monitoring hemoglobin saturation by oximetry. Medicare and third-party payers have specific indications for oxygen therapy. These indications may differ and physical therapists need to identify these in the practice setting and provide the documentation required for patients to receive the oxygen they need. Initially, a patient may need oxygen only with higher levels of activity or exercise; that needs to be documented by an exercise test that shows desaturation by oximetry. As a patient's disease progresses, continuous oxygen may be indicated. Careful monitoring of patients will determine when the need for continuous oxygen occurs. Oxygen therapy is usually administered by one of two methods: low-flow or high-flow systems.

Low-Flow Systems

A low-flow oxygen system is one that is not intended to meet the total oxygen requirements of the patient (does not deliver atmospheric oxygen concentration to the patient). For example, using a normal minute ventilation (minute ventilation = tidal volume [TV] × respiratory rate [RR]) of 8 L/min (500 mL × 16 breaths per minute) with a patient receiving 1 L/min of oxygen, the patient is breathing 8 L/min but the device only provides 1 L/min. Thus 7 L/min are contributed from room air. Each time there is a change in the patient's breathing pattern, tidal volume, and respiratory rate, the fraction of inspired oxygen (Fi_{O_2}) may also change. Ideally, for efficient use of a nasal cannula, the patient should have a normal tidal volume, respiratory rate, and breathing pattern. This is often not the case, but the cannula is used because it is well tolerated by the patient. This method of oxygen delivery is not used when a specific concentration of oxygen is needed.[8]

Nasal Cannulas

The nasal cannulas (also called nasal prongs) are one of the most common low-flow devices encountered because of low expense and high patient compliance (Figure 43-1). This device supplies an Fi_{O_2} of approximately 24% to 40% oxygen with flow rates from 1 L/min to 6 L/min. Flow rates greater than 6 L/min can cause nasal mucosal irritation and drying. The approximate liter flow and resultant Fi_{O_2} values are shown in Table 43-1.

Nasal cannulas deliver 100% oxygen; however, this percentage significantly lessens as the oxygen mixes with inspired air from the room. The amount of oxygen delivered depends on the flow rate and the ventilatory pattern of the patient. A larger minute volume (TV × RR) would dilute the oxygen at any given flow rate and cause a greater decrease in the percentage delivered to the lungs. In other words, the faster and deeper a patient breathes, the more diluted the oxygen becomes. On the other hand, if a patient has a low minute volume, the oxygen percentage delivered increases.[7] If precise control of Fi_{O_2} is needed, the nasal cannula should not be used.[9] In these cases a high-flow system (i.e., a Venturi mask) may be used.

Skin integrity, especially behind the ears, needs to be evaluated because the pressure of the cannula can cause skin breakdown. Patients at times will pull on the cannula or take the oxygen off. It is important to check for skin breakdown behind the ears, especially if patients are not able to communicate.

Fig. 43-2 From left to right: Mask without bag, partial rebreathing bag, nonbreathing bag. Note the valves on the mask and at the junction between the mask and bag.

Mouth-breathing by patients using a nasal cannula typically causes concern from some of the health care team. This concern, however, may be unnecessary. If the nasal passages are unobstructed, then oxygen is able to collect in the oral and nasal cavity (anatomical reservoir). On inspiration, the oxygen collected in this area is drawn into the airways and lungs. If a patient with a nasal cannula is mouth-breathing, the practitioner should ensure the nasal passages are unobstructed. If there is concern that the patient is not receiving adequate oxygen, a blood gas or oxygen saturation measurement should be obtained. If this is not feasible, or if the patient is unable to breathe through the nose, it may be appropriate to switch the patient to a mask.

The patient should be encouraged to breathe through the nose to receive maximum benefit from the nasal cannula; however, mouth breathing does not mean the patient will not receive appropriate oxygen.[10] Clinically, it is found that some patients who mouth-breathe do so because of nasal polyps, sinus congestion, deviated septum, or other physical issues. If the work of breathing is increased when the patient tries to breathe through the nose, it may be counterproductive.

Simple Mask

The simple mask is another commonly used low-flow oxygen-delivery device. It can deliver from 40% to 60% oxygen, depending on the flow rate and the patient's ventilatory pattern. This device requires a flow rate of 5 to 6 L/min to prevent rebreathing carbon dioxide and excessive respiratory work.[11] As with the nasal cannula, this type of oxygen delivery method should not be used if precise control of oxygen concentration (Fio_2) is required because the simply mask is still considered a low-flow oxygen system.

Partial Rebreathing Mask

The partial rebreathing mask is basically a mask with a reservoir bag attached. The oxygen source supplies the bag with 100% oxygen, which then mixes with exhaled anatomical dead-space air that has not taken place in gas exchange. This exhaled air is rich in oxygen. The exhaled air that has taken place in gas exchange and contains CO_2 is vented through the open port on each side of the mask. This mask can deliver oxygen concentrations from 70% to more than 80%. It requires flows between 7 and 10 L/min to keep the bag from fully collapsing during inspiration.[7]

Nonrebreathing Mask

Another low-flow delivery device, the nonrebreathing mask, also contains a bag reservoir, but it can deliver up to 100% oxygen. This mask has valves on the reservoir bag and side vents. This feature prevents ambient air mixing on inspiration and exhaled air mixing on expiration. For this mask to operate effectively, a good seal between the patient's face and the mask must be achieved. The bag should partially deflate during inspiration (Figure 43-2).

Transtracheal Oxygen Catheter

Another form of low-flow oxygen delivery is the transtracheal oxygen catheter. This has been used for pediatric and adult patients.[12,13] It is a cannula that is surgically placed into the trachea via a small incision between the second and third tracheal rings. Generally these devices are used by patients at home who need continuous oxygen therapy. Transtracheal oxygen catheters are more efficient than nasal cannulas, and they have a high patient acceptance rate with low complications.[14] Because the oxygen is administered directly into the trachea, 50% less oxygen is needed.[7] For people who use portable oxygen systems and for those who require high oxygen flow rates, transtracheal oxygen catheters may be beneficial.[15] The catheter can be covered by the patient's clothing and is therefore cosmetically appealing. Complications such as plugging of the catheter and subcutaneous emphysema have been reported.[16,17] These complications may be avoided with proper care of the catheter, good hydration, and maintenance as directed by the patient's health care team. The transtracheal procedure is not routine in many practice settings; thus if a patient is interested in this form of oxygen therapy, it is wise to find a team that has done the procedure frequently enough to become highly skilled at it.

High-Flow Systems

A high-flow oxygen delivery system delivers a specific oxygen concentration (FiO_2) despite the patient's ventilatory pattern. This system delivers atmospheric oxygen pressure to the patient, which means that the entire volume that is breathed is delivered through the device. A patient requires oxygen delivered at specific FiO_2 of 50% to keep the arterial oxygen and oxygen saturation at a safe level, then a high-flow system is the method of choice. If a patient has CO_2 retention and a hypoxic drive to breathe, a high-flow system with an exact FiO_2 can be used. This is often the case when a patient with COPD who is a CO_2 retainer has pneumonia and goes into respiratory failure. The physician wants to provide adequate oxygen to the patient and avoid having to mechanically ventilate. The ideal choice would be a high-flow device at a lower FiO_2 to prevent CO_2 retention while not reducing the hypoxic drive to breathe. Unfortunately, patient tolerance of the high-flow oxygen-delivery mask, which covers both the nose and mouth, is often less than optimal. Patients who are acutely ill and very dyspneic or those who have decreased cognitive awareness may tolerate the mask, but as these patients begin to improve, they may have a claustrophobic reaction to the mask and the high flow of gas.

Venturi Mask

The Venturi mask is a common method of delivering high-flow oxygen concentrations from 24% to 50%. This mask operates via the Venturi principle, which provides for a mixing of 100% oxygen and entrained ambient air. The oxygen flows though a narrow orifice at a high velocity, causing a subatmospheric pressure. This drop in pressure is what causes the ambient air to be entrained through a port. The size of the port determines the amount of air that is entrained, thus the percentage of oxygen delivered. The Venturi mask has a rotating air entrainment port that allows the health care provider to "dial in" the desired FiO_2 (Figure 43-3). Flow rates of 40 to 80+ L/min provide minute ventilation at rates that are higher than those the patient could breathe without assistance; consequently, the mask provides the entire inspired atmosphere to the patient. This means that regardless of the patient's respiratory rate, tidal volume, or breathing pattern, the oxygen delivery (FiO_2) will be consistent.

Mechanical aerosol systems also operate via air entrainment, but the mask is connected to the aerosol unit by large-bore tubing to allow a specific FiO_2 to be delivered with high humidity (Figure 43-4). Although drainage bags are usually attached to the tubing to collect condensation, the tubing must be monitored for possible pooling of water, which causes flow obstruction to the patient. If partial obstruction occurs, a mild back pressure results in the tubing, causing less air entrainment. This means that a higher concentration of oxygen results and potentially a higher dosage of oxygen than desired may be delivered to the patient.

Portable Oxygen

As health care continues to move out of the hospital setting and into the home, more health care practitioners will provide care to patients who require oxygen in their homes. When this is the case, it is essential that a sign be posted about the use of oxygen in the home. Patient teaching before hospital discharge should include a discussion of safety concerns—for example, not cooking with a gas stove, not smoking, and allowing anyone to smoke in the home (or anywhere around the patient). In addition, it must be made clear to the patient that oxygen is considered a prescription medication and thus the amount of oxygen delivered should not be changed unless ordered by the doctor.

Oxygen is most commonly provided in the home for those patients with long-term oxygen needs, usually patients with COPD who are hypoxemic. Generally 1 to 2 L/min is prescribed via nasal cannula, but the flow rate will depend on the patient's need.

Home oxygen-delivery systems include high-pressure oxygen cylinders, low-pressure liquid oxygen,[18] and oxygen concentrators.[8] Additional options include continuous flow versus demand or pulsed oxygen delivery.[19-21] There are also a number of oxygen-conserving devices from which to choose.[22] When a continuous system is changed to either a demand or pulsed system, or when a new oxygen-conserving device is started, the patient must be monitored carefully. Clinical experience has shown that some patients may not tolerate the same liter flow with a pulsed system, and oximetry and perceived exertion must be evaluated when there is any change in oxygen delivery. The oxygen delivery may not be as effective as a continuous flow device when changing to a pulsed oxygen system. Unfortunately, there is no mandate for clinical testing of the devices before they come to market, so documented effectiveness of one versus another in clinical use is not available.[23]

Heliox, a combination of 21% oxygen and 79% helium, has been used in acute care for patients who have upper airway obstruction and increased work of breathing (spontaneously breathing patients, as well as those on a ventilator). However, use of heliox has not been widespread because of its cost, which has been estimated to be 13 times that of oxygen. Heliox for portable oxygen and home use has been documented as effective for patients with asthma and COPD. It has been shown to decrease airway resistance and decrease the work of breathing and has also been effective with patients who have increased mucus secretions. Studies have demonstrated an increase in patients' ability to exercise using heliox; however, it has not been shown to significantly decrease dyspnea.[24-26]

High-pressure oxygen tanks are not used as frequently as are low-pressure tanks, but they are used in some settings. High-pressure tanks come in various sizes. The larger ones, such as the H and K sizes, are used as a base unit or reservoir. Long oxygen tubing connected to these tanks allows for patient mobility. Smaller tanks (such as E cylinders) are used for portability and can provide up to 3 hours of use depending on the liter flow of oxygen. Some systems allow for the smaller tank to be refilled by transferring gas from the larger reservoir tank. The primary concern with the high-pressure tanks is guarding them against tipping over. They must be well tied and secured because if a tank tips over or falls, the neck that holds the regulator could break. If this happens, the high pressure inside can propel the tank at a very high velocity, causing damage to surrounding structures and posing a danger to anyone around. The tanks are usually tied to a bed, put in a standard box, or secured on a portable wheeled cart. Thus the high-pressure tanks are difficult to move and maneuver, especially up and down stairs, making their use less than optimal for most patients, especially those who wish to be more active. In terms of cost, the high-pressure tanks are less expensive overall, but deliveries and replacements need to occur regularly.

Liquid oxygen, a low-pressure oxygen delivery method, tends to be more convenient than the high-pressure oxygen tanks, especially for active patients on oxygen. The canisters are lightweight and allow patients to be away from the home reservoir for up to 8 hours. The downside is that liquid oxygen costs more and, with heavy use, the reservoirs may need to be filled up to twice a week. If high flows are needed, these units are not recommended.

Oxygen concentrators are commonly used in the home health setting, especially because Medicare offers coverage for these devices (Figure 43-5). They are electrically powered and create oxygen by drawing ambient air across a semipermeable membrane, separating oxygen from nitrogen. They generally operate at 2 L/min and provide FiO_2 90% oxygen output. Long oxygen tubing, up to 50 feet, allows patients extra mobility. Patients using concentrators should have a back-up device, such as a portable tank, in case of a power outage. In addition, the electrical power company should be notified of any patient who is using oxygen by concentrator so that the patient's location is designated as a high priority for backup and restoration of power if an outage occurs.

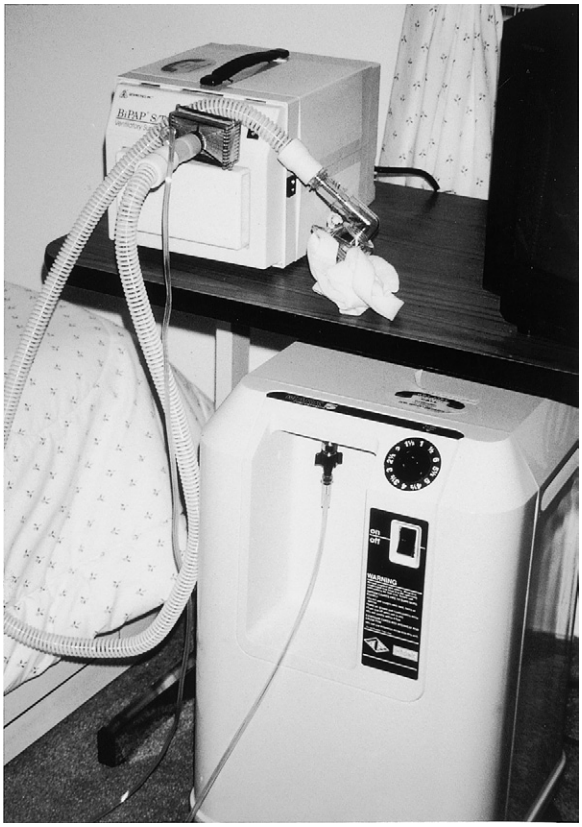

Fig. 43-5 Oxygen concentrator.

The local fire department should also be informed of any patient who is on oxygen therapy, especially if the patient is limited physically. Oxygen devices will not "explode," but oxygen does support combustion. As noted, high-pressure tanks, if knocked over, have a tremendous force due to the pressurized oxygen and there have been reports of these tanks going through walls. Firefighters, or any emergency personnel, should be informed that oxygen is in use so that in the case of a fire or other emergency, they are aware of this potential danger.

Continuous (Constant) Positive Pressure Breathing

Continuous positive airway pressure (CPAP) is oxygen delivered with pressure above atmospheric pressure (i.e., positive airway pressure). Whereas normally during the respiratory cycle there is a negative pressure during inspiration, the pressure curve in CPAP is always above atmospheric pressure (positive pressure) on the airways.

CPAP may be used to improve oxygenation[27,28] in patients for whom the usual means of oxygen delivery is not effective or for those with obstructive sleep apnea.[29] Sleep apnea and COPD often occur together; recently, recognition of when "overlap syndrome" occurs there is higher mortality than either disease process alone.[30] CPAP has also been used to help the transition of weaning patients from mechanical ventilation,[31] including infants who have had cardiac surgery. CPAP can help stabilize these infants and normalize their spontaneous breathing pattern.[32] It has also been useful in the management of respiratory distress in premature babies and decreases the need for invasive mechanical ventilation.[33] Early intervention using CPAP in older patients with cardiogenic pulmonary edema has also been effective.[34] Quality-of-life predictors have been shown to be positive a year after initiation of CPAP; improvement was noted at 3 months after initiation of CPAP and continued at 1 year.[35,36]

Patients who are mouth breathers may have difficulty adjusting to CPAP, thus rendering it less effective in these cases. Those with moderate to severe sleep-disordered breathing have been found to be less adherent to CPAP therapy than are who are nose breathers. This is related to a leak that compromises the CPAP.[37]

Use of Oxygen to Improve Exercise

Oxygen has been shown to increase exercise performance in patients with COPD who have moderate to severe airflow obstruction and mild hypoxemia at rest.[38-40] It has also been shown to benefit patients with COPD who are nonhypoxemic at rest.[41,42] Breathlessness is the most common symptom that limits exercise tolerance. Oxygen supplementation will often provide an increased driving pressure of oxygen, which allows the patient to decrease the work of breathing.[43] Peripheral muscle weakness has been found in many patients with COPD. Improving exercise tolerance will result in improved muscle strength and endurance. Another consideration, if hyperoxia is not enough, is the use of noninvasive positive pressure (NPPV). This is still somewhat controversial and requires more study, but in this author's clinical opinion, NPPV can be very beneficial.[44] As previously discussed in this chapter, heliox has been shown to improve exercise tolerance in patients with asthma and COPD who have upper airway obstruction, inflammation, and increased mucus secretions.

Noninvasive ventilation will be discussed later in the chapter, but it is interesting to note that in some pulmonary rehabilitation programs it is being used in addition to supplemental oxygen with very positive results. The combination of oxygen and noninvasive ventilation was shown to be better than supplemental oxygen alone.[45] The rationale for this improvement when using both oxygen and noninvasive ventilation is that in patients with severe COPD, the ventilatory muscles can be "unloaded" and this may promote higher levels of exercise.[46]

Additional Respiratory Modalities

Incentive Spirometry

Incentive spirometry (IS), also called sustained maximum inspiration (SMI), is a visual and/or audio feedback device that encourages slow, deep inspiration (Figure 43-6). Generally this treatment is performed frequently, up to every hour, and its purpose is to treat and prevent atelectasis and pneumonia, especially in postoperative patients who are considered a high risk for postoperative complications.[47-51] In many acute care settings, IS is done routinely. Several articles challenge the routine use of IS and have found that the addition of IS added no benefit to breathing exercise postoperatively.[52-55] In a study of patients scheduled for lung resection, when a combination of inspiratory muscle training and IS was performed before and after lung resection, there were significant lung function improvements in FEV_1 that were higher postoperatively than preoperatively.[52]

There may be potential benefits to using IS with patients with neuromuscular and musculoskeletal impairments as

Fig. 43-6 Incentive spirometry device in use.

well. They often demonstrate a decreased vital capacity and decreased chest wall mobility. IS devices encourage deep breathing and a sustained inspiration. During the sustained inspiration, collateral ventilation can occur as well-ventilated areas of the lung equilibrate with areas that are poorly ventilated. This is an area for future research, perhaps combining inspiratory muscle training and IS.

Many commercial incentive spirometers are available. Some are focused on volume, others on flow rates. Regardless of the type, the importance of patients using them should be stressed. Patients with COPD may have these devices prescribed when they are undergoing surgical procedures. Care must be taken not to have patients continue to use them when the acute episode is over. Patients with COPD have air trapping, which can be made worse by using an incentive spirometer and will not take deeper breaths needed to prevent respiratory problems post op when they have pain.

Airway Clearance Devices

Several airway clearance devices are currently available. These are discussed fully in Chapter 21.

Humidity and Aerosol Therapy

Humidity Therapy

Under normal circumstances, when inhalation takes place, air becomes 100% saturated with water vapor before entering the lower airway tracts below the carina. This humidification process is important to mucus production, ciliary activity, and a healthy respiratory tract. When this normal humidification process is interfered with, such as in patients with endotracheal or tracheostomy tubes, other methods of adding moisture to the respiratory system must be employed.

Humidification is the addition of water vapor in its molecular form to a gas. When a dry gas is administered to a patient (e.g., via a nasal cannula), some type of humidification appliance is used to prevent unnecessary complications. Flows of 2 L/min or less may not require humidification when using a nasal cannula. Humidification therapy is also indicated in the presence of thick tenacious secretions and when an artificial airway is in place. Artificial airways, such as endotracheal and tracheostomy tubes, bypass the normal humidification system (the upper airway); therefore supplementation is essential.[56]

There are basically two types of humidifiers. Bubble-through humidifiers are those that are generally used with simple oxygen appliances. The passover type of humidifier is usually found in conjunction with a mechanical ventilator. Both bubble-through and passover humidifiers are available for ventilators,[57] and they are usually heated to warm the humidified air to body temperature before it enters the airway.[7]

Aerosol Therapy

An aerosol is created when a suspension of liquid or solid particles exists in a gas. Two common forms of aerosol medication delivery in the clinical setting are the small-volume nebulizer (SVN) and the metered-dose inhaler (MDI). A bland aerosol is administration of water or saline solution to the patient's lungs.[58]

In general the goals of aerosol therapy are to hydrate dried retained secretions, to improve cough efficiency, to restore and maintain function of the mucociliary escalator, to deliver medications, and to humidify gases delivered through artificial airways. The MDI is strictly used for medication delivery (see Chapter 45).

Other forms of aerosol delivery are the spinning disk (such as in a room humidifier or mist) and the ultrasonic nebulizer. Both of these are electrically powered as opposed to the SVN, which is pneumatically powered (Figure 43-7).[59]

A key element in aerosol delivery is particle size. The size of the aerosol particle will determine its ability to penetrate the airway before depositing or raining out. The therapeutic range is considered 1 micron, with the smaller range of particles having the greatest penetrating ability. The larger particles deposit sooner. If they are greater than 5 microns, then the chances of entry into the airway are less. The particles may deposit in the nose and proximal airway. The greatest amount of alveolar deposition (95% to 100%) occurs in the 1 to 2 micron range. On the other hand, aerosol particles smaller than 1 micron are so stable that they may not deposit at all.[7]

Although particle size is important in determining appropriate deposition, a patient's ventilatory pattern is probably more important in that it is the more variable and controllable of the two. Gravity also plays a factor, and it too can be used to benefit particle deposition. Patients should be sitting up as much as possible while taking slow, deep breaths with a short 3- to 4-second inspiratory hold. Mouth breathing is encouraged if aerosol therapy is delivered by mask. Nasal breathing may filter out particles of optimal size. Not all patients will be able to achieve this position and ventilatory pattern, and the therapist must modify accordingly.

Comparisons between the ability of SVNs and MDIs to deliver medications have found that the MDI is either equal in efficacy or outperforms nebulizers. Significant cost savings are also realized by those institutions that recognize MDI usage as an effective means of aerosol medication delivery over SVN.[60]

To further enhance the efficacy of the MDI treatment, the recommendation is that a spacer or holding chamber may be attached to hold the aerosol particles before inhalation. This

Fig. 43-7 Commonly used spacer device.

device allows greater drug particle deposition to the airways and reduces oropharyngeal deposition.[61] Ventilator patients who are receiving drug aerosol therapy also receive greater benefit from an in-line MDI with a holding chamber compared with a jet nebulizer.[62]

Aerosol-Therapy Precautions

It should be mentioned that there are hazards associated with aerosol therapy. Bronchospasm may occur as the smooth muscles of the bronchial passages react to foreign particles entering the lung. Shortness of breath and respiratory distress may also occur as a result of dried retained secretions swelling and occluding portions of the lung. Cross contamination is a concern in that aerosol devices may harbor organisms that can be transmitted to patients. Frequent equipment changes and proper sterilization and cleaning techniques are key in preventing this occurrence.

Intermittent Positive Pressure Breathing

Intermittent positive pressure breathing (IPPB) continues to be used in some settings, but there is little evidence to support its efficacy as a treatment modality.[58]

This particular technology was developed during World War II to assist pilots breathing in unpressurized cabins at high altitudes. IPPB subsequently became a very popular respiratory therapy device in the 1960s and 1970s (Figure 43-8). Its use began to decline in the 1980s. In 1983 the National Heart, Lung, and Blood Institute reported that IPPB has limited therapeutic benefit. This clinical trial is only one of several studies that show IPPB is an outmoded medical technology. Research dating back to the 1950s questions the efficacy of this device.[63]

The purpose of the IPPB machine is to increase alveolar ventilation, improve the ventilation-perfusion ratio, mobilize and facilitate expectoration of thick secretions, decrease the work of breathing, and deliver aerosolized medications. It is a pressure-cycled ventilator that, when triggered by a patient's inhalation, delivers ambient air or oxygen to the patient until a preset pressure is reached. It is basically a lung expansion device that helps deliver an increased tidal volume. IPPB is used for a variety of pulmonary conditions, and treatment sessions usually last 10 to 15 minutes.

The modality of IPPB comes into question in the clinical setting because it has not been shown to provide benefits over that of other simpler respiratory treatment methods. It also introduces potential complications and hazards that the other treatments do not. Typically, IPPB has been used to treat asthma, COPD, and postoperative atelectasis; however, other therapies, such as IS, airway clearance techniques and devices, and aerosol therapy, tend to prevail as the treatment of choice over IPPB, which is virtually no longer used. This discussion is included because IPPB is the precursor to mechanical ventilation.

Although the use of IPPB is questionable in regard to its clinical efficacy, it may be a beneficial form of treatment in acute asthma or COPD that is refractory to standard therapy, atelectasis that has not responded to simpler therapy, and the prevention of respiratory failure in patients with kyphoscoliosis and neuromuscular disorders.[64]

Mechanical Ventilation

Many disease states that lead to cardiac and/or respiratory failure will require mechanical ventilation to support the patient's effort to ventilate and oxygenate (Figure 43-9). Patients receiving mechanical ventilator support can be found in many settings, from the acute care hospital to skilled nursing facilities and home care. Children needing continuous mechanical ventilation who live in the home and community need to be integrated into the school system and community recreational facilities. Patients with acute exacerbations of disorders such as emphysema, COPD, and chronic bronchitis may require mechanical ventilation and are generally seen in hospital intensive care units and weaned before they are discharged home. Patients with disorders requiring long-term ventilation, such as spinal cord injury, brain injury, and certain neuromusculoskeletal diseases, may be found receiving mechanical ventilation in rehabilitation hospitals, the home, or a long-term care facility. According to the American Association for Respiratory Care (AARC), the scope of practice for the respiratory therapist has expanded to include anywhere that patients with respiratory disease present. Therapists currently practice in hospitals, long-term care, pulmonary rehabilitation, patients' homes, and pulmonary physicians' offices.

Fig. 43-9 Puritan Bennett 7200a microprocessor driven ventilator.

Mechanical ventilator assistance in the past was provided primarily by machines that deliver preset volume and/or positive pressure breaths to the patient. Positive pressure ventilation is the opposite of normal physiological ventilation in that normal ventilation occurs when negative pressure, created by contraction of the diaphragm, causes air to enter the lungs. Whereas normal inspiration occurs by pulling air into the lungs, ventilators push air into the lungs (positive pressure) or apply pressure to the airways and thus increase ventilation. This is important because the thoracic cavity becomes an area of higher pressure, which may create adverse cardiovascular and hemodynamic events. Monitoring of heart rate and blood pressure is vital when patients are placed on a mechanical ventilator to make sure there are not cardiovascular compromises with increase in pressure and/or volume in the lungs.

Over the past 20 years there has been an increase in the use of noninvasive mechanical ventilation (NIMV) in patients with respiratory failure to avoid the risks involved with intubation. It is becoming the standard "first line therapy in several situations" in acute care.[65]

Several other patient populations have also been supported and their health and sleep improved through the use of NIMV, among them patients with end-stage Duchenne muscular dystrophy, cystic fibrosis, and other neuromuscular dysfunction. In patients with Duchenne MD the pulmonary function data are monitored and the patient may be started on NIMV only at night, progressing to continuous ventilation as needed.[66] This has also been shown to prolong life and eliminate the need for tracheostomy in these patients needing ventilation.[67] In patients with cystic fibrosis, as the disease process progresses, a heavier workload is placed on the respiratory muscles. The patient will often develop a rapid, shallow breathing pattern that results in decreased alveolar ventilation. NIMV may reduce respiratory muscle work of breathing and improve gas exchange. It can decrease oxygen desaturation during exercise and airway clearance and help in patient recovery following an exacerbation. More data are needed to evaluate long-term benefits and criteria for the use of NIMV in people with cystic fibrosis.[68]

Invasive Versus Noninvasive Mechanical Ventilation

Invasive mechanical ventilation involves the insertion of an artificial airway into the trachea that attaches to ventilator tubing. Noninvasive mechanical ventilation (NIV) is delivered by a nasal or facial mask that attaches to a positive airway pressure BiPAP machine. Patient preferences are observed in an attempt to have them feel comfortable and increase adherence to using NIV. In one study of 60 patients with acute respiratory failure being treated with NIV, no preference between the standard oronasal mask and a total face mask was found.[69] Noninvasive mechanical ventilation is growing in use, especially for acute exacerbations of COPD. It has been used primarily for patients with acute hypercapnic ventilatory failure, but its use is now expanding to larger populations. Benefits of NIV include a reduction in the need for intubation, a decrease in complication rate, and a reduced length of hospitalization. One factor in the success of NIV is the early delivery of ventilation in patients with respiratory failure.[70]

In a study involving medical-surgical intensive care units in North American, South America, Spain, and Portugal, 1638 patients were studied who were receiving mechanical ventilation. The median age of study patients was 61 years. Indications for mechanical ventilation were acute respiratory failure (66%), acute exacerbation of COPD (14%), coma (10%), and neuromuscular disorders (10%). Mechanical ventilation was administered via endotracheal tube in 75%, tracheostomy tube in 24%, and facial mask in 1% of patients. A total of 47% of patients were ventilated on an assist-control mode and 46% were ventilated with synchronized intermittent mandatory ventilation (SIMV), pressure support, or a combination of both modes.[71] In North America it seems that, clinically, the trend toward NIV is growing significantly.[72-74]

Patients with chest wall restriction such as severe kyphoscoliosis also benefit from NIV. Ventilation and oxygenation go hand in hand. If the chest wall is not moving, ventilation is decreased. Just giving oxygen to patients with severe thoracic restriction will not bring them to optimal respiratory function. The NIV provides improved ventilation that will improve patient function and endurance.[75]

BiPAP is a noninvasive form of ventilation that uses a tightly fitted oronasal mask that delivers positive pressure at two different levels, one for inspiration and another for exhalation, both of which are above atmospheric pressure. It may also be referred to as pressure release ventilation. Indications for BiPAP include signs of respiratory failure or chronic respiratory failure in patients with severe COPD, increased work of breathing, patients with neuromusculoskeletal impairments that limit ventilation and thus oxygenation, and sleep disordered breathing. Use of BIPAP has improved outcomes in terms of less daytime fatigue and improved activity levels. In addition, it may be used as a bridge for patients such

as those at the end stage of cystic fibrosis who need lung transplants.[76,77]

It is important to assess skin integrity because the pressure from the strap on the face and around the head can cause skin breakdown. This is an important consideration to discuss with the patient.

Modes of Mechanical Ventilation for Positive Pressure Ventilation (Invasive Mechanical Ventilation)

The physician and respiratory therapist have a wide variety of choices from which to select the most appropriate method of ventilation for a given patient. Terms defining properties of mechanical ventilation can be confusing. Choosing the appropriate mode of ventilation is at times considered more of an art than a science. There are basic fundamental starting points for mechanical ventilation; then the variable modes are adjusted to optimize each individual patient's needs. Before describing the modes of ventilation, the following terms are defined.

Trigger. Variable that causes a breath to be delivered by the ventilator. A patient may inhale, causing the ventilator circuit pressure to drop to a preset number (i.e., less than 1 or 2 cm H_2O). This is called a pressure trigger. Some ventilators are volume and flow triggered.

Flow rate. The speed at which the ventilator breath is delivered. This parameter is usually measured in liters per minute.

Frequency. Refers to the number of breaths delivered over time (e.g., 10 breaths per minute).

Spontaneous breath. Breathing through the ventilator circuit without assistance.

The following are descriptions of common current ventilator modes.[78]

Controlled mechanical ventilation (CMV) or total support of ventilation. The control mode is now a lesser-used method of ventilation and generally requires the patient to be sedated and paralyzed. The ventilator delivers all breaths at a preset frequency, volume or pressure, and flow rate. The patient cannot take spontaneous breaths or trigger the machine. This mode may be used when total control of ventilation is needed (e.g., during surgery, in patients with high-level quadriplegia).

Assist control (AC) or partial support of ventilation. The patient receives a preset pressure or volume, frequency or number of breaths, and flow rate. In between machine-cycled breaths, the patient can trigger the machine to deliver another breath at the preset parameters. All breaths are machine delivered. No spontaneous breathing can occur.

Assisted mechanical ventilation. This mode is similar to AC; however, there is no set frequency. The patient triggers the machine at will to deliver a set pressure or volume at a set flow rate.

Intermittent mandatory ventilation (IMV). As the ventilator delivers a set mandatory frequency and volume or pressure, the patient is allowed to take spontaneous breaths between cycles. The problem with this mode is that the breath is delivered without regard to the patient's breathing cycle. This has usually been replaced by an improved method, synchronous intermittent mandatory ventilation (SIMV).

SIMV. This mode synchronizes the machine-delivered breaths (IMV) with the patient's spontaneous breaths. In IMV the machine may cycle a breath before the patient can completely exhale a spontaneous breath. If no inspiratory effort is present, the machine delivers the mandatory breaths. Usually, the preset number of breaths is low, allowing more effort with support on the part of the patient.

CPAP. The patient allows the patient to spontaneously breathe and has a preset level of pressure that is constantly maintained during the whole respiratory cycle. This method of positive pressure support can also be achieved through use of commercially available pneumatically powered units that hook directly into the oxygen wall outlet. A tight-fitting mask is secured around the patient's mouth and nose, and a preset pressure and oxygen percentage is delivered.

BiPAP. A noninvasive form of mechanical ventilation usually delivered through a tight-fitting oronasal mask. There are different pressures for inspiration and exhalation, which are always above atmospheric levels. Inspiratory pressure is higher than expiratory pressure.

Airway pressure release ventilation (APRV). This may also be called pressure release ventilation. The patient is allowed to spontaneously breathe with a set amount of CPAP. If additional ventilation is required, the CPAP will be dropped periodically, releasing the pressure, causing the patient to exhale. When the exhalation is complete, CPAP is restored. Proponents of this mode claim that by allowing the patient control, patient comfort and compliance are high.

Pressure support ventilation (PSV). When using pressure support, the patient is allowed to breathe spontaneously, triggering a preset amount of inspiratory support until the flow rate reaches a minimal level of preset pressure in the airway. The patient controls the frequency, tidal volume, and inspiratory time. This mode is often used in conjunction with SIMV. This mode is also popular because of high patient compliance. The pressure is set for safe levels, and the volume is variable. When the patient breathes in, the volume continues until the preset pressure is reached. That is the end of inspiration.

Mandatory minute ventilation (MMV). The patient is allowed to breathe spontaneously; however, a minimal level of minute ventilation will be achieved through ventilator-assisted breaths. This is usually accomplished by using PSV.

Volume-assured pressure support (VAPS). This is one of the newest modes of ventilation. It allows the patient to breathe spontaneously in the PSV mode and monitors each breath's tidal volume. If the breath is not going to reach the set volume, the ventilator will hold the flow rate constant and increase the pressure until the desired volume is reached.

Alarm Management and Precautions

When patients are using mechanical ventilators, it is inevitable that alarms will sound. Alarms are important indicators of a

change in patient condition or a machine malfunction. All alarms should be recognized and valued as excellent sources of information. If alarms are silenced or ignored without interpretation, patient fatalities may result. Alarms should not be turned off. When therapy is being delivered, the alarms are a valuable tool. Therapists, however, need to realize they are treating the patient, not the machine. If an alarm sounds during a therapy treatment, stop the intervention and wait a few seconds to see whether the alarm stops. Before continuing therapy, identify which alarm went off and evaluate why. If it is not clear why the alarm sounded, contact the respiratory care practitioner or the patient's nurse immediately.

The most common alarms are those that monitor high and low pressure, Fio_2, apnea, disconnection, and volume. The high-pressure alarm is the one that sounds most commonly when the patient is receiving physical therapy. This alarm indicates that more than the preset pressure is needed to deliver the volume of ventilation. Generally, if the high-pressure alarm continues to sound, the patient should be checked for secretions. Suctioning can remedy this problem. The ventilator tubing should also be checked for possible occlusion from compression or excessive water buildup (Figure 43-10). High-pressure alarms may also sound in the case of bronchospasm or breath holding. Do not use strong resistance exercise with patients on mechanical ventilation because they may hold their breath and perform a Valsalva maneuver, which will cause increased circuit pressure to deliver the tidal volume to the patient. Low pressure alarm may signify a leak in the ventilator circuitry or a disconnection from the machine. Before turning a patient or performing upper extremity exercise, make sure there is clearance and ease of movement in the ventilator circuit tubing to prevent it from coming off during the interventions. In one case (in an unnamed medical center's intensive care unit) a patient's low-pressure alarm sounded and the patient was bagged while the cause was evaluated. The source was a disconnection that occurred when a new employee from the housekeeping department unplugged the ventilator to use the plug for a cleaning machine. When the low-pressure alarm sounds, first consider that the patient is not being ventilated.

Fig. 43-10 Condensation build-up in ventilator tubing—a potential hazard.

If you are unfamiliar with a particular ventilator and an alarm sounds that you are unable to identify and/or remedy, first ensure the patient is not in any extra distress. Assess the overall appearance of the patient and, most important, the rise and fall of the patient's chest as the ventilator cycles. If the patient does not appear to be receiving breaths, immediate action should be taken to remove the ventilator from the patient and begin manual ventilation with a self-inflating bag. The respiratory care practitioner should be called to rectify the situation. When the problem is resolved, the patient should be returned to the mechanical ventilator.

Another significant precaution to take when working with a patient on a ventilator is to watch for condensation in the tubing that could accidentally be poured directly into the patient's lungs, especially during turning. When moving a patient who is using a ventilator, plan ahead by securing all lines, wires, and tubing. Follow the appropriate procedure for emptying any water from the ventilator tubing before moving the patient. If the patient aspirates water from ventilator tubing, it can be fatal.

Weaning from Mechanical Ventilation

Weaning is generally initiated when the reason for placing the patient on mechanical ventilation is reversed. Several factors need to be evaluated. Is there adequate ventilation and oxygenation? During weaning, the work required by the patient to breathe may increase and oxygen may need to be titrated appropriately. Hemodynamic stability must be monitored. Using CPAP during weaning may provide the bridge necessary to wean with less stress and decreased ventilatory demand. In general in patients who are receiving mechanical ventilation, the ventilator is discontinued and then the artificial airway is evaluated and removed. In some patients with neuromuscular and musculoskeletal issues, however, ventilator weaning by lung expansion with NIV and decannulation will be a better solution.[79]

Some patients with neuromusculoskeletal concerns may use other mechanical means of ventilation, such as a pneumobelt.[80] The pneumobelt is a noninvasive device placed over the abdomen. It has a bladder that inflates and mechanically puts pressure on the abdomen, thereby causing exhalation. When the bladder deflates, the diaphragm descends and inspiration occurs. Another negative pressure device used to help patients with neurological deficits is the chest cuirass, which resembles a turtle shell placed over the chest wall. Negative pressure is applied to the chest wall, which elevates the thorax to provide inspiration and then releases to allow for exhalation. The benefits of these mechanical aids are that the patient does not need an artificial airway and he or she is provided with a more physiological means of ventilation. They are well received by many people with neurological impairments.

Role of the Physical Therapist

The physical therapist can have a significant role in keeping the patient who is mechanically ventilated from having decreased aerobic capacity by helping the patient perform aggressive mobilization (see Chapters 18, 19, and 20), exercise, airway clearance techniques, and breathing strategies and interventions (see Chapters 21, 22, and 23). The physical therapist can also play a role in finding optimal positions to support the patient who is being weaned. Therapists who have been working on breathing strategies can be a source of comfort and encouragement for the patient during the weaning periods. Active mobilization early in the course of mechanical ventilation will result in more successful outcomes.

Evidence now supports the use of early physical and occupational therapy by giving patients sedation breaks and rousing patients to exercise. This has been shown to result in better functional outcomes at discharge, fewer ventilator days, and fewer days of delirium compared with standard ventilator treatment without waking patients for therapy.[81,82]

Summary

Physical therapists need to understand the basic equipment and principles of respiratory care in order to optimize the functional outcomes of their patients. The interprofessional team approach is vital in acutely ill patients. Working in collaboration with respiratory care practitioners and nurses will maximize interventions and improve patient outcomes.

Review Questions

1. Why does a high-flow system provide the most accurate oxygen delivery?
2. What circumstances will drive the physician to order a low-flow system when a high-flow system would be optimal?
3. Why do low-flow oxygen masks require a certain minimum-liter flow (i.e., 5 to 10 L/min for a simple mask)?
4. How does noninvasive mechanical ventilation improve exercise performance?
5. Which ventilator monitor would alert the therapist that the patient has become disconnected from the machine?
6. If the high-pressure alarm sounds during a patient treatment with resistance to the lower extremity, how can the intervention be changed?
7. What parameters should a physical therapist use when exercising a patient who is mechanically ventilated?
8. What is the role of the physical therapist in the interprofessional health care team that cares for patients who are receiving NIMV?

An artificial airway is a tube inserted in the trachea either through the mouth or nose or by a surgical incision. Artificial airways have been known to medical science for 3000 years. George Washington ultimately died of upper airway obstruction because his physicians could not agree on the use of tracheostomy. It was not until 1909, when Chevalier Jackson published his classic paper on tracheotomy,[1] that this procedure gained some acceptance. The procedure did not become a highly specialized technique in patient care until the invention of modern tracheostomy tubes and the development of intermittent positive-pressure ventilators. In today's clinical practice, artificial airways have the following four basic purposes: to bypass upper airway obstruction, to assist or control respirations over prolonged periods, to facilitate the care of chronic respiratory tract infections, and to prevent aspiration of oral and gastric secretions. Multiple disease processes and traumatic problems can require an artificial airway, but each situation, simple or complex, can fit into one or several of these categories (Box 44-1).

Indications of Need

The respiratory care team can play a vital role in recognizing patient need for a tracheostomy by noting physiological changes that indicate respiratory distress.[2] Cardinal signs of dangerous airway obstruction are stridor and chest wall retractions. Early clinical signs may include restlessness, agitation, tachycardia, confusion, motor dysfunction, and decreased oxygen saturation on pulse oximetry. These signs may be accompanied by headache, flapping tremor, audible wheezing, congestion, and diaphoresis. Cyanosis from impaired oxygenation of the blood is a late, ominous sign.

In children, restlessness is due to the lack of oxygen unless another factor (e.g., thirst) is clearly evident. Extreme fatigue and an inability to sleep indicate impending danger. Apprehension, restlessness, and mental confusion at any age may be taken as early signs of hypoxemia.

Complications of Tracheostomy

Depending on the patient's impairment, selection of the appropriate airway is made by considering the following factors: What is the best means of accomplishing the goal? Is it an emergency or a controlled, determined situation? Will the airway be needed for long-term care? In general, oral endotracheal tubes are inserted in emergencies. They are the quickest and easiest tubes to insert, even for relatively

Box 44-1 Disease Processes That Could Require an Artificial Airway Because of Respiratory Insufficiency

- Primary lung disease (e.g., emphysema, chronic bronchitis, pulmonary fibrosis, cystic fibrosis, severe pneumonia, burned lung, and toxic inhalation)
- Systemic disease with secondary lung involvement (e.g., cardiac failure, renal failure [fluid overload], and multiorgan system failure)
- Neuromuscular disease (e.g., polio, Guillain-Barré syndrome, myasthenia gravis, use of muscle relaxants, and tetanus)
- Central nervous system depression (e.g., drugs, postanesthesia, metabolic coma, cerebrovascular accident, meningitis, and central nervous system tumors)
- Trauma (e.g., head/neck/chest surgery or injuries)
- Diseases complicated by extremes of age (e.g., premature infant or older adult)
- Mechanical obstruction (e.g., upper airway infection, laryngeal paralysis, tumor, edema, bleeding, foreign body, and thyroid malignancy)
- Recurrent aspiration (e.g., glottic incompetence, occlusive diseases of the esophagus, and swallowing disorders of various causes)

From Selecky PA: Tracheostomy—a review of present-day indications, complications, and care, *Heart Lung* 3:272-283, 1974.

untrained personnel. A nasotracheal tube will generally replace the oral endotracheal tube for a long-term intubation. The nasal tube is more efficient in that it is better secured, allows the patient to eat, is easier to suction, and is generally more comfortable for the patient.

There are certain complications with nasotracheal tubes. Among these are sinus blockage and pain, vocal cord damage, and pressure necrosis to the cartilaginous structure of the nose. To reduce these complications, the airway should be evaluated daily. The tube should be removed as quickly as possible when the indication for intubation is reversed. If there appears to be a need for a more long-term airway, however, a tracheostomy should be considered. The procedure should not be taken lightly because many additional complications may occur.

Complications of tracheostomy can be surgical, postoperative, or physiological. Complications that occur at the time of the operation are more frequently direct results of the surgical procedure itself. Delayed complications may result directly or indirectly from surgery, postoperative care, or the abrupt physiological changes resulting from tracheostomy. Objectives of caring for the patient after a tracheostomy are to maintain patency of the tube, cleanliness of the wound site, and good aeration of the lungs, as well as to observe any changes in the patient's vital signs and oxygenation by pulse oximetry.

In patients with artificial airways, the normal physiological mechanism for adding moisture to the air via the nasal mucosa is bypassed. Therefore supplemental humidification is extremely important to protect the mucosa from drying and crusting, which results in obstruction.

The dressing under the tracheostomy tube and tracheostomy ties should be changed when they become soiled because dried blood and other secretions near the incision can encourage bacterial growth. The incision should be checked frequently for bleeding. The skin may be cleaned with half-strength hydrogen peroxide and sterile saline when a new dressing is applied. The dressing should be folded into place, never cut. This eliminates the possibility of lint or frayed threads being aspirated. Commercially prepared dressings best meet these criteria.

When changing the tapes that hold the tube in place, it is best to have one nurse hold the tube in place while another replaces the old tapes. An angle is cut at the end of the tape to facilitate its placement through the flange of one side of the tube. The tape is then threaded through the back of the tracheostomy tube and through the other flanged opening and tied securely with a square knot placed on one side of the patient's neck. One finger should be placed under the twill tape while tying it; this will prevent the tape from being tied too tight.

Pneumothorax can occur immediately after tracheostomy because of laceration of the mediastinal pleura at the time of or within 24 hours of surgery (this arises often in children and patients with chronic obstructive lung disease). Other problems include air embolism, aspiration, and subcutaneous and mediastinal emphysema. Recurrent laryngeal nerve damage or posterior tracheal penetration may occur but is uncommon.

Postoperative Physiological Complications

Attentive nursing care is the single most essential factor in postoperative tracheostomy management. Vigilant monitoring and observation by the entire respiratory care team is of vital importance.

Patients with an artificial airway are understandably apprehensive and have special communication needs. They should be reminded that their inability to speak is only temporary. These patients must be reassured that they will be monitored frequently and can trust and depend fully on the health care team to attend to their needs. If alert, patients must be equipped with a signal light or bell, paper and pencil, magic slate, or picture board for communication.

Airway obstruction is the foremost complication that exists postoperatively for the patient who has undergone tracheostomy. Tracheal secretions are the major source of obstruction, particularly if they are excessive or viscous. When using a cuffed tube, acute obstruction might occur from overinflating the cuff, which allows it to balloon over the end of the tube. Other causes of obstruction are dislodgement of the tube into a false tract anterior to the tube tracheal opening, and kinking of softened plastic cannula.

Tracheobronchitis, inflammation of the trachea and bronchus, is a complication resulting primarily from irritation due to incorrect suctioning technique and the presence of a foreign body in the trachea.

Crusting is a common and complex problem that may result from inadequate humidification of inspired air or patient dehydration. In many instances, ulceration of the tracheal mucosa results from irritation by the airway or incorrect suctioning. This ulcerated area becomes infected with various organisms and is virtually covered by crust. Further suctioning

removes the crust, causing discharge of serum and bleeding. The discharge produces a wet eschar that is covered with mucus. Because of the drying effect of air passing over this mass, a hard crust can form. The development of this crust in the trachea might eventually produce a mass large enough to completely plug the tracheal cannula and almost completely obstruct the trachea. Cases have been cited in which an entire cast of the tracheobronchial tree has been removed.

Other physiological complications may be related to the following: hypoxemia developing before or during the procedure and resulting in an uncontrollable patient, cardiac arrest, and increased myocardial sensitivity to adrenalin; alkalosis developing from rapid carbon dioxide washout after establishment of the airway, resulting in myocardial fibrillation and apnea; and cardiac failure, resulting in profuse bronchorrhea caused by pulmonary edema and shock.

A less commonly known physiological complication is related to lack of good oral care. This means the patient with an artificial airway should have his or her teeth brushed at least twice a day (if this is not possible, the green disposable oral swabs can be used) to decrease potential pathogens as *Staphylococcus aureus* or gram-negative rods.

Chronic complications cited by Dailey and colleagues (1992)[3] include the following: infection at the surgical site, aspiration, aerophagia, persistent stoma, and tracheal stenosis.

Postoperative Mechanical Complications

Dislocation of the tube may result from unsatisfactory nursing care, poor attention to the airway during positioning, or ventilator tubing pulling on the airway. If the tracheostomy tube tapes are not kept tight and tied with a square knot or if they become loose as a result of subcutaneous emphysema or edema, the tube may be coughed out of the trachea and become lodged in the tissues of the neck and obstruct the airway. In pediatric patients, stay sutures are frequently used to prevent dislodgement of the tracheostomy tube. These sutures are valuable during recannulization of the tube if it comes dislodged before a tract has been well established. Stay sutures will prevent entry into a false tract. Advantages of this technique include the following: rapid replacement of blocked or displaced tubes, improved exposure of the trachea at surgical intervention, firm anchoring of the trachea at the moment of incision, decreased trauma associated with extubation, and uniform tracheostomy technique for all ages.

Dislodgement of the outer cannula or required removal before a tract has been well established (usually 5 to 10 days) again requires diligence and quick action by the nurse. No attempt at reinsertion should be made without adequate light, satisfactory tissue retraction, tracheal hook, and a Trousseau's dilator. A Trousseau's dilator and tracheal hook should be readily available. A spare tracheostomy tube of the correct size should be kept at the patient's bedside at all times. Should the tube be coughed out, the nurse uses the Trousseau's dilator to hold the wound apart while summoning the physician. Tragedies have occurred from inserting the tube into the soft tissues of the neck or mediastinum because of a dislodged cannula and the frantic efforts to replace it. Once the tracheostomy tract has been firmly established, the tube can be replaced by the nurse on written order of the physician.

Tracheostomy Tubes

Metal Tubes

Tracheostomy tubes are of two basic types: metal and polyvinyl chloride (hard and soft). Metal tubes are no longer commonly used, but some patients with long-standing metal tracheostomies may prefer not to switch to a polyvinyl chloride tube. Metal tubes can be made of either stainless steel or sterling silver and are composed of the following three parts: an outer cannula that fits into the tracheal incision, an inner cannula that fits into the outer cannula, and an obturator that facilitates insertion of the tube. These three parts constitute a metal tracheostomy set and are not interchangeable with the parts of any other set. Before the outer cannula is inserted into the tracheal incision, the obturator is placed inside. The lower end of the obturator protrudes from the end of the outer cannula and facilitates its insertion into the trachea. This is the only purpose of the obturator. The protruding end of the obturator obstructs the lumen of the outer cannula. When the obturator is removed, it is immediately replaced with the inner cannula. If one part is lost or damaged, the entire set is useless. Therefore each part, including the obturator, must be accounted for carefully. Care should be exercised in handling sterling silver tubes because silver is easily dented.

The inner cannula should always be inspected to be sure it is clean and clear of secretions before it is reinserted. Mucus that has dried inside the inner cannula cannot be cleaned by merely rinsing it with water. The cannula should be soaked in hydrogen peroxide, scrubbed with a tracheostomy brush, and rinsed with saline to be sure all secretions have been removed. If a silver inner cannula becomes discolored, it may be cleaned with silver polish.

To prevent dislodgement, lock the inner cannula into position after reinsertion. The locking mechanism is different with each tube, and the therapist should become familiar with the types used. If the inner cannula is not locked, it may come out if the patient has a forceful exhalation or position change. It is vital that the inner cannula be reinserted quickly if the patient is on mechanical ventilation, especially if the patient is on full support.

Polyvinyl Chloride (Plastic) Disposable Tubes

The development of plastic tracheostomy tubes brought about three major improvements that account for their widespread use: application of silicone to the inner surface of the plastic tube minimizes crusting and adherence of secretions; it is easier to attach a safe, dependable, permanent inflatable cuff to the plastic tube that cannot slip off and occlude the tracheal opening; and lower costs allow the tube to be disposable. Plastic tubes, unlike metal sets, generally have interchangeable parts. The tubes come with and without cuffs.

The cuffed tracheostomy tube is primarily used in conjunction with a positive-pressure ventilator to form a closed system (Figure 44-1). It is also used to reduce the possibility of aspiration because of absent reflexes, protective laryngeal reflexes, or pharyngeal reflexes. The inflatable cuff is located around the lower portion of the tube and, when inflated, seals the trachea from most airflow except through the tube itself (see Figure 44-1). The cuff, usually made of pliable plastic, is inflated by injecting air into the fine-bore tubing. A small pilot balloon is

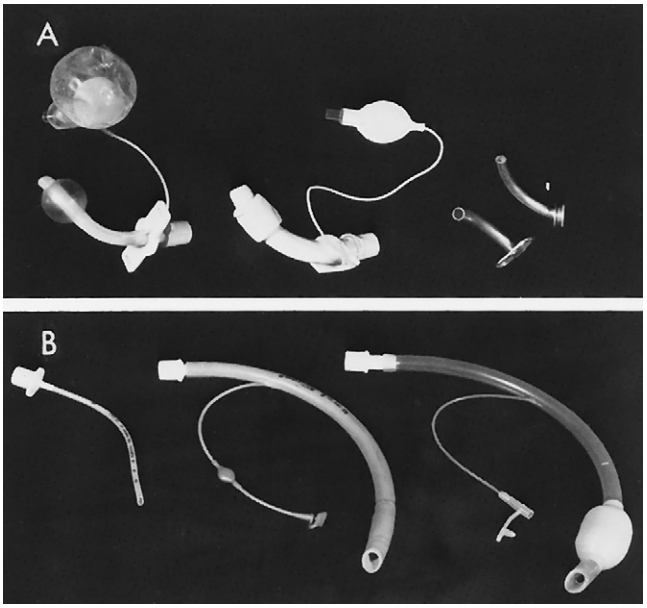

Fig. 44-1 **A,** Cuffed adult tracheostomy tubes, uncuffed pediatric tracheostomy tube *(far left)*. **B,** Cuffed adult endotracheal tubes, uncuffed pediatric endotracheal tube *(far left)*.

located proximally in the tubing and indicates that the cuff is inflated. The inflation end of the cuff and the balloon must be checked before insertion of the tube into the trachea to be certain that there are no leaks. The Luer valve inflation port to the pilot balloon is self-sealing. Some Luer valves have a relief valve when pressure exceeds 25 mm Hg.

Cuff Inflation

There are two commonly used methods of cuff inflation: minimal air leak, in which a small amount of air escapes on inspiration; and minimal occlusive volume, in which just enough air is placed in the cuff to stop air from escaping on inspiration. According to Crabtree Goodnough (1988)[4], the minimal leak cuff technique may produce less injury than the minimal occlusive volume inflation technique. Regardless of which technique is used, the pressure of the cuff should be checked every 4 to 8 hours and the pressures documented. With continued research and monitoring of tracheal cuff pressures, potential tracheal injury can be prevented.

Once the cuff is inflated, the only route for air exchange is through the patient's tracheostomy tube; therefore careful observation of the patient is essential. If the patient is on mechanical ventilation, observation is essential. Alarms are always to be in the "on" position when a patient is being mechanically ventilated. Some means of resuscitation, such as a manual resuscitation bag with mask, must be available at the bedside to ventilate the patient in case the tracheostomy tube comes out or is dislodged.

Considerable emphasis has been given to the incidence of tracheal ischemia and resulting stenosis from the use of a cuffed tube. Tracheal ischemia results from the pressure of the cuffed tube against the tracheal wall, which heals with scar formation and thereby leads to subsequent stenosis. This complication can be reduced or eliminated by minimal air leak or minimal occlusive volume. For the minimal occlusive volume, the cuff must be inflated to eliminate any air leak on inspiration. Cuff pressures should be monitored and documented every 4 to 8 hours to prevent tracheal injury. The recommended cuff pressure is 15 to 25 mm Hg. The cuff is inflated until there is no air leak between the wall of the trachea and the cuff, and then a small amount of air is released to allow only a slight air leak between the walls of the trachea and the cuff. This reduces the pressure of the cuff, still allows the ventilator to function properly, and reduces the likelihood of tracheal ischemia. Any difficulty in properly inflating the cuffed tracheostomy tube should be reported to the physician immediately.

If the tracheotomized patient is conscious, he or she may attempt to speak. If the cuff is properly inflated, the patient will be aphonic because no air can pass over the vocal cords. If the patient needs to speak, the cuff can be deflated, and the patient may be given a sterile dressing to hold over the tube. This will allow him or her to speak and also clear secretions by rapid exhalation (simulated cough).

To prevent the formation of crusts, inspired air must be continuously and adequately humidified by means of nebulizing equipment. The equipment used for this purpose can be a possible source of infection. Ideally, the nebulizer and tubing should be changed every 8 hours—at the very least, once every 24 hours.

The Communitrache I is a tracheostomy tube that permits the removal of secretions above the inflation cuff without nasotracheal suctioning. The other benefit to this tracheostomy tube is the patient's ability to communicate, especially while on a ventilator. When the patient is weaned from the ventilator, a fenestrated tube may be used. The term *fenestrated* comes from the French word *fenestre*, meaning "window." There is a window (fenestration) in the outer cannula. When the tube is used for speaking, the cuff is deflated, the inner cannula is removed, and an external plug is inserted to cap the tracheostomy tube to allow the patient to speak. The cuff must be deflated when the cap is in place. If the cuff is inflated, the patient is unable to breathe air into the lungs and will exhibit immediate distress. If a patient with a fenestrated tube needs to be suctioned, the inner cannula must be replaced so that the suction catheter does not enter the fenestration and cause injury to the tracheal wall mucosa.

Other Airway Devices

The Olympic tracheostomy button is used as an interim airway after tracheostomy tube removal (Figure 44-2). This method is another example of weaning a patient from the tracheostomy tube but still maintaining the stoma should a tracheostomy be again needed. Patients that may benefit most from this device are those with chronic obstructive pulmonary disease (COPD). This is one method used to facilitate secretion removal after hospitalization when it becomes necessary because of the disease process. The Olympic tracheostomy button allows the tracheostomy patient the opportunity to reestablish an unobstructed airway and at the same time allows the patient to speak.

Many other speaking tracheostomy tubes are available.[5] Airway clearance needs to be optimized before a speaking valve is used. If a patient has increased secretions, he or she may find it difficult to tolerate the procedure. A benefit of the

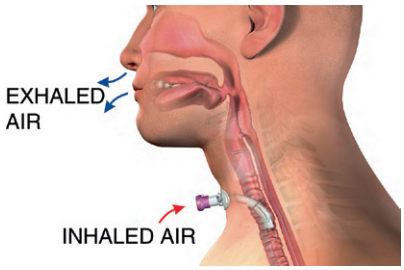

Fig. 44-3 The Passy-Muir Valve. This valve attaches to a standard 15-mm tracheostomy adapter. It allows inspiration via the valve, but exhalation must occur via the upper airway. *(Courtesy Passy-Muir.)*

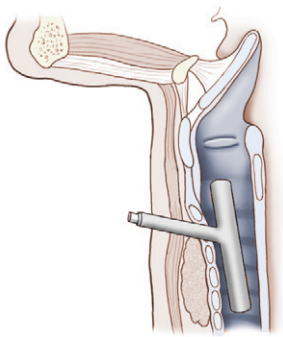

Fig. 44-4 The Montgomery T tube. *(From Montgomery WW: Manual care of the Montgomery silicone tracheal T tube,* Ann Otol, Rhinol & Laryngol *89 [Suppl 73]:3, 1980.)*

valve, however, is that the patient may be able to simulate coughing and promote mobilization of upper airway secretions.

One common speaking valve is the Passy-Muir Swallowing and Speaking valve (Figure 44-3). The Passy-Muir is a one-way valve that allows inspiration only and redirects exhalation through the upper airway. It is important to note that the cuff must be deflated when using the valve, or a cuffless tracheostomy tube may be used. Breath stacking exercises (taking a few breaths in without exhaling) can be used to get more air into the lungs before exhalation. Using the valve, the upper airway muscles gradually recover, allowing for transition to a fenestrated tube or a smaller size tracheostomy tube and thereby preparing the patient for eventual decannulation.[6] Another benefit may be an improved ability to swallow. Also, some patients claim that they can taste their food again, which may promote improved nutrition and hydration.[7,8]

The management of major airway obstruction by tracheal tumor, external compression, or tracheal disease below the thoracic inlet still presents difficult problems. The Montgomery T tube is a bifurcated silicone rubber stent designed to preserve patency of the airways in a patient with injury to the trachea or main stem bronchi (Figure 44-4). When the T tube is in place, the patient breathes normally through the nose and mouth and can speak. The T tube is helpful in long-term therapy to alleviate obstruction or during reconstructive surgery. This device does not cause any adverse tissue reaction on a long-term basis, according to Montgomery.[9,10]

Table 44-1 The Three Phases of Suctioning

Before suctioning	Patient assessment and preparation, as well as hyperoxygenation, are essential. Proper catheter size will be discussed later in the chapter.
During suctioning	Awareness of the appropriate depth of insertion is essential, and time limits for the procedure must be observed. A decision must be made as to how many passes of the catheter will be needed. Monitoring of the patient by ECG and pulse oximetry will demonstrate the patient's tolerance of the procedure.
After suctioning	The patient needs to be reassured and positioned comfortably. Reconnection to the ventilator or previous level of equipment must be completed in cases of open-system suctioning.

Airway Care

Normally, the mucociliary escalator and the cough reflex provide airway clearance. When these mechanisms fail, suctioning of the airways, manual cough assistance, or the cough machine is indicated. Suctioning does have potential hazards, but it should be a safe procedure with proper guidance and care.[11] Health care professionals also need to protect themselves during open system suctioning. This procedure can cause dissemination of particle droplets in the immediate area. Ng and colleagues (1999)[12] studied 50 consecutive suctioning procedures with intubated patients using an open system (i.e., the mechanical ventilator tubing is removed from the tracheostomy or endotracheal tube to suction the patient). Visible droplets were scattered from 25 to 168 cm from the artificial airway. When they were cultured, the same bacteria aspirated grew on the agar plates. This highlights how important it is for the person performing the suction procedure to use protective eyewear and to take necessary precautions.[12]

Suctioning

When preparing to suction, three phases should be considered (Table 44-1)[13,14]:

1. Preparation before suctioning
2. The actual suctioning procedure
3. Postsuctioning

Open Versus Closed Suctioning Systems

Patients on mechanical ventilators may be suctioned by disconnecting the ventilator tubing and suctioning (open system), or suctioning may be done directly in-line with the ventilator tubing (closed system). Studies have shown that a closed system maintains better physiological stability, less oxygen desaturation, and fewer dsyrhythmias.[15-18]

Suction Procedure

Proper explanation of the suctioning technique to the patient helps allay apprehension and enhance cooperation. Medicate the postoperative patient before suctioning to decrease the pain of coughing. Always maintain a calm and reassuring manner.

Maintain aseptic technique throughout the entire procedure. Use sterile gloves and a sterile, disposable catheter for each suctioning.

Position the patient properly unless contraindicated. Nasotracheal and/or pharyngeal suctioning should be done with the patient in Fowler position, 60 to 70 degrees (Figure 44-5, *A*), or semi-Fowler position, approximately 45 degrees, with the neck hyperextended (Figure 44-5, *B*). The supine position is best for the patient with tracheostomy or endotracheal tubes (Figure 44-5, *C*).

Pharyngeal suctioning may be necessary before deflating the cuffed tracheostomy tube. The nurse should not suction the pharynx and then the trachea with the same catheter; however, the trachea may be suctioned first and then the pharynx with the same catheter.

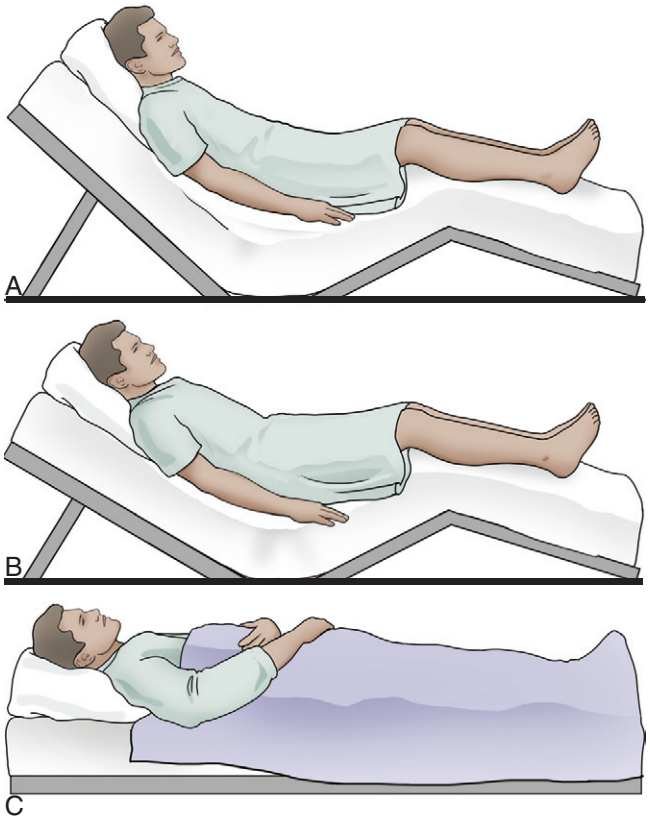

Fig. 44-5 Positioning for suction. **A,** Fowler's position. **B,** Semi-Fowler's position. **C,** Supine position.

Duration of suctioning is very important. Each suctioning procedure should last no longer than 5 to 10 seconds to avoid hypoxia.

Prolonged suctioning may result in precipitating a dysrhythmia or cardiac arrest. A good way to judge the elapsed time is to hold one's own breath and be guided by the development of discomfort. This is most important for the patient who depends on ventilatory assistance.

Use the lowest possible vacuum settings (below 120 mm Hg) that will still support suctioning the tracheostomy tube. The higher the setting is raised, the greater the risk for trauma to the tracheal mucosa. Caution should be exercised to avoid kinking the suction tubing or catheter. When negative pressure is excessive and released suddenly, inadvertent removal of portions of tracheal mucosa may occur.

Insertion of the suction catheter should be done gently, using aseptic technique and sterile gloves. Goggles are used as part of universal precautions if there is any danger of coughed-out secretions. The catheter should first be moistened in sterile saline or with a water-soluble gel. Suction is not applied while the catheter is passed down into the trachea. Proper insertion of the catheter will stimulate coughing when it contacts the carina (Figure 44-6, *A*). It is then immediately withdrawn one cm before suction is applied (Figure 44-6, *B*). Do not force the catheter up and down while suctioning. Suction is applied only while the catheter is being withdrawn. Rotating the catheter during withdrawal results in suctioning a larger area and increases the surface contact of the trachea and tracheostomy tube (Figure 44-7).

Left main-stem bronchus aspiration is more difficult because of the anatomical arrangement of the bronchus. It was formerly thought that left bronchial aspiration was facilitated by turning the patient's head to the right. Studies by Kirimli and colleagues (1970)[19] and Panacek and colleagues (1989)[20] indicate that left bronchial aspiration is best accomplished by using a Coudé tip catheter. After its insertion into the trachea, the curved tip should be positioned to point toward the left main-stem bronchus. Even so, insertion is difficult, and auscultation by stethoscope is necessary to thoroughly access the suctioning.

Right main-stem bronchus aspiration is the usual method because of the more direct alignment of this bronchus with the trachea. This can almost always be carried out with a straight tracheal catheter. The deeper suction would rarely be indicated; generally when the catheter hits the carina, it is withdrawn before suctioning.

Excessive suctioning can be harmful. Use judgment to determine just how often a patient requires suctioning. It should not be routine; rather, it should be based on the need of the patient.[21,22] Assessment by auscultation and patient clinical observations should be used to determine the need for suctioning. Suction only when it is needed.[23] Allow the patient to rest and breathe between each insertion of the suction catheter and, if necessary, ventilate the patient for a few minutes before further suctioning. Remember that each suctioning attempt removes air as well as secretions. Hyperoxygenation with 100% oxygen has been suggested to provide better results and fewer complications. Hyperventilation was previously encouraged, but studies have shown that it is not necessary; hyperoxygenation is the important factor.[24,25]

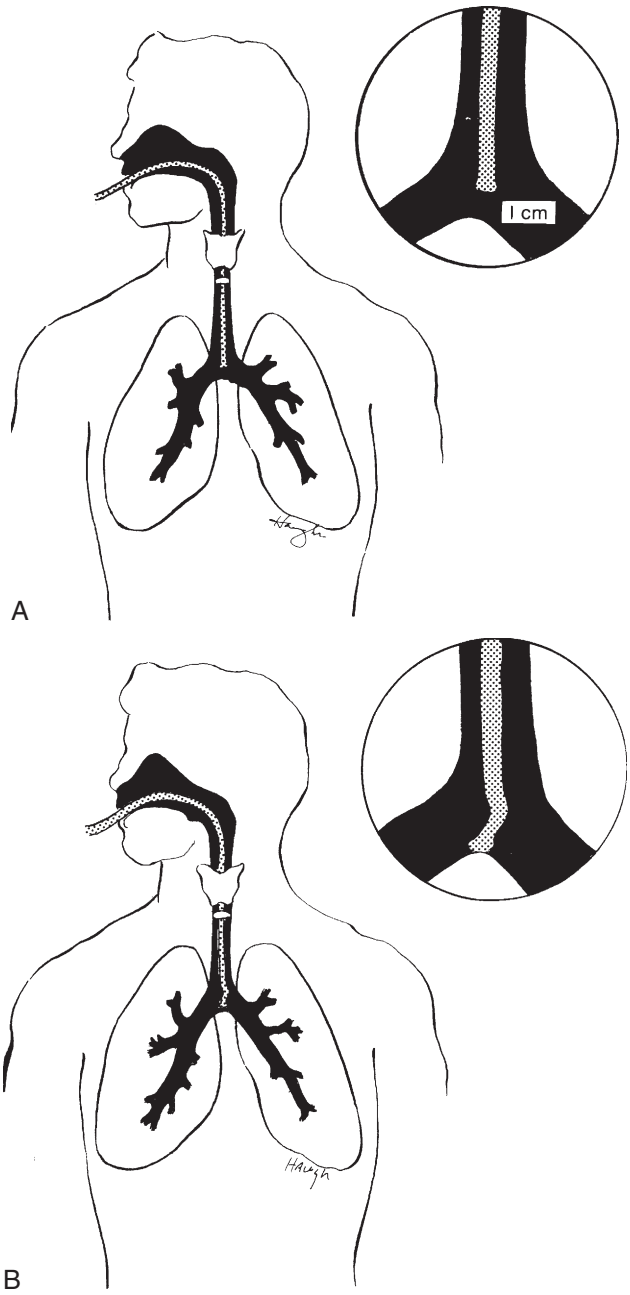

Fig. 44-6 Suctioning procedures. **A,** The catheter will stimulate coughing when it contacts the carina (in a patient with cough reflex). **B,** The catheter is withdrawn 1 cm after it reaches the carina, before applying suction.

Complications

Complications from tracheal suctioning include hypoxemia, cardiac dysrhythmia, bronchospasm, and infection.

HYPOXIA

Suctioning can lead to hypoxemia because oxygen is removed from the airways, and this could lead to tissue hypoxia. To minimize this problem, patients should be given preoxygenation with 100% oxygen for three to five breaths. This can be done on the ventilator without disconnection.

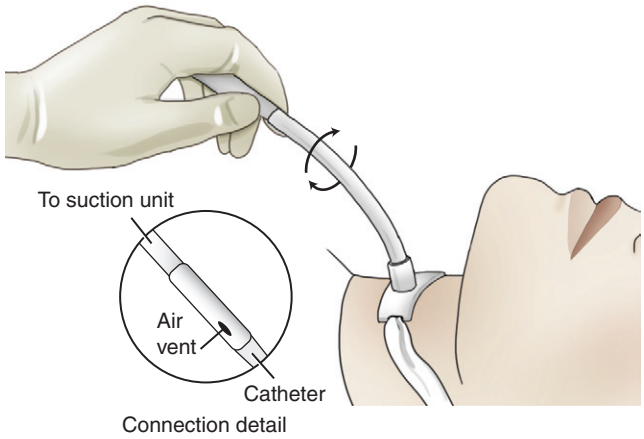

Fig. 44-7 The catheter is rotated during withdrawal in order to suction a larger surface area.

CARDIAC DYSRHYTHMIA

Cardiac dysrhythmias, such as premature ventricular contractures, bradycardia, and tachycardia, can be diminished by hyperoxygenating the patient with 100% oxygen. If any dysrhythmias occur on the monitor, the suctioning procedure should be discontinued momentarily to allow the patient to stabilize and increase his or her oxygen level.

BRONCHOSPASM

Bronchospasm may be effectively prevented by administration of a bronchodilator, such as albuterol, before suctioning.

INFECTION

Infection can be decreased by maintaining sterile techniques with sterile gloves and sterile catheters when suctioning.

Suctioning Artificial Airways

Nasopharyngeal Airways

When frequent, aggressive nasopharyngeal suctioning is indicated in a patient who is comatose, a nasopharyngeal airway (NPA) will lessen the trauma of frequent passage of the catheter. The NPA is a soft latex material that provides easy access to the trachea for nasopharyngeal suctioning. The nasal and pharyngeal mucosa are protected, and the procedure thus becomes more comfortable to the patient. In addition, a fiberoptic bronchoscope may be passed through the airway if the procedure is indicated.

Endotracheal or Tracheostomy Suctioning

Sterile technique is followed for endotracheal and tracheostomy suctioning. Usually no lubrication is necessary, although it may be used if there is difficulty passing the catheter.

Sterile Suctioning

The technique for correct sterile suctioning of artificial airways is perhaps the most important and vital segment of care for the patient because it removes secretions that would otherwise

obstruct the airway. If suctioning is not performed properly, it can cause physiological or psychological trauma to the patient.

The equipment necessary for proper sterile suctioning includes the proper mechanical apparatus, connecting tubing, sterile gloves, sterile saline, suction catheters, dressings, and goggles as indicated with universal precautions. It must be remembered that during suctioning, the patient's only air passage is being partially occluded. Thus the suction catheter should never be larger than one-half the diameter of the tube opening; if it is larger, it may completely occlude the patient's air passage.

One method for determining the size of the catheter used for suctioning is to double the size of the tracheostomy tube in place and add 2. For example, if the patient has a #6 tube, the calculation would be as follows: 6 + 6 = 12, 12 + 2 = 14. Therefore a 14-F catheter would be the largest catheter that could be used to suction the #6 tracheostomy. See Table 44-2 for a correlation of tracheostomy sizes to catheter sizes.

The catheter used for pharyngeal suctioning should never be used for subsequent suctioning of the artificial airway, but using an artificial airway suction catheter for pharyngeal suction is acceptable. Aseptic technique is absolutely necessary to minimize the risk for infection, and ideally, only disposable catheters should be used.

Suctioning may be necessary every few minutes when the patient initially returns from surgery because there is an increase in secretions, which is usually the result of irritation of the endotracheal tube plus a reflex mechanism initiated by the surgical trauma. Usually, by paying attention to the patient's color, respiratory rate, lung sounds, and oxygen saturation on pulse oximetry, the nurse or therapist can determine the amount of secretions present. Excessive mucus in the trachea or large bronchi is usually indicated by coarse, rattling sounds. Fine bubbling sounds usually suggest fluid located more peripherally (i.e., in the alveolar spaces). If accumulated secretions are not cleared, they can cause respiratory and cardiac rates to increase; effective oxygen and carbon dioxide transfer is impaired, causing cyanosis to appear and low-grade fever to develop.

General Suctioning Procedure for an Artificial Airway

The procedure for suctioning an artificial airway begins after the clinician has taken all of the same appropriate procedure preparatory measures, including sterile technique procedures, as are required when suctioning without an artificial airway.

- Hyperoxygenate with 100% oxygen for three to five breaths with manual resuscitation bag.
- Place the patient's neck in extension.
- Lubricate the catheter with sterile saline or water-soluble gel.
- Place the catheter (without suction) upward and backward in short increments. Continue until an obstruction (the carina) is reached.
- When the carina is stimulated, the patient will generally cough unless his or her reflexes are obtunded.
- Pull the catheter back slightly from the carina; then apply suction with no more than 120 mm Hg pressure as the catheter is withdrawn in a rotating motion.
- Aspiration time should be within 10 to 15 seconds total. A good guideline is for the therapist to hold his or her own breath during suctioning (because the patient is also not breathing). This gives the therapist a better sensitivity for what the patient is experiencing.
- Allow the patient to rest for several seconds and preoxygenate the patient again.
- Check the patient's breath sounds and repeat the procedure, if necessary, to remove more secretions.
- Suction pharynx.
- Observe the patient and monitor for any dysrhythmias.
- Use pulse oximetry to monitor desaturation.

Instillation of Saline

Saline instillation is not recommended. Studies have shown that it is ineffective and can cause reflex and uncomfortable airway responses (i.e. cough, bronchospasm). Also, the saline instillation potentiates infection. It is not a recommended practice.[26,27]

Extubation/Decannulation

Extubation or decannulation is the removal of the artificial airway. In general, this is done when the reason for establishing the artificial airway no longer exists. In certain cases the artificial airway may be removed to facilitate airway clearance and aspiration. This can be prevented with thorough attention and care of the tracheostomy tube.[28,29] The patient is aided in gradually relearning normal breathing through his or her upper respiratory tract before the tube is removed. This can be a time of considerable fear and anxiety for patients because they have learned they can breathe safely through their tracheostomy, and they may become apprehensive when asked to

breathe in a normal manner. The relearning process can be accomplished under the physician's direction by reducing the lumen of the tube for a day or two or by partially obstructing the tube's outer opening for increasing lengths of time. Eventually the patient is able to tolerate the complete occlusion of the tracheostomy opening. This is sometimes difficult and similar to breathing through a straw.

When occluding the tracheostomy opening with a cuffed tube, the cuff must be deflated first. Failure to do this will result in total obstruction of the patient's airway as the tube opening is occluded.

Fenestrated tubes are excellent for weaning the patient from the tracheostomy tube. They are probably more effective than using cuff tubes; furthermore, they do not actually increase the airway resistance, as do cuffed tubes. Fenestrated tubes also allow the patient to talk and attempt to cough to mobilize secretions. Other methods used in decannulation include the Olympic tracheostomy button and the Passy-Muir valve. The Olympic tracheostomy button allows the airway to remain patent for suctioning and reinsertion of a tracheostomy tube should it become necessary. The Passy-Muir valve allows for normal recovery of the upper airway muscle, making it possible to reduce the size of the tracheostomy tube, leading to eventual plugging and decannulation. Careful observation and documentation of the patient's ability to ventilate must be done when any of these devices are used in the decannulation process.

Close supervision should continue after extubation. After a tracheostomy tube is removed, the skin edges are usually taped together with butterfly strips for a few days until the wound heals. During healing, air will escape through the wound and reduce the effectiveness of the patient's cough. The patient should be instructed that the noise from the partially closed trachea is normal, and small secretions should be removed from this area. The patient should be taught and instructed to hold a sterile dressing firmly over the incision when coughing until the opening heals.

Summary

Artificial airways are commonly used, so the health care team needs to be proficient at using them and comfortable working with patients who have them. Precautions need to be observed and techniques consistently applied to prevent respiratory tract infections and unplanned decannulation. Training and orientation need to be thorough so that suctioning procedures are safe for the patient and the health care team. Knowing the indications for the artificial airway will help identify when the airway is no longer needed. For patients who require lifelong use of tracheostomy tubes, the patient, family, and care-taker need to be instructed in the airway clearance and cleaning procedures.

Review Questions

1. What physiological changes occur with surgical placement of a tracheostomy tube?
2. Discuss possible psychosocial concerns of patients with an artificial airway.
3. When would a speaking valve be indicated? What is the cuff position?
4. How does the patient-care team prepare the patient with a tracheostomy for self-care?
5. Compare emergency care, acute care, and long-term care for a patient with upper airway obstruction and tracheostomy placement.

The respiratory and cardiovascular systems have many built-in mechanisms for controlling their functions during health and disease. In healthy individuals, both systems act quickly and positively to maintain proper functioning under the most complicated conditions. Even during trauma or disease, these systems often overcome distress and regain normal function. Disease sometimes alters the physiology of respiration or circulation to the extent that the homeostatic mechanisms are no longer effective. In such a case, a drug with the appropriate action becomes necessary to restore normal physiological function.

Before a drug can be used effectively, the system it is to modify must be understood. How the mechanism of the drug action relates to the biological system must be clear before an effect can be predicted.

This chapter describes much of the basic respiratory and cardiovascular physiology that underlies the action of the drugs presented, with the goal of elucidating the relationship between basic physiology and the drug mechanism of action (Table 45-1). Some of the trade names of the medications mentioned in the text will be changing, but the generic names will remain the same. Not all pharmacological interventions for the respiratory and cardiovascular systems are covered. Certainly, no attempt has been made to describe the pharmacology of other systems or disease states. For further study, any of the texts listed in the reference section at the end of the chapter are highly recommended.

Sympathetic neurotransmission	Adrenergic (sympathomimetic) drugs	Norepinephrine Epinephrine Isoproterenol Phenylephrine and metaraminol Ephedrine Amphetamine $Beta_2$-receptor stimulants
	Alpha-adrenergic blocking drugs	Phentolamine Phenoxybenzamine Prazosin, doxazosin, and terazosin
	Beta-adrenergic blocking drugs	Propranolol Metoprolol and atenolol
	Sympatholytic drugs	Reserpine Guanethidine Methyldopa and clonidine
Parasympathetic neurotransmission	Cholinergic drugs	Acetylcholine Bethanecol Carbachol Pilocarpine
	Anticholinesterase drugs	Physostigmine Neostigmine Edrophonium Donepezil, rivastigmine, and galantamine
	Cholinergic blocking drugs	Atropine Ipratropium and tiotropium Homatropine and cyclopentolate Dicyclomine Trihexyphenidyl HCL and benztropine mesylate Trimethaphan and mecamylamine
Special considerations	Adrenergic (sympathomimetic) drugs	Epinephrine Ephedrine Albuterol, metaproterenol, terbutaline, pirbuterol, formoterol, and salmeterol
	Anticholinergics	Ipratropium and tiotropium
	Methylxanthines	Theophylline and aminophylline
	Corticosteroids	Budesonide, flunisolide, fluticasone, and triamcinolone
	Mediator inhibitors	Cromolyn sodium and nedocromil sodium
	Antileukotrienes	Zileuton, zafirlukast, and montelukast
	Mucolytics and expectorants	Acetylcysteine Guaifenesin

Autonomic Pharmacology

This section introduces the basic aspects of drug action related to both components of the autonomic nervous system: sympathetic and parasympathetic. For both systems, synthesis, storage, and release of the chemical neurotransmitter are described to emphasize the places in the metabolic scheme where drugs can intervene. The sites of action for the adrenergic (sympathetic) and cholinergic (parasympathetic) transmitters and blockers are also described.

The autonomic nervous system controls all of the bodily functions over which the individual has no voluntary control (and which the individual might not control well given the opportunity). These functions include regulation of respiratory airway diameter, respiratory secretions, blood vessel diameter, heart rate, intestinal motility, and pupil size, among many others. It is easy to see that it might take more than the talents of a well-trained expert to keep an active person functioning day and night.

The sympathetic nervous system is the half of the autonomic system that takes a dominant role in the cardiovascular and respiratory systems when bodily activity is necessary. This includes actions such as increasing ventilation capacity, elevating blood pressure, and shunting blood flow to the skeletal muscles. Classically, the sympathetic component of the autonomic nervous system has been called the fight-or-flight system. The other half of the autonomic system is called the parasympathetic nervous system. This system is most important in maintaining the "less exciting" functions of the body, such as digestion, salivation, and urination. In some organs the two systems work in a complementary way to provide very fast and very fine control. For example, the size of the pupil responds quickly to a change in light intensity. The parasympathetic system actively functions to decrease the size of the opening while the sympathetic system relaxes, thereby causing a quick decrease in pupil size. If the light is turned down, the opposite occurs just as quickly. This is a good example of the antagonistic action of the two components of the autonomic nervous system.

Some organs, however, have only one innervation. Much of the arterial blood vessel network is controlled only by sympathetic nerves, whereas gastric secretion and gastric

motility are primarily regulated by the parasympathetic system.

Sympathetic Neurotransmission

Sympathetic nerves transport impulses from the vasomotor center in the medulla of the brain through the spinal cord and out to the smooth muscle, heart muscle, and secretory cells. These tissues have receptor sites that will accept the norepinephrine released from the nerve ending. Norepinephrine, also called noradrenalin, is synthesized in the nerve ending only in the sympathetic neurons. It is stored in the terminal until an electric impulse reaches the terminal; then it is released into the synapse.

The norepinephrine molecule attaches to a receptor molecule on a cell surface in the immediate vicinity of its release. This drug-receptor combination causes a biological change, such as stimulation of the pacemaker cells in the heart to fire more frequently (increased heart rate). The effect is terminated when the norepinephrine is reabsorbed into the nerve terminal. About 90% of the released norepinephrine is taken back into the neuron, where it is either restored into granules for future release or destroyed by the enzyme monoamine oxidase (MAO).

There are two types of sympathetic receptors: alpha and beta. The alpha-receptor is found in the arterioles, and the beta-receptor is found in the arterioles, heart, and bronchioles. Stimulation of the alpha-receptor in the arteriole causes vasoconstriction, which results in increased blood pressure. Stimulation of the beta-receptor in the arteriole causes vasodilation and lowered blood pressure. Some drugs stimulate both receptors, and in those cases the effect will be determined by the degree of alpha or beta activity of the drug. One example is norepinephrine. It has 90% alpha activity and 10% beta activity, and it always causes vasoconstriction. Epinephrine is 50% alpha and 50% beta and may cause a rise or drop in blood pressure.

Stimulation of the beta-receptor in the heart results in increased heart rate (HR) (beats per minute) and increased stroke volume (SV) (number of milliliters of blood the left ventricle pumps out into the aorta every time it contracts). Incidentally, the combination of HR and SV changes is another way to express cardiac output (CO) (milliliters of blood pumped per minute):

$$\text{beats/min (HR)} \times \text{mL/beat (SV)} = \text{mL/min (CO)}$$

This expression, cardiac output, is a common one, and it constitutes half of the blood pressure regulation equation: CO × TPR = BP, where CO is cardiac output, TPR is total peripheral resistance, and BP is blood pressure. TPR is determined by vasoconstriction or vasodilation in the arterioles. For example, vasoconstriction increases resistance; therefore TPR and BP go up.

Stimulation of smooth muscle beta-receptors will relax these tissues wherever they are found. Respiratory airway smooth muscle will decrease tension when the beta-receptor is activated by beta-acting drugs like epinephrine or isoproterenol. The functional result will be an increase in air flow because of a larger airway diameter, otherwise referred to as bronchodilation. Likewise, blood vessels respond to beta-acting drugs by dilating as well, allowing a greater rate of flow. In this case, TPR has decreased and blood pressure will drop.

Adrenergic (Sympathomimetic) Drugs

Norepinephrine

As mentioned previously, norepinephrine (Levarterenol, Levophed) is a mixed-activity drug (90% alpha, 10% beta). It stimulates beta-receptors in the heart, which results in an increase of heart rate and stroke volume (increased cardiac output). In the arterioles, norepinephrine causes vasoconstriction via the alpha-receptor, resulting in increased total peripheral resistance. The total effect is an increase in blood pressure. Norepinephrine has little effect on the bronchioles. This drug is given only intravenously, and it is reserved for use in hypotensive emergencies to raise blood pressure, therefore preserving blood supply to the brain and heart. The natural sympathetic compounds are known as catecholamines.

Epinephrine

Epinephrine (Adrenalin) is also a mixed-activity drug (50% alpha, 50% beta). It is naturally produced in the adrenal medulla and can be released during sympathetic nervous system activation. When this occurs, it acts as a circulating hormone, stimulating both alpha- and beta-receptors. This drug will increase heart rate and stroke volume and may slightly increase or decrease total peripheral resistance at the arterioles. In any case, cardiac output always goes up; blood pressure may go up or down slightly.

In the bronchioles, epinephrine exerts a dramatic dilating effect that is mediated by the beta-receptor. Epinephrine can be administered by inhalant aerosol to reverse a bronchoconstrictive episode. It is also administered intramuscularly and subcutaneously to treat asthma and anaphylactic reactions to an allergic response, cardiac arrest, heart block, and as a mild vasoconstrictor to keep local anesthetics at the injection site.

Isoproterenol

Isoproterenol (Isuprel) is a synthetic compound that has 100% beta activity. This means that it can increase heart rate and stroke volume to produce a great rise in cardiac output, and it stimulates the beta-receptor on the arterioles to cause a profound vasodilation. The final result can be a high cardiac output with low blood pressure. This drug improves blood circulation in shock patients by increasing local blood flow (vasodilation) and elevating cardiac output. Isoproterenol has been useful for treating acute asthmatic conditions because of its bronchodilating action; however, it is seldom used currently, because new safer, $beta_2$ selective drugs have been developed.

Phenylephrine and Metaraminol

Both phenylephrine (Isophrin, Neo-Synephrine) and metaraminol are powerful and prolonged stimulators of alpha-receptors. The action is directly on the receptor site itself. The response to the administration of either of these drugs is a rise in blood pressure because of vasoconstriction accompanied

by a reflex bradycardia, which causes a decrease in cardiac output. Reflex alterations of cardiovascular function are explained later in this chapter. The primary usefulness of these drugs is in various hypotensive states. Phenylephrine is used as a nasal decongestant, mydriatic, and for the relief of paroxysmal atrial tachycardia. Phenylephrine affords relief from tachycardia because it increases blood pressure and evokes the cardiovascular reflex that is marked by high vagal tone and bradycardia.

Ephedrine

Ephedrine has both alpha and beta activity as direct effects, and it also causes release of epinephrine and norepinephrine. Its pharmacological actions are similar to epinephrine, with the main exception that the duration of action of ephedrine is longer. Ephedrine increases cardiac output and vascular resistance, resulting in increased blood pressure. Ephedrine also causes bronchial muscle relaxation, which is less potent than that of epinephrine but has a longer duration. Although this drug has been useful in controlling milder cases of bronchoconstriction, it is also seldom used since the development of new $beta_2$ selective drugs.

Amphetamine

Amphetamine (Dextroamphetamine, Dexedrine) drug has pharmacological properties related to the catecholamines because it causes release of norepinephrine from the nerve terminal. Amphetamine has both alpha- and beta-receptor activity, although indirectly, through its release of norepinephrine. The usual cardiovascular response is an increase in blood pressure often accompanied by a reflex bradycardia. Amphetamine also has potent central nervous system (CNS) activity. It is a stimulant of the medullary respiratory center, and it can antagonize drug-related central nervous system depression. Respiratory depression often accompanies overdoses of CNS depressant drugs and this effect may be overcome by amphetamine. This drug is usually used for its CNS effects and not for peripheral cardiovascular or respiratory effects.

$Beta_2$-Receptor Stimulants

As mentioned above, there are several drugs that act primarily at the $beta_2$ smooth muscle receptor site, causing selective actions in the bronchioles and arterioles but not in the heart (Box 45-1). These drugs will produce a bronchodilation without increasing cardiac output. This particular lack of cardiovascular effect makes them safer than drugs like isoproterenol or ephedrine in treatment of bronchial asthma. This class of drugs is currently part of the mainstay of treatment for asthma and chronic obstructive pulmonary disease (COPD).

Alpha-Adrenergic Blocking Drugs

The alpha-adrenergic blocking class of drugs should not be used as monotherapy because of their propensity to cause fluid retention. When combined with diuretics, there is no evidence to contraindicate their use. Diuretics are drugs that act on the kidney to increase the formation of urine, therefore decreasing blood volume and fluid accumulation.

Box 45-1 $Beta_2$-Receptor Stimulants

- Albuterol (Proventil, Ventolin)
- Metaproterenol (Alupent, Metaprel)
- Terbutaline (Brethine, Bricanyl)
- Isoetharine (Bronkosol, Bronkometer)
- Pirbuterol (Maxair)
- Bitolterol (Tornalate)
- Formoterol (Foradil)*
- Salmeterol (Serevent)*

*Formoterol and salmeterol are used primarily in combination with inhaled steroids for long-term use.

Phentolamine

Phentolamine (Regitine) is a competitive alpha-receptor blocker. Its action is reversible. This drug prevents the hypertensive effect of norepinephrine and reverses the blood pressure elevating effect of epinephrine (epinephrine reversal). Epinephrine reversal looks like an isoproterenol effect with high cardiac output and low blood pressure. Phentolamine may be used clinically as a vasodilator. It is useful in the emergency treatment of hypertensive patients who have pheochromocytoma, which is a tumor that grows most commonly on the adrenal glands. The tumor produces epinephrine and norepinephrine and may be responsible for one aspect of a clinical hypertension.

Phenoxybenzamine

Phenoxybenzamine (Dibenzyline) is also an alpha-adrenergic blocking agent. It has effects similar to phentolamine in the cardiovascular system, but it is less reversible. This is the drug of choice for preoperative management of pheochromocytoma. This drug is gaining some usefulness in the treatment of shock syndromes characterized by high vascular tone.

Prazosin, Doxazosin, and Terazosin

Prazosin (Minipress), doxazosin (Cardura), and terazosin (Hytrin) are $alpha_1$ selective for arterioles and venules and are the most useful drugs in this class to deal with hypertension. They also have a dilatory effect on urethral smooth muscle and are therefore useful agents in males with enlarged prostates. Although they act by vasodilation, these drugs exert minimal reflex tachycardia because they do not potentiate the vasomotor center and the increased venous capacitance reduces venous return and cardiac output.

Beta-Adrenergic Blocking Drugs

The beta-blocker class of drugs is highly effective for the treatment of hypertension. They are commonly prescribed in conjunction with diuretics. The following drugs are just a few examples of the many beta-blockers available.

Propranolol

Propranolol is a beta-adrenergic blocker. This drug occupies the beta-receptor sites of the heart, the blood vessels, and the bronchioles. It prevents the beta-adrenergic effect usually seen

with drugs such as epinephrine, norepinephrine, and isoproterenol. In the arterioles, when epinephrine is given after propranolol, the usual mixed alpha and beta effect is eliminated, leaving only an alpha-adrenergic action. This causes profound vasoconstriction, allowing greater increase in blood pressure than is normally seen with epinephrine alone. In the heart the beta-receptors are blocked, and because there are no alpha-adrenergic receptors in this organ, all effects of catecholamine drugs on the heart are effectively eliminated, allowing the vagal influence on the heart to predominate. Propranolol decreases the heart's requirement for oxygen because it blocks the cardiac stimulant action of norepinephrine. In the respiratory system the administration of propranolol results in bronchoconstriction. This effect is increased dramatically in patients who are susceptible to asthma. The main use for propranolol is in conditions related to hypertension and tachycardia, where a decrease in cardiac output is beneficial.

Metoprolol and Atenolol

Metoprolol (Lopressor) and atenolol (Tenormin) are beta-adrenergic antagonists that have been designed to be cardioselective. This offers an advantage in safety when a beta-blocker must be used in patients with asthma because this disease would be aggravated if respiratory beta-receptors were blocked. The natural beta-adrenergic agonist, epinephrine, is a bronchodilator, and an important class of bronchodilating drugs acts at bronchiolar beta-adrenergic receptors.[1]

Sympatholytic Drugs

The sympatholytic drugs are highly effective as antihypertensive agents; however, their clinical utility is limited by their side-effects profile.

Reserpine

Reserpine is an alkaloid of *Rauwolfia serpentina,* also known as the Indian snake root plant. Many commercial preparations of this compound are available, but it is widely sold as the simple plant extract. This compound depletes norepinephrine from the nerve endings in the various tissues of the body that produce and store norepinephrine, including the brain. The depletion takes several days to accomplish, and it may take several weeks to restore catecholamine levels to normal after therapy is discontinued. During this time, there is a decrease in catecholamine response to sympathetic stimulation. Blood pressure in humans does not drop dramatically with therapeutic doses of reserpine, but when reserpine is used in combination with diuretics or other antihypertensive agents, a significant antihypertensive effect is obtained. Reserpine is used in this way to treat essential hypertension. One serious side effect related to reserpine use is the behavioral modification that can result in severe depression and suicide.

Guanethidine

Guanethidine (Ismelin) is an adrenergic neuron-blocking agent that works by replacing norepinephrine in the nerve terminal. Norepinephrine is usually taken up by the nerve terminal after its discharge and is reused to maintain granule concentrations. Guanethidine takes the place of norepinephrine in the granules and prevents the reuptake of norepinephrine, thereby causing its metabolism outside of the neuron and its eventual depletion. The result on the cardiovascular system of this action is postural hypotension. The patient is unable to control blood pressure by sympathetic activity. This drug is no longer commonly used in the treatment of hypertension.

Methyldopa and Clonidine

Methyldopa (Aldomet) and clonidine (Catapres) decrease the activity of the sympathetic nervous system at its control center in the brain. The consequence is a total decrease in sympathetic activity in the heart and blood vessels, which leads to a reduction in blood pressure. These agents are primarily used as second- and third-line treatments because of adverse side effects such as sedation, dry mouth, postural hypotension, impotence, and rebound hypertension. However, methyldopa remains the drug of choice for nonemergent hypertension in pregnancy. Clonidine comes in a patch form (transdermal administration), which is a longer-acting preparation that decreases the deleterious side effect of rebound hypertension.

Parasympathetic Neurotransmission

The center for parasympathetic control is the vagal nucleus in the medulla. The vagus nerves pass through the spinal cord and out to the heart, the smooth muscle, and exocrine glands (salivary glands and pancreas). In all of these tissues, acetylcholine (ACh) is released from the nerve terminals and combines with receptor sites to cause an effect such as bradycardia (slowing of the heart) or an increase in gastric motility. ACh is found in many parts of the central and peripheral nervous system. ACh is the only transmitter used in the parasympathetic system. It is used to transmit impulses from the nerve that comes out of the spinal cord to the nerve that finally reaches the cells in the organ being affected. This connection is called a ganglion and exists in both sympathetic and parasympathetic systems. ACh is also the neurotransmitter that makes the connection between the voluntary (somatic) nerves and the skeletal muscle.

There are two types of receptors in the central and peripheral nervous systems. ACh affects both, but some drugs affect only one and not the other. These two types of receptors are called nicotinic and muscarinic, named after the drugs that selectively stimulate them. Nicotine stimulates only those receptors in the ganglia and at the neuromuscular junction. The muscarinic receptor site is found everywhere that a parasympathetic nerve terminal synapses at a tissue. The biological effects usually attributed to the parasympathetic nervous system, such as bradycardia, salivation, and bronchoconstriction, are produced when the muscarinic receptors are stimulated. It is also possible to stimulate muscarinic receptors indirectly with a nicotinic drug by activating the parasympathetic ganglia. In a similar way, it is possible to stimulate the entire sympathetic nervous system. The neurotransmitter at the sympathetic ganglia is ACh, and it affects nicotinic receptor sites there. One of the toxic effects of ACh (and similar-acting drugs) is hypertension with tachycardia, which is the result of stimulation of the sympathetic postganglionic fibers.

To better understand the action of ACh and related drugs, let us consider the synthesis, release, and inactivation of this transmitter. ACh is synthesized inside the nerve terminal from acetyl-CoA and choline. The ACh is then stored in granules and released out into the synapse when an action potential reaches the terminal. The ACh molecule attaches to a receptor site, muscarinic or nicotinic, or to the enzyme that breaks it apart. Combination with the receptor site results in biological action, and coupling with the enzyme ends in destruction. The enzyme, acetylcholinesterase, is found at all cholinergic synaptic sites. A nonspecific variety of the enzyme is also prevalent in many other tissues. It too will break down ACh. The final action of either enzyme is the production of acetic acid and choline. The acetic acid is washed away for further metabolism, and the choline is reabsorbed into the nerve terminal for resynthesis to ACh.

Cholinergic Drugs

Acetylcholine

ACh is the endogenous cholinergic transmitter that accounts for nicotinic and muscarinic actions within the autonomic nervous system (Table 45-2). It is rapidly hydrolyzed by acetylcholinesterase and the nonspecific cholinesterase and therefore has a short duration of action if administered parenterally. Therefore, in general, this drug is not very efficacious.

Bethanecol

Bethanecol (Urecholine) is a synthetic choline ester that is not destroyed as easily as ACh by cholinesterase enzymes. It is useful in treating patients with urinary retention and paralytic ileus, and it is administered orally or subcutaneously. The side effects and toxicities for this drug are the same as those for ACh. Because the drug is not given intravenously, however, cardiac and respiratory effects are minimized.

Table 45-2 Effects of Acetylcholine

Nicotinic effects	Stimulation of parasympathetic ganglia, causing occurrence of all muscarinic effects Stimulation of sympathetic ganglia, causing increase in vascular resistance and cardiac output to produce hypertension Stimulation of the neuromuscular junction (NMJ) at the skeletal muscle (muscle contraction and movement)
Muscarinic effects	Bradycardia Salivation Pinpoint pupils Bronchial constriction Gastric and intestinal hypermotility Increased gastric acid and mucous secretion Facilitated urination
Toxic effects*	Diarrhea Urinary incontinence Bradycardia Bronchoconstriction Excessive salivation CNS excitement Respiratory collapse

*With all of these toxic effects, atropine, a competitive muscarinic blocker, is the antidote of choice.

Carbachol

Carbachol (Carcholin) is a mixed nicotinic and muscarinic drug because it releases ACh from the nerve ending, producing the expected cholinergic effects at all receptor sites. The drug has been used for treatment of glaucoma (applied topically), paralytic ileus, and urinary retention (orally and subcutaneously).

Pilocarpine

Pilocarpine (Pilocar) is a cholinomimetic that is useful in ophthalmology as an antiglaucoma agent. Cholinergic compounds decrease intraocular pressure by relieving the obstruction to the canal of Schlemm, a drainage circuit for the eye. Miosis (pinpoint pupils) is one feature of cholinergic therapy and may be beneficial to glaucoma treatment because the muscular base of the relaxed iris may contribute to the drainage block. Another use of pilocarpine (Salagen) is to promote salivary flow in patients with a ganglionic blockade.

Anticholinesterase Drugs

Before proceeding to specific anticholinesterase drugs, it is important to understand the basic mechanism of action for these compounds. Acetylcholinesterase is the enzyme responsible for destroying ACh at the various nerve junctions where it is released. The class of drugs that interfere with this function is called the anticholinesterases. These drugs attach to the enzyme and thereby block the enzymatic hydrolysis of ACh, causing ACh to accumulate outside of the nerve ending. This results in a greater response than normal to any cholinergic nerve stimulation. Some of these anticholinesterases are relatively short-acting compounds and are therapeutically important, whereas others are extremely long-lasting and potent compounds that are important only as poisons. The long-acting compounds have been used as insecticides and as nerve gases in chemical warfare. The therapeutically useful anticholinesterases are beneficial in problems related to the eye, intestine, and the skeletal neuromuscular junction (NMJ). In these applications, these drugs increase the amount of ACh available for activity, an effect that is especially important in cases in which the synthesis or release of ACh is lower than normal, as in myasthenia gravis.

There is great medical interest in the toxicology of the anticholinesterases, especially the extremely potent irreversible anticholinesterases. Toxicity due to these compounds is not uncommon and is often severe. When a toxic irreversible anticholinesterase, such as diisopropylfluorophosphate (DFP) or sarin, is ingested, inhaled, or absorbed across the skin, a great variety of toxic cholinergic effects are seen. The first effects seen after exposure to an anticholinesterase are often ocular and respiratory effects. In the eyes, marked miosis is produced quickly. In the respiratory system, bronchoconstriction and bronchial secretions combine to produce tightness in the chest and wheezing. Gastrointestinal symptoms include nausea, vomiting, cramps, and diarrhea. Other muscarinic effects are severe salivation, involuntary defecation and urination, sweating, lacrimation, bradycardia, and hypotension.

Further effects of anticholinesterases are related to nicotinic functions of ACh. These include skeletal muscle twitching, weakness, and paralysis. CNS effects include depression of the

respiratory and cardiovascular control centers, leading to respiratory collapse. At the time of death, respiratory paralysis is evident, caused by a combination of bronchoconstriction, bronchosecretions, respiratory muscle paralysis from overstimulation, and CNS/control center depression. The treatment of this toxicity is closely related to preserving respiratory function. Administration of atropine, a muscarinic blocker, will effectively decrease bronchoconstriction and secretion. Another drug, pralidoxime (Protopam), is used to reactivate the acetylcholinesterase. It is most effective shortly after exposure to the toxic agent because it breaks down the anticholinesterase so it can be removed from the enzyme site. Additional measures are related to physiological support of the patient. Maintenance of an airway, artificial respiration, and oxygen administration are important therapeutic applications for these patients.[2]

Physostigmine

Physostigmine (Eserine) is useful in glaucoma and in selected therapeutic measures where a cholinergic effect is beneficial. It can also be used as an antidote for various anticholinergic agents. It functions as an indirect cholinomimetic by blocking the acetylcholinesterase.

Neostigmine

Neostigmine (Prostigmine) is useful in patients with nonobstructive paralytic ileus to increase tone and motility of the small and large intestines. It is also useful for stimulating skeletal neuromuscular junction (NMJ). Neostigmine is used for treating myasthenia gravis because it indirectly increases ACh at the NMJ and it acts directly at the nicotinic receptor site itself. Myasthenia gravis is marked by subnormal response to ACh, resulting in skeletal muscle weakness. Neostigmine temporarily restores muscle strength.

Edrophonium

Edrophonium (Tensilon) is a very short-acting anticholinesterase. It is primarily useful as a diagnostic agent in myasthenia gravis to reveal, for a few minutes, whether the dose of neostigmine is appropriate. A longer-acting drug would risk a serious cholinergic toxicity if the neostigmine dose was already at the therapeutic limit.

Donepezil, Rivastigmine, and Galantamine

Donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl) increase ACh levels, which are found to be decreased in patients with Alzheimer disease. These drugs are not only efficacious in improving cognition but are found to improve activities of daily living and other neuropsychiatric symptoms. However, none of these have been proven to slow the disease progression. Donepezil (Aricept) is currently most often prescribed due to the advantage of once-a-day dosing.

Cholinergic Blocking Drugs

Cholinergic antagonists block the various receptor sites where ACh is a transmitter. There are specific blocking drugs for each type of ACh receptor. Atropine blocks all cholinergic action right at the muscarinic receptor site on smooth muscle, exocrine glands, and myocardium. The cholinergic antagonist curare works only at the neuromuscular junction to block the nicotinic effect of ACh, resulting in paralysis of skeletal muscle. Still another type of nicotinic blocker is the ganglionic blocker hexamethonium, which blocks both sympathetic and parasympathetic ganglia by occupying the ACh receptor there. These drugs are useful wherever sympathetic or parasympathetic tone needs to be decreased. It is possible to selectively inhibit cholinergic effects in the body to produce a desired effect or to eliminate an undesirable effect. Because of this selectiveness, cholinergic antagonists have widespread use in many areas of medicine.

Atropine

Atropine is an extract from the plant *Atropa belladonna,* also known as the deadly nightshade. Another plant extract, scopolamine, has action similar to atropine. Atropine works by establishing a competitive blockage at the muscarinic receptor site, which is the effector at all tissues innervated by the parasympathetic nervous system. This blockade is selective for the tissue effect of the parasympathetic system and does not counteract the nicotinic ganglionic effects or the nicotinic effects at the NMJ.

Because heart rate is controlled by both sympathetic and parasympathetic tone, atropine will eliminate the parasympathetic effect on the heart, allowing the sympathetic system to increase heart rate and stroke volume to cause an increase in cardiac output. In fact, tachycardia may occur after atropine administration. In cases where bradycardia exists because of high vagal tone, atropine can be used to reverse this depression.

In the respiratory tract, atropine is a bronchodilator. It is also possible to delay respiratory depression associated with anesthetic, tranquilizing, and anticholinesterase drugs by using atropine, either as a pretreatment agent or as an antidote during overdose.

Atropine is used widely as pre-anesthetic medication to prevent bronchiolar secretions and laryngeal spasm, as well as bradycardia. A more general medical use for atropine exists as an emergency tool. It is the antidote of choice for all cholinergic toxicities.[3]

One of the most important clinical uses for atropine is in the gastrointestinal (GI) tract as an antiulcer and antispasmodic agent. This drug acts to decrease motility in the GI tract so that other antiulcer agents can remain in contact with the GI mucosa longer, and it is possible that it also decreases acid secretion. Other problems related to hypermotility of the GI tract are treated with atropine, mainly to decrease gastric muscle activity during treatment of conditions such as cramping and diarrhea.

In ophthalmology, atropine is useful for producing mydriasis, which is pupillary dilation. It is contraindicated in glaucoma patients because it may precipitate an acute attack.

Atropine itself is also capable of producing toxic effects, including mydriasis, tachycardia, dry mouth, constipation, and urinary retention. Effects related to the CNS are also apparent and include initial sedation followed by delirium and hallucinations, leading to a coma. In severe toxicities the patient convulses and experiences severe respiratory depression, which may be the final course. Anticholinesterase drugs,

such as physostigmine and neostigmine, are effective antidotes for atropine because they increase the amount of ACh that will compete with atropine for the receptor site.

Ipratropium and Tiotropium

Ipratropium (Atrovent) is a synthetic analog of atropine and is more frequently used than atropine in the treatment of asthma. It has also proved useful in the treatment of COPD. It is administered in aerosolized form. This route provides the advantage of maximal concentration at the bronchial target tissue with limited systemic effects. Tiotropium (Spiriva) is a long-acting anticholinergic, exhibiting bronchodilation in the lungs with indications for COPD. Like ipratropium, it exerts site-specific effects. Tiotropium is a dry powder that is inhaled.

Homatropine and Cyclopentolate

Homatropine (Novatrin) and cyclopentolate (Cyclogyl) are anticholinergic drugs related in action to atropine. They are useful in ophthalmology to produce mydriasis.

Dicyclomine

Dicyclomine (Bentyl) is considered very useful in the gastrointestinal tract to decrease secretions and motility. It is sometimes called a chemical vagotomy.

Trihexyphenidyl HCL and Benztropine Mesylate

Trihexyphenidyl HCL (Artane) and benztropine mesylate (Cogentin) are primarily antiparkinson drugs that enter the CNS to reverse the imbalance between the cholinergic and dopaminergic systems in this disease. They have some of the same side effects as atropine.

Trimethaphan and Mecamylamine

Trimethaphan (Arphonad) and mecamylamine (Inversine) are currently the only ganglionic blockers available in the United States. They block the ACh receptor site in the ganglia in both the sympathetic and parasympathetic nervous systems. Because of their blocking action at the sympathetic ganglion, these drugs will produce a postural hypotension. They will also decrease cholinergic effects at the parasympathetic effector sites because they block the ganglia for the entire parasympathetic nervous system as well. This means that a patient may experience blurred vision, dry mouth, and tachycardia, as well as other atropine-like peripheral effects. They have been surpassed by many other drugs to control hypertension. Their only remaining use is occasionally for the initial control of blood pressure in patients with an aortic dissection who have preexisting contraindications to other drugs. Another clinical use is to induce controlled hypotension during surgery to minimize blood loss.

Cardiovascular Reflex

The cardiovascular reflex involves many of the components of the autonomic nervous system to maintain a normal blood pressure. This mechanism is important for maintaining blood pressure within certain limits during all phases of physical activity. Even the simple act of standing from a seated position requires prompt compensation by this reflex system. If in some way this reflex is interrupted, a condition known as orthostatic hypotension will exist. A common manifestation of this condition is fainting upon standing because of inadequate blood flow to the brain. This section is devoted to the functional aspects of the reflex after a change in blood pressure.

Carotid Baroreceptors

Neuronal elements, known as baroreceptors, exist in the sinus of the carotid arteries supplying the brain. These are stretch receptors that fire electrical impulses at a rate directly related to blood pressure. As the pressure in the artery increases, the vessel wall (and baroreceptor) stretches, causing an increase in the receptor firing rate. Conversely, a decrease in blood pressure results in a decrease in stretch receptor firing rate. This firing rate signal is sent directly to the brain, where the vasomotor center and vagal nucleus respond to it.

Functional Reflex

As an example to demonstrate this reflex, let us assume we have just experienced a loss of blood pressure. The carotid baroreceptors shorten and slow their firing. This message is then delivered to the brain, and the vasomotor center responds by increasing sympathetic nerve activity. This control always responds to information regarding blood pressure in the carotid artery by directly opposing the baroreceptors. If the pressure had risen, the baroreceptors would have increased their firing rate and the vasomotor center would have responded by slowing the sympathetic nerve firing rate. Because blood pressure in this example is low, the vasomotor center increases sympathetic nerve firing, resulting in increased release of norepinephrine from the nerves that reach the heart and arterioles. Norepinephrine increases the heart rate and stroke volume, thereby producing an increase in cardiac output. In the arterioles, norepinephrine stimulates the alpha-receptors, producing vasoconstriction, which results in increased resistance and ultimately raised blood pressure. A third component of the sympathetic nervous system can be involved during sympathetic activation: epinephrine released from the adrenal medulla also increases cardiac output. Meanwhile the vagal nucleus responds to the decreased baroreceptor firing by decreasing its own activity. The vagus nerve to the heart releases less ACh, allowing the sympathetic effect to predominate. The total effect becomes an increase in blood pressure, which is the response required to return the systemic pressure to normal. If the original pressure alteration had been an increase to above normal blood pressure, the opposite reflexive actions would have occurred to return pressure to a normal range. The predominant effect would have been an increase in vagal nerve tone to release high amounts of ACh at the heart, causing a dramatic slowing of heart rate accompanied by a decrease in stroke volume. This combination produces a decrease in cardiac output. The sympathetic system would have responded to the increased baroreceptor firing by decreasing firing in all sympathetic nerves, thereby decreasing norepinephrine and epinephrine release. All of these factors combine to decrease blood pressure to normal.[2]

Other Drug Classes Used in the Treatment of Hypertension

As mentioned in the previous sections, many drugs have the potential to affect blood pressure, cardiac output, heart rate, etc. Many studies have been done to establish appropriate guidelines for patients with hypertension, which is an important risk factor for heart disease and stroke. The Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) found that it takes at least two medications of different classes to treat most cases of mild hypertension, and three to four medications for those with severe hypertension.[4] The latest Joint National Committee JNC report (2003)[5] recommends starting patients on a two-drug regimen in which one of the drugs is a diuretic. There are many types of diuretics, all classified according to which part of the kidney is affected and what type of action is performed. Some examples are hydrochlorothiazide (HCTZ) (HydroDIURIL), furosemide (Lasix), and spironolactone (Aldactone). In addition to the diuretics and beta-blockers discussed previously, there are angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), calcium-channel blockers, and many drugs that combine two of these classes. These drugs are commonly used for the treatment of hypertension but are also used in heart failure and other heart diseases. Recently, more focus has been put on hypertension in the context of overall cardiovascular risk and the importance of the long view. Evidence from the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT)[6] shows that in addition to blood pressure lowering medications, cholesterol-lowering medications (such as the statins) should be considered as part of primary therapy in certain patients.

ACE inhibitors and ARBs affect a cascade of events that ultimately leads to an increase in blood pressure. This is known as the renin-angiotensin system. The endogenous components of this system effect vascular tone and thereby affect blood pressure. Renin is an enzyme produced by the kidneys and released in response to changes in blood pressure. When renin is circulated throughout the blood stream, it comes in contact with angiotensinogen, which is synthesized by the liver and circulates throughout the body. The angiotensinogen is then converted to angiotensin I. With the aid of ACE, angiotensin I is converted to angiotensin II, which has vasoconstricting effects. Bradykinins are inflammatory mediators that are also broken down by ACE. ACE inhibitors block the enzyme and do not allow angiotensin I to be converted or bradykinins to be broken down.[7] Excessive bradykinins can cause many systemic effects, one of them being chronic cough. Some patients need to be taken off their ACE inhibitor for that reason. Two examples of the many ACE inhibitors commonly used are enalapril (Vasotec) and lisinopril (Prinivil). There has been a significant debate over the recommendation for first-line drugs in the treatment of hypertension. Some feel beta-blockers should be used, and others feel ACE inhibitors are a better first line medication, but most agree that both should be used in combination with diuretics. Many ongoing studies continue to address those options. The JNC guidelines primarily are responsible for publishing these recommendations, and healthcare providers should frequently check for updates by going to the National Institute of Health (NIH) website (http://www.nih.gov/) and searching for "JNC Guidelines."

Another class of drugs known as the ARBs has helped eliminate chronic cough as well as many other side effects. ARBs work by blocking the receptor to which angiotensin II binds. Therefore angiotensin II is not able to exert its vasoconstrictive effects on the body, and the result is a decrease in blood pressure. Some examples of ARBs are losartan (Cozaar), candesartan (Atacand), and valsartan (Diovan).

Calcium-channel blockers are another class of drugs used to treat HTN, but these are unrelated to the renin-angiotensin system. There are calcium channels on the cardiac myocytes that, when activated, increase heart rate and contractility as well as vasoconstriction. Therefore when these channels are blocked, the opposite occurs: heart rate, contractility, and vasodilation decrease. In addition to the treatment of hypertension, calcium-channel blockers can be used in heart failure and other heart diseases. Some examples of calcium-channel blockers are diltiazem (Cardizem), nifedipine (Procardia-XL), and verapamil (Calan).

The ACE inhibitors, ARBs, and calcium-channel blockers have many side effects and contraindications that are not discussed here but can be reviewed in any of the texts listed in this chapter's references. Although these drug have different mechanisms of action, they all work toward reducing blood pressure and decreasing the risk for heart damage.

Drugs Used in Obstructive Airway Disease

Patients suffering from asthma or COPD (emphysema or chronic bronchitis) may have an obstructed airway for several reasons. Acute asthmatic obstruction and some chronic airway obstructions are due to bronchial smooth muscle contraction, which results in a smaller diameter airway. Inflamed passageways, which are swollen because of edema, may also constitute an airway obstruction. A further complication seen in many respiratory diseases is the thickening and collection of secretions that cannot be eliminated from the respiratory tree and subsequently block the airway. In this section, the various drugs that can reverse smooth muscle contraction, inflammatory edema, and collection of secretions are presented.

A variety of therapeutic mechanisms are useful against this collection of obstructive conditions. The single most effective mechanism for relief of smooth muscle spasm is the aerosolized beta$_2$ activity that is available in some of the adrenergic agents. Other useful mechanisms aim at potentiating the beta activity of adrenergic agents, decongesting the inflamed airway, and in a broader approach, generally stabilizing cells that can release mediators of the disease, thereby lowering the severity of the disease. The following drugs will be discussed in regard to their actions in obstructive airway disease.

Adrenergic (Sympathomimetic) Drugs

Epinephrine

The muscle-relaxant bronchodilator effect attributed to the beta-adrenergic sympathomimetic compounds is most commonly required for asthmatic or allergic emergencies. During a severe exacerbation of asthma, when a patient is unable to coordinate aerosolized treatments, epinephrine can be given via subcutaneous routes. It is commonly used in systemic

anaphylactic reactions as well. As mentioned earlier, epinephrine has 50% beta-adrenergic activity and exerts a great bronchodilating effect. Epinephrine may cause an anxiety reaction in a patient, along with headache, palpitations, and respiratory difficulty. It can also cause serious cardiac reactions (dysrhythmias), which have resulted in death.[3]

Ephedrine

Ephedrine is a sympathomimetic that acts by liberating norepinephrine and epinephrine from storage sites, in addition to possibly directly affecting adrenergic receptors. Its usefulness and side effects are similar to those of epinephrine. Because of the development of more efficacious and beta$_2$-selective agonists, it is used infrequently in the treatment of asthma.

Albuterol, Metaproterenol, Terbutaline, Pirbuterol, Formoterol, and Salmeterol

Albuterol (Proventil, Ventolin), metaproterenol (Alupent, Metaprel), terbutaline (Brethine, Bricanyl), pirbuterol (Maxair), and salmeterol (Serevent) are isoproterenol analogs that are specific beta$_2$-receptor agonists. They therefore exert most of their action on respiratory or vascular smooth muscle but have little effect on the heart. They are useful compounds for selectively relaxing bronchial smooth muscles in asthma and COPD. The major advantage of these drugs is that their action on the heart is minimal or absent, and their potential for inducing cardiac toxicities is correspondingly reduced. Although these beta agonists can be given orally, they are most often given by inhalation, which minimizes their systemic absorption and potential for side effects. Formoterol (Foradil) and salmeterol (Serevent) are long-acting beta$_2$ agonists and are recommended to be used in combination with an inhaled steroid for the treatment of asthma (i.e., budesonide/formoterol [Symbicort] and fluticasone/salmeterol [Advair]).

Anticholinergics

Ipratropium and Tiotropium

Ipratropium (Atrovent), mentioned earlier in this chapter, is a synthetic analog of atropine used for its bronchodilatory effects. It is commonly used in conjunction with a beta$_2$ agonist to provide effective control in chronic stable asthma and in acute exacerbations of asthma. It has also proved useful in the treatment of symptomatic COPD. Response to the medication varies widely from patient to patient; this is attributed to the difference in parasympathetic tone in individuals. Because it is delivered in aerosolized form, ipratropium provides maximal concentration at the bronchial target tissue with limited systemic effects. As mentioned before, tiotropium (Spiriva) is a new anticholinergic on the market also used in patients with COPD. This drug can be taken in once-a-day doses and is indicated only for maintenance treatment. It is dispensed in a powder form from a multi-dose powder inhaler.

Methylxanthines

Methylxanthines have effects similar to the catecholamines in the respiratory and cardiovascular systems. This similarity in effect may be due to the elevation of cyclic adenosine monophosphate (AMP.) Both the catecholamines and methylxanthines are known to produce elevated cyclic AMP levels in the tissues they stimulate. The catecholamines activate adenylate cyclase, the enzyme that converts adenosine triphosphate (ATP) to cyclic AMP. The newly formed cyclic AMP exerts its effects on the local tissue (e.g., bronchial muscle relaxation) and is inactivated by the enzyme phosphodiesterase. The methylxanthines inhibit phosphodiesterase, conserving cyclic AMP and thereby promoting its effects. Additional actions of methylxanthines may be direct smooth muscle relaxation, which could increase airway diameter, and antagonism of adenosine, which is bronchoconstricting.

Theophylline and Aminophylline

Theophylline and aminophylline are structurally very similar to caffeine. Treatment with either of these drugs is recommended only for patients with moderate or severe persistent asthma who are receiving other controller medications, such as inhaled steroids or antileukotrienes, but whose asthma is still not adequately controlled. These drugs are given orally or intravenously and can be used in the inpatient or outpatient setting. In either situation, drug levels in the blood must be monitored because of the toxic effects and the difference in metabolism among patients. Theophylline and aminophylline are not frequently used since advancements have been made in other asthma therapies.

Corticosteroids

The antiinflammatory steroids (prednisone, methylprednisolone, and beclomethasone) are related to the naturally occurring glucocorticoid cortisol. Many compounds have been synthetically derived to produce a variety of antiinflammatory potencies. The usefulness of corticosteroids in treating respiratory diseases depends on the ability of these drugs to depress the symptoms of inflamed tissue. The mechanism of action for the drugs, however, has not clearly been defined. Some specific effects of corticosteroids that relate to the antiinflammatory action are decreased capillary dilation and permeability, as well as stabilization of lysosomal membranes in white blood cells. In addition, these compounds decrease the synthesis of compounds that can promote broncho-obstructive disease—prostaglandins and leukotrienes. The long-term use of the corticosteroids is recommended only after other measures fail. The reason for this caution is that they produce serious side effects and permanent changes if used for 2 weeks or longer. After one week of corticosteroid therapy, behavioral changes and acute peptic ulcers may be observed. When longer therapy is instituted and adrenal suppression occurs, however, the patient requires supplemental corticosteroid therapy until normal adrenal cortex function is restored. This state of insufficiency may last for as long as several months after suppression. Most patients who receive corticosteroids for long-term therapy develop a condition called Cushing's syndrome. It is characterized by wasting of muscles because of protein breakdown and by redistribution of fat from the extremities to the face and trunk. Eventually these patients develop osteoporosis and diabetes. Other serious complications are peptic ulcers, psychosis, glaucoma, intercranial hypertension, and growth retardation. The time to onset of these side effects can be prolonged and their severity minimized by applying dosing

strategies that provide antiinflammatory benefit in the lung at low systemic doses. Corticosteroids can be given at low doses in alternate-day administration or by inhalation in a form that is not systemically absorbed.

Budesonide, Flunisolide, Fluticasone, and Triamcinolone

In the treatment of persistent asthma, inhaled steroids are shown to be effective and safer treatments. They do not modify the progression of the disease; however, they improve the day-to-day symptoms. Some examples of these are budesonide (Pulmicort), flunisolide (Aerobid), fluticasone (Flovent), and triamcinolone (Azmacort). Oral steroids such as methylprednisolone or prednisone are reserved for acute exacerbations of asthma. In a life-threatening situation, intravenous methylprednisolone can be given and then switched to oral administration and tapered off over 2 to 3 weeks. If the patient is not on an inhaled steroid at the time, one is initiated. In rare cases when a patient has continued difficulty controlling asthma, the steroids can be taken every other day. This type of treatment is not routinely recommended because of the deleterious side effects of chronic steroid use. In the treatment of severe COPD with multiple exacerbations, evidence shows that inhaled steroids in combination with beta$_2$ agonists reduce the frequency and severity of the exacerbations. As mentioned in the previous section, an example of a steroid/beta$_2$ agonist is fluticasone/salmeterol (Advair). As in the treatment of asthma, oral steroids (methlyprednisolone, prednisone) are reserved for acute exacerbations of COPD, and usually patients are sent home on a short, tapered course.[8]

Mediator Inhibitors

Cromolyn Sodium and Nedocromil Sodium

Cromolyn sodium and nedocromil sodium can prevent asthma attacks that are normally triggered by specific stimulants, such as exercise or allergen exposure. The mechanism of action is presumed to be regulation of mast cell mediator release and eosinophil recruitment, therefore inhibiting responses to allergen challenge and exercise-induced bronchospasm. These drugs are administered by inhalation and are frequently used in the pediatric population and/or when a specific stimulant is identified. The antileukotrienes are becoming more popular for nonsteroid long-term treatment of asthma, slowly replacing this class of drugs.[8]

Antileukotrienes

Zileuton, Zafirlukast, and Montelukast

Leukotrienes are eicosanoids that are prevalent in many body tissues. In the lungs they are potent bronchoconstrictors that can be up to 1000 times more potent than histamine. They also are responsible for increasing mucus production and they enhance eosinophil and basophil influx into the airways. The development of the class of drugs referred to as antileukotrienes works in two ways. They are classified as either leukotriene-synthesis inhibitors (zileuton) or leukotriene-receptor antagonists (zafirlukast and montelukast). These drugs have been shown to improve lung function and reduce asthma symptoms, thereby lessening the need for rescue B_2-agonist therapy. They are used as alternatives to low-dose inhaled steroids in patients with mild persistent asthma. Continued studies are investigating more uses for this class of drugs. For example, montelukast (Singulair) is commonly used for patients with allergies who do not have asthma. These drugs are dispensed in oral form.

Mucolytics and Expectorants

Acetylcysteine

Acetylcysteine (Mucomyst) is a mucolytic that acts by breaking the chemical bonds that hold together the large protein structure that contributes to the viscosity of mucus. Mucolytics are inhaled to liquify mucus so that it can be moved out of the bronchial tract to prevent airway obstruction. Side effects associated with these drugs are bronchospasm, nausea, and vomiting. Acetylcysteine also inactivates the penicillin antibiotics and is contraindicated in their presence. Mucolytics are used in conjunction with other medications in COPD or asthma, but they are most commonly used in patients with upper respiratory illnesses. They are usually administered by inhalation.

Guaifenesin

Guaifenesin (Mucinex) is an expectorant that acts by increasing production of respiratory secretions, therefore encouraging their ejection and making coughs more productive. It can be used in chronic disease but is most commonly used in acute respiratory illnesses. It is dispensed in oral form. The primary side effect is gastrointestinal upset.

Drug Inhalation Devices

Most drugs administered by inhalation in respiratory disease are delivered by pressurized metered-dose inhalers (MDI) (Figure 45-1) or nebulizers. MDIs rely on pressurized chlorofluorocarbon or hydrofluoroalkane propellants to deliver very small drug particles (less than 5-micron diameter) into the airway. Each activation of the metered valve allows an

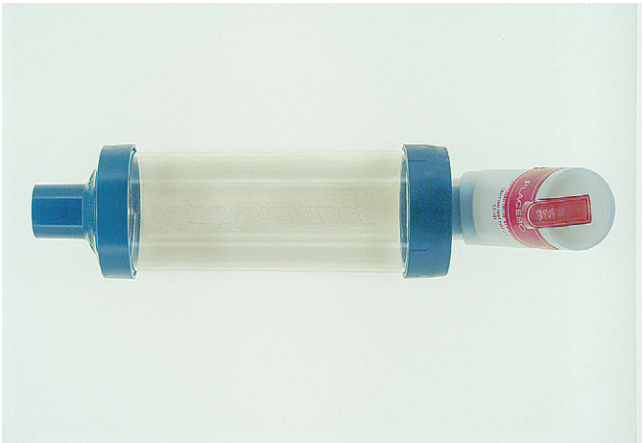

Fig. 45-1 Metered-dose inhaler (MDI) with spacer.

Fig. 45-2 Multi-dose powder inhaler.

accurately determined volume (dose) of propellant and drug mixture to be released at a high velocity. As of 2010, most CFC based MDIs have been removed from the market in attempts to protect the environment.[9] A nebulizer is a machine that delivers the drug after it has been aerosolized with room air. One important advantage of a nebulizer is that the patient does not need hand/breathing coordination, which is further discussed below. The nebulizer, however, is not portable like an MDI and is more expensive than an MDI.

The delivery of drugs to the site of action in the airway by any type of inhalation is inefficient, and therefore, correct technique in MDI use is an important concern. The MDI will allow delivery of 20% of the metered drug to the airway if the patient correctly coordinates the proper rate of inhalation with activation of the device and then adequately holds his or her breath before exhalation. Unfortunately, it is estimated that 50% or fewer patients manage the drug delivery correctly. In response, patient education on correct MDI technique is an important part of therapy, and additional devices, called spacers, have been developed to allow success with variations in technique. The spacers come in various configurations, but they all provide a chamber between the patient and the MDI, which can be charged with the drug-propellant mixture that is then inhaled without concern for critical timing. Patients with poor MDI technique should benefit from the addition of a spacer (see Figure 45-1).

An alternative to the MDI, for patients who have difficulty with the inhalation technique, is the single-dose or multi-dose powder inhaler (Figure 45-2). This device offers a drug compounded into a fine powder that is delivered from a container on simple inhalation by the patient. Coordination of drug delivery is simple and not a problem because only inspiration by the patient drives powder delivery to the airway. The method offers the same or lower efficacy of drug delivery (6% to 20%) when compared with MDI. Also, a relatively high airflow is needed to suspend the powder properly. Therefore young children and the older adults may not benefit from this type of device. Overall, studies have shown that if the patient uses the correct technique, each of the delivery devices provides similar outcomes.[10]

Summary

This chapter describes the basic respiratory and cardiovascular physiology that underlies pharmacological considerations of drug prescription for people with heart and lung conditions. The actions of common drugs are presented. The relationship between physiology and the mechanisms of action of these drugs is highlighted. Medications for hypertension and chronic airway disease are given special consideration. Finally, drug inhalation devices are reviewed because it is important that physical therapists understand these devices and their proper use for effective outcome.

Review Questions

1. Why is it important to have an understanding of the system that a drug is to modify?
2. Describe the function of beta-blockers, diuretics, ACE inhibitors, and ARBs in the treatment of high blood pressure.
3. What is the cardiovascular reflex, and why is it important to physical therapists?
4. What is the pharmacologic rationale for treatment of patients with obstructive airway disease?
5. Why is a patient's compliance with medications a concern of the physical therapist?

Appendix A

Elements of International Standards for a Cardiac Rehabilitation Program

	Cardiac Rehabilitation Program
Aims	Increase functional capacity Return to safe vocational and recreational activities Restore patients to active and productive lifestyle Improve health-related quality of life Increase ischemic threshold and decrease signs and symptoms such as angina Decrease fear of angina, disease progression, and premature mortality Offset deleterious psychological and physiological effects of bedrest/acute incidence Support mental health and minimize anxiety and depression Risk factor reduction through patient and family education and lifestyle-related health behavior change Prevent progression of atherosclerosis and cardiovascular disease Promote reversal of atherosclerosis and cardiovascular disease Reduce risk of re-infarction and sudden death Develop and help patient implement a safe and effective home exercise/activity program Communication: Provide feedback to referring physician regarding efficacy of medical management
Setting	Inpatient and outpatient Outpatient physical therapy clinic Fitness and wellness facilities School or community gymnasium
Target Population	Medical patients—for example, after myocardial infarction, cardiomyopathy, heart failure Surgical patients—for example, after coronary artery bypass surgery, valve replacement, left ventricular assist device, heart transplant, heart/lung transplant Patients with cardiac dysrhythmias and pacemakers Patients with peripheral vascular disease Primary/secondary prevention for people with risk profiles for vascular disease (cardiovascular and cerebrovascular conditions)
Recruitment of Potential Participants	Physician, cardiac care manager, and physical therapist referrals Community health and wellness fairs Advertising, social media, and marketing programs
Components of Cardiac Rehabilitation/Secondary Prevention Programs (available on-site or through referral to satellite facility)	Patient assessment Physical activity counseling Exercise training Weight management Nutritional counseling Lipid management Hypertension management Smoking cessation Type 2 diabetes mellitus management Psychosocial management

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

	Cardiac Rehabilitation Program
Initial Intake and Assessment	Patient medical history and chart review Assessment of patient's goals and readiness for lifestyle modification Symptom assessment Cardiac risk assessment and risk stratification Physical examination and system review Diagnostic tests—for example, ECG, scans (pulmonary function and oximetry may be included) Vascular assessment (cardiac, cerebrovascular, and peripheral) Musculoskeletal assessment Nutrition assessment Psychosocial assessment Exercise testing assessment
Program Time Frame for Phase 2 Outpatient Cardiac Rehabilitation	Low-risk patients: 6-18 sessions or 30 days post-event or post-procedure Moderate-risk patients: 12-18 sessions or 60 days post-event or post-procedure High-risk patients: 18-30 sessions or 90 days post-event or post-procedure Frequency of outpatient visits: May vary greatly based on patient access to cardiac rehabilitation program, patient resources, and individual program structure
Personnel	Medical director Program director Patient care coordinator Cardiac rehabilitation specialists Physical therapist or nurse professional with specialization in cardiovascular and pulmonary care Health care consultants Dietitian or nutritionist Diabetes counselor Psychologist Social worker or counselor Health educator Occupational therapist Pharmacist Other exercise specialists
Exercise Assessment	Pretest procedures Informed consent Patient orientation and instructions Resting ECG Resting vital signs Exercise test modalities and protocols Standard and modified Bruce treadmill protocol Standard and modified Balke-Ware treadmill protocol USAFSAM treadmill protocol Incremental cycle ergometer protocol Treadmill or cycle ergometer ramping protocols Individualized, mode-specific protocols Standardized submaximal exercise testing protocols Clinical submaximal exercise tolerance test Vocational job simulation tests Exercise testing measures Heart rate and blood pressure Monitoring of signs or symptoms of cardiovascular compromise Oximetry ECG monitoring Rating of perceived exertion, dyspnea, angina, fatigue, claudication pain Ventilation gas analysis to measure oxygen uptake, anaerobic threshold, and minute ventilation Exercise testing with imaging modalities Radionuclear imaging stress test Exercise echocardiography Staff qualifications and medical supervision requirements
Training Interventions	Aerobic or endurance conditioning exercise Resistance exercise training Flexibility exercise Relaxation exercise Job simulation training

Continued

	Cardiac Rehabilitation Program
Education	Individualized to each patient's needs based on diagnosis, health status, comorbidities, lifestyle, and vocational/recreational/home environment Delivery methods and considerations Cultural appropriateness Literacy appropriateness Small group classes One-on-one consultation sessions Printed material for self-study Online education sessions One-on-one consultation during exercise training sessions Educational content Normal cardiovascular anatomy and physiology Pathophysiology of vascular conditions (cardiac, cerebrovascular, and peripheral) Interpretation of medical tests and procedures General principles of self-management of chronic heart conditions Cardiovascular medications Reduced periods of sedentary activity Exercise and physical activity Nutrition and weight management Risk factors for vascular conditions (cardiac, cerebrovascular, and peripheral) Stress reduction and relaxation techniques
Self-Management	Home-based cardiac rehabilitation programs Home program with outpatient initial evaluation and follow-up Internet-based home exercise and monitoring Internet-based interactive education Social support network
Outcomes	Patient-centered outcomes Increase in peak oxygen consumption or physical work capacity Reduction in symptoms such as angina or exertional dyspnea Risk factor modification, including smoking cessation, improved blood pressure, blood glucose control, lipid profile, body weight, and body composition Improved functional performance Return to work and recreational activities Increased home- and community-based physical activity Improved health-related quality of life Medication compliance and needs Program performance measures Patient satisfaction Patient adherence Decreased health care utilization Mortality and morbidity statistics
Facility Considerations	Adequate floor space for activities Emergency access and regularly tested emergency call system Adequate temperature and humidity control Clean water source for hydration Patient privacy and confidentiality of patient records Toilet, locker, and shower facilities
Equipment Considerations	High-quality, commercial-grade exercise equipment Aerobic training equipment Treadmill, upright and recumbent cycle ergometer, elliptical trainer Combined arm/leg ergometer, arm cycle ergometer Walking track Resistance training equipment Weight machines, weight pulleys Resistance bands, cuff/hand weights Free weights—dumbbells and barbells Testing and monitoring equipment Calibrated treadmill, cycle ergometer, and other exercise machines if available Electrocardiographic monitoring system Sphygmomanometer Cardiology-grade stethoscope Rating scales for perceived exertion, dyspnea, angina, fatigue, claudication pain Calibrated weight scale Regular scheduled maintenance and calibration

	Cardiac Rehabilitation Program
Emergency Management	Emergency resuscitation equipment and crash cart Appropriate cardiac life support training and certification by all staff members Appropriate medical supervision Emergency policies and procedures Regular emergency procedure in-services and drills
Quality Control	Regular review of detailed policy and procedure manuals Evaluation of staff performance Evaluation of client satisfaction Evaluation of program outcomes Review of medical records and documentation Facility and program review by mandatory regulatory agencies

Appendix **B**

Elements of International Standards for a Pulmonary Rehabilitation Program

	Pulmonary Rehabilitation Program
Aims	Reduce symptoms (particularly breathlessness) to manageable levels Optimize functional capacity Increase participation in vocational and recreational activities Improve health-related quality of life Reduce health care costs through stabilizing or reversing disease symptoms Support mental health and minimize anxiety and depression Reduce risk factors through patient and family education and behavior change Develop and help patient implement a safe and effective home exercise/activity program Communication: Provide feedback to referring physician regarding efficacy of medical management
Setting	Inpatient and outpatient Outpatient physical therapy clinic Fitness and wellness facilities School or community gymnasium May be combined with cardiac rehabilitation program
Target Population	Patients with chronic lung conditions, including cystic fibrosis, asthma, bronchiectasis, bronchiolitis obliterans, and restrictive lung conditions such as interstitial pulmonary fibrosis Patients with associated activity and participation limitations due to respiratory symptoms Patients with chronic lung conditions after acute exacerbations Surgical patients after thoracic surgery, lung reduction surgery, or lung transplant
Recruitment of Potential Participants	Physician, pulmonary care manager, and physical therapist referrals Advertising, social media, and marketing programs Community health and wellness fairs
Components of Pulmonary Rehabilitation Programs (available on-site or through referral to satellite facility)	Patient assessment Physical activity counseling Smoking cessation Exercise training Psychosocial management Weight management Nutritional counseling Lipid management Hypertension management Diabetes management
Initial Intake and Assessment	Patient medical history and chart review Assessment of patient's goals and readiness for lifestyle modification Symptom assessment Physical examination and system review Diagnostic tests—for example, pulmonary function testing, oximetry, ECG, cardiac testing Vascular assessment (cardiac, cerebrovascular, and peripheral) Musculoskeletal assessment Nutrition assessment Psychosocial assessment Exercise testing assessment

	Pulmonary Rehabilitation Program
Program Time Frame for Outpatient Pulmonary Rehabilitation	6-12 weeks of participation in pulmonary rehabilitation results in significant benefits in program outcomes Longer pulmonary rehabilitation programs produce greater sustained benefits than do shorter programs Frequency of outpatient visits may vary based on patient access to pulmonary rehabilitation program, patient resources, and individual program structure
Personnel	Medical director Program director Patient care coordinator Pulmonary rehabilitation specialists Physical therapist, respiratory therapist, or nurse professional with specialization in pulmonary care Health care consultants Dietitian or nutritionist Psychologist Social worker or counselor Health educator Occupational therapist Pharmacist Other exercise specialists
Exercise Assessment	Objectives Measure exercise capacity to determine baseline for exercise prescription, outcome assessment, and goal setting Detect exercise-induced hypoxemia Screen for exercise-induced bronchoconstriction Screen for signs or symptoms suggestive of cardiac disease Pretest procedures Informed consent Patient orientation and instructions Pulmonary function testing Resting oximetry Resting dyspnea score Resting vital signs Resting ECG Administration of inhaled bronchodilator medicine if prescribed Exercise test modalities and protocols 6-minute walking test Incremental shuttle test Endurance shuttle walk Incremental maximal treadmill protocols, such as the standard or modified Bruce treadmill protocol, Balke-Ware, or USAFSAM treadmill protocol Incremental cycle ergometer protocol Treadmill or cycle ergometer ramping protocols Individualized, mode-specific protocols Standardized submaximal exercise testing protocols Clinical submaximal exercise tolerance test Vocational job simulation tests Exercise testing measures Oximetry Heart rate and blood pressure Monitoring of signs or symptoms of cardiovascular compromise ECG monitoring Rating of dyspnea, perceived exertion, angina, fatigue, etc. Ventilator gas analysis to measure oxygen uptake, anaerobic threshold, and minute ventilation Staff qualifications and medical supervision requirements
Training Interventions	Aerobic or endurance conditioning exercise Resistance exercise training Flexibility exercise Respiratory muscle training Relaxation exercise Job simulation training

Continued

	Pulmonary Rehabilitation Program
Education	Individualized to each patient's needs based on diagnosis, health status, comorbidities, lifestyle, and vocational/recreational/home environment, etc. Delivery methods and considerations Cultural appropriateness Literacy appropriateness Small group classes One-on-one consultation sessions Printed material for self-study Online education sessions One-on-one consultation during exercise training sessions Educational content Normal pulmonary anatomy and physiology Pathophysiology of chronic lung conditions Interpretation of medical tests and procedures Pulmonary medications and respiratory devices General principles of self-management of chronic lung conditions Breathing control strategies Secretion clearance techniques Reduced periods of sedentary activity Exercise and physical activity Nutrition and weight management Risk factors for respiratory conditions and smoking cessation Stress reduction and relaxation techniques
Self-Management	Home-based pulmonary rehabilitation programs Home program with outpatient initial evaluation and follow-up Internet-based home exercise and monitoring Internet-based interactive education Social support network
Outcomes	Patient-centered outcomes Increase in physical work capacity or peak oxygen consumption Symptom reduction Risk factor modification including smoking cessation, improved blood pressure, blood glucose control, lipid profile, body weight, and body composition Improved functional performance Increased home- and community-based physical activity Improved health-related quality of life Medication compliance and needs Program performance measures Patient satisfaction Patient adherence Decreased health care utilization Mortality and morbidity statistics
Facility Considerations	Adequate floor space for activities Low-traffic hallway for walk tests Emergency access and regularly tested emergency call system Adequate temperature and humidity control Clean water source for hydration Patient privacy and confidentiality of patient records Toilet, locker, and shower facilities
Equipment Considerations	High-quality, commercial-grade exercise equipment Aerobic training equipment Treadmill, upright, and recumbent cycle ergometer, elliptical trainer Combined arm/leg ergometer, arm cycle ergometer Walking track Resistance training equipment Weight machines, weight pulleys Resistance bands, cuff/hand weights Free weights—dumbbells and barbells Testing and monitoring equipment Calibrated treadmill, cycle ergometer, and other exercise machines if available Electrocardiographic monitoring system Sphygmomanometer Cardiology-grade stethoscope Rating scales for perceived exertion, dyspnea, angina, fatigue, pain Calibrated weight scale Oxygen with delivery apparatus Regular scheduled maintenance and calibration

	Pulmonary Rehabilitation Program
Emergency Management	Emergency resuscitation equipment and crash cart Appropriate cardiac life support training and certification by all staff members Appropriate medical supervision Emergency policies and procedures Regular emergency procedure in-services and drills

Appendix C

Exercise Testing and Prescription Considerations for People with Primary Cardiovascular, Pulmonary, and Endocrine Conditions

Basal activity and exercise status consistent with maximal health condition: *To the greatest extent possible*, to be physically active throughout each day and engage in structured exercise, depending on an individual's basal physical activity demands (for example, a heavy laborer may be sufficiently fit and not in need of a structured exercise program; on the other hand, for a sedentary office clerk, a structured exercise program may be a high priority).

Requirements for deriving maximal health benefits from being physically active throughout each day:

- Decreased periods of sedentary activity (particularly screen-based activities such as television viewing and computer use)
- Increased periods of regular physical activity of low to moderate intensity (ideally integrated into ADL, stairs, foot/cycle transportation, and occupation, as well as recreation and leisure)

Requirements for deriving maximal health benefits from a structured exercise program for an apparently healthy person; parameters may be approximately in individuals with mild signs and symptoms of chronic conditions:

- Stretching:
  - 5-10 min after warm-up/cool-down before and after each exercise (e.g., aerobic and strengthening)
- Aerobic:
  - F(requency): 3-5 days/week
  - I(ntensity): Moderate to high
  - T(ype): Aerobic walking, cycling, jogging, hiking, rowing, dancing
  - T(ime): 20-40 min
- Strengthening:
  - F(requency): 2-3 days/week
  - I(ntensity): Low to moderate weights; 40%-70% capacity; one repetition maximum
  - T(ype): Weights, bands, pulleys, weight-training equipment
  - T(ime): 3 sets of 8-15 repetitions maximum

Note: Regarding the guidelines below, exercise parameters are modified based on individual differences in age, body weight, baseline conditioning level, pathologies and their severities, comorbidities and their severities, and other factors extracted from the assessment, physical examination, and laboratory investigations.

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

CARDIOVASCULAR CONDITIONS: HYPERTENSION (MEDICALLY CONTROLLED)	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Multisystem review, including heart, CNS, kidneys, vision, hearing Secondary complications, such as involvement of the brain, heart, kidneys Medical management and response Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Electrolytes and fluid balance ECG Adherence to medication Change in blood pressure profile Reduction or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to high BP, medication types, and medication use Resting HR, BP, RPP, RR, RPE, and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to reduce BP Adequate BP control Avoidance of excessive increases (secondary to extreme weight or effort such as in isometric contractions and breath holding) Close monitoring of HR, BP, and RPP Depending on the medications being taken and the patient's responses, objective parameters may be blunted and subjective parameters (such as exertion) may be more valid indicators of exercise intensity Optimal weight control Aerobic: F: 2-5 times/day I: Light to moderate T: Rhythmic whole body exercise; primarily legs with less arm work, particularly heavy resistance or isometric work T: 15-30 min, at minimum Progress as needed commensurate with reduction in resting and exercise BPs; typically, the more severe the hypertension, the shorter and more frequent sessions may be effective; less severe hypertension may respond to a daily bout of moderate continuous aerobic exercise Progress in accordance with musculoskeletal adaptation as well as cardiovascular and respiratory adaptations As resting and exercise BPs drop in response to increased volume of physical activity, intensity can progressively increase and frequency decrease Emphasize self-monitoring of HR and BP during home program, and indications for modifying activity Other activities—brisk leisure activities such as gardening, dancing; stress-reducing activities such as yoga, meditation, and tai chi (possibly gardening for some people)
Potential Pre-exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Fluid balance Specialized diets (e.g., DASH diet) Salt restriction Weight control Body composition Sleep hygiene Relaxation Stress reduction Biofeedback Education regarding regular use of medication Partner with physician to reduce or eliminate medication as nondrug interventions take effect Partner with other health professionals as needed (e.g., nutritionist)

Continued

CARDIOVASCULAR CONDITIONS: ANGINA (MEDICALLY CONTROLLED)	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Multisystem review to assess atherosclerosis throughout body systems Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Risk factor review to target risk factor modification Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in angina profile Reduction or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to angina and related symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to reduce the signs and symptoms of angina and prevent future episodes Avoidance of excessive increases (secondary to extreme weight or effort such as in isometric contractions and breath holding) Aerobic: F: 5 days/week I: Moderate intensity; depending on disease lability or severity 40%-80% HRR (Karvonen formula if severe) or 60%-80% peak exercise capacity within anginal threshold Progress in accordance with musculoskeletal adaptation as well as cardiovascular and respiratory adaptations Emphasize self-monitoring of signs and symptoms and indications for modifying activity Other activities—brisk symptom-free performance of leisure activities; may include yoga, meditation, and tai chi
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Lipid control Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Use of anti-angina medication Education regarding avoiding anginal threshold Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
CARDIOVASCULAR CONDITIONS: MYOCARDIAL INFARCTION	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Cardiovascular, cerebrovascular, and metabolic risk factors Pulmonary function Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Assessment and Outcome Evaluation	Risk factor review to target risk factor modification Hgb, HgbA1c, lipids, homocysteine, and blood glucose Fluid and electrolyte balance Presence of peripheral edema Baseline fatigue and breathlessness Adherence to medication Change in angina profile Reduction or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Fatigue Sleep quality and quantity Stress Frequency and causes of visits to physician and hospital Patient's health knowledge and literacy with special reference to MI and related symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, and exercise test responses, including recovery; Spo_2 should remain within normal limits
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to help reverse MI signs and symptoms and prevent future episodes Avoidance of excessive increases (secondary to extreme weight or effort such as in isometric contractions and breath holding) Aerobic: F: 5 days/week I: Moderate intensity (70%-85% peak exercise capacity); if severe heart damage, begin at 40% T: Whole body rhythmic continuous exercise T: 20 to 40 min Strengthening: F: 2-3 days/week I: 3 sets, 30% to 60% capacity, 8-15 estimated repetitions maximum T: Weights, dumbbells, pulleys, bands T: Contractions performed deliberately with rest and recovery time between sets Emphasize self-monitoring of signs and symptoms and indications for modifying activity Progress in accordance with musculoskeletal adaptation as well as cardiovascular and respiratory adaptations Other activities—brisk leisure activities (may include yoga, meditation, and tai chi)
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Lipid control Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
CARDIOVASCULAR CONDITIONS: STENTS/BYPASS SURGERY	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Continued

Assessment and Outcome Evaluation	Risk factor review to target risk factor modification Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Fluid and electrolyte balance Baseline fatigue and breathlessness Peripheral edema Adherence to medication Change in blood pressure profile Reduction or cessation of medication Musculoskeletal status, including chest wall symmetry and trunk strength (absence of surgical residua) BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Sleep quality and quantity Stress Frequency and causes of visits to physician and hospital Patient's health knowledge and literacy with special reference to cardiac signs and symptoms, related medication types, and medication use Resting HR, BP, RPP, RR, RPE, and exercise test responses, including recovery; Spo_2 should remain within normal limits
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to reverse and prevent cardiac signs and symptoms Aerobic: F: 5 days/week I: Moderate intensity (70%-85% peak exercise capacity) if little comorbidity; reduce intensity if severe cardiac muscle damage T: Whole body rhythmic exercise T: 20 to 40 min Strengthening (>6 weeks after surgery): F: 2-3 days/week I: 3 sets, 30% to 60% capacity, 8-15 estimated repetitions maximum T: Weights, dumbbells, pulleys, bands T: Contractions performed deliberately with rest and recovery time between sets Emphasize self-monitoring of signs and symptoms and indications for modifying activity Progress in accordance with musculoskeletal adaptation as well as cardiovascular and respiratory adaptations Other activities—brisk leisure activities (may include yoga, meditation, and tai chi)
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Lipid control Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Minimize indications for "re-do" surgeries Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
CARDIOVASCULAR CONDITIONS: VALVE REPLACEMENT	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Assessment and Outcome Evaluation	Risk factor review to target risk factor modification Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Fluid and electrolyte balance Adherence to medication Change in blood pressure profile Reduction or cessation of medication Musculoskeletal status, including chest wall symmetry and trunk strength (absence of surgical residua) BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy, related medication types, and medication use if indicated Resting HR, BP, RPP, RR, RPE, and exercise test responses, including recovery; Spo_2 should remain within normal limits
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to maximize fitness and health Aerobic: F: 5 days/week I: Moderate intensity (70%-85% peak exercise capacity) T: Whole body rhythmic continuous exercise T: 20 to 40 min Strengthening (>6 weeks after surgery): F: 2-3 days/week I: 3 sets, 30% to 60% capacity, 8-15 estimated repetitions maximum T: Weights, dumbbells, pulleys, bands T: Contractions performed deliberately with rest and recovery time between sets Emphasize self-monitoring of signs and symptoms and indications for modifying activity Progress in accordance with musculoskeletal adaptation as well as cardiovascular and respiratory adaptations Other activities—brisk leisure activities, including yoga, meditation, and tai chi
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Lipid control Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Liaison with other health professionals as needed (e.g., nutritionist)
CARDIOVASCULAR CONDITIONS: HEART FAILURE	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Quality of life Mental health, anxiety, and depression Condition severity, medical management, and response Comorbidities and their severities (including COPD, type 2 diabetes mellitus, and renal disease, as well as how these are being managed; bone health and musculoskeletal symptoms/deformity) Cardiovascular, cerebrovascular, and metabolic risk factors Pulmonary function Ventilatory support (e.g., supplemental O_2 and nighttime CPAP) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Continued

Assessment and Outcome Evaluation	Risk factor review to target risk factor modification Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Fluid and electrolyte balance Peripheral edema BMI WHR Baseline breathlessness and fatigue Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to heart failure (worsening/improving signs and symptoms), medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2, and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	Frequent periods of paced activity interspersed between sitting and rest periods guided by symptoms (i.e., within breathing tolerance to avoid exacerbating cardiopulmonary congestion) Stretching: Low-level warm-up/cool-down commensurate with goal activity or exercise Aerobic: F: Several times daily I: 40% to 80% HRR or less (Karvonen formula), guided by responses and avoidance of cardiopulmonary congestion T: Gently paced physical activity and aerobic walking T: From a couple to several minutes of exercise interspersed with rests guided by recovery (increasing length of exercise duration with reduced duration of rests between) Strengthening (Note: The responsivity of muscle exposed to chronic hypoxia secondary to chronic heart failure and associated myopathy has not been well documented; assess and monitor the individual's response): F: Daily (if moderately severe); 2-3 times/week (if less severe or well tolerated) I: Low-level resistance (arms and legs) coordinated with breathing control; commensurate with tolerance and avoidance of strain and cardiopulmonary congestion T: Weights, dumbbells T: 3 sets of 5-10 estimated repetition maximum contractions performed deliberately with rest and recovery time between sets Other activities—restorative rest and activity-to-rest pacing
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Lipid control Salt restriction Weight control Relaxation Sleep hygiene Stress reduction Liaison with other health professionals as needed (e.g., nutritionist)
CARDIOVASCULAR CONDITIONS: PERIPHERAL VASCULAR DISEASE	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity Comorbidities and their severities (including heart disease, cerebrovascular disease, and type 2 diabetes mellitus, as well as how these are being managed; bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Assessment and Outcome Evaluation	Risk factor review to target risk factor modification Multisystem review, particularly with respect to systemic atherosclerosis Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to atherosclerosis and its multisystemic effects, medication types, and medication use Resting HR, BP, RPP, RR, RPE, and exercise test responses, including recovery; Spo_2 should remain within normal limits Claudication pain: VAS (0-10); ideally returning to 0 within several minutes of exercise cessation
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to reduce claudication discomfort and potential for arterial narrowing elsewhere, including the coronary vessels Aerobic: F: Depending on severity from several times to once daily I: Set below claudication threshold OR at threshold (if no cardiac involvement or symptoms); patient adjusts walking pace to make claudication discomfort manageable (objectify on the VAS scale) while ensuring gait is not changed T: Aerobic walking (preferable) or cycling; rhythmic continuous alternating extremity exercise T: Up to 40 min, beginning with several minutes that are tolerable with rest periods between (guided by claudication recovery time); with vascular collateralization adaptation to exercise, periods and intensity of exercise will increase and rest periods or reduced intensity bouts will decrease) Other activities—activity-rest pacing may be an effective strategy to push into claudication zone
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Lipid control Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Wound surveillance and care Intermittent claudication management Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
PULMONARY CONDITIONS: ASTHMA	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review as a basis for lifestyle modification Pulmonary function profile (volumes, capacities, and flow rates) within 3 months Vascular screen as indicated based on lifestyle and family history—blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in asthmatic attacks (frequency, severity, recovery, and recovery time) Reduction or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to asthma triggers and attenuators (self-management strategies and their effectiveness), breathing distress, and medication types and use Resting HR, BP, RPP, RR, Spo_2, and breathlessness and exercise test responses, including recovery

Continued

Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to reduce asthmatic attack frequency and severity and increase recovery Activity/exercise-rest pacing Stretching: Chest wall mobility stretching exercises in three planes of movement Upper extremity and shoulder girdle movements in three planes of movement Stretching coordinated with breathing control strategies as indicated Aerobic: F: Daily I: Below disabling breathlessness threshold (objectify on VAS scale) and/or Spo_2 <90%; coordinate with breathing control and premedicate as needed, allowing sufficient time for meds to reach peak effectiveness; avoidance of disabling wheezing; coordinate with breathing control strategies depending on condition severity T: Rhythmic progressively continuous exercise (e.g., walking, jogging, cycling, rowing) T: Shorter, more frequent periods for more severe asthma; for less severe asthma, use longer, less frequent periods of exercise that may approximate 20 to 40 min; cut back intensity or rest if breathlessness unmanageable and/or Spo_2 <90%; reinitiate exercise after recovery and stabilization of breathlessness and Spo_2 recovery for several minutes Other activities—daily walking; stress the oxygen transport pathway at a consistent level
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Allergy surveillance and education Asthmatic attack management Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g. nutritionist)
PULMONARY CONDITIONS: CHRONIC BRONCHITIS	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review as a basis for lifestyle modification Pulmonary function profile (volumes, capacities, and flow rates) within 3 months Vascular screen as indicated based on lifestyle and family history—blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Immune status Adherence to medication Change in exacerbations (frequency, severity, recovery, and recovery time) Reduction or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to infection and bronchitis triggers and attenuators (self-management strategies), breathing distress, medication types, and medication use Resting HR, BP, RPP, RR, Spo_2 (as indicated), breathlessness and exercise test responses, including recovery

Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to reduce infections and exacerbations and speed recovery in the event of an exacerbation Activity/exercise-rest pacing Stretching: Chest wall movements as well as extremity muscles and joints in three planes of movement; coordinate with breathing control strategies as indicated Aerobic: F: Daily for less severe disease; more frequent bouts of exercise for more severe symptoms and disease I: Guided by breathlessness tolerance (objective on VAS 0-10); intermittent exercise and rest as needed (e.g., 2-3 min tolerable exercise to 1 min of rest) and coordinated with breathing control strategies as indicated T: Continuous rhythmic walking, cycling, rowing movements T: If frequent bouts, then shorter periods; less frequents bouts, longer periods of exercise; as patient adapts to exercise stimulus, frequent short exercise bouts progress to less frequent longer exercise bouts
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Infection control Breathing control Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
PULMONARY CONDITIONS: EMPHYSEMA	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review as a basis for lifestyle modification Pulmonary function profile (volumes, capacities, and flow rates; potentially, V/Q scan, closing volume, and diffusing capacity) within 3 months Respiratory muscle strength and endurance General muscle strength and endurance Use of home oxygen (mode, delivery, and concentration) Vascular screen—blood work profile, including Hgb, HgbA1c, lipids, homocysteine and blood glucose, and red and white blood cell counts, platelets ECG Involvement of right and left sides of the heart Peripheral swelling Immune status Respiratory muscle strength and endurance General muscle strength and endurance Adherence to medication Change in exacerbations (frequency, severity, recovery, and recovery time) Reduction or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity (use of nocturnal noninvasive ventilation, such as CPAP) Stress Patient's health knowledge and literacy with special reference to infection and exacerbation triggers and attenuators (self-management strategies), breathing distress, and medication types and use Resting HR, BP, RPP, RR, Spo_2, breathlessness and exercise test responses, including recovery

Continued

Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to reduce episodes of breathlessness, improve recoverability, and reduce exacerbations and visits to physician and hospital Activity/exercise-rest pacing Monitor upper extremity exercises to ensure muscle work does not compete with the work of breathing and compound breathlessness Stretching: Upper extremity, shoulder, and chest wall movements (trunk forward flexion, side flexion, extension, and rotation to either side), as well as extremity muscles and joints in three planes of movement Coordinate with breathing control strategies as indicated based on condition severity Aerobic: F: Daily for less severe disease; for more severe symptoms and disease, use more frequent short bouts of exercise throughout the day I: Guided by breathlessness tolerance (objective on VAS 0-10); intermittent exercise and rest as needed (e.g., 2-3 min tolerable exercise to 1 min of rest to stabilize Spo_2 and breathing demands) and coordinated with breathing control strategies and medication as indicated T: Rhythmic whole body exercise; may need to be supported if symptoms are severe (ergometer handle bar); may need to support shoulder girdle; single leg exercise (e.g., ergometer cycling) may reduce respiratory demand and produce more work T: If frequent bouts, then shorter periods; less frequents bouts, then longer periods of exercise; rest periods between bouts of exercise based on physiologic recovery of Spo_2, RR, HR, BP and RPP, and breathlessness Strengthening (Note: The responsivity of muscle exposed to chronic hypoxia secondary to chronic respiratory dysfunction and associated myopathy has not been well documented; assess and monitor the individual's response): F: Daily if severe symptoms (light intensity) to 2-4 days/week if mild to moderate symptom severity I: Light if severe symptoms; if mild to moderate symptoms, 20%-60% capacity, estimated 1 repetition maximum T: Weights, dumbbells, bands T: 3 sets of 5-12 estimated repetitions maximum Breathing control and oxygen or medications as needed to promote exercise endurance and maintain Spo_2 within acceptable limits Avoidance of excessive increases (secondary to extreme weight or effort such as in isometric contractions and breath holding) Close monitoring of HR, BP, RPP, Spo_2 Optimal nutrition and weight control Emphasize self-monitoring of signs and symptoms and indications for modifying activity
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Infection control Breathing control Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
PULMONARY CONDITIONS: INTERSTITIAL PULMONARY FIBROSIS	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Assessment and Outcome Evaluation	Lifestyle risk factor review as a basis for lifestyle modification Pulmonary function profile (volumes, capacities, and flow rates; potentially, V/Q scan, closing volume, and diffusing capacity) within 3 months Vascular screen as indicated based on lifestyle and family history—blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in infection rate Reduction or cessation of medication In severe cases, use of home oxygen (mode, delivery, and concentration) Respiratory muscle strength and endurance General muscle strength and endurance BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) ECG Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to triggers and attenuators of respiratory distress (self-management strategies and their effectiveness), medication types, and medication use Resting HR, BP, RPP, RR, Spo_2 (as indicated), breathlessness and exercise test responses, including recovery Exercise desaturation profile
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to reduce episodes of breathlessness and associated desaturation, infection rate, and visits to physician and hospital Stretching: Chest wall mobility and upper extremity and should girdle mobility (three planes of movement) Aerobic: F: Daily (light intensity) if severe symptoms; 3-5 days/week if mild or moderate symptoms I: Guided by breathlessness tolerance (visual analog scale 0-10) and in some patients Spo_2 >90% T: Whole body continuous rhythmic aerobic exercise; rest periods as needed for physiologic recovery of breathlessness and Spo_2 to comfortable and acceptable limits T: If severe symptoms, several minutes interspersed with rest periods for recovery; if mild to moderate symptoms, longer periods of continuous exercise Strengthening: F: Daily if severe symptoms (light intensity); 2-4 days/week if mild to moderate symptom severity I: Light if severe symptoms; if mild to moderate symptoms, 20%-60% capacity, estimated 1 repetition maximum T: Weights, dumbbells, bands T: 3 sets of 5-12 estimated repetitions maximum
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Liaison with other health professionals as needed (e.g., nutritionist)
PULMONARY CONDITIONS: LUNG CANCER	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health, anxiety and depression Condition severity (stage), including metastases (sites and severity), medical management (chemotherapy and radiation) and response Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Continued

Assessment and Outcome Evaluation	Lifestyle risk factor review as a basis for lifestyle modification Pulmonary status and consistency over the recent past Vascular screen as indicated based on lifestyle and family history—blood work profile, including Hgb, HgbA1c, platelets, red and white blood cell counts, lipids, homocysteine, and blood glucose Immune status Discomfort/pain profile Fatigue profile ECG Adherence to medication Reduction or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to cancer, treatment, responses (self-management strategies for countering treatment side effects and their effectiveness), medication types, and medication use Resting HR, BP, RPP, RR, Spo_2 (as indicated), breathlessness, fatigue and discomfort/pain, and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to improve tolerance for activities of daily living, activity and participation, and overall quality of life Guided by enjoyment as well as physical parameters Guided by Hgb, platelet, and white blood cell counts when undergoing treatment Minimize discomfort/pain and undue fatigue and breathlessness Stretching: Whole body stretching program Aerobic (Note: If patient undergoing radiation therapy or chemotherapy, coordinate exercise program with patient's status on any given day): F: Multiple times daily if severe symptoms, within limits of tolerance (light intensity) I: Guided by breathlessness tolerance (visual analog scale 0 to 10); intermittent exercise and rest as needed (e.g., 2 to 3 min tolerable exercise followed by 1 min of rest) T: Gentle aerobic walking, ergometer cycling, or rowing with breathing control T: From several minutes with rests as indicated to 20-30 min of continuous exercise as tolerated Strengthening: F: Daily if severe symptoms (light intensity); 2-4 days/week if mild to moderate symptom severity I: Light if severe symptoms; if mild to moderate symptoms, 20%-60% capacity, estimated 1 repetition maximum T: Weights, dumbbells, bands T: 3 sets of 5-12 estimated repetitions maximum
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Support group Palliative care Liaison with other health professionals as needed (e.g., nutritionist)
ENDOCRINE AND METABOLIC CONDITIONS: TYPE 1 DIABETES MELLITUS (CONTROLLED)	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Assessment and Outcome Evaluation	Lifestyle risk factor review as a basis for lifestyle modification Multisystem assessment to establish the multisystemic signs and symptoms of the diabetes Vascular screen as indicated based on lifestyle and family history—blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adequacy of medical control over the years (degree of lability with exercise and stress) Cardiovascular function Peripheral vascular function CNS and autonomic nervous system function Muscle function Vision and hearing Wounds, healing, and healing rate Adherence to healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to diabetes, treatment, responses (self-management strategies for countering treatment side effects and their effectiveness), medication types, and medication use Resting HR, BP, RPP, RR, Spo_2 (as indicated), RPE, and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to maximize oxygen transport, collateralization to improve blood flow, and tissue perfusion Sugar source available throughout exercise; patient should develop exceptional self-monitoring skills Abrasions of extremities are to be avoided Patient knowledge of how to inspect extremities for abrasions; proper use of socks and footwear; recognition that modifications of exercise are indicated if any abrasions occur and to promote healing Adjust carbohydrate load to metabolic demands May need to check blood glucose levels during an exercise bout (at least initially) May have abnormal ANS responsivity; need to be closely assessed and monitored in regard to exercise responses, at least initially Subjective responses (breathlessness) may be blunted; closely assess and monitor, at least initially Angina awareness may be blunted; if patient has history of angina, closely assess and monitor Aerobic: F: 3-7 days/week I: 50%-80% HRR (Karvonen formula) T: Aerobic walking and/or cycling (steady work rate) T: 20-40 min Strengthening: As tolerated; low-intensity multiple repetitions can improve and regulate glucose metabolic activity of peripheral muscle Other activities—stress the oxygen transport pathway at a consistent level to minimize extreme fluctuations in blood glucose; always have a sugar source at hand
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Wound surveillance and care Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
ENDOCRINE AND METABOLIC CONDITIONS: TYPE 2 DIABETES MELLITUS (CONTROLLED)	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health Condition severity, medical management, and response Comorbidities and their severities (including heart, peripheral vascular, renal, vision and hearing; bone health and musculoskeletal symptoms/deformity) Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Continued

Assessment and Outcome Evaluation	Lifestyle risk factor review as a basis for lifestyle modification (atherosclerosis is accelerated with type 2 diabetes mellitus) Multisystem assessment to establish the multisystemic signs and symptoms of the diabetes Vascular screen as indicated based on lifestyle and family history—blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Cardiovascular function Peripheral vascular function CNS and autonomic nervous system function Muscle function Vision and hearing Hemoglobin HgbA1c Wounds and healing Adherence to healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to diabetes, treatment and responses (self-management strategies for countering treatment side effects and their effectiveness), medication types, and medication use Resting HR, BP, RPP, RR, Spo_2 (as indicated), RPE and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) to maximize oxygen transport, collateralization to improve blood flow, and tissue perfusion Sugar source available throughout exercise; patient should develop exceptional self-monitoring skills Avoidance of abrasions to extremities Patient knowledge of how to inspect extremities for abrasions; proper use of socks and footwear; recognition that modifications of exercise are indicated if any abrasions occur and to promote healing Adjust carbohydrate load to metabolic demands May need to check blood glucose levels during an exercise bout (at least initially) May have abnormal ANS responsivity; need to be closely assessed and monitored in regard to exercise responses, at least initially Subjective responses (breathlessness) may be blunted; closely assess and monitor, at least initially Angina awareness may be blunted; if patient has history of angina, closely assess and monitor Aerobic: F: Daily I: 50%-80% HRR (Karvonen formula) T: Aerobic walking and/or cycling (steady work rate) T: 20-60 min Strengthening: As tolerated; low-intensity multiple repetitions can improve and regulate glucose metabolic activity of peripheral muscle Other activities—stress the oxygen transport pathway at a consistent level to minimize extreme fluctuations in blood glucose; always have a sugar source at hand
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Wound surveillance and care Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)

Appendix D

Exercise Testing and Prescription Considerations for People with Nonprimary Heart, Lung, and Endocrine Conditions

Basal activity and exercise status consistent with maximal health condition: *To the greatest extent possible*, to be physically active throughout each day and engage in structured exercise, depending on an individual's basal physical activity demands (for example, a heavy laborer may be sufficiently fit and not in need of a structured exercise program; on the other hand, for a sedentary office clerk, a structured exercise program may be a high priority).

Requirements for deriving maximal health benefits from being physically active throughout each day:

- Decreased periods of sedentary activity (particularly screen-based activities such as television viewing and computer use)
- Increased periods of regular physical activity of low to moderate intensity (ideally integrated into ADL, stairs, foot/cycle transportation, and occupation, as well as recreation and leisure)

Requirements for deriving maximal health benefits from a structured exercise program for an apparently healthy person; parameters may be approximately in individuals with mild signs and symptoms of chronic conditions:

- Stretching:
  - 5-10 min after warm-up/cool-down before and after each exercise (e.g., aerobic and strengthening)
- Aerobic:
  - F(requency): 3-5 days/week
  - I(ntensity): Moderate to high
  - T(ype): Aerobic walking, cycling, jogging, hiking, rowing, dancing
  - T(ime): 20-40 min
- Strengthening:
  - F(requency): 2-3 days/week
  - I(ntensity): Low to moderate weights; 40%-70% capacity; one repetition maximum
  - T(ype): Weights, bands, pulleys, weight-training equipment
  - T(ime): 3 sets of 8-15 repetitions maximum

Note: Regarding the guidelines below, exercise parameters are modified based on individual differences in age, body weight, baseline conditioning level, pathologies and their severities, comorbidities and their severities, and other factors extracted from the assessment, physical examination, and laboratory investigations.

NEUROMUSCULAR CONDITIONS: STROKE	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications (e.g., involvement of the brain, heart, kidneys) Medical management and response Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: cardiovascular, pulmonary (spirometry in moderate to severe cases), musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry, and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to risk factors for vascular conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) for fitness, health promotion, prevention and amelioration of lifestyle-related conditions Adequate control of BP and/or blood coagulability Avoidance of excessive increases (secondary to extreme weight or effort such as in isometric contractions and breath holding) Minimize activities that unduly aggravate spasticity Close monitoring of HR, BP, RPP, RR, ECG, and Spo_2 (as indicated); breathlessness and discomfort/pain in some patients (VAS 0-10) Guide progression of exercise program also based on recovery of objective and subjective exercise parameters Optimal weight control Optimal selection and use of walking aids and devices Stretching: Muscles and joints daily, and pre-exercise as indicated Aerobic: F: 2-5 times daily if moderately severe disability/deformity; daily if mild to moderately severe disability/ deformity I: if light to moderate, 40%-80% HRR (Karvonen formula if severe involvement); 60%-75% age-predicted maximum HR if mild to moderate severe disability/deformity T: continuous rhythmic whole body exercise; primarily legs with less arm work, particularly heavy resistance or isometric (walking, ergometer cycling); use of body harness on a treadmill with supervision may be effective in some patients to help restore some bilateral symmetric muscle activation and balance T: 15-30 min at least Strengthening: F: 2-3 days/week I: low to moderate weight, 40%-70% capacity, estimated one repetition maximum (avoid undue strain, breath holding, and intensity that increases spasticity) T: weights, dumbbells, pulleys, bands T: 3 sets of 8-15 repetitions Other activities: Bilateral activities commensurate with capacity Progress as needed commensurate with reduction in resting HR, BP, and RPP; typically, with more severe disability/deformity, shorter and more frequent sessions may be effective; less severe signs and symptoms may respond to a daily bout of moderate continuous aerobic exercise Progress in accordance with musculoskeletal adaptation as well as cardiovascular and respiratory adaptations Resting and exercise HR and BP may drop in response to increased volume of physical activity, intensity

Continued

Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet, Mediterranean-type diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with other health professionals as needed (e.g., nutritionist)
NEUROMUSCULAR CONDITIONS: PARKINSON SYNDROME	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health and cognitive well-being (life satisfaction, anxiety, depression) Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications (e.g., involvement of the brain, heart, kidneys) Medical management and response Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: CNS (sensorimotor status), cardiovascular, pulmonary, musculoskeletal (muscle symmetry, rigidity, spasticity, gait and coordination, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication ↓ Or cessation of medication (exercise can improve L-dopa effectiveness) BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Premedication to reduce rigidity may be beneficial Stretching: Whole body ROM, particularly spine and shoulder and pelvic girdles (daily) Aerobic: F: daily (shorter, more frequent sessions throughout the day with increased severity and disability) I: low to moderate, within subjective limits of coordination and comfort T: whole body (e.g., walking, aquatic, ergometer) T: 10-30 min; with intermittent rests and recovery as needed Strengthening: Guided by biomechanical considerations such as not exacerbating rigidity Other activities: Of interest to the patient (yoga, tai chi, dancing)
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)

NEUROMUSCULAR CONDITIONS: MULTIPLE SCLEROSIS	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Cognitive status and mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: CNS (sensorimotor status), cardiovascular, pulmonary, musculoskeletal (muscle symmetry, spasticity, gait and coordination, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status) and ANS status (response to position change), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular), renal (continence) Monitor disease progression (peaks and troughs) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Consider morning exercise program to maximize higher energy time of day Stretching: Whole body gentle stretching regime Aerobic: F: daily (shorter, more frequent sessions throughout the day with increased severity and disability) I: low to moderate, within subjective limits of coordination and comfort (VAS 0-10) T: whole body (e.g., walking, aquatic, ergometer) T: 10-30 min; with intermittent rests and recovery as needed Strengthening: Guided by biomechanical considerations such as not exacerbating incoordination Other activities: Of interest to the patient (yoga, tai chi, dancing)
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)

Continued

NEUROMUSCULAR CONDITIONS: CEREBRAL PALSY	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mobility status (wheelchair dependency) Cognitive and mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications, (e.g., involvement of the brain, heart, kidneys) Medical management and response Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: cardiovascular, pulmonary, musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Consistent with cognitive capacity, patient's health knowledge and literacy with special reference to risk factors for lifestyle-related conditions, medication types, and medication use (or, knowledge of the primary caregiver) Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Focus on exercise effects of functional activities Coordinate activity intensity with minimizing spasticity and discoordination as much as possible Stretching: Gentle active, active assisted, or assisted movements (all planes), particularly muscles with excessive tone Aerobic: Commensurate with capacity F: daily (shorter, more frequent sessions throughout the day with increased severity and disability) I: low to moderate, within subjective limits of coordination and comfort T: whole body (e.g., walking, aquatic, ergometer) T: 10-30 min; with intermittent rests and recovery as needed Strengthening: Guided by biomechanical considerations such as not exacerbating spasticity Other activities Of interest to the patient (yoga, tai chi, dancing)
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)

NEUROMUSCULAR CONDITIONS: SPINAL CORD INJURY (HIGH)	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: cardiovascular, pulmonary (baseline spirometry and respiratory muscle strength and endurance measures), musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, spinal alignment, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living and aging with a spinal cord injury, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Minimize overuse; incorporate activity-rest regimen Focus on exercise effects of functional activities Assess ANS involvement to determine the validity of exercise responses to exercise; establish a meaningful baseline of responsivity of the patient Stretching: Whole body, particularly of paretic or paralyzed muscles and involved joints Avoid overstretching and traumatizing affected muscles, fragile connective tissue, and joints Aerobic: F: alternate days I: 60%-80% HRR (Karvonen formula) provided adequate ANS responsiveness to maintain HR and BP T: upper extremity (avoiding stress) cycling T: 5-10 min with a few minutes recovery between, progressing to 30-40 min without rest (provided no musculoskeletal strain) Strengthening: As tolerated for upper extremities Use breathing control Minimize overuse muscle and chronic stress on other soft tissues; allow at least a day of rest between exercise days
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)

Continued

NEUROMUSCULAR CONDITIONS: SPINAL CORD INJURY (LOW)	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: cardiovascular, pulmonary, musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living and aging with a spinal cord injury, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Minimize overuse; incorporate activity-rest regimen Focus on exercise effects of functional activities Assess ANS involvement to determine the validity of exercise responses to exercise; establish a meaningful baseline of responsivity of the patient Stretching: Whole body, particularly of paretic or paralyzed muscles and involved joints Avoid overstretching and traumatizing affected muscles, fragile connective tissue, and joints Aerobic: F: alternate days I: 60%-80% HRR (Karvonen formula) provided adequate ANS responsiveness to maintain HR and BP T: upper extremity (avoiding stress) cycling T: 5-10 min with a few minutes recovery between progressing to 30-40 min without rest (provided no musculoskeletal strain) Strengthening: As tolerated for upper extremities Use breathing control Minimize overuse muscle and chronic stress on other soft tissues; allow at least a day of rest between exercise days
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)

NEUROMUSCULAR CONDITIONS: POST POLIOMYELITIS SYNDROME	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: cardiovascular, pulmonary, musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry and functional integrity, muscle and joint pain), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Ventilator support (garments, bed, CPAP, O_2) Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living and aging with the effects of poliomyelitis, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Plan exercise program for mornings to maximize energy levels (avoid contributing to some patients hitting the "polio wall" in the afternoon) Stretching: Whole body, particularly of paretic or paralyzed muscles and involved joints Avoid overstretching and traumatizing affected muscles, fragile connective tissue, and joints Aerobic: F: daily with recovery I: intensity within limits of discomfort/pain and fatigue that recovers within a few hours of discontinuation of exercise; guided by capacity to recover satisfactorily without undue fatigue, discomfort/pain in a few hours of exercise cessation; activity-rest regimen as indicated with recovery being a defining factor T: walking or ergometer T: intermittent exercise (e.g., 5-10 min with 1-2 min rest between bouts, up to 30-60 min continuous with fewer rests) Strengthening: Differentiate weak muscle from chronically fatigued muscle (from chronic overuse); weak muscle needs conditioning and fatigued muscle needs judicious rest F: daily to 2-3 days/week; target unaffected deconditioned, and polio-affected muscles that can recover (absence of prolonged muscle fatigue) I: low (gauged by capacity for recovery and by discomfort/pain and fatigue) T: weights, dumbbells, bands, pulleys T: 3 sets of 8-12 repetitions (starting at 4-6) Alternate days provided muscle and subjective recovery has occurred
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)

Continued

NEUROMUSCULAR CONDITIONS: MUSCULAR DYSTROPHY	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including ventilatory status; bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses Spinal alignment and symmetry Pulmonary function, including respiratory muscle status Ventilatory support (e.g., supplemental O_2 and nighttime CPAP) Medications that augment or attenuate exercise responses
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: cardiovascular, pulmonary (baseline spirometry and respiratory muscle strength and endurance), musculoskeletal (muscle symmetry, strength, flaccidity, gait if ambulatory, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Necessity for ventilatory (daytime and/or CPAP) and O_2 support Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to progression of muscular dystrophy, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↑ Periods of regular movement Avoidance of prolonged periods of unaltered movement or body position (including chest wall) Aids and devices Wheelchair (manual or electric) Stretching: 10 minutes after warm-up/cool-down Aerobic: F: 3 to 5 times a week I: moderate intensity (40%-80% of HRR; Karvonen formula) T: aerobic walking if ambulatory; gentle low intensity exercise in sitting and supine/prone if no undue respiratory distress T: 20-40 min Strengthening: F: 2 or 3 times a week I: low to moderate weight, 40%-70% capacity, estimated one repetition maximum T: weights T: 3 sets of 8 to 15 repetitions
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet or Mediterranean-type diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Liaison with other health professionals as needed (e.g., nutritionist)

MUSCULOSKELETAL CONDITIONS: OSTEOPOROSIS	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses Fracture history Balance and stumbling/falling history
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: CNS (neuropathies), cardiovascular, pulmonary, musculoskeletal, including baseline bone mineral density (examine factors that contribute to patient's osteoporosis diet, lack of exercise, ethnicity, gender; gait, chest wall symmetry and functional integrity, posture and postural curvatures consistent with vertebral compression fractures, balance and coordination), endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular), renal status Movement efficiency Movement economy Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living with osteoporosis, principles of calcium balance, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery Medications (past or current use of long-term steroids) Supplement use (Ca and vitamin D)
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Note: Ensure safety from loss of balance and falling Hip protectors during exercise if risk factors are high Stretching: 10 min after warm-up/cool-down Aerobic: F: daily I: moderate intensity (70%-85% of peak exercise capacity) T: weight bearing with a lower extremity rotation movement to knees, hips, and ankles; aerobic walking, cycling, jogging, hiking, dancing T: 20-40 min Strengthening: F: 2-3 times/week I: low to moderate weight, 40%-70%, one repetition maximum T: weights T: 3 sets of 8 to 15 repetitions Core strength; include spinal extension exercises Other activities: activities that create rotational stress on lower extremity joints augment osteoblast activity (e.g., dancing)
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Restrict caffeine and alcohol Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)

Continued

COLLAGEN/CONNECTIVE TISSUE CONDITIONS: SYSTEMIC LUPUS ERYTHEMATOSUS	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses
Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: CNS (neuropathies), cardiovascular, pulmonary (baseline spirometry), musculoskeletal (arthralgia, muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Cardiac dysfunction and ECG (associated dysrhythmias) Adherence to medication ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living and aging with lupus, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE; Spo_2 (as indicated), and subjective pain and fatigue status; and exercise test responses, including recovery Muscle function (complaints of weakness and delayed recovery) Fatigue Discomfort/pain
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Stretching: Gentle whole body and joint stretching daily; yoga, tai chi Aerobic: F: alternate days I: moderate activity commensurate with desaturation, RR, and fatigue and discomfort/pain levels T: aerobic (e.g., walking, aquatic, ergometer) T: 10-40 min with rest intervals as needed; goal to reduce number and length of rests Strengthening: F: 2-3 times/week I: Low-to-moderate weight T: weights, dumbbells, pulleys, bands T: 3 sets of 8-15 repetitions Other activities: yoga
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
COLLAGEN/CONNECTIVE TISSUE CONDITIONS: SCLERODERMA	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) BP profile and responsivity to body position change, exercise, and rest and recovery Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses

Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: cardiovascular, pulmonary (baseline spirometry and desaturation profile; and respiratory muscle strength and endurance as indicated), musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Cardiac dysfunction and ECG (associated dysrhythmias) Adherence to medication ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living and aging with scleroderma, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery Muscle function (complaints of weakness and delayed recovery) Fatigue Discomfort/pain
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Stretching: Gentle whole body and joint stretching daily; yoga, tai chi Aerobic: F: alternate days I: moderate activity commensurate with desaturation, RR, and fatigue levels T: aerobic (e.g., walking, aquatic, ergometer) T: 10-40 min with rest intervals as needed; goal to reduce number and length of rests Strengthening: F: 2-3 times/week I: low-to-moderate weight T: weights, dumbbells, pulleys, bands T: 3 sets of 8-15 repetitions maximum
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
COLLAGEN/CONNECTIVE TISSUE CONDITIONS: ANKYLOSING SPONDYLITIS	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression Condition severity and adequacy of control BP profile and responsivity to body position change, exercise, and rest and recovery Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses

Continued

Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: CNS (neuropathies), cardiovascular, pulmonary (baseline spirometry and respiratory muscle strength and endurance), musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Fatigue profile Discomfort/pain profile Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living and aging with ankylosing spondylitis, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Coordinated with exacerbations as indicated Stretching: Gentle whole body and joint ROM daily; be guided by discomfort/pain; gentle mobility exercise Aerobic: F: 3-5 days/week I: moderate activity commensurate with desaturation, RR, and fatigue and discomfort/pain levels T: aerobic (e.g., walking, aquatic in heated pool, ergometer) T: 10-40 min with rest intervals as needed; goal to reduce number and length of rests Strengthening: F: 2-3 times/week I: Low-to-moderate weight T: weights, dumbbells, pulleys T: 3 sets of 8-15 repetitions maximum Other activities: yoga, tai chi
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
COLLAGEN/CONNECTIVE TISSUE CONDITIONS: RHEUMATOID ARTHRITIS	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses

Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification Multisystem status: CNS (neuropathies), cardiovascular, pulmonary (restrictive profile and effusion risk), musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), and endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular) Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Discomfort/pain profile Fatigue profile Adherence to medication Change in blood pressure profile and general hemodynamic status ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living and aging with rheumatoid arthritis, risk factors for lifestyle-related conditions, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery Muscle function (complaints of weakness and delayed recovery)
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity If severe signs and symptoms, focus on functional activity primarily Activity-rest balance Pacing and energy conservation Stretching: Gentle whole body and joint stretching daily; yoga, tai chi Aerobic: F: alternate days I: moderate activity commensurate with desaturation, RR, and subjective parameters of discomfort/pain and fatigue levels—VAS (0-10) low for discomfort/pain as tolerated (<3), and VAS; SOB 3-5 T: aerobic (e.g., walking, ergometer, and aquatic exercise in warm/hot water) T: 10-40 min with rest intervals as needed; goal to reduce number and length of rests Strengthening: F: 2-3 times/week I: low-to-moderate weight T: weights, dumbbells, pulleys T: 3 sets of 8-15 repetitions maximum
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Education regarding regular use of medication Liaison with physician to reduce or eliminate medication as nondrug interventions take effect Liaison with other health professionals as needed (e.g., nutritionist)
CHRONIC RENAL INSUFFICIENCY	
Baseline Considerations	Age and wellness (based on a standardized outcome measure) Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, structured exercise, sleep status, and stress) Mental health (well-being, life satisfaction, anxiety, depression) Condition severity and adequacy of control Comorbidities and their severities (including bone health and musculoskeletal symptoms/deformity) Secondary complications—involvement of the brain, heart, kidneys (continence status) Medical management and response Medications that augment or attenuate exercise responses Dialysis candidate

Continued

Assessment and Outcome Evaluation	Lifestyle risk factor review to target risk factor modification (particularly heart disease, high BP, and diabetes) Multisystem status: cardiovascular, pulmonary, musculoskeletal (muscle symmetry, flaccidity, spasticity, gait, chest wall symmetry and functional integrity), neurological (including balance; swallowing and choking status), endocrine (type 2 diabetes mellitus risk factors/manifestations, in particular), and renal status Fluid and electrolyte balance Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Dyspnea profile Fatigue profile Adherence to medication ↓ Or cessation of medication BMI WHR Adherence to a healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity Stress Patient's health knowledge and literacy with special reference to living and aging with chronic renal insufficiency, its associated risk factors and risk factors for lifestyle-related conditions in general, triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, RPE, Spo_2 (as indicated), and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	↓ Periods of sedentary activity (particularly screen-based activities such as TV viewing and computer use) ↑ Periods of regular physical activity Progress based on serial and frequent monitoring; patient needs to be proficient at self-monitoring Stretching: Gentle whole body and joint stretching daily; yoga, tai chi Aerobic: F: walking daily (non-dialysis days if applicable); ergometer (dialysis days if applicable); commensurate with capacity I: low to moderate based on subjective tolerance and well-being on any given day T: cycle ergometry preferable for monitoring and physical support if on dialysis T: intermittent exercise protocol (e.g., 5 min of exercise, followed by 1 min of rest; progress to 60 min continuous) Strengthening: Gentle whole body and joint stretching daily; yoga, tai chi
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Renal status Mental status Fatigue Muscle comfort
ENDOCRINE AND METABOLIC CONDITIONS: OVERWEIGHT AND OBESITY	
(Note: Overweight and obesity are frequently coupled with preclinical or frank type 2 diabetes mellitus, so the special considerations for each condition apply.)	
Baseline Considerations	Age and wellness (based on a standardized outcome measure); quality of life Health status and potential education outcomes (smoking, nutrition, general profiles of daily physical activity and prolonged sedentary activity, sleep status, and stress) Mental health (anxiety and depression) Body image Condition severity, medical management and response Comorbidities and their severities Cardio/cerebrovascular and metabolic risk factors Medications that augment or attenuate exercise responses Psychosocial considerations: Social network and support system Health literacy Self-efficacy Readiness to change lifestyle-related health behavior

Assessment and Outcome Evaluation	Lifestyle risk factor review (particularly metabolic syndrome and obstructive sleep apnea) as a basis for lifestyle modification Vascular screen as indicated based on lifestyle and family history: Blood work profile, including Hgb, HgbA1c, lipids, homocysteine, and blood glucose Adequacy of medical control over the years (degree of lability with exercise and stress) Body composition measures (e.g., skin fold measurements, BMI, and WHR) Cardiovascular function Peripheral vascular function CNS and autonomic nervous system function Muscle function and musculoskeletal status/deformity Adherence to healthy diet (e.g., DASH diet, Mediterranean diet) Status of activity and participation Sleep quality and quantity (use of modalities such as CPAP) Stress and self-management strategies Patient's health knowledge and literacy with special reference to weight control and associated conditions, risk factors for lifestyle-related conditions in general (addressing weight will mitigate risk factors for a wide range of lifestyle-related conditions including musculoskeletal conditions), triggers for worsening and lessening symptoms, medication types, and medication use Resting HR, BP, RPP, RR, (Spo_2 as indicated particularly in morbid obesity), RPE and exercise test responses, including recovery
Exercise Prescription Parameters: Special Considerations	Goal: To achieve optimal basal physical activity and exercise status (to be physically active and participate in a structured exercise program) and to maximize oxygen transport, collateralization to improve blood flow and tissue perfusion Restructuring prolonged periods of sedentary activity Caution: Exercise in accordance with cardiac, respiratory, or musculoskeletal limitations (limit undue work of breathing or work of the heart, as well as musculoskeletal strain) and appropriately monitor depending on extent and severity of secondary comorbidity Walking aid may be required that relieves potential musculoskeletal strain Ensure physical activity and exercise program are being maintained by healthy nutrition and salt restriction Stretching: Whole body stretching to prepare the individual to what may be unfamiliar activity Aerobic: F: 2-3 time/day; as frequently as possible for morbidity obese I: low to moderate to minimize musculoskeletal strain, yet elicit an aerobic response that burns maximal number of calories in a given period To lose weight: 250-300 min/week To prevent weight regain: 150 min/week T: Whole body continuous rhythmic aerobic exercise; "aquacize" (water height adjusted to level of patient's tolerance—pressure of water on chest wall can restrict ventilation, level maintained at leg or abdomen level) T: 10-min bouts with rests to recover; to 60 min continuous exercise without rests Strengthening (Note: Objective is multiple repetitions at low intensity to burn calories): F: 1-2 times/day I: low intensity, 20%-60%, repetitions maximum T: weights, dumbbells, pulleys T: 3 sets of 10-20 repetitions performed deliberately Other activities: sports, gym activities of interest and intrinsically motivating to the individual; consider leisure time activities that are metabolically demanding (gardening, cleaning, walking)
Potential Pre-Exercise or Concurrent Interventions Initiated and/or Supported by the Physical Therapist	Smoking cessation Optimize nutrition Specialized diets (e.g., DASH diet and Mediterranean-type diets) Salt restriction Weight control Sleep hygiene Relaxation Stress reduction Counseling

BMI, Body mass index; *WHR,* waist-to-hip ratio; *HR,* heart rate; *BP,* blood pressure, *HRR,* heart rate reserve; *RR,* respiratory rate; *Spo2,* arterial saturation assessed with the pulse oximeter; *DASH diet,* Dietary Approaches to Stop Hypertension diet; *VAS,* visual analog scale.

Appendix E

Common Complementary Therapies

MANUAL THERAPIES

Myofascial Release

Myofascial release is a manual therapy that utilizes energy from the therapist along with mechanical pressure of the hands to "release" fascia that is constricted. As taught by John F. Barnes, PT,[101] this therapy includes release, unwinding, and rebounding as a triad of approaches that releases "stuck" fascia to further enhance the flow of chi, which is thought to travel over the fascia much like electrons of energy travel over copper wire.

Craniosacral Therapy

Developed by John Upledger, DO, FAAO, craniosacral therapy is a manual therapy that uses light touch to balance energy flow, in part by balancing the flow of the cerebral spinal fluid as it circulates around the meninges of the cranium and down the spinal column. Those who have attempted to criticize this technique by asserting that the cranial plates are fused in adulthood and thus cannot move are now conceding that electron microscope pictures of the cranial sutures reveal blood vessels and fascia that may indicate that the plates are not fused.

Rosen Method Body Work

Founded by Marion Rosen, PT, Rosen method body work is a form of hands-on therapy, the goal of which is to enhance relaxation and emotional awareness by helping the patient identify holding patterns and assisting in the release of the physical and emotional tension, thereby allowing more of the "true self" to emerge and facilitating healing.

Rolfing, Soma, Neuromuscular Therapy, Hellerwork

Rolfing was first developed by Ida Rolf, PhD, and is sometimes referred to as structural integration. This approach uses a deep connective tissue massage to loosen fascial restrictions and line up the structure of bones, muscles, and organs so that the body/mind has a more vertical relation to gravity. After 10 prescribed sessions, it is reasoned that the body is more in alignment and can heal itself. Soma, Hellerwork, and neuromuscular therapy are slight variations on this same theory.

Massage

Massage is the manipulation of tissue through the skin with the intention of bringing about a change in the present condition of the mind/body. Massage from a mechanistic perspective may be intended to move fluid from the extremities to the core or simply to mechanically break up fibrocystic nodules in muscle. Massage from an energy-based intention is carried out with similar physical maneuvers, but the intention of the practitioner is to influence the body energy, or chi, to flow so that the mind/body can then heal itself; thus manual techniques are less vigorous and more gentle.

Osteopathic Medicine

In contrast to allopathic medicine, osteopathic medicine stresses the importance of holistic health, nutrition, and joint mobilization to maintain proper balance and homeostasis. At one time, curricula in osteopathic medical schools were quite different from that in allopathic schools and thus deemed inferior. Over time, osteopathic schools have become more rigorous and similar to allopathic medical schools and have increased in stature and reputation in Western medicine.

Chiropractic Medicine

Chiropractic medical education is oriented toward the belief that illness and disease result from vertebral misalignment and that regular manipulation can maintain flow of energy to organs and the body/mind, thus maintaining health.

MIND/BODY INTERVENTIONS

Psychotherapies, Hypnosis

The approach to healing taken by psychotherapies and hypnosis suggests that bringing to awareness incorrect or harmful ways of thinking about something and using this insight to change the way one thinks can remove blocks in energy flow and open up, for example, improved

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

neurotransmitter flow. PET scans have shown that cognitive therapy and serotonin reuptake inhibitors work in similar ways to change synaptic transmission, resulting in the patient feeling better.

Meditation

With meditation the emphasis is on purposely shifting awareness away from logical, left-brain thought (some call the ceaseless left-brain chatter "monkey mind") to the rhythmical flow of the breath, or the peace of a pleasant sound, thus closing off the stream of worry about the past and fear about the future. Meditation lowers stress by lowering cortisol levels, thus balancing blood pressure and other physiological responses to stress.

Mindfulness meditation is sometimes called Vipassana meditation and has been developed very successfully as a stress reducer by Jon Kabat-Zinn. It comes from the Buddhist tradition.

Transcendental meditation (TM) stems from the Hindu tradition and emphasizes focused concentration on a mantra that is given to a person after a period of initiation. Maharishi University in Fairfield, Iowa was founded by Maharishi Mahesh Yogi, the person most known for bringing TM to the United States. All campus personnel at Maharishi University meditate regularly.

Imagery

Imagery purposefully replaces stressful thought with images that enhance relaxation, thus affecting the ANS. One can use imagery alone or participate in a group led by a person suggesting an imagery exercise.

Prayer for Self

Prayer for the self involves quieting the mind and purposefully intending communication with the transcendent, or God, for the well-being of the self.

Support Groups

Support groups allow the individual to meet with others and share experiences to lessen the feeling of powerlessness. Religious groups can be included in this category.

Dance, Music Therapy, and Art Therapy

Dance, music, and art therapy work by altering the existing flow of energy by movement, pulling up creative feelings, and unleashing "stuck" energy by focusing concentration outward.

Neurolinguistic Psychology

Originally named neurolinguistic programming, neurolinguistic psychology is a psychotherapeutic approach that brings to awareness ways in which the use of certain words, body postures, and eye movements reveal "stuck" energy, thus allowing a person to choose a way in which to think and move that will enhance energy flow and bring a more relaxed state.

Biofeedback

Biofeedback involves the use of external monitoring devices that record autonomic and cortical nervous system and muscle action, so that a person can, through thought, change the reading on the monitor and thus alter the body/mind function. External monitors include EMG and oscilloscopes that quantify thermal energy.

Yoga

Yoga is an eight-fold path, comprising eight separate activities that emphasize physical, mental, and spiritual elements that enhance union of body and mind. Yoga means union. The most widely known yogic practice is hatha yoga, which features a variety of physical postures and exercises called asanas. Meditative asanas stress alignment of the spine with the head and focus on proper breathing. Therapeutic asanas, such as the cobra and shoulder stand, feature elongation of fascia and soft tissue. Both are done with discipline, awareness, and relaxed openness and thus help to stimulate prana—or life energy or chi.

Pilates

Named for its founder, Joseph Pilates, this is an exercise system that aims to facilitate successful movement with less effort, less fatigue, and greater movement awareness retention. Often using equipment such as the Clinical Reformer and the Cadillac, the practitioner can manipulate gravity, the base of support, the length of levers, and the center of gravity with a series of springs and slings to assist or resist smooth movement.

Tai Chi

Tai chi is a mind/body exercise that features slow, controlled, nonimpact movement that gently moves the center of the mind/body mass over the base of support without loss of balance. It is an ancient physical art form that was developed by families in China as a way of defending the household from attack and passed on from generation to generation. The specific form of tai chi used would carry the family name, such as Chin, Yang, Wu, Chuan, etc. These are further condensed, at times, into short forms. Tai chi develops both mind and body as the movement and breath facilitate the proper balance between the yin and yang energies, reducing yang and increasing yin and thus contributing to the healthy flow of chi.

MOVEMENT AWARENESS

Feldenkrais Method

The Feldenkrais method was developed by Moshe Feldenkrais, a physicist and judo expert athlete. When told an injury he sustained would require fusing his knee, Feldenkrais developed a way of thinking that emphasized being able to purposely choose how he might move to protect his knee and avoid fusion. He adapted. He then identified habitual movements and helped others to recognize endless options for adapting to a particular blockage or restriction in a movement, avoiding pain or perception of strain and thus avoiding reflex muscle splinting. Two strategies, awareness through movement (ATM) and functional integration (FI), are used in

class "lessons." ATM is mainly verbal and visual; FI adds positioning, contact, and pressure.

Alexander Technique

The Alexander technique was developed by Frederick Matthias Alexander, who used himself in a single-case research design. Alexander discovered how habitual positions in the body affect movement and organ function. Through consciously inhibiting automatic ways of holding positions, we can choose to act in healthier ways. By integrating proper awareness and attention, movement can bring the mind and body into harmony and meet goals of efficient function. Alexander teachers assist students to learn by using touch to bring the student's awareness to areas of tension, inhibiting habitual use and facilitating a redistribution of postural tone, thus providing a different kinesthetic experience. In this way it is somewhat similar to the Feldenkrais method, without words.

Trager Approach

Developed by Milton Trager, MD, the Trager Approach uses a process of rhythmic "rocking, fluffing, jiggling, lengthening, and shimmering" motions to trigger tissue relaxation reflexively.

ENERGY WORK

Traditional Chinese Medicine

Traditional Chinese medicine is an entire health care system made up of various specific practices or approaches. Rather than treating disease, this approach looks for underlying systems of imbalance and patterns of disharmony in each individual and treats the whole patient by influencing the flow of chi along meridians. It features pulse and tongue diagnosis, acupuncture, qi gong, herbal medicine, and tui na, a form of massage that combines acupressure, massage, and deep tissue manipulation.

Acupuncture, Acupressure

Acupuncture and acupressure are modalities of traditional Chinese medicine in which various points along meridians or pathways are stimulated by way of very fine needles (acupuncture) or by way of touch or tapping (acupressure). This mechanical stimulation of the various points is hypothesized to facilitate the flow of electrons along the fascia, thus opening up blocked energy and facilitating the flow of chi.

Reflexology

Reflexology posits that organs and body parts are represented as zones on the feet; the practice works by way of stimulating the corresponding zone with a constant deep pressure for 1 or 2 minutes. Energy, circulation, and nerve impulses are stimulated, raising the vitality of the body and restoring homeostasis and flow of chi.

Qi Gong

An aspect of traditional Chinese medicine, qi gong (pronounced chee-kung) ranges from simple positions to rather complicated movements that emphasize, at the same time, rhythmic breathing and deep relaxation in order to facilitate the flow of chi. In external qi gong a master projects or emits his or her own chi to serve to heal another. Internal qi gong is breathing without movement to enhance self-healing and self-maintenance (meditation is sometimes referred to as internal or quiescent qi gong). Dynamic qi gong includes movement; as such, tai chi is often classified as dynamic qi gong.

Therapeutic Touch

Developed by Delores Krieger and Dora Kunz, therapeutic touch is sometimes referred to as an energetic therapy and sometimes as a manual therapy. The therapist's hands are used, but they do not come in contact with the skin. Instead the therapist "smoothes" the energy field surrounding the mind/body, thus gaining access to the flow of energy by way of the ethereal body or energetic field surrounding the mind/body.

BIOELECTROMAGNETICS/ENERGY WORK

Laser

Cold laser, or soft laser, uses a beam of low-intensity laser to initiate a series of enzymatic reactions and bioelectrical events that stimulate the natural healing process at the cellular level. It is often used to stimulate acupuncture points.

TENS Units

Although transcutaneous electrical neuromuscular stimulation (TENS) is most commonly used to block noxious pain stimulus in physical therapy, TENS units have been shown to stimulate the production of the neurotransmitters and thus increase flow.

Pulsed Electromagnetic Field Therapy

Pulsed electromagnetic field therapy uses small, battery-powered pulse generators to produce a magnetic field that induces currents to flow in nearby tissues, "jump starting" bone repair.

Magnets

The use of magnets involves magnetized substances against the skin or close to the skin (as in a cloth packet) to bring about a physiochemical or physiological effect. Monopolar magnets have only one pole (north or south) in contact with the skin, whereas bipolar magnets have both north and south poles in contact. Strength of the magnets is measured in gauss units. The literature on magnets has been confusing, in part because of inconsistent meanings of the terms *north pole* and *south pole* and inadequate true measures of magnet strength by manufacturers.

Reiki

Reiki (pronounced ray-kee) is a healing system from Japan (*rei,* meaning "universal" or "omnipresent," and *ki,* meaning "life force" or "energy"). A Reiki practitioner channels the universal life force through the hands to promote energy

balancing, healing, and a state of well-being. The universal life force energy can be transmitted through direct touch or by "intending" its transmission from a distance. The belief is that the life force has intelligence and will flow to where it is needed.

Distant Healing Prayer

In distant healing prayer, focused attention is given to the person being prayed for with the intention of causing a positive outcome to result. In intercessory prayer, healing is requested for the self or for others. Directed prayer specifies a particular outcome that is desired. Nondirected prayer intends only that God's will be done in the life of the subject. At the heart of this method is the concept of nonlocal mind, or the belief that a person's consciousness is not limited to distance or time and that individuals can influence the world at a distance through their focused thoughts.

HERBAL APPROACHES

Homeopathic Medicine

Homeopathic medicine is an approach to health and healing developed by Samuel Hahnemann, MD. This practice suggests that reactions to diluted tinctures of natural substances (herbs that cause symptoms similar to those of the disease) can be used to treat disease.

Naturopathy

Naturopathy is a holistic system of healing that requires practitioners to complete a 4-year medical degree. Naturopathic doctors study herbal medicine, homeopathy, osteopathy, nutrition, and some forms of physical therapy as part of their curriculum, which is geared to prepare holistic diagnosticians and therapists.

Bibliography

This appendix is summarized from the following texts.

Burton Goldberg Group, editors: *Alternative medicine—the definitive guide*, Fife, Wash., 1995, Future Medicine Publishing, Inc.

Davis CM, editor: *Complementary therapies in rehabilitation/holistic approaches for prevention and wellness*, Thorofare, N.J., 1997, SLACK, Inc.

Glossary

Acid-base balance: A condition that exists when the net rate at which the body produces acids or bases equals the net rate at which acids or bases are excreted. The result of acid-base balance is a stable concentration of hydrogen ions in body fluids. The amount of acid or base in the arterial blood is measured by pH.

Acidosis: A process causing acidemia, which is a blood pH of less than 7.38.

Acoustic airway clearance: Form of airway clearance using acoustic vibrations to clear secretions from the lungs.

Active cycle of breathing technique: Technique for clearing bronchial secretions in patients with asthma, consisting of repeated cycles of three ventilatory phases: breathing control, thoracic expansion exercises, and the forced expiration technique.

Acute exacerbation of chronic airflow limitation: An increase in the severity of the signs and symptoms of chronic airflow limitation, usually triggered by infection, inflammation, or increased sputum production.

Acute lung injury: Injury to the lung characterized by a clinical spectrum of parenchymal lung dysfunction resulting from multiple etiologies and leading to alveolar capillary membrane leaking (high protein content). Mild-to-moderate injury results in noncardiogenic edema, and severe injury results in adult respiratory distress syndrome. The hallmarks of worsening lung injury include refractory hypoxemia, right-to-left shunt, and reduced lung compliance.

Adrenergic drugs: Class of drugs acting on the sympathetic nervous system.

Adult respiratory distress syndrome (ARDS): A respiratory syndrome characterized by respiratory insufficiency and hypoxemia. Triggers include aspiration of a foreign body, cardiopulmonary bypass surgery, gram-negative sepsis, multiple blood transfusions, oxygen toxicity, trauma, pneumonia, and other respiratory infection.

Aerosol: Nebulized particles suspended in a gas or air.

Airway clearance: The removal of mucus and foreign material from the airways.

Airway-clearance deficits: Deficits in the ability to remove mucus and foreign material from the airways.

Alveolar proteinosis: A disorder marked by the accumulation of plasma proteins, lipoproteins, and other blood components in the alveoli of the lungs. The cause is unknown and clinical symptoms vary, although only the lungs are affected. Some patients are asymptomatic, whereas others show dyspnea and an unproductive cough.

Alveolar ventilation: The volume of inspired air that reaches the alveolar level and participates in gas exchange, measured by PCO_2.

Alveolitis: An allergic pulmonary reaction to the inhalation of antigenic substances characterized by acute episodes of dyspnea, cough, sweating, fever, weakness, and pain in the joints and muscles lasting from 12 to 18 hours. Recurrent episodes may lead to chronic obstructive lung disease with weight loss, increasing exertional dyspnea, and interstitial fibrosis.

Anesthesia: The absence of normal sensation, especially sensitivity to pain, as induced by an anesthetic substance or by hypnosis or as occurs with traumatic or pathophysiological damage to nerve tissue.

Angina (often angina pectoris): A paroxysmal thoracic pain caused most often by myocardial anoxia as a result of atherosclerosis of the coronary arteries. The pain usually radiates down the inner aspect of the left arm and is frequently accompanied by a feeling of suffocation and impending death. Attacks of angina pectoris are often related to exertion, emotional stress, and exposure to intense cold.

Ankylosing spondylitis: A chronic inflammatory disease of unknown origin, first affecting the spine and adjacent structures and commonly progressing to eventual fusion (ankylosis) of the involved joints. In addition to the spine, the joints of the hip, shoulder, neck, ribs, and jaw are often involved. Physical therapy aids in keeping the spine as erect as possible to prevent flexion contractures. In advanced cases, surgery may be performed to straighten a badly deformed spine.

Arrhythmia: An abnormal heart rhythm represented by an irregularity of the timing or appearance of the ECG tracing. This term is often used synonymously with dysrhythmia.

Arterial blood gas: A test to evaluate the acid-base balance and partial pressures of oxygen and carbon dioxide in the arterial blood.

Arteriovenous-oxygen difference (a-vO_2 difference): The difference between the oxygen content in arterial blood versus venous blood.

Artifact: Extraneous deflection of the ECG waveform caused by movement or electrical interference. Artifact may be mistaken for a dysrhythmia.

Artificial airway: A plastic or rubber device that can be inserted into the upper or lower respiratory tract to facilitate ventilation or the removal of secretions.

Assessment: An evaluation or appraisal of a condition.

Assisted cough: Physical assistance with coughing, provided either by the patient or an assistant.

Asthma: A respiratory disorder characterized by recurring episodes of paroxysmal dyspnea, wheezing on expiration/inspiration because of constriction of the bronchi, coughing, and viscous mucoid bronchial secretions. Treatment may include elimination of the causative agent, hyposensitization, aerosol or oral bronchodilators, beta-adrenergic drugs, methylxanthines, and short-term use of corticosteroids.

Atelectasis: An abnormal condition characterized by the collapse of lung tissue, preventing the respiratory exchange of carbon dioxide and oxygen. Symptoms may include diminished breath sounds, a mediastinal shift toward the side of the collapse, fever, and increasing dyspnea.

Atherosclerosis: A common arterial disorder characterized by yellowish plaques of cholesterol, lipids, and cellular debris in the inner layers of the walls of large and medium-sized arteries. The vessel walls become thick, fibrotic, and calcified, and the lumen narrows, resulting in reduced blood flow to organs normally supplied by the artery. Antilipidemic agents do not reverse atherosclerosis, but a diet low in cholesterol, calories, and saturated fats, adequate exercise, and the avoidance of smoking and stress may help prevent the disorder.

Athletic heart syndrome: Cardiovascular adaptation to intense exercise in athletes.

Autogenic drainage: An "antidyspnea" technique based on quiet expirations in a relaxed state and without use of postural drainage positions.

Blood: The liquid pumped by the heart through all the arteries, veins, and capillaries. Blood is composed of a clear yellow fluid (called plasma), the formed elements, and a series of cell types with different functions. The major function of the blood is to transport oxygen and nutrients to the cells and remove carbon dioxide and other waste products from the cells for detoxification and elimination.

Body mechanics: Using one's body effectively to prevent injury.

Bradycardia: An abnormally slow heart rate.

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

Bradypnea: A decreased respiratory rate under 10 breaths per minute.

Bronchiectasis: An abnormal condition of the bronchial tree characterized by irreversible dilatation and destruction of the bronchial walls. Symptoms of bronchiectasis include a constant cough productive of copious purulent sputum, hemoptysis, chronic sinusitis, clubbing of fingers, and persistent moist, coarse rales. Treatment includes mobilization, frequent postural drainage, antibiotics, and, rarely, surgical resection of the affected part of the lungs.

Bronchiolitis: An acute viral infection of the lower respiratory tract that occurs primarily in infants under 18 months of age, characterized by expiratory wheezing, respiratory distress, inflammation, and obstruction at the level of the bronchioles.

Bronchitis: An acute or chronic inflammation of the mucous membranes of the tracheobronchial tree. Acute bronchitis is characterized by a productive cough, fever, hypertrophy of mucus-secreting structures, and back pain. Most common in adults, it is often a complication of cystic fibrosis in children. Treatment includes the cessation of cigarette smoking, avoidance of airway irritants, the use of expectorants, and postural drainage. Currently, prophylactic antibiotics, steroids, and desensitization therapy are not recommended.

Bronchopulmonary dysplasia: An iatrogenic condition observed in neonates that resembles chronic airflow limitation and is associated with positive pressure mechanical ventilation and oxygen therapy.

Burns: An injury to tissues of the body caused by heat, electricity, chemicals, radiation, or gases in which the extent of the injury is determined by both the amount of exposure of the cell to the agent and the nature of the agent. Treatment of burns includes pain relief, careful asepsis, prevention of infection, maintenance of the balance of body fluids and electrolytes, and good nutrition. Severe burns of any origin may cause shock, which is treated before the wound.

Cardiac output (Q): The amount of blood ejected from the heart into the aorta each minute.

Cardiac rehabilitation: A supervised program of progressive exercise, psychological support, and education or training to enable a patient who has had a myocardial infarction to resume the activities of daily living on an independent basis. Special training may be needed to adapt the patient to a new occupation and lifestyle.

Cardiac silhouette: Outline of the heart visible on a chest radiograph.

Cardiopulmonary failure: Progressive insufficiency of cardiopulmonary function resulting in significant impairment of cardiac output and/or ventilation that cannot be adequately compensated without ventilatory support.

Cardiopulmonary function: Integrated function of the heart and lungs.

Cardiopulmonary unit: The heart and lungs, which function interdependently as a unit.

Catabolic: Relating to catabolism, which is the breaking down in the body of complex chemical compounds into simpler compounds, often accompanied by the liberation of energy.

Cellular respiration: The processes involved with cellular metabolism, including energy transfer, oxygen utilization, and carbon dioxide production.

Cerebral palsy: A motor function disorder caused by a permanent, nonprogressive brain defect or lesion present at birth or shortly thereafter. Early identification of the disorder facilitates the handling of infants with cerebral palsy and the initiation of an exercise and training program. Treatment is individualized and may include the use of braces, surgical correction of deformities, speech therapy, and various indicated drugs, such as muscle relaxants and anticonvulsants.

Childhood asthma: Reversible airway hyperreactivity and edema affecting children that is often triggered by dust or animals. It is hallmarked by narrowing of the airways, wheezing, shortness of breath, accessory muscle use, and impaired oxygenation.

Cholinergic drugs: Class of drugs acting on the parasympathetic nervous system.

Chronic airflow limitation: A more precise term for chronic obstructive pulmonary disease (e.g., chronic bronchitis and emphysema).

Chronic bronchitis: Lung condition characterized by the presence of a chronic productive cough for at least 3 months in each of 2 successive years.

Chronic renal insufficiency: Impaired function of the kidneys manifested by impaired blood urea nitrogen, creatinine clearance, and reduced urinary output. Renal insufficiency may precipitate renal failure.

Clinical decision making: The process of making decisions based on a thorough history, assessment, integration of the results of laboratory tests and investigations, and the patient's needs and wants.

Complementary therapy: Holistic, mind/body, or energy-based therapy techniques used by physical therapists to complement (usually not replace) traditional therapy techniques. Also known as alternative therapies, alternative medicine, or integrative therapies.

Complications with coughing: Complications associated with an impaired cough (e.g., impaired mucociliary transport, mucus accumulation, pulmonary aspiration, and increased risk for infection).

Computed tomography: Diagnostic tool using ionizing radiation to generate pictures as "slices" through the patient in the axial plane. CT allows for rapid scanning in much more detail than a radiograph.

Congestive heart failure (CHF): An abnormal condition that reflects impaired cardiac pumping, caused by myocardial infarction, ischemic heart disease, or cardiomyopathy. Failure of the ventricle to eject blood efficiently results in volume overload, chamber dilatation, and elevated intracardiac pressure. Retrograde transmission of increased hydrostatic pressure from the left heart causes pulmonary congestion; elevated right heart pressure causes systemic venous congestion and peripheral edema.

Connective tissue dysfunction: Impaired function of connective tissue observed in connective tissue and vascular collagen conditions.

Continuity of care: The provision of continuous care from one setting to another (e.g., inpatient to outpatient facilities).

Continuous positive airway pressure: Oxygen delivery system in which pressure is maintained on the airways above atmospheric pressure.

Control of breathing: The central and peripheral regulation and control mechanisms of breathing.

Control of the heart: The central and peripheral regulation and control mechanisms of the heart.

Controlled breathing: Teaching a patient ventilatory strategies to exert cognitive control over ineffective breathing patterns.

Coronary artery disease: Any one of the abnormal conditions that may affect the arteries of the heart and produce various pathological effects, especially the reduced flow of oxygen and nutrients to the myocardium. Any of the coronary artery diseases, such as coronary atherosclerosis, coronary arteritis, or fibromuscular hyperplasia of the coronary arteries, may produce the common characteristic symptom of angina pectoris. Studies over the last 30 years confirm that coronary atherosclerosis occurs most frequently in populations with regular diets high in calories, total fat, saturated fat, cholesterol, and refined carbohydrates. Other risk factors include cigarette smoking, hypertension, serum cholesterol levels, coffee intake, alcohol intake, deficiencies of vitamins C and E, water hardness, hypoxia, carbon monoxide, social overcrowding, heredity, climate, and viruses.

CoughAssist machine: A commercially produced noninvasive machine used for airway clearance. Earlier versions of this product were known as the Cofflator and the Mechanical In-Exsufflator (MI-E).

Cough pump: The integrated thoracic and abdominal mechanisms involved in cough resulting in forced expiration and evacuation and clearance of the airways.

Cough stages: The stages of cough include maximal inspiration, closure of the glottis, increased intraabdominal pressure, opening of the glottis, and forced expiration.

Cough: A sudden, audible expulsion of air from the lungs. Coughing is preceded by inspiration—the glottis is partially closed, and the accessory muscles of expiration contract to expel the air forcibly from the respiratory passages. Coughing is an essential protective response that serves to clear the lungs, bronchi, or trachea of irritants and secretions or to prevent aspiration of foreign material into the lungs. It is a common symptom of diseases of the chest and larynx. Because the function of coughing is to clear the respiratory tract of secretions, it is important that the cough bring out accumulated debris. When it does not, because of weakness or inhibition of the force of the cough caused by pain, instruction and assistance in effective coughing and deep-breathing exercises are required.

Crackles: Discontinuous, low-pitched lung sounds. Crackles occur predominantly during inspiration. Also known as rales.

Cystic fibrosis: An inherited disorder of the exocrine glands that causes exocrine gland production of abnormally thick secretions of mucus, elevation of sweat electrolytes, increased organic and enzymatic constituents of saliva, and overactivity of the autonomic nervous system. The glands most affected are those in the pancreas, the respiratory system, and the sweat glands. Because there is no known cure, treatment is directed at the prevention of respiratory infections, which are the most frequent cause of death. Mucolytic agents and bronchodilators are used to help liquefy the thick, tenacious mucus. Physical therapy measures, such as exercise, postural drainage, and breathing exercises, can also dislodge secretions. Life expectancy in cystic fibrosis has improved markedly over the past several decades, and with early diagnosis and treatment, most patients can be expected to reach adulthood.

Dead space: The amount of lung in contact with ventilating gases but not in contact with pulmonary blood flow. Alveolar dead space refers to alveoli that are ventilated by the pulmonary circulation but not perfused. Anatomical dead space is an area in the trachea, bronchi, and air passages containing air that does not reach the alveoli during respiration. Physiological dead space is an area in the respiratory system that includes the anatomical dead space together with the space in the alveoli occupied by air that does not contribute to the oxygen-carbon dioxide exchange.

Denervation of heart: The transplanted heart initially loses its innervation (i.e., it is denervated and relies on exogenous catecholamines for cardiac acceleration and deceleration).

Dependent patients: Patients who are unable to help themselves.

Depolarization: Changes in ionic concentrations across muscle cell membranes leading to contraction of the cell.

Diabetes: A clinical condition characterized by the excessive excretion of urine. The excess may be caused by a deficiency of antidiuretic hormone (ADH), as in diabetes insipidus, or it may be the polyuria resulting from the hyperglycemia occurring in diabetes mellitus.

Diagnosis: Specific analysis of the patient's health problem(s).

Diaphragmatic breathing pattern: Involves teaching patients with COPD how to relax the accessory muscles and perform controlled diaphragmatic breathing.

Diffusion: The process in which solid, particulate matter in a fluid moves from an area of higher concentration to an area of lower concentration, resulting in an even distribution of the particles in the fluid. No energy is required.

Diuretics: Drugs that act on the kidney to increase the formation of urine, therefore decreasing blood volume and fluid accumulation.

Documentation: Written material associated with the history, the compilation of laboratory reports and investigations, and the results of clinical assessment.

Dyspnea: The sensation of difficulty in breathing.

Echocardiography: Evaluation of cardiac structure and function by using the properties of sound. Quantitative and qualitative measurements can be derived. The most common types include two-dimensional, Doppler, and transesophageal.

Ectopic focus: A beat or rhythm that does not originate in the SA node. Also known as pacemaker.

Ejection fraction: The amount of ventricular volume ejected with each heart beat. Expressed as a percentage, ejection fraction is determined by the following equation: [(end-diastolic volume – end-systolic volume) × 100]/end-diastolic volume.

Electrocardiogram (ECG): The tracing produced by the sequential depolarization and repolarization of myocardial cells as detected by surface electrodes placed on the skin.

Electrocardiographic monitoring: Electrocardiographic monitoring involving electrode placement on the chest wall and on the limbs for a 12-lead ECG. Such monitoring provides a tracing of the electrical activity of the heart.

Electromechanical coupling: The coupling of electrical and mechanical events of the heart to effect cardiac output.

Electromyographic (EMG) power spectrum: Electromyography is the process of recording the electrical activity of muscle on a cathode-ray oscilloscope. The electromyographic (EMG) power spectrum is the full range of electrical activity of the muscle.

Emphysema: Lung condition characterized by an abnormal, permanent enlargement of the air spaces distal to the terminal bronchioles accompanied by destruction of their walls.

Endocardial cushion defect: Any cardiac defect resulting from the failure of the endocardial cushions in the embryonic heart to fuse and form the atrial septum.

Endocrine function: The function of the endocrine glands responsible for normal physiological function.

Evidence-informed practice: Practice indicated or informed by epidemiological indicators and prioritized on that basis, e.g., premature death and prolonged morbidity from lifestyle-related conditions.

Evidence-based practice: Evidence for specific interventions based on scientific evaluation and appraisal.

Exercise blood gases: Blood gases taken before, during, and after exercise to determine the effect of exercise on oxygen transport.

Exercise prescription: Intervention plan based on the patient's presentation, history, premorbid status and conditioning level, lab and investigative reports related to physiological reserve capacity, the exercise test, and the goals of the exercise prescription.

Exercise stress: Physical stress imposed by movement (i.e., mobilization and exercise).

Exercise testing: A series of select tests and procedures aimed at evaluating a patient's physical health. Exercise testing is the first step in exercise prescription.

Exercise: (1) The performance of any physical activity for the purpose of conditioning the body, improving health, or maintaining fitness, or as a means of therapy for correcting a deformity or restoring the organs and bodily functions to a state of health. (2) Any action, skill, or maneuver that exerts the muscles and is performed repeatedly in order to develop or strengthen the body or any of its parts. (3) To use a muscle or part of the body in a repetitive manner to maintain or develop its strength. The physical therapist constantly assesses the patient's needs and provides the proper type and amount of exercise, taking into account the patient's physical or mental limitations. Exercise has a beneficial effect on each of the body systems, although in excess it can lead to the breakdown of tissue and cause injury.

Expiratory reserve volume (ERV): The maximum volume of gas that can be expired from the resting expiratory level.

Extracorporeal life support: Life support with artificial heart and lung, commonly called extracorporeal membrane oxygenation (ECMO). ECMO is a temporary means of providing partial or total life support; it stabilizes the patient by regulating gas exchange and perfusion.

Extrinsic factors: Factors related to the patient's care that contribute to cardiopulmonary dysfunction and impaired gas exchange.

Fluid and electrolyte status: The status of blood volume and distribution, and the status of electrolyte balance in the body; fluid balance often has a direct effect on electrolytes.

Forced expiratory volume in 1 second (FEV_1): Amount of air expired in 1 second during a forced exhalation after a maximal inhalation.

Forced vital capacity (FVC): Total amount of air exhaled during a forced exhalation after a maximal inhalation.

Function optimization: Optimal functioning of the patient as a whole person based on optimal physiological functioning at an organ system level.

Functional residual capacity: Volume of gas in the lungs at the end of a normal expiration. Functional residual capacity is equal to the residual volume plus the expiratory reserve volume.

Gas exchange: The movement of oxygen and carbon dioxide between the pulmonary capillary blood and the alveolar tissue and between the systemic capillary blood and peripheral tissue cells.

Gastrointestinal dysfunction: Abnormal function of the gastrointestinal system.

Gravitational stress: Stress imposed on the human body by gravity and its physiological effects.

Gravity: The heaviness or weight of an object resulting from the universal effect of the attraction between any body of matter and any planetary body. The force of the attraction depends on the relative masses of the bodies and on the distance between them.

Head injury: Any traumatic damage to the head resulting from blunt or penetrating trauma of the skull. Blood vessels, nerves, and meninges can be torn; bleeding, edema, and ischemia may result.

Health According to the World Health Organization, health is a complete state of physical, social, and emotional wellbeing; rather than being the objective of living health is conceptualized as a resource for everyday life.

Health behavior: An action taken by a person to maintain, attain, or regain good health and to prevent illness. Health behavior reflects a person's health beliefs. Some common health behaviors are exercising regularly, eating a balanced diet, and obtaining necessary inoculations.

Health Literacy: A person's ability to comprehend health information and use that information to make informed decisions about one's health and medical care.

Heart: The muscular, cone-shaped organ, about the size of a clenched fist, that pumps blood throughout the body and beats normally about 70 times per minute by coordinated nerve impulses and muscular contractions. Enclosed in pericardium, the heart rests on the diaphragm between the lower borders of the lungs, occupying the middle of the mediastinum. The sinoatrial node of the heart sets the rate. Other factors affecting the heartbeat are emotion, exercise, hormones, temperature, pain, and stress.

Heart-lung interdependence: The heart and lung are structurally and functionally interdependent and form a cardiopulmonary unit.

Hemiplegia: Paralysis of one side of the body.

Hemodynamic status: Status of the heart and its capacity to effect blood movement to perfuse the tissues of the body.

Henderson Hasselbach equation: Equation demonstrating how H^+ concentration results from the dissociation of carbonic acid and the interrelationship of the blood acids, bases, and buffers.

Hibernating myocardium: Contractile dysfunction of the myocardium resulting from prolonged ischemia, appearing as a regional wall motion abnormality.

High-frequency chest wall oscillation: A large-volume, variable-frequency air-pulse delivery system that can be used by patients with obstructive lung disease to promote mucus clearance.

HIPAA guidelines: Federal guidelines in the United States that protect the confidentiality of health information (also known as personal protected health information, or PHI). Acronym stands for Health Insurance Portability and Accountability Act.

Holistic approach: An interventional philosophy that considers both the body and the mind as contributors to health and/or intervention.

Home care: A health service provided in the patient's place of residence for the purposes of promoting, maintaining, or restoring health or minimizing the effects of illness and disability.

Humidity: Pertaining to the level of moisture in the atmosphere, the amount varying with the temperature. The percentage is usually represented in terms of relative humidity, with 100% being the point of air saturation or level at which the air can absorb no additional water.

Hyaline membrane disease: Disease of the newborn, characterized by airless alveoli, inelastic lungs, more than 60 respirations a minute, nasal flaring, intercostal and subcostal retractions, grunting on expiration, and peripheral edema. This is also called respiratory distress syndrome (RDS) of the newborn.

Hypercapnia: The presence of an abnormally large amount of carbon dioxide in the circulating blood.

Hyperpnea: Rapid, shallow breathing.

Hyperresonant: Lung sound with a very low pitch and prolonged duration.

Hypertension: A common, often asymptomatic disorder characterized by elevated blood pressure persistently exceeding 140/90 mm Hg. Patients with high blood pressure are advised to follow a low-sodium, low-saturated-fat diet, reduce calories to control obesity, exercise, avoid stress, and take adequate rest.

Hypoxemia: A low level of oxygen in the blood, often characterized by a PaO_2 of less than 80 mm Hg.

Immune function: Function of the immunological system and its components to effect optimal immunological protection.

Immunological dysfunction: Abnormal function of the immunological system.

Immunosuppression: Of or pertaining to a substance or procedure that lessens or prevents an immune response.

Incentive spirometry: A visual and/or audio feedback device that encourages slow, deep inspiration. Also known as sustained maximum inspiration (SMI).

Inspiratory capacity (IC): Maximum volume of gas that can be inhaled from the resting expiratory level. Equal to the sum of the tidal volume and the inspiratory reserve volume, it is measured with a spirometer.

Inspiratory muscle training: Resistance ventilatory training designed to increase the strength and endurance of the inspiratory muscles.

Inspiratory reserve volume: Maximum volume of gas that can be inspired from the end-tidal inspiratory level.

Inspiratory resistance breathing: A method of respiratory muscle training that includes normal ventilation with added external threshold loading on inspiration and consists of 15 to 30 minutes of training five days per week. External loading is increased from 30% of maximal inspiratory pressure to 60% of maximal inspiratory pressure as the patient's tolerance increases.

Intermittent positive pressure breathing (IPPB): A form of assistive or controlled respiration produced by a ventilatory apparatus in which compressed gas is delivered under positive pressure into the patient's airways until a preset pressure is reached. Passive exhalation is allowed through a valve, and the cycle begins again as the flow of gas is triggered by inhalation. This is also called intermittent positive pressure ventilation (IPPV).

Interstitial pulmonary fibrosis: A classification of restrictive lung disease including conditions that result in a final common pathway of bouts of chronic lung infection and irreversible fibrosis.

Intervention prescription: Intervention plan consisting of optimal interventions and intervention parameters identified for each problem.

Intraaortic balloon counterpulsation: Procedure for assisting left ventricular function and coronary perfusion that involves inserting a balloon into the femoral artery. The inflation and deflation of the balloon is synchronized with the ECG such that the balloon inflates during diastole and deflates during systole.

Intracardiac pressures: Pressures within the chambers of the heart. Optimal movement of blood through the heart depends on pressure

gradients throughout the heart. Normal pressures within each heart chamber are within a restricted range.

Intracranial pressure monitoring: Invasive monitoring instituted to measure changes in cranial pressure usually resulting from increased volume of the brain because of injury, bleeding, fluid accumulation, or an intracranial mass.

Intrinsic factors: Factors that are related to a patient's personal characteristics and that affect the patient's care.

Isocapnic hyperpnea: A method of respiratory muscle training that includes high ventilation with low external loading consisting of sustained periods of hyperpnea lasting 15 to 30 minutes daily for several weeks with the addition of carbon dioxide to maintain a normal level.

Jacobsen's progressive relaxation exercise: A technique involving contraction followed by relaxation to progressively relax muscle groups.

Kidneys: A pair of bean-shaped urinary organs in the dorsal part of the abdomen, one on each side of the vertebral column. The kidneys produce and eliminate urine through a complex filtration network and reabsorption system comprising more than 2 million nephrons. All the blood in the body passes through the kidneys about 20 times every hour but only about one-fifth of the plasma is filtered by the nephrons during that period. The kidneys remove water as urine and return water that has been filtered to the blood plasma, thus helping to maintain the water balance of the body. Hormones, especially the antidiuretic hormone (ADH) produced by the pituitary gland, control the function of the kidneys in regulating the water content of the body.

Kyphoscoliosis: An abnormal condition characterized by an anteroposterior curvature and a lateral curvature of the spine. It occurs in children and adults and can be associated with cor pulmonale.

Late sequelae of poliomyelitis: Late effects of poliomyelitis that may occur in poliomyelitis survivors 30 to 35 years after onset. These effects include disproportionate fatigue, weakness, pain, reduced endurance, choking and swallowing problems, altered temperature sensitivity, and psychological problems.

Learning theory: A group of concepts and principles that attempts to explain the learning process. One concept, Guthrie's contiguous conditioning premise, postulates that each response becomes permanently linked with stimuli present at the time so that contiguity rather than reinforcement is a part of the learning process.

Lifestyle-related behaviors: Behavioral choices a person makes related to lifestyle, e.g., smoking, nutrition, and physical activity.

Lifestyle-related conditions: Conditions significantly related to lifestyle behaviors, e.g., smoking-related conditions, high blood pressure, stroke, type 2 diabetes mellitus, obesity, and cancers.

Liver: Largest gland of the body and one of its most complex organs. More than 500 of its functions have been identified. It is divided into four lobes, contains as many as 100,000 lobules, and is served by two distinct blood supplies. Some of the major functions performed by the liver are the production of bile by hepatic cells, the secretion of glucose, proteins, vitamins, fats, and most of the other compounds used by the body, the processing of hemoglobin for vital use of its iron content, and the conversion of poisonous ammonia to area.

Lung cancer: Pulmonary malignancy attributable to cigarette smoking in 50% of cases. Lung cancer develops most often in scarred or chronically diseased lungs and is usually far advanced when detected because metastases may precede the detection of the primary lesion in the lung. Symptoms of lung cancer include persistent cough, dyspnea, purulent or blood-streaked sputum, chest pain, and repeated attacks of bronchitis or pneumonia. Surgery is the most effective treatment, but only one half of cases are operable at the time of diagnosis and of these 50% are not resectable. Thoracotomy is contraindicated if metastases are found in contralateral or scalene lymph nodes. Irradiation is used to treat localized lesions and unresectable intrathoracic tumors and as palliative therapy for metastatic lesions. Radiotherapy may also be administered after surgery to destroy remaining tumor cells and may be combined with chemotherapy.

Lung capacities: Lung volumes that consist of two or more of the four primary nonoverlapping volumes. Functional residual capacity is the sum of residual volume and expiratory reserve volume. Inspiratory capacity is the sum of the tidal volume and inspiratory reserve volume. Vital capacity is the sum of the expiratory reserve volume, the tidal volume, and the inspiratory reserve volume. Total lung capacity, at the end of maximal inspiration, is the sum of the functional residual capacity and the inspiratory capacity.

Lung compliance: Volume change per unit of pressure change in the lungs.

Lung volume: Volume of the lungs that may be compartmentalized into component volumes and capacities.

Lungs: Pair of light, spongy organs in the thorax, constituting the main component of the respiratory system. The two highly elastic lungs are the main mechanisms in the body for inspiring air, from which oxygen is extracted for the arterial blood system, and for exhaling carbon dioxide, which is dispersed from the venous system.

Magnetic resonance imaging: Diagnostic tool using magnetic energy to create detailed views of anatomy. MRI images provide better views of soft tissues than CT scans, but MRI scans are more expensive and time-consuming (a chest CT can be done in less than a minute; an MRI takes about an hour).

Malnutrition: Any disorder of nutrition. It may result from an unbalanced, insufficient, or excessive diet or from the impaired absorption, assimilation, or use of foods.

Managed care: Health care system in which there is administrative control over primary health care services in a medical group practice. Redundant facilities and services are eliminated and costs are reduced. Health education and preventive medicine are emphasized. Patients may pay a flat fee for basic family care but may be charged additional fees for secondary care services of specialists.

Measurement: The determination, expressed numerically, of the extent or quantity of a substance, energy, or time.

Mechanical ventilation: Use of artificial mechanical means to support ventilation.

Metabolic demand: The energy and oxygen demands of the body required to support metabolism. Metabolic demand fluctuates depending on the activity level of the individual, the presence of illness and increased temperature, and the requirements of healing and repair.

Method: A technique or procedure for producing a desired effect, such as a surgical procedure, a laboratory test, or a diagnostic technique.

Mind/body therapy: Movement, and verbal and nonverbal communication, with the mind/body open up new pathways for thought and thereby unblock what might be blocked energy flow, or chi. The treatment of stress involves mind/body therapeutic techniques.

Minute ventilation (VE): Amount of air inspired in 1 minute. It is the product of tidal volume and respiratory rate.

Mobilization: Therapeutic and prescriptive application of low-intensity exercise in the management of cardiopulmonary dysfunction, usually in acutely ill patients. The primary goal of mobilization is to exploit the acute effects of exercise to optimize oxygen transport.

Morbid obesity: Excess of body fat that threatens normal bodily functions, such as respiration.

Mucous blanket: Normal layer of mucus lining the bronchopulmonary tree. This blanket provides a medium through which foreign material and bacteria can be wafted centrally by the cilia for eventual removal by coughing or swallowing.

Multiple sclerosis (MS): A progressive disease characterized by disseminated demyelination of nerve fibers of the brain and spinal cord. It begins slowly, usually in young adulthood, and continues throughout life with periods of exacerbation and remission.

Multisystem assessment: Assessment of multiple organ systems based on clinical examination and investigative laboratory reports.

Such assessment helps identify all factors that contribute to deficits in oxygen transport.

Muscle endurance: Ability to sustain repetitive contraction against a given load.

Muscle strength: Maximum force that a muscle can develop with maximal stimulation.

Muscular dystrophy (MD): A group of genetically transmitted diseases characterized by progressive atrophy of symmetrical groups of skeletal muscles without evidence of involvement or degeneration of neural tissue.

Myocardial infarction: Necrosis of a portion of cardiac muscle caused by obstruction in a coronary artery from either atherosclerosis or an embolus. Also called a heart attack.

Needs assessment: Assessment of the patient's specific physical, functional, and psychological needs.

Nocturnal ventilation: Selective use of mechanical ventilation during the night. Patients with cardiopulmonary dysfunction are at greater risk during the night when they are recumbent and the respiratory drive is depressed.

Obesity: Abnormal increase in the proportion of fat cells, mainly in the viscera and subcutaneous tissues of the body. Obesity may be exogenous or endogenous. Hyperplastic obesity is caused by an increase in the number of fat cells in the increased adipose tissue mass. Hypertrophic obesity results from an increase in the size of the fat cells in the increased adipose tissue mass.

Objective: (1) A goal. (2) Of or pertaining to a phenomenon or clinical finding that is observed; not subjective. An objective finding is often described in health care as a sign, as distinguished from a symptom, which is a subjective finding.

Obstructive lung disease: Classification of lung disease referring to airflow limitation secondary to obstruction and increased airway resistance (e.g., chronic bronchitis and emphysema).

Osteoporosis: A disorder characterized by abnormal rarefaction of bone, occurring most frequently in postmenopausal women, in sedentary or immobilized individuals, and in patients on long-term steroid therapy. The disorder may cause pain, especially in the lower back, pathological fractures, loss of stature, and various deformities.

Outpatient: A patient, not hospitalized, who is being treated in an office, clinic, or other ambulatory care facility.

Oxygen (O_2): Tasteless, odorless, colorless gas essential for human respiration.

Oxygen consumption (V_{O_2}): The difference between the amount of inspired oxygen and the amount of oxygen exhaled. The difference between inspired and expired oxygen is a primary measure of aerobic fitness.

Oxygen delivery (D_{O_2}): Delivery of oxygen to the tissues of the body; an essential component of oxygen transport.

Oxygen desaturation: Desaturation of oxygen from the hemoglobin molecule in the blood in response to a reduction of tissue oxygen levels.

Oxygen saturation: Measurement of the amount of oxygen attached to a hemoglobin molecule.

Oxygen transport pathway: Pathway for oxygen delivery to the tissues from the ambient air: through the airways and lungs, across the alveolar capillary membrane, into the pulmonary circulation through the chambers of the heart via the peripheral and regional circulation to the tissues and the mitochondria where oxygen is used in cellular respiration.

Oxygen transport: Process by which oxygen is absorbed in the lungs by the hemoglobin in circulating deoxygenated red cells and carried to the peripheral tissues. The process is made possible because hemoglobin has the ability to combine with oxygen present at a high concentration, such as in the lungs, and to release this oxygen when the concentration is low, such as in the peripheral tissues.

Oxyhemoglobin dissociation: Dissociation of oxygen from the hemoglobin molecule in peripheral tissues when the concentration of oxygen is low.

Paradoxical breathing: Paradoxical movements of the chest wall during normal breathing; sometimes clinically referred to as belly breathing, see-saw breathing, or reverse breathing.

Parenchyma: The tissue of an organ, as distinguished from supporting or connective tissue.

Parkinson's disease: A slowly progressive, degenerative, neurological disorder characterized by resting tremor, pill rolling of the fingers, a masklike expression, shuffling gait, forward flexion of the trunk, loss of postural reflexes, and muscle rigidity and weakness. It is usually an idiopathic disease of people over 60 years of age, although it may occur in younger people, especially after acute encephalitis or carbon monoxide or metallic poisoning, particularly by reserpine or phenothiazine drugs.

Partial pressure of gases: Pressure exerted by an individual gas, a percent of the total pressure of gases.

Patent ductus arteriosus (PDA): An abnormal opening between the pulmonary artery and the aorta caused by failure of the fetal ductus arteriosus to close after birth. The defect, which is seen primarily in premature infants, allows blood from the aorta to flow into the pulmonary artery and recirculate through the lungs, where it is reoxygenated and returned to the left atrium and left ventricle, causing an increased workload on the left side of the heart and increased pulmonary vascular congestion and resistance.

Pediatric cardiac rehabilitation: Specialized cardiac rehabilitation for children instituted in the chronic stage of heart disease or after cardiovascular surgery when the patient is through the acute phase.

Pediatric pulmonary rehabilitation: Specialized pulmonary rehabilitation for children instituted in the subacute or chronic stages of lung disease or after thoracic surgery when the patient is through the acute phase.

Perfusion: Passage of a fluid through a specific organ or an area of the body.

Perioperative complications: Complications before, during, and after surgery.

Peripheral circulation: The systemic circulation, which excludes the circulation to the heart and lungs (the central circulation).

Peripheral vascular disease: Any abnormal condition that affects the blood vessels outside the heart and the lymphatic vessels.

Pneumonia: An acute inflammation of the lungs, usually caused by inhaled pneumococci of the species *Streptococcus pneumoniae*. The alveoli and bronchioles of the lungs become plugged with a fibrous exudate. Pneumonia may be caused by other bacteria, as well as by viruses, rickettsiae, and fungi.

Positron emission scans: Tomographic scans using positron emitting radionuclides. The tracers used are often taken up in the metabolic pathways of the tissues being studied (e.g., oxygen metabolism or glucose metabolism).

Post polio syndrome: A collection of symptoms present in survivors of poliomyelitis. New delayed symptoms include disproportionate fatigue, increased weakness, deformity, pain, reduced endurance, breathing and swallowing problems, and respiratory insufficiency.

Postural drainage: A passive technique in which the patient is placed in positions that allow gravity to assist with the drainage of secretions from the bronchopulmonary tree. Also known as bronchial drainage.

Prescription: An order for medication, therapy, or a therapeutic device given by a properly authorized person to a person properly authorized to dispense or perform the order. A prescription is usually in written form and includes the name and address of the patient, the date, the [4]+ symbol (superscription), the medication prescribed (inscription), directions to the pharmacist or other dispenser (subscription), directions to the patient that must appear on the label, the prescriber's signature, and in some instances, an identifying number.

Prevention: Any action directed toward preventing illness and promoting health to avoid the need for secondary or tertiary health care.

Primary cardiopulmonary dysfunction: Cardiopulmonary dysfunction resulting from a primary condition of the heart, lungs, or both.

Pulmonary circulation: Blood flow through a network of vessels between the heart and the lungs for the oxygenation of blood and removal of carbon dioxide.

Pulmonary development: Anatomical and physiological development of the cardiopulmonary system during normal growth and development.

Pulmonary rehabilitation: Rehabilitation of cardiopulmonary dysfunction including the acute, subacute, and chronic phases of the disease or after thoracic surgery. The long-term management includes a comprehensive program of exercise, ventilatory support, additional airway clearance interventions as needed, nutrition, stress reduction, smoking cessation, pacing and energy conservation, vocational rehabilitation, sexual rehabilitation, and education.

Quality care: Provision of holistic care in which the needs and wants of the patient are considered.

Radiolucent: Pertaining to the darkest areas on a radiograph film.

Radiopaque: Pertaining to dense areas of material (i.e., metal) on a radiographic film; these areas will appear opaque.

Recumbency: The state of lying down or leaning against something.

Reflex cough: A cough stimulated reflexively.

Reliability: The extent to which a test measurement or a device produces the same results with different investigators, observers, or administration of the test over time. If repeated use of the same measurement tool on the same sample produces the same consistent results, the measurement is considered reliable.

Residual volume: Volume of air remaining in the lung after a maximal expiration.

Resources: Services, personnel, and treatment options that can be drawn on to maximize treatment delivery and effectiveness.

Respiratory failure: Inability of the cardiac and pulmonary systems to maintain an adequate exchange of oxygen and carbon dioxide in the lungs. Respiratory failure may be oxygenation or hypercapnic. Treatment of respiratory failure includes maximizing ventilation, clearing the airways by suction, bronchodilators, or tracheostomy, antibiotics for infections usually present, anticoagulants for pulmonary thromboemboli, and electrolyte replacement in fluid imbalance. Oxygen may be administered in some cases; in others it may further decrease the respiratory reflex by removing the stimulus of a decreased elevated level of oxygen.

Respiratory mechanics: The physical properties of the lung, including resistance and compliance characteristics.

Respiratory muscle fatigue: Loss in the capacity of a muscle under load to develop force or velocity that is reversible by rest.

Respiratory muscle weakness: Chronic loss in the capacity of a rested muscle to generate force.

Respiratory muscles: Muscles that produce volume changes of the thorax during breathing. The inspiratory muscles include the hemidiaphragms, external intercostals, scaleni, sternomastoids, trapezius, pectoralis major, pectoralis minor, subclavius, latissimus dorsi, serratus anterior, and muscles that extend the back. The expiratory muscles are the external intercostals, abdominals, and the muscles that flex the back.

Restrictive lung disease: Category of lung disease involving restriction of the lung parenchyma and characterized by stiffness (reduced compliance) and reduced lung volume.

Rheumatoid arthritis: A chronic, destructive, sometimes deforming collagen disease that has an autoimmune component. Rheumatoid arthritis is characterized by symmetric inflammation of the synovium and increased synovial exudate, leading to thickening of the synovium and swelling of the joint.

Rhonchi: Lung sound with a low but continuous pitch. Snoring is a term used to describe its quality.

Risk factors: Factors that cause a person or a group of people to be particularly vulnerable to an unwanted, unpleasant, or unhealthful event. Examples include immunosuppression, which increases the incidence and severity of infection, and cigarette smoking, which increases the risk for developing a respiratory or cardiovascular disease.

Routine body positioning: Routine use of body positioning in the management of patients to minimize the negative effects of static positioning and maximize comfort. The purposes of routine body positioning are distinct from the specific goals of prescriptive body positioning, which are related to optimizing particular components of cardiopulmonary function and gas exchange.

Sandifer's syndrome: A condition marked by posturing in infants of thoracic extension and right head rotation in supine position. This posturing may be mistaken initially for a neuromuscular lesion; the infant may use this posturing to move away from the noxious stimulus of reflux experienced whenever he or she moves into a flexed thoracic posture of head turning and lateral thoracic bending to the left.

Scleroderma: A relatively rare autoimmune disease affecting the blood vessels and connective tissue. The disease is characterized by fibrous degeneration of the connective tissue of the skin, lungs, and internal organs, especially the esophagus, digestive tract, and kidneys. Scleroderma is most common in middle-aged women.

Secretion management: Management of airway secretions.

Sedation: An induced state of quiet, calmness, or sleep, as by means of a sedative or hypnotic medication.

Sepsis and multiorgan system failure: Overwhelming systemic infection and pathogens leading to failure within multiple organ systems.

Shock: An abnormal condition of inadequate blood flow to the body's peripheral tissues, with life-threatening cellular dysfunction, hypotension, and oliguria. The condition is usually associated with inadequate cardiac output, changes in peripheral blood flow resistance and distribution, and tissue damage. Causal factors include hemorrhage, vomiting, diarrhea, inadequate fluid intake, or excessive renal loss, resulting in hypovolemia.

Skilled nursing and rehabilitation facilities: An institution or part of an institution that meets criteria for accreditation established by the sections of the Social Security Act that determine the basis for Medicaid and Medicare reimbursement for skilled nursing care, including rehabilitation and various medical and nursing procedures.

Spinal cord injury: Disruptions of the spinal cord, often associated with extensive musculoskeletal involvement. Common spinal cord injuries are vertebral fractures and dislocations, such as those commonly experienced by individuals involved in car accidents, airplane crashes, or other violent impacts. Such trauma may cause varying degrees of paraplegia and quadriplegia.

Stable angina: Anginal pain that is well-controlled, medically stable, and has a predictable activity/exercise threshold.

Status asthmaticus: An acute, severe, and prolonged asthma attack. Hypoxia, cyanosis, and unconsciousness may follow. Treatment includes bronchodilators given intravenously or by aerosol inhalation, corticosteroids, controlled positive pressure ventilation, sedation, frequent therapy, and emotional support. A bronchodilator may be given by aerosol inhalation from a ventilator.

Stroke volume (SV): The amount of blood ejected from the ventricles during systole.

Stunned myocardium: Contractile dysfunction of the myocardium as a result of an acute episode of ischemia that persists even after perfusion has returned to normal.

Subacute hospitals: Hospitals that specialize in the management of nonacute conditions.

Subjective: (1) Pertaining to the essential nature of an object as perceived in the mind rather than to a thing in itself. (2) Existing only in the mind. (3) That which arises within or is perceived by the individual, as contrasted with something that is modified by external circumstances or something that may be evaluated by objective standards.

Suctioning: Use of mechanical airway suctioning that uses a catheter and negative pressure to remove oropharyngeal or airway secretions when the patient is unable to spontaneously or voluntarily take deep breaths and cough effectively.

Supraventricular: Pertaining to a feature or event occurring superior to the ventricles of the heart.

Surgery: The branch of medicine concerned with diseases and trauma requiring operative procedures.

Syncytium: The arrangement of cells, as in the myocardium, such that stimulation of one cell causes stimulation of adjacent cells, thus causing an action potential to spread from the initial focus.

Systemic disease: Dysfunction or condition affecting one or more systems.

Systemic inflammatory response syndrome (SIRS): Loss of local control or an overly active response that results in an exaggerated systemic response.

Systemic lupus erythematosus (SLE): A chronic inflammatory disease affecting many systems of the body. The pathophysiology of the disease includes severe vasculitis, renal involvement, and lesions of the skin and nervous system. The primary cause of the disease has not been determined; viral infection or dysfunction of the immune system has been suggested. Adverse reaction to certain drugs also may cause a lupus-like syndrome. SLE occurs four times more often in women than in men.

Tachycardia: Abnormally rapid heart rate.

Tachypnea: Increased respiratory rate over 20 breaths per minute.

Tactile fremitus: Vibrations of spoken words palpable when the therapist's hands are placed on the patient's chest wall.

Thallium-201 scan: A radionuclide scan that evaluates myocardial perfusion. The tracer is taken up in the myocardium based on perfusion of the area. This agent can be used for rest studies, exercise stress studies, and pharmacological stress studies.

Thoracic cavity: The cavity enclosed by the ribs, the thoracic portion of the vertebral column, the sternum, the diaphragm, and associated muscles.

Thoracic surgery: The branch of medicine that deals with disease and injuries of the thoracic area by manipulative and operative methods.

Throat clearing: Spontaneous elicitation of a cough-like maneuver to clear secretions or an obstruction from the oropharynx that may be threatening the upper airway.

Tidal volume (TV): Amount of air inhaled and exhaled during normal ventilation. Inspiratory reserve volume, expiratory reserve volume, and tidal volume make up vital capacity.

Total lung capacity (TLC): Volume of gas in the lungs at the end of a maximum inspiration. It equals the vital capacity plus the residual capacity.

Tracheobronchial tree (TBT): Anatomic complex that includes the trachea, the bronchi, and the bronchial tubes. It conveys air to and from the lungs.

Tracheostomy tube/cuff: A tube/cuff that is positioned directly through the trachea in the neck to provide a functioning airway that bypasses the nares and oropharynx.

Tracheostomy: An opening through the neck into the trachea through which an indwelling tube may be inserted.

Transitional care units: Settings that specialize in providing care between the acute, subacute, and long-term stages of a patient's illness.

Transitional circulation: A transition from one type of blood vessel to another on moving peripherally through the circulation.

Treatment selection and prioritization: The process of selecting treatments and then prioritizing the order in which these treatments are administered. This process is based on the relative contribution of the pathogenesis that each treatment addresses with respect to oxygen transport deficiencies.

Trunk-ventilation interaction: Interrelationship of the shape and movement of the trunk or chest wall on alveolar ventilation. Trunk and ventilation interaction depends on body positioning and movement.

Tuberculosis: A chromic granulomatous infection caused by an acid-fast bacillus, mycobacterium tuberculosis, generally transmitted by the inhalation or ingestion of infected droplets and usually affecting the lungs, although infection of multiple organ systems occurs.

Type I fiber: Type of skeletal muscle fiber that is also called slow-twitch and is suitable for sustained tonic activity (e.g., the maintenance of posture or breathing, which require resistance to fatigue).

Type IIA fiber: Type of skeletal muscle fiber that is used for short-term, fast, powerful activity in which endurance to fatigue is not required; also called fast-twitch fiber.

Validity: Extent to which a device measures what it is intended to measure.

Valvular heart disease: An acquired or congenital disorder of a cardiac valve, characterized by stenosis and obstructed blood flow or by valvular degeneration and regurgitation of blood.

Ventilation and perfusion matching: Matching of ventilation and perfusion in the lungs. Optimal ventilation and perfusion matching occurs in the midzones of the upright lung, where the ratio is 0.8 to 1.0.

Ventilation: Process by which gases are moved into and out of the lungs.

Ventilation-perfusion scan: Two scans that are used to assess patients for the presence of pulmonary emboli. Criteria (BIELLO or PIOPED) are used to determine whether matched defects present with high, intermediate, or low probability of pulmonary embolus.

Ventilatory strategies: Teaching patients to control breathing with the use of ventilatory patterns (e.g., combining inspiration with trunk extension and exhalation with trunk flexion).

Vital capacity (VC): A measurement of the amount of air that can be expelled at the normal rate of exhalation after a maximum inspiration, representing the greatest possible breathing capacity. The vital capacity equals the inspiratory reserve volume plus the tidal volume plus the expiratory reserve volume.

Work of breathing: Total amount of effort required to expand and contract the lungs; the physiological "cost" of breathing. Generally, quiet breathing consumes 2% to 3% of the oxygen consumption and requires 10% of the vital capacity. If a greater amount is used, one would say the work of breathing is increased.
