Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

Writing the Preface for a book or its revision is an opportunity to pause and reflect. As we take a collective breath seeing the next edition become an entity, we inevitably reflect on our vision for this edition, and the degree to which we have achieved this.

Our vision has always been an ambitious one. This is appropriate given the power of nondrug and nonsurgical approaches to health promotion and remediation of chronic conditions injury and illness. In this fifth edition, specifically, we have revised the title further to reflect changes in theory and practice, and knowledge translation. In the fourth edition, we changed the title from "Cardiopulmonary Physical Therapy: Evidence and Practice" to "Cardiovascular and Pulmonary Physical Therapy: Evidence and Practice" to align the title with the change in the name of the Cardiovascular and Pulmonary Section of the American Physical Therapy Association. In this revised edition, our intention was to further link evidence and practice with a minor yet important change, i.e., the replacement of "evidence and practice" with "evidence to practice"; thus, the revised title is now "Cardiovascular and Pulmonary Physical Therapy: Evidence to Practice."

The merits of the structure of the book and the interrelationship of its Parts and component chapters have held up well with intense scrutiny by external reviewers and users of the book. Therefore, we have concentrated on strengthening the emphasis on the epidemiological basis for content and lifestyle-related conditions given that most patients today have risk factors or manifestations of these conditions, and, in turn, these conditions invariably impact the cardiovascular and pulmonary systems either primarily or secondarily. In addition, contributors were committed to reporting the highest level of physiological and scientific evidence for overall management approaches and treatment interventions. Because of the international appeal of the book over its multiple editions, we remain committed to using boxes, tables, figures, appendices, and pictures as strategically and selectively as possible to best illustrate concepts, ideas, and management considerations. We have paid particular attention to these materials to ensure they reinforce the information in the text to the utmost degree. We take the book's reputation most seriously; therefore we have attempted to incorporate changes that meet the needs of as many stakeholders as possible including students, educators, clinicians across specialties and areas of care, specialists, and other health professionals. We are most appreciative of these stakeholders who have taken time to advise us in this revision.

In ensuring the appeal of the book to users, we have made several changes. First, we have further improved chapter flow and the consistency of their information with additional cross referencing. To enhance the learning experience for students we have contextualized the academic content wherever possible into a clinical framework, which in turn is further reinforced in the cases in the accompanying online Clinical Case Study Guide. Throughout editions, the book has been acknowledged for its user-friendly approach and continues to be a primary textbook in the field. Consistent with the needs in health care this century, we have attempted to broadly consider the impact of multisystem influences on the cardiovascular and pulmonary systems across the continuum of health and dysfunction (consistent with the International Classification of Functioning, Disability and Health [World Health Organization]). Our commitment to the content being both evidence-informed and evidence-based has led us to consider this perspective, in the selection of invited contributors and in the case examples in the accompanying online Clinical Case Study Guide. Each chapter has key terms and review questions to guide the reader in grasping central concepts and translating these into practice. In addition, to serve as an authoritative resource to colleagues developing specific programs such as pulmonary rehabilitation and cardiac rehabilitation that have established international standards, we have outlined the standards for these programs in an easy to use format in appendices for handy reference.

To meet the needs of busy faculty and instructors who need to keep up to date, we provide learning resources and outlines, PowerPoint slides for lectures, and review questions for group work. These resources complement the online Clinical Case Study Guide that accompanies the text. We have further responded to clinicians who need updated information on examination, evaluation, interventions, and outcomes for patients with cardiovascular and pulmonary limitations. In the literature, examination and evaluation tools focus increasingly on the use of standardized outcome measures and professional associations are increasingly encouraging clinicians and students to use these measures routinely and systematically. This is considered essential in contemporary practice to evaluate patients' progress objectively and in a clinically relevant manner. Further, such practice provides an indicator in deciding whether to treat a patient, for changing interventions or their parameters, and as a basis for discontinuing treatment or discharging the patient.

It has been a pleasure for us to reflect on our vision for this edition and how well we have achieved our goals. We sincerely hope the fifth edition meets and surpasses your expectations. With years in the field, we appreciate more than ever that "every patient is a cardiovascular and pulmonary patient" and hope that the information in the book will help ensure health is promoted in every patient, and also ensure we provide "the right treatment, for the right patient, at the right time" in pursuit of the best physical therapy outcomes based on best practice.

We very much look forward to your feedback and welcome suggestions for the sixth edition at any time.

Acknowledgments

The tenets of Hippocrates of "first do no harm" and "the function of protecting and developing health must rank even above that of restoring it when it is impaired" have provided an overarching philosophy and context of practice for this book. It is this perspective that I believe has largely distinguished its contribution and ongoing favorable reception by students, clinicians, and educators worldwide. Over the years, I have often reflected on the wisdom of Hippocrates and cite him frequently. It therefore seems fitting that I formally acknowledge him and his seminal work. The tenets of Hippocrates are as relevant today as they were more than two millennia ago in providing a context in which to address the pandemic of lifestyle-related conditions today. This vision has become blurred in a care arena with competing interests, e.g., a disproportionate emphasis on illness care than on health care and the lens of illness care as a lucrative business. We have attempted to do justice to the ideas and wisdom of Hippocrates in the context of today's health-care needs and priorities. In fact, as one of the leading established health professions and, of these, the primary profession committed to non invasive approaches, physical therapy is in a strategic position to lead in the pursuit of "health and participation for all."

As yet another edition of the book goes to press, I reflect on how we arrived here. No foreword material would be complete without primary acknowledgment of my long-time colleague and friend, the primary co-editor of the book, Donna Frownfelter. I think back to her first edition of the book, a best-seller in the field in North America. I continue to marvel at Donna's unwavering commitment to her original vision through each edition of the book, yet her ever willingness to adapt and change as the world and the needs of the profession evolve along with the demand for evidence-based practice. Thank you, Donna, for the opportunity to be on this journey with you. It has been a phenomenal one.

Few words can express my appreciation to my family, more recently new husband Lawrence Aronsen, and friends for your unending support, inquiries, and quality time. During book revisions, my conversation becomes rather single focused when asked "how are things?" Thank you for your forbearance and understanding and in seeing this project through once again. And, Lawrence, yourself having been through this process several times, your quiet implicit understanding and no-explanation-needed support were invaluable to me in moving things along each day.

My sincere appreciation to the Elsevier team. There are many people behind the scenes in a major undertaking such as the fifth edition of a major textbook. You have contributed in many ways to this new and improved edition. In particular, I would like to thank Kathy Falk, Megan Fennell, and Celeste Clingan. In each of your roles, I thank you for your commitment, support, and adaptability during this revision. You have added to its quality while supporting us and our vision.

Finally, I would like to express my gratitude to the international physical therapy community and my colleagues around the world for your insights and shared vision. In the preface of the fourth edition, I had said that "…by the fifth edition, physical therapists around the world will have increasingly made their mark as primary health care professionals and leaders in the assault on the diseases of civilization by being effective agents of change." Based on multiple international visits since that time, I am heartened to see the groundswell of change taking place in several countries at the levels of our professional bodies, entry-level physical therapy programs, educators, researchers, and clinicians, and their emerging impact on policy makers and ministries of health. By the sixth edition, I look forward to this groundswell becoming a tsunami with physical therapists making major inroads across all of these levels and collectively impacting global health.

I continue to look forward to working with international colleagues toward a shared vision of "health and participation for all." By collectively translating our substantial knowledge base to address the world's leading health-care challenges, we shall make a difference.

This past century, health care priorities have shifted from the prevention and management of acute infectious diseases to the prevention and management of lifestyle-related conditions. These include ischemic heart disease (IHD), smoking-related conditions (including chronic obstructive pulmonary disease [COPD]), hypertension and stroke, diabetes, obesity, and cancer. Not only have the morbidity and mortality resulting from these conditions escalated to their current pandemic proportions, but the probability that an individual (child or adult) has at least one risk factor is high.

To address the gap between lifestyle practices and the body of knowledge on the relationship between lifestyle choices and health,[1] a societal commitment to reducing the number of patients rather than increasing the focus on biomedical care (drugs and surgery) has never been more urgent. Physical therapists are uniquely qualified and strategically positioned as health care professionals to lead in the translation of this well-established body of knowledge into daily practice.[2] A consideration of the risks of lifestyle-related conditions in every individual is consistent with a comprehensive model of best practice in the context of epidemiological trends—that is, evidence-based practice in the context of practice priorities that are themselves informed by evidence. This chapter expands these concepts and outlines principles for applying them proactively and as a priority in the health care of every patient. Physical therapists can have a major impact on the leading priorities of health care, one individual at a time.

What Is Health?

Consistent with the tenets of Hippocrates to which all health care professions aspire—"first do no harm" and "the function of protecting and developing health must rank even above that

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

of restoring it when it is impaired"—the primary objective of health care is to promote health and wellness, to prevent illness and disability and, in the event that these occur, to exploit the least invasive interventions.

The World Health Organization (WHO) defines health as "a complete state of physical, emotional and social well-being"—not merely the absence of disease and impairment.[3] Although physical well-being contributes to health in the other dimensions, it does not ensure health. Thus emotional and social well-being should be assessed as systematically as is physical well-being in a model of care based on health. Collectively, these domains of health translate into an individual's capacity to perform activities that enable him or her to participate fully in life.[4] The WHO's definition of health has not been amended since 1948. Although having withstood time, this definition has failed to be incorporated as the primary goal of contemporary health care.

Over the past century, the primary determinants of improved health have been the provision of clean water, sanitation, basic nutrition, shelter, and security, rather than biomedical advances (other than mass vaccination programs). In addition, education and socioeconomic and employment status are independent determinants of health. Biomedical care has had particular success in controlling infection, providing symptomatic relief of acute problems, and providing emergency care. Such care, however, has not had the impact on health that the primary determinants of health have had overall, nor has biomedical care achieved major success in preventing, reversing, and managing chronic lifestyle-related conditions.

By the time an individual has entered the biomedical system, health care in its truest sense has failed. Without question, the need exists for invasive care (drugs and surgery), well-equipped hospitals, and highly qualified health care professionals. On the other hand, as practitioners committed to noninvasive care, physical therapists have the capacity to promote health and well-being in their practices, with the global goals of reducing the number of patients and minimizing the need for invasive care. The role of physical therapists in preventing and managing chronic lifestyle-related conditions is essential.

Because of widespread immigration, the cultural and ethnic demographic profiles of high-income countries such as those in North America and Europe are changing rapidly. Beliefs, attitudes, values, cultures, ethnicity, and traditions affect health, ill health, and their interactions, including how often individuals seek health care. For example, Asian immigrants to the United States report fewer stress-related and psychological problems than do non-Hispanic Caucasians.[5] With increasing time in the United States, however, reports of stress increase for Asian Americans. This may reflect a number of factors: cultural differences in the acceptability of reporting psychological distress (leading to underreporting by members of some cultural groups), sensitization to the definition and the awareness of stress with increasing duration of residence, or the compounding effect of increasing stress in the new culture. How best to reduce racial and ethnic disparities through culturally competent health care is a matter of debate and requires such outcomes as client satisfaction, improved health status, and culturally appropriate management and delivery across racial and ethnic groups.[6,7]

Since the psychobiological adaptation model was posited over 25 years ago,[8] the few models of physical therapy practice that have been reported have included psychosocial and other nonphysiological components.[9-11] Psychosocial components include health belief, self-efficacy, and perceived control. The Health Belief Model is useful in appreciating the ways in which belief may affect health, illness, and the responses and reactions to them (Table 1-1).[12] Assessment of self-efficacy provides an index of an individual's sense of mastery over his or her health and well-being. These concepts can be used in a clinician's practice setting. A few questions can help assess a patient's perception of susceptibility to risk or a condition. These concepts can provide a basis for health education that includes increasing the patient's awareness of the effects of lifestyle factors on health and of their consequences. The action necessary to avoid the condition or minimize its risk can be selectively targeted for each individual when the individual's context is known.

The International Classification of Functioning, Disability and Health advocated by the WHO interrelates body functions and structures, activity, and participation in life.[4] The biomedical model focuses on impairment (i.e., body functions and structures), with less attention to health and wellness,

Table 1-1 Concepts of the Health Belief Model

Concept	Definition	Application
Perceived susceptibility	One's belief of the chances of getting a condition	Define the population(s) at risk and their risk levels Personalize risk based on a person's traits or behaviors Heighten perceived susceptibility if too low
Perceived severity	One's belief of the seriousness of a condition and its consequences	Specify and describe consequences of the risk and the condition
Perceived benefits	One's belief in the efficacy of the advised action to reduce risk or seriousness of impact	Define action to take—how, where, when Clarify the expected positive effects Describe evidence of effectiveness
Perceived barriers	One's belief in the tangible and psychological costs of the advised behavior	Identify and reduce barriers through reassurance, incentives, and assistance
Cues to action	Strategies to activate "readiness"	Provide how-to information Promote awareness Provide reminders
Self-efficacy	Confidence in one's ability to take action	Provide training, guidance, and positive reinforcement

From Stretcher VJR, Rosenstock IM: The health belief model. In Glanz K, Lewis FM, Rimer BK, editors: *Health behavior and health education: theory, research and practice,* San Francisco, 1977, Jossey-Bass.

sickness impact, life satisfaction, and quality of life, which reflects an individual's participation in life and associated activities. One problem that occurs when the primary focus is on the remediation of limitations of function and structure in managing the leading health care priorities of our day (i.e., chronic lifestyle-related conditions) is that such limitations do not necessarily affect activity and participation—the essence of a meaningful life. These relationships need to be evaluated in each case rather than assumed.

The integration of health belief and motivational models has been a means of incorporating psychosocial dimensions of care, interventions, and outcomes so as to directly focus on an individual's limitations of activity and participation. As a result of this paradigm shift, an increasing number of measurement tools are available to assess the dimensions of health. These tools can be categorized as generic, as having general application across individuals and conditions, or as having specific application to a cohort of individuals, based on age, condition, or some other variable (see examples in Chapter 17). Many of these scales have been validated on a subset of these cohort groups. Physical therapists need to be able to use these tools knowledgeably and specifically to assess outcomes in their practices, just as they use conventional tools to assess and evaluate anatomic structure and physiological function. One such measure is the Short Form-36, which evaluates health-related quality of life and has become an established tool for general use and has been adapted cross-culturally.[13,14] Such tools can be used to evaluate the individual's perception of health improvement, which supplements conventional objective clinical measures.

The Paradox

People living in high-income countries (e.g., countries in North America and Europe, and some Asian countries) and, increasingly, in countries whose economies are growing are experiencing a paradox: an increase in the negative impact of a more Western lifestyle combined with an increase in advances in biomedicine. Technological and economic advances have been proposed as factors contributing to an obesity-conducive environment.[15] The effects of low activity (hypokinesis) and poor nutritional choices on health in Western countries have been reported to be synergistic and partially additive,[16] although a potent interaction may exist. The power of non-pharmacological interventions and solutions to affect global health priorities related to chronic lifestyle-related conditions can no longer be considered secondary to pharmacological solutions.[17,18] Rather, they may need to be considered foremost.

A nationwide, population-based strategy to improve lifestyle is the primary means of improving a country's overall health and minimizing morbidity and premature mortality from chronic lifestyle-related conditions with the least risk and cost.[19-21] Even a modest reduction in cardiac risk factors, for example, could save approximately three times as many life-years as invasive interventions.[22] Preserving and maximizing health in the most cost-effective, low-risk, and ethical manner warrant being universal health care priorities in the 21st century to stem the tide of chronic lifestyle-related conditions.

Lifestyle-Related Conditions

Poor nutritional choices and sedentary lifestyles combined with tobacco use, excessive alcohol consumption, and stress underpin chronic lifestyle-related conditions in high-income countries, and they pose the greatest threats to public health.[23-25] Eight major risk factors related to lifestyle and their documented impacts on health appear in Table 1-2. This trend has given rise to dramatic increases in a relatively newly defined condition, metabolic syndrome, which includes insulin resistance, high blood pressure, elevated triglycerides and cholesterol, and obesity. With industrialization and technological advances, lifestyle-related conditions are on the rise in low- and middle-income countries as well.[26,27] Despite their prevalence, however, the WHO has long proclaimed that lifestyle-related conditions are largely preventable.[28]

Table 1-2 Major Modifiable Risk Factors for Lifestyle-related Conditions

Risk Factor	Cardiovascular (IHD & Hypertension) and Peripheral Vascular Disease	Obstructive Lung Disease	Stroke	Type 2 Diabetes Mellitus	Cancer	Osteoporosis
Smoking	X	X	X	X	X*	X
Physical inactivity	X		X	X	X	X
Obesity	X	X	X	X	X	
Nutrition	X		X	X	X	X
High blood pressure	X		X	X		
Dietary fat†/blood lipids	X		X	X	X	
Elevated glucose levels	X		X	X	X	
Alcohol‡	X		?	X	X	X

*An increased risk of all-cause cancer. Smoking is not only related to cancer of the nose, mouth, airways, and lungs; smoking increases the risk of all-cause cancer.

†Partially saturated, saturated, and trans fats are the most injurious to health.

‡Alcohol can be protective in moderate quantities, red wine in particular.

Modified from the Heart and Stroke Foundation of Canada, 2003; Bradberry JC: Peripheral arterial disease: pathophysiology, risk factors, and role of antithrombotic therapy, *Journal of the American Pharmacy Association* 44(2 Suppl 1):S37–S44, 2004; Charkoudian N, Joyner MJ: Physiologic considerations for exercise performance in women, *Clinics in Chest Medicine* 25:247–255, 2004.

Atherosclerosis is the major common denominator and contributor to lifestyle-related conditions, including ischemic heart disease (IHD), hypertension, and stroke. Factor analysis supports a two-factor solution for heart disease and possibly for other lifestyle-related conditions: family history (factor 1) and lifestyle factors such as smoking, serum cholesterol, blood pressure, nutrition, exercise, and weight control (factor 2).[29] At the population level, choosing health—which includes smoking abstinence along with optimal nutrition and exercise throughout life—can enhance the quality of life, decrease the prevalence of chronic lifestyle-related conditions, and reduce the burden of these conditions on individuals, families, communities, and countries, including suffering and health care costs.[30-32]

Life Cycle and Lifestyle-Related Conditions

Lifestyle-related conditions have their foundation in childhood because their associated underlying health behaviors are rooted during this critical period. The latency period before developing significant signs and symptoms can be decades.

IHD secondary to atherosclerosis continues to be the leading cause of premature mortality and disability in industrialized countries. The prevention and management of risk factors of systemic atherosclerosis should be a primary target of contemporary care for children as well as for adults.[33-35] Ischemic cerebrovascular, coronary, and peripheral vascular conditions are manifestations of the same underlying pathological process, blood vessel narrowing caused by atherosclerosis and thrombosis. Smoking, a high-fat diet, and inactivity can precipitate damage to the endothelium and fat deposition within arterial walls. This common pathway has been associated with increased fibrinogen and C-reactive protein, markers of inflammation.[36] The focus of biomedical research has shifted to the role of inflammatory mediators and the contribution of low-density lipoproteins to atherosclerosis and away from the concept of degenerative vessel disease. Fibrinogen is an inflammation mediator and a clotting factor. People with cardiovascular disease have high fibrinogen levels, which further increase the risk for thrombosis and manifestations of circulatory disease. Inflammation has been implicated in a growing number of chronic conditions, such as IHD, stroke, asthma, gastrointestinal ulcers, cirrhosis of the liver, Alzheimer disease, cancer, and autoimmune conditions.[37,38] Unhealthy lifestyle choices have been thought to contribute to a proinflammatory state, giving rise to low-grade infection in various organ systems and leading to the signs and symptoms associated with various chronic degenerative processes.[39] Although this is an important finding, a proinflammatory milieu and inflammation are not the causes of the chronic conditions with which they have been associated but, rather, are precipitating effects of traumas resulting from lifestyle.

Promotion of a healthy lifestyle early in life transfers responsibility to the individual as much as possible and away from some inherent pathophysiological cause. Although conventional invasive biomedical care with medications and surgery may provide symptomatic relief, only fundamental changes in lifestyle can address the root cause in the majority of cases of chronic lifestyle-related conditions. The physical therapist as a contemporary health care provider can serve as an effective health coach in the care of children and adults.

Lifestyle-related conditions can no longer be considered adult conditions or age-related conditions. Children are exhibiting signs of cardiovascular disease, including arterial atherosclerotic streaking, hypertension, type 2 diabetes mellitus, and obesity.[40] Forty years ago, these conditions manifested in adults. With sedentary lifestyles, low activity, and poor nutrition, children are showing the results of accumulated injury to blood vessels and larger body frames and weights. As a consequence, children today are manifesting lifestyle-related conditions earlier than previous generations and are thus expected to die prematurely from these conditions and to have shorter life expectancies than their parents. Throughout their lives, these individuals can expect to have prolonged morbidity associated with these conditions, the secondary complications of these conditions, associated adverse responses to other health complaints, and increased iatrogenic problems (secondary to drugs and surgery).[41,42] Health promotion strategies directed toward parents and young children will help to offset the population's health threat of lifestyle-related conditions.

Life expectancy has almost doubled since 1900. The post–World War II baby-boom generation characterizes the demographics of many industrialized countries. This cohort has lived in prosperous times and up to that time was the longest living generation in history. Despite the prosperity seen by the baby boomers, this era was associated with more sedentary lifestyles and access to food products low in nutritional value. Although the manifestations of lifestyle-related conditions are associated with aging, they are not necessary consequences of aging. This is based on cross-cultural comparison studies. Optimal nutrition, exercise, stress control, smoking abstinence, and moderate alcohol consumption, if any, are central to reducing the probability of chronic lifestyle-related conditions and associated disability and maximizing quality of life as people age.[43] In particular, increased quality of life with a higher threshold for chronic lifestyle-related conditions and less morbidity toward the end of life is the objective. Figure 1-1 shows the theoretical increase in the threshold of these conditions with healthy lifestyle choices (i.e., not smoking,

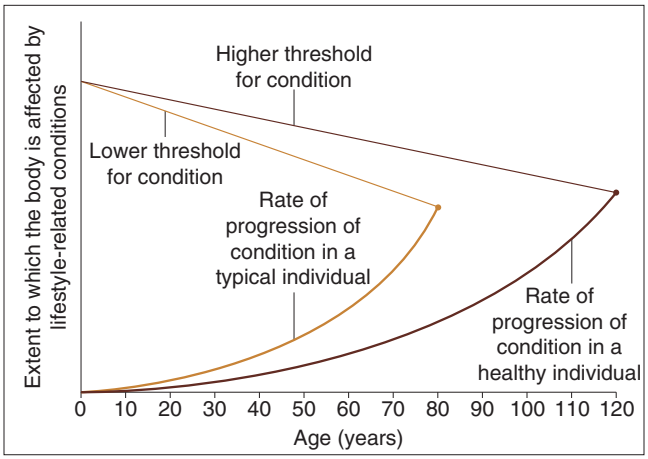

Fig. 1-1 Theoretical relationship between the threshold of lifestyle-related conditions and their rate of progression over the life cycle. *(From Dean E, Lomi C, Bruno S, et al: Addressing the common pathway underlying hypertension and diabetes in people who are obese: the ultimate knowledge translation gap,* International Journal of Hypertension *[in press].)*

optimal nutrition and weight control, regular physical activity and exercise, optimal sleep, and reduced stress) and reduced rate of progression of chronic conditions. Ostensibly, the net result is more "life to years" as well as more "years to life."

"First Do No Harm"

As primarily a noninvasive health care profession, physical therapy is uniquely positioned to have a primary role in promoting health and wellness, while also preventing, managing, and in some cases, reversing these pandemic lifestyle-related conditions, objectives that commonly coexist because they share a common pathway.[44] Integrating health promotion into practice would directly address the ultimate knowledge translation gap in health care (with respect to the benefits of healthy living).[45] Indeed, focusing on health promotion, in addition to directly addressing the risk factors and/or manifestations of secondary lifestyle-related conditions, may result in more favorable outcomes for a patient's presenting problem. Triage of individuals by both noninvasive practitioners and invasive practitioners would constitute a bold initiative in health care. Such triage could establish whether a patient's complaint is best managed in the short and long term wholly noninvasively, wholly invasively, or by some combination, with a view to weaning the patient off medications or minimizing the medication. Similarly, every effort should be made to avoid surgical intervention and its risks whenever possible (i.e., surgical intervention as a last resort rather than a first resort) by exploiting noninvasive interventions and strategies to restore health and promote lifelong health. When an individual enters the health care delivery system, her or his receptivity to health information is likely to be high. This is a prime opportunity to evaluate risk factors and prescribe a lifelong health plan.

The effectiveness of nonpharmacological treatments in the management of chronic lifestyle-related conditions has been well documented, but implementation has been poor.[46-48] As noninvasive practitioners, physical therapists have a primary role on the health team, which may include physicians and surgeons (i.e., invasive practitioners), nurses, nutritionists, pharmacists, social workers, psychologists, respiratory therapists, spiritual leaders, and others, depending on the requirements of each case. On a broader level, physical therapists can serve in a multisector capacity as consultants and work alongside health care policy makers, corporate business people, urban planners, and architects in developing healthy and safe homes, workplaces, recreational facilities, and communities. The role of the physical therapist clinician is shifting from hospital-based acute care and private practice to the community, schools, industry, home, workplace, and playing field.

Biomedical research that evaluates drugs and surgery often lacks control groups that are otherwise healthy or a comparative group in the research design that includes a potentially superior, noninvasively managed group where feasible. For example, a 12-month exercise program involving selected individuals with stable coronary artery disease has shown superior event-free survival and exercise capacity when compared with individuals who received percutaneous coronary intervention.[49] In another study, the mortality rate of individuals with heart disease has been estimated to be reduced by 20% to 25% with cardiac rehabilitation, which is comparable to the results of established therapies such as beta blockers.[50] Cardiac rehabilitation is noninvasive; thus it is cheaper and has few side effects. Management is focused on changing negative health behaviors and maximizing lifelong health rather than on simply altering a sign or a symptom.

Changing one's lifestyle can be more challenging than taking a drug or undergoing surgery. In both cases, the patient is a passive recipient of treatment. Being an effective agent of change and promoting active participation by clients in their own health are fundamental to the expertise of the physical therapist who specializes in noninvasive, long-term health and care. In societies with open and free marketplaces (such as in North American and European countries), people are presented with seemingly endless choices, many of which can be injurious to lifelong health. Thus physical therapists need superior skills in educating people regarding their lifestyle choices and promotion of health.

In contrast to biomedical advances, progress in these noninvasive yet high-impact interventions receives much less coverage and attention as lead articles in peer-reviewed medical journals or by the popular press. Yet these noninvasive advances show significant promise for having a major impact on the population's health and well-being, including increased probability of lifelong health at minimal cost, compared with the results of invasive interventions, which frequently do not address the causes or contributing factors. Such findings need to be integrated into contemporary practice to ensure that individuals are not subjected unnecessarily to the risks associated with prolonged courses of medication and invasive procedures, along with the high probability of repeated invasive procedures. Noninvasive interventions have a distinct advantage over drugs and surgery—they empower individuals to manage their own long-term health by learning skills that will change deleterious lifestyle habits and reduce the risks and costs of hospitalization and its recurrence. Considering the risks and costs of an invasive procedure such as revascularization, the advantages of noninvasive interventions are worthy of much greater attention.

Evidence-Informed Practice

Addressing the Health Care Priorities of the Day

Physical therapists treat individuals with chronic lifestyle-related conditions as either primary or secondary diagnoses. Smoking is currently the leading cause and contributor to chronic conditions and premature death in the United States, with poor diet and sedentary lifestyle anticipated soon to overtake tobacco use.[51] Television viewing, an indicator of sedentary living, is associated with obesity and is a marker of cardiovascular disease independent of total reported physical activity.[51] As noninvasive practitioners, physical therapists have a responsibility to manage these conditions and their risk factors in all patients so as to prevent or control their physical, psychosocial, economic, and societal impact and to promote health in their practices. By prioritizing health and addressing suboptimal health behaviors, regardless of a patient's primary complaint, the complaint may be mitigated, the rate and quality of recovery potentially improved, and the potential for recurrence reduced.

Our Village

Fundamental to the principle of evidence-informed practice is the fact that health care providers respond to epidemiological indicators and an understanding of the changing demographics and face of our "village." Lifestyle-related conditions are the leading killers in our village. Men can expect to live 75 years; women, 82 years.[52] Functional capacity, however, is estimated to decrease 10% per decade, and half of this decrement is due to sedentary living. Raising children to be healthy and physically active will promote a generation of healthy adults and will thereby delay their physical dependence by 10 to 20 years.

Health care workers with international health organizations are trained to manage the unique needs of their villages. This entails knowing the health priorities of the village and making decisions that positively affect the problems and reduce their impact on the community as a whole. In some parts of the world, a health care worker who focuses on malaria when intestinal parasites are the priority is a hindrance, rather than a help, to that village. Similarly, in our health care climate, physical therapists need to make it a priority to meet the leading needs of their "villages." Smoking abstinence, good nutrition, weight control, exercise, and stress management are evidence-based noninvasive interventions consistent with the needs of contemporary physical therapy practice; the therapeutic potential and impact of those elements on the health of our village are enormous. For example, each kilogram of weight loss has a dose-dependent effect on health outcomes. Further, as little as 30 minutes of moderately intense activity on most days of the week offsets the deleterious effects of sedentary living.[53] With the aging of the people of our village and the signs of lifestyle-related conditions now evident in children and young people, the burden of chronic conditions will be prolonged, particularly as individuals approach the end of life. It has been suggested that life expectancy will plateau or even decrease as a result.[42]

Indigenous peoples in North America and Australasia have unique health challenges and needs. They tend to be less well educated than the dominant culture, have fewer employment opportunities, experience more violent injuries and deaths, and have poorer health and shorter lives. They have significant health risks because of sociocultural factors and genetic predisposition, such as higher rates of IHD, stroke, type 2 diabetes mellitus, obesity, hypertension, tobacco use, and alcoholism. Large-scale intervention programs are needed for the Native American population based on studies of the health of its children.[54] The past few generations have witnessed a shift from indigenous foods to refined grains and foods high in fat and sugar and from active to inactive lifestyles. These trends have exacted an enormous toll in terms of personal and social health indicators.

As individuals age in industrialized countries, their activity levels tend to decline. With relatively long life expectancy in these countries, sedentary lifestyles may prolong end-of-life morbidity. A study of individuals who adhered to exercise programs and those who did not revealed the importance of variables such as self-efficacy, perceived fitness, social support, and enjoyment.[55] The results of this study have important implications for urban planning; they can inform the design of healthy communities, as well as individual activity and exercise programs.

A study of black Seventh-day Adventists has provided a unique opportunity to isolate the effects of lifestyle on African Americans. Seventh-day Adventists promote spiritual well-being and a healthy diet and lifestyle. As a result, the health of black Seventh-day Adventists is better and the incidence of chronic lifestyle-related conditions is lower than that of African Americans who are not Seventh-day Adventists.[56] In addition, based on the results of a study of a large cohort, Mormons tend to be fitter and have fewer risk factors for IHD than do other Americans.[57]

The physical activity profiles of African American women have been compared with recommendations for moderate levels of activity.[58] In this study, findings showed that few subjects met the recommended levels of daily physical activity. Exercise was performed on fewer than the recommended number of days per week and for less than the recommended 8 to 10 minutes per session. Attention to frequency and duration may be particularly important when counseling African American women about regular physical activity.

African American women have a higher risk for cardiovascular disease and stroke than do Caucasian American women.[59] Based on a cross-sectional study of 399 urban African American women, correlates of physical activity within this cohort were identified. Programs to promote physical activity should address the safety of the physical environment and psychosocial factors. Inactive women with less than a high school education and those who perceive themselves to be in poor health should be considered special target groups.

Latina women have a higher risk for cardiovascular disease and stroke than do Caucasian American women; this has been attributed to the higher incidence of obesity and type 2 diabetes mellitus among Latinas.[60] The facilitators and barriers to exercising in this cultural cohort have been examined in a cross-sectional study of 300 Latinas. Physical activity has been reported to be higher in younger women, in married women, and in women who had confidence that they could become more active, who saw people exercising in the neighborhood, and who attended religious services.[60] The church was recommended as a suitable community setting for initiating programs that provide women with the knowledge, skills, and motivation to become more active and to transmit this information to others in the community through their families.

The impact of gender is being increasingly appreciated in terms of health affliction, access to health care, and physiological responses and psychological reactions to illness.[61,62] In a Swedish cohort of older adult individuals, obesity-related health indicators and risk factors were reported to differ in men and women and also to differ on the basis of socioeconomic status.[63] In response to cardiac rehabilitation, gender-specific effects on high-density lipoprotein cholesterol have been documented.[64] Women demonstrate greater improvement in high-density lipoprotein than do men.

Urbanization, modernization, and immigration are affecting global health. Within industrialized countries, indigenous people are moving from rural to urban areas; this is occurring in the United States, Canada, Australia, New Zealand, and many African countries. Rather than seeing improvements in their health overall, relocated rural people are succumbing to lifestyle-related conditions. Middle-aged black men who move to urban areas from rural South Africa, for example, increase

their risk for IHD and stroke.[65] One explanation for this observation is increased autonomic reactivity to the stress of relocation; however, other lifestyle factors may be implicated. These patterns have been reported for other groups as well; for example, Mexicans and Asians who move to affluent industrialized countries.[66] The typical health advantage for people who move to the West from certain Asian countries, such as Japan, is lost with increasing numbers of years in the new culture.[67]

Principles of Evidence-Informed Practice

The efficacy of the quick fix (drugs and surgery) in the management of chronic conditions, particularly lifestyle-related conditions, is being seriously questioned. With respect to long-term outcomes, noninvasive interventions may often be more successful.[68] Premature mortality can be significantly reduced with regular physical activity, optimal nutrition and weight control, and avoidance of smoking.[69] Relative to invasive care, noninvasive interventions associated with physical therapy (health education and exercise) are low in cost; yet access to these noninvasive measures is commonly more limited than access to invasive care.

The Priorities of Our Village

Health risks and the causes of premature death today are largely related to lifestyle-related conditions, namely:

- Ischemic heart conditions
- Smoking-related conditions, including COPD
- Hypertension and stroke
- Type 2 diabetes mellitus, obesity and metabolic syndrome
- Cancers

These conditions are frequently either the primary or the secondary diagnoses of the patients treated by physical therapists. This positions physical therapists favorably to make direct assaults on the risk factors of lifestyle-related conditions, as well as on their manifestations in patients. Physical therapists have the advantage of prolonged patient contact during treatments compared with other health care providers, and such contact can be exploited in targeting teachable moments and health education opportunities.

Although most people are aware of the positive benefits of healthy choices, what is less apparent to them is that small changes in health behaviors can result in major effect sizes. These effect sizes most often surpass those of medications targeted at a single sign or symptom. In a study of over 23,000 people between 35 and 65 years old, for example, Ford and his colleagues[70] showed that over an 8-year period, people who did not smoke, had a body mass index under 30, were physically active for at least 3.5 hours a week, and followed healthy nutritional principles had a 78% lower risk for developing a chronic lifestyle-related condition. Specifically, the risk for type 2 diabetes mellitus was reduced by 93%, myocardial infarction by 81%, stroke by 50%, and cancer by 36%. Even if not all four of these health factors were present, the risk for developing one or more chronic lifestyle-related conditions decreased commensurate with an increase in the number of positive lifestyle factors. Should a medication be found to have such potent benefits, it would be hailed as nothing short as miraculous.

The goal in health care is to exploit the benefits of lifestyle modification and supplement those benefits with medication only if necessary,[71] rather than the other way around (supplementing medication with lifestyle modification). A healthy lifestyle is the treatment of choice for lifestyle-related conditions; it is also the primary intervention for their prevention.[72] The translation of these research findings into health care practice is a priority.

Ischemic Heart Disease

The risk factors for IHD are well established.[73] They contribute to atherosclerotic deposits not only throughout coronary vessels but throughout the systemic arterial vasculature.[74] Nonmodifiable risk factors include age, sex, family history, and past history. Modifiable risk factors include increased cholesterol, increased homocysteine, smoking, inactivity, high blood pressure, diabetes, weight, and stress.[75-77] Less commonly acknowledged risk factors include elevated C-reactive proteins (markers of inflammation[37]), sharing a lifestyle with someone who has IHD,[78] and having overweight parents.[79] Further, a shared lifestyle confers increased evidence of IHD in and health risk for children.[80] Other emerging risk factors include passive smoking, level of education, depression, anger coupled with hostility, and social isolation.[81,82]

Based on epidemiological evidence, a 1% decrease in cholesterol reduces the risk for IHD by 3%, and a long-term reduction in diastolic blood pressure of 5 to 6 mm Hg reduces the risk by 20% to 25%.[83] Thus even modest changes can have a sizable impact on health. Most risk factors are associated with behavior choices and can be substantially modified.[84]

Risk factors for IHD are prevalent in the general population. When a cross section of people in their later middle-age years was screened, atherosclerosis involving the femoral artery affected two-thirds of them.[85] Further, a direct relationship existed between the degree of atherosclerosis and cardiovascular and general circulatory health. Individuals with peripheral artery disease have a several-fold increased risk for IHD; thus peripheral artery disease can be considered a marker of systemic atherosclerosis. It is estimated that optimal lifestyle could reduce cardiac events related to atherosclerosis by 70% to 80%. Regular walking has a significant effect on reducing the risk for IHD, as has vigorous activity.[86] In men with left ventricular hypertrophy, moderate physical activity reduces the risk for stroke by 49% compared with sedentary men who do not have left ventricular hypertrophy.[87] Type 2 diabetes mellitus has been reported to be a strong risk factor (and hypertension a less strong risk factor) for IHD in women when compared with men.[88]

Self-reported fitness has been reported to be independently related to fewer risk factors for IHD and angiographic evidence of IHD in women undergoing coronary angiography for suspected ischemia.[89] Measures of obesity are not independently associated with these outcomes. Thus fitness appears to be more important than body weight for cardiovascular risk in women. Physical activity and fitness warrant detailed assessment. They should be an integral part of the cardiovascular risk-factor stratification, and interventions should aim at long-term increases in physical activity and fitness. Assessment of physical activity and exercise programs should be included in the management of all people, particularly in women and those at risk for IHD.

Nutrition is a well-established determinant of health and an independent risk factor for lifestyle-related conditions and other chronic conditions. The average North American diet, which tends to be monotonous and unbalanced, has been thought to be a primary contributor to the prevalence of lifestyle-related conditions. Despite its unhealthy characteristics, the North American diet is increasingly being emulated in other parts of the world.

Mediterranean-type diets have been increasingly shown to have multiple health benefits and are superior to the North American diet in terms of food diversity and healthfulness. These diets are high in fish, fresh fruit and vegetables, and multigrains. Mediterranean-type diets are also low in added sugar and salt, and they favor unsaturated vegetable oil over saturated animal fats. When diet-related studies are evaluated, people who consume fish twice a week have a 47% reduced risk for cardiac mortality compared with those who eat fish less than once a month.[90] Cereal fiber (two whole-grain slices of bread daily) is associated with a 14% reduced risk for myocardial infarction or stroke. Cereal fiber consumption even later in life is associated with a reduced incidence of cardiovascular disease.[91] One alcoholic drink a day is associated with the least number of cerebrovascular abnormalities. Moderately and highly physically intense leisure-time activities predict 28% and 44% lower mortality rates, respectively, compared with little activity. Low, moderate, and high levels of exercise are associated with 30%, 37%, and 53% more years of healthy life, respectively. Aerobic training can reduce serum lipids even in older individuals; high-density lipoproteins increase and low-density lipoproteins decrease.[92] With lifestyle change, atherosclerosis can regress and associated cardiac events can be minimized.[93-96]

Psychosocial factors have been identified as risk factors for IHD. Difficulty in managing anger and hostility is one such risk factor, regardless of whether a person has a type A or a type B personality.[97] Stress is a risk factor that can be classified as minor daily hassles or as major negative events. Lipoprotein levels increase with both levels; however, coping style and subjective appraisal of stressors are powerful mitigating factors.[98] Cumulative daily hassles may be underestimated in terms of their impact on health compared with major life stressors. After an individual's first coronary event, avoidance strategies are inversely associated with healthy lifestyles, whereas positive reappraisal and problem solving are directly associated.[99] Positive reappraisal and problem solving, program participation, rather than adopting distancing and escape strategies predict a person's capacity to change lifestyle after a coronary episode. Stress management should consider the type of stressor and help to modify the individual's coping strategies and interpretation of stressors.

The risk for a cardiac event after the first one is high.[100,101] Thus there is a high prevalence of repeated revascularization procedures and the prescription of more drugs with increased potency to help offset worsening pathophysiological changes. Ornish[102] reported that 194 individuals with previous revascularization procedures avoided repeat procedures for at least 3 years (the duration of follow-up in the study) when they participated in a comprehensive lifestyle-change program. Compared with individuals who also had had a previous revascularization procedure but did *not* participate in the lifestyle-change program, those who did participate reported a level of angina comparable to that experienced with revascularization. The effects of noninvasive intervention can be considered long term, given their multisystem benefits. Revascularization focuses on the repair of an impairment and does not provide the additional multisystem benefits of the lifestyle-change program.

To date, efforts to champion aggressive modification of risk factors have been modestly successful. Optimal control of modifiable risk factors for coronary atherosclerosis, including cigarette smoking, dyslipidemia, hypertension, and sedentary lifestyle are well known to reduce the incidence of IHD and, in turn, revascularization procedures and health care utilization.[103] Our major health crisis can be addressed only by means of a system of care committed to health, wellness, aggressive risk-factor prevention, and lifestyle modification.

Smoking-Related Conditions

Smoking is the leading cause of preventable death in the United States, as well as the rest of the world.[51] Despite the well-documented health hazards, smoking remains prevalent in industrialized and nonindustrialized countries and is estimated to shorten life by 11 minutes for each cigarette smoked.[104] Thus smoking cessation is a primary health care goal, as well as a professional goal. (In 1996, the APTA adopted guidelines from the Agency for Health Care Policy and Research [AHCPR], which have subsequently been revised.[105]) The danger of smoking extends beyond COPD and cancer. Overall morbidity and all-cause mortality, including cancer of organs other than the respiratory tract, are higher in smokers.

Of the leading causes of mortality worldwide, COPD is typically among the top killers and is associated with the loss of a million years of life each year.[106] In the United States, COPD ranks fourth behind IHD, cancer, and stroke. Long-term smokers have higher incidences of all-cause morbidity and mortality (Table 1-3); thus smoking leads to life-threatening conditions that are systemic and are related not just to the respiratory tract.[90] Former and current smokers have 25% and 44% fewer healthy years of life, respectively, compared with lifelong nonsmokers. Smoking cessation is a priority for all individuals, not only those with lung disease, regardless of disease severity.[107] Smoking by children is highly associated with parental smoking; thus smoking by adults with young families has become a primary focus of public health initiatives.[79] Smoking is the single most important preventable cause of illness and death.

Pulmonary rehabilitation has demonstrated sustainability of smoking cessation and other health benefits in individuals with COPD;[108] thus its use is warranted as a preventive measure, as well as for the remediation and management of disease.[109] Rehabilitation programs have proven efficacy, independent of pharmacotherapy, so they should be considered primary interventions rather than priorities after conventional expensive medical care has failed.[110] Only with health coaching and follow-up can these individuals effect lifelong health behavior change to minimize exacerbations, reduce doctor and hospital visits, continue working, and reduce overall morbidity. Innovative smoking cessation programs warrant development so that they have maximal impact in the most significant window of opportunity and stage of readiness of a smoker to quit. One such program consisted of 5 weeks of counseling.[111] The mean time to deliver the intervention was 44 minutes. At 1 month, 70% of participants had

Table 1-3 **Tobacco Facts and Multisystem Consequences of Smoking**

Type/Area of Effects	Effects and Conditions That Are More Common in Smokers
Mortality from smoking	Tobacco causes 30% of all deaths of people between 35 and 69 years of age Tobacco reduces a person's life as follows: Ages 35 to 59 years: Those killed by tobacco lose about 27 years of life Ages 60 to 69 years: Those killed by tobacco lose about 16 years of life
Brain	Stroke
Mouth	Lip and oral cancers
Pharynx and larynx	Cancers of the pharynx and larynx
Esophagus	Cancer of the esophagus
Lungs	Cancer of the lungs
Heart	Ischemic heart disease, hypertension, and circulatory diseases
Chronic lung disease	Bronchitis and emphysema; 90% of deaths from chronic lung disease attributable to smoking Upper respiratory tract infections and increased days of absenteeism
Gastric and duodenal ulcers	Higher risk in smokers
Bladder and kidney cancers	Higher risk in smokers
Bone	Postmenopausal women who smoke have reduced bone density compared with nonsmokers Increased risk of bone fractures and delayed healing
Fertility and Pregnancy	Infertility Increased risk for spontaneous abortions, still births, pre-term deliveries, low-birth-weight babies, and sudden infant death syndrome Potential developmental and learning delays in children

Data from National Cancer Institute: Cancer Facts, 2010; U.S. Department of Health and Human Services: The health consequences of smoking: a report of the Surgeon General, U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Chronic Disease Prevention and Health Promotion, Office on Smoking and Health, 2004; Peto R, Lopez AD, Boreham J, et al: Mortality from tobacco in developed countries: indirect estimation based on national vital statistics, *Lancet* 339:1268–1278, 1992; Twardella D, Kupper-Nybelen J, Rothenbacher D, et al: Short-term benefit of smoking cessation in patients with coronary artery disease: estimates based on self-reported smoking data and serum cotinine measurements, *European Heart Journal* 25:2101–2108, 2004.

continued to abstain. The mean cost of the intervention was approximately $50 for each person.

Smoking cessation is the most cost-effective intervention for smokers with heart disease in terms of health protection and risk reduction. Further, treatment of hyperlipidemia and referral to cardiac rehabilitation are highly cost-effective per quality-adjusted life-year and are relatively cost-effective per year of life saved. Smoking is an established risk factor for ischemic stroke, subarachnoid hemorrhage, and intracerebral hemorrhage,[112] as well as for IHD. The risk is directly proportional to the amount smoked. Risk factor detection and management are the cornerstones of high-impact and high-quality care of cardiovascular disease.

Hypertension and Stroke

Stroke is a preventable tragedy for nearly 750,000 people in the United States annually; hypertension is the most common risk factor.[113] Although lowering blood pressure below 130/85 mm Hg is well accepted across ages, the success of blood pressure control has been reported to be less than 25% in the hypertensive population.[114] Stroke risk is far from being well controlled despite considerable understanding of its causes, and it remains a major health threat. Risk factors for stroke include previous stroke, hypertension, IHD, atrial fibrillation, hyperlipidemia, diabetes, abnormal ankle-to-brachial pressure index, reduced exercise endurance, retinopathy, albuminuria, autonomic neuropathy, smoking, alcohol consumption, and lack of exercise.[113,115-119]

Risk factors for hypertension and stroke can be accentuated by smoking, elevated cholesterol, glucose intolerance, inactivity, and obesity.[120] In addition to stroke, serious consequences of hypertension include hypertension heart disease and renal disease. Implicated as a cause of stroke is increased sympathetic reactivity.[121]

In the adult population between 60 and 74 years of age, almost 75% of African Americans and 50% of Caucasians have high blood pressure.[122] As with IHD, risk factors for high blood pressure consist of nonmodifiable and modifiable risk factors. Nonmodifiable risk factors include age, sex, race, and other genetic factors. Modifiable risk factors include diets high in sodium and low in potassium, alcohol consumption, reduced physical activity, and being overweight.[123] Obesity is a strong predictor of hypertension.[124] Although significant reduction of hypertension has been attributed to low-dose thiazide diuretics and beta blockers, the first line of defense to prevent high blood pressure and normalize blood pressure should be nutritional approaches, weight reduction, and regular physical activity and exercise.[125] In individuals whose hypertension is controlled, the combination of a Mediterranean diet and physical activity can reduce health risk substantially.[126] Like other lifestyle-related conditions, hypertension is increasingly common in American children; thus screening should be included in routine pediatric assessments.[127]

With respect to nutrition, high sodium and low potassium have been implicated in hypertension and stroke, as have lipids. The National Academy of Science has recently announced that reducing added salt by as little as one-third would reduce hypertension in the United States by 25% (11 million fewer cases). Low plasma vitamin C is associated with a several-fold increased risk for stroke, particularly in men who are overweight and hypertensive.[128] A minimal reduction in diastolic blood pressure (5 to 6 mm Hg) reduces the risk for stroke by 35% to 40%.[83] Thus weight control; regular exercise; a diet rich in fruits, vegetables, and whole-grain cereals; smoking cessation; and blood pressure control are central to stroke prevention, as well as to the comprehensive management of stroke.

Although weight reduction is an essential component of hypertension prevention and management, the protective

effect of physical activity may be unrelated to the degree of obesity.[129] A 4% to 8% reduction in body weight can reduce blood pressure by 3 mm Hg, and physical activity can reduce blood pressure by 5/3 mm Hg.[130]

In normotensive African American men, aerobic exercise can attenuate an exaggerated blood pressure response.[131] Similarly, normotensive fit African American women have blunted blood pressure responses to experimental stressors.[132] One study reported no relationship between physical activity and hypertension, flow-mediated dilation of the brachial artery, or an index of angiogenesis assessed with plasma vascular endothelial growth factor (the latter two being indicators of endothelial dysfunction).[133] In this study, however, physical activity was based on self-report in a questionnaire rather than on fitness outcomes, so the results of the study are difficult to interpret.

Physical activity and optimal nutrition can reduce the risk for early atherosclerosis, a precursor to stroke, in lifelong nonsmokers.[134] Smokers benefit less from this protective effect. Physical activity seems not only to reduce the risk for stroke but also to provide a potent prophylactic strategy for increasing blood flow and reducing brain injury during cerebral ischemia.[135] A possible mechanism is augmented endothelium-dependent vasodilation via up-regulation of endothelial nitric oxide synthase throughout the vasculature. Aerobic exercise three times a week reduces cerebral infarct size and functional deficits in a mouse model and improves endothelium-dependent vasorelaxation.[135]

Assessment of risk for hypertension is an important component of each patient's assessment. The management strategy should be based on an analysis of the overall risk assessment rather than on blood pressure alone. The prevention of hypertension requires more than normalizing blood pressure if the deadly manifestations of high blood pressure including IHD are to be avoided. Because of the dire consequences of hypertension, the American Heart Association advocates stringent blood pressure limits—specifically, below 130/85 mm Hg, regardless of age.[136] Recommendations by the American Heart Association concerning physical activity and exercise guidelines for survivors of stroke concur that physical conditioning is a primary goal in these individuals, who must contend with both the pathological effects of stroke and the effects of deconditioning.[137] Walking as little as 2 hours a week can reduce the risk for stroke by 50%.[130] Improved conditioning may help to reduce limitations of activity and participation and hence improve quality of life. The burden of disease and disability and their risk factors may be correspondingly reduced.

To affect the health of the population, stroke prevention depends on the dissemination of these well-established and widely available interventions to a large number of people through public health policy. Advice given by a health provider to individuals with stroke for the purpose of prevention of a second stroke can have significant impact. In one study, individuals were simply advised to eat fewer high-fat and high-cholesterol foods and to exercise more.[138] Compared with a control group that received no advice, those receiving advice reported fewer days with limited activity, fewer days that "were not good physically," and more "healthy" days. The results of this study are compelling in that even simple advice by a health care provider can have a major impact on important health behaviors and on potential health outcomes.

Type 2 Diabetes Mellitus and Metabolic Syndrome

Type 2 diabetes mellitus is a serious multisystem condition that has rapidly become pandemic in Western countries and some other countries where its incidence was previously minimal. In addition to the serious physical and functional consequences of this condition, perceived health status and quality of life are also compromised.[139] By 2010, an estimated 250 million people will be affected worldwide.[140] Formerly known as adult-onset diabetes, type 2 diabetes mellitus is now being diagnosed in children, predisposing them to blindness, IHD, stroke, renal disease, peripheral neuropathies, vascular insufficiency, and amputations.[141,142] Inositol acts as a poison on the membranes of cells in the presence of high blood sugar, and it has been implicated in the deadly systemic consequences of diabetes. The primary consequences include pathological changes to the macro- and microvasculature and to the nerve endings. Impaired glucose tolerance is a marker of vascular complications in the large and small blood vessels, independent of an individual's progression to diabetes. Early detection of glucose intolerance allows intensive dietary and exercise modifications, which have been shown to be more effective than drug therapy in normalizing postprandial glucose and inhibiting progression to diabetes.[143] Diabetic autonomic neuropathy as an independent risk factor for stroke may reflect increased vascular damage and effect on the regulation of cerebral blood flow in individuals with diabetes.[115]

Individuals with type 2 diabetes mellitus have increased risk for cardiovascular disease compared with individuals without diabetes, so strict control is essential. Moderate physical activity (such as brisk walking[144]) along with weight loss is a powerful combination to reduce the risk for type 2 diabetes mellitus, as well as to reverse it. These interventions combined with a balanced diet can reduce the risk for developing diabetes among those who are at high risk by 50% to 60%.[86] Cigarette smoking is an independent risk factor for type 2 diabetes mellitus[145] and is particularly dangerous for individuals who already have diabetes.[141]

Metabolic syndrome refers to a virulent and lethal group of atherosclerotic risk factors, including dyslipidemia, obesity, hypertension, and insulin resistance, and it affects some 47 million people in the United States.[146] The incidence of the syndrome is increasing and warrants aggressive noninvasive management. Insulin sensitivity is predicted primarily by body mass index, smoking, age, and daily physical activity. Weight reduction counters the effects of metabolic syndrome and may counter the associated hypertension and dyslipidemia as well. Diet and exercise are primary components of the multifactorial approach to preventing and managing this lethal condition.

Obesity

Obesity has been increasing exponentially over recent decades; currently, 61% of the American population is overweight.[147] Obesity is becoming a global pandemic that rivals malnutrition as a health priority in some low-income countries,[148] and it contributes to health risks for all lifestyle-related conditions. The complications and risks for which each patient should be assessed include IHD, cardiac myopathy, and chronic heart and lung dysfunction; hypertension and stroke; some cancers;

insulin insensitivity and type 2 diabetes mellitus; gallbladder disease; dyslipidemia; osteoarthritis and gout; and pulmonary conditions, including alveolar hypoventilation and sleep apnea.[149-153] With each kilogram of weight above normal, the risk for hypertension, IHD, and type 2 diabetes mellitus increases proportionately. Obesity is commonly linked with insulin resistance and high blood pressure, which may reflect reduced activity and exercise. Reduced physical activity is a predictor of obesity.[154] Insulin resistance associated with lack of exercise in people who are overweight may be further compounded by insulin resistance associated with chronic inflammation observed in fat cells.[155] Abdominal obesity, lipid metabolism, and insulin resistance are interrelated markers for coronary artery disease.[156] In addition to cardiovascular and general health risk, being overweight affects quality of life.[157,158]

Comprehensive management of an individual who is overweight and has abnormal blood glucose levels includes normalizing blood glucose (with recommendations for low-glycemic foods and small, frequent snacks rather than infrequent large meals), weight reduction, restricted intake of trans fats and saturated fats, strict blood pressure and lipid control, regular physical activity and exercise, and avoidance of tobacco.[159]

Nutritional habits during childhood are associated with lifestyle-related conditions in adulthood.[160] Obesity in children is associated with parental obesity.[79] Maintaining weight within a healthy body mass index range throughout life is recommended for optimal health. Although body mass index may be limited with respect to assessing adiposity because it fails to discriminate between muscle and fat and identify regional adipose depositions, it remains a useful supplementary clinical index.[161] Physical therapy has a primary role in preventing and managing overweight and obesity in every client or patient, regardless of age, given obesity's serious multisystem consequences, psychosocial sequelae, and threat to life participation and satisfaction.[162]

Cancer

The risk factors for cancer are well documented and include environmental and behavioral factors such as nutrition (fats and refined foods), inactivity, poor air quality and smoking, psychological factors, and ingestion of and exposure to chemicals. Cancer, hallmarked by an overgrowth of cells, eventually compromises normal organ function.

Cancers associated with the highest mortality rates include lung, colorectal, and pancreatic cancer.[163] Smoking has been implicated as a risk factor for many cancers, not only those involving the respiratory tract. The role of lifestyle factors in cancer remission has not been studied in detail.

Cancer prevention and rehabilitation have become a specialty area, requiring an integrated knowledge of pathophysiology, psychosocial implications, and management interventions.[164,165] Routine assessment of health behaviors and risk factors and healthy living recommendations may help avert the diagnosis of many cancers or mitigate their effects. To date, evidence that walking is an effective strategy to prevent cancer has been best established for colon cancer,[86] although breast cancer and prostate cancer have also been reported to be positively affected by regular aerobic exercise including walking.[166,167]

Musculoskeletal Health

Osteoporosis and arthritis contribute to considerable morbidity and secondarily to mortality. Because both of these conditions have lifestyle components, a lifestyle risk factor review should be included in every initial assessment to establish a baseline of musculoskeletal health. Moderate levels of physical activity, including walking, are associated with a substantially lower risk for hip fractures in postmenopausal women.[168] Thus assessment of both nonmodifiable and modifiable risks is a major component of the health assessment as a means of minimizing morbidity and potential mortality.[9] Osteoporosis and associated morbidity, particularly in older age groups, is a serious health issue that warrants monitoring. Establishing baseline information on bone health in every patient is prudent, given the relationship between bone health and lifestyle behaviors (e.g., activity and nutrition—smoking and heavy consumption of meat, alcohol, and coffee). Although older, postmenopausal women have been the focus of bone health studies, other groups are also at risk for osteoporosis and should not be overlooked: older men; inactive children, particularly girls; and individuals with chronic conditions who may be less able to undertake weight-bearing activities and physical activity. In a study of the development of bone mass and strength in girls and young women, only exercise (not daily calcium intake) was associated with bone density and strength.[169] This finding stresses the singular importance of bone building in young people to help offset osteoporosis later in life and associated decrement in quality of life.

Psychological Health

Mental health problems and depression are prevalent in Western society despite its affluence. Based on one descriptive study, individuals with mental health conditions such as schizophrenia tend to have poor physical health and die prematurely from cardiovascular disease.[170] Compared with women who have schizophrenia, men with the condition consumed less fruit, vegetables, whole grains, and rice than recommended. Further, the incidence of smoking and obesity in both sexes was higher than in the general population. Cholesterol levels were high and activity levels low. This study suggested cause for concern about both the physical and psychological well-being of individuals with mental health conditions and indicated the need for further investigation of the physical health and well-being of people with mental challenges.

Dementia and Alzheimer disease appear to be increasing. Aging has been countered as a primary argument for this trend in favor of lifestyle-related influences including nutrition, specifically, processed meat consumption. Recently, Alzheimer disease has been associated with the consumption of meat from animals that have been fed nonnatural foods. This has been thought to lead to misfolding of DNA, thus affecting cognitive function in people who have consumed such products over many years.[171] Other factors that have been associated with the condition include decreased cerebral blood flow.[172] Understanding the vascular component of this condition along with food-related explanations will be an important advance in its prevention and management. In a cohort of older African Caribbean individuals, vascular risk has been associated with cognitive impairment and physical activity is

inversely related to impaired cognition.[173] Exercise training has been reported to improve physical health and depression in individuals with Alzheimer disease.[174] Whether this reflects a vascular component of the pathogenesis of the disease that is offset by exercise warrants elucidation.

Dental Health

Periodontitis, characterized by low-grade infection of the gums, is widespread and may be associated with serious systemic health problems. In a study of 39,461 men, periodontitis risk decreased with increased physical activity, independent of such risk factors as age, smoking, diabetes, body mass index, alcohol consumption, and total calories.[175] Inactivity and the typical Western diet have been described as proinflammatory. Whether the benefits of a physically active lifestyle and an optimal diet can extend to dental health warrants investigation.

Promoting Healthy Living: The Contemporary Physical Therapist's Role

Assessment of health behaviors and recommendations for healthy living can be put into practice in every patient interaction[176] and, in turn, help reduce the population's health risk and mitigate the economic cost of lifestyle-related conditions.[177] Increased consumption of meat, fat, and sugar has contributed to the increased prevalence of lifestyle-related conditions in low- and middle-income countries, as well as in high-income countries.[178] An associated increase in the prevalence of insulin-resistance syndromes is further increasing the incidence of cardiovascular disease.[179] Anthropologists have argued that food abundance and inactivity may be altering evolutionary processes and that these factors contribute to the current pandemic of chronic conditions.[180] Attitudes toward factors contributing to lifestyle-related conditions reflect the values and behaviors of society. Optimal control will be achieved only with widespread public health policy, social action involving health care providers, and an increase in individual responsibility.

Why Physical Therapists Need to Understand and Advocate Optimal Nutrition

Physical therapists use exercise as a primary intervention to prevent, remediate, or mitigate the effects of disease and disability. As clinical exercise physiologists, they need substantial understanding of healthy nutrition, nutritional assessment, and nutritional regimens that will maximize human performance in patient populations. Such populations are comparable to athletes in that they need to meet the metabolic demands of their day (or event), as well as maximizing their health overall. Without such knowledge, assessment and exercise prescription are suboptimal and, in turn, therapeutic outcomes are suboptimal.

Given that an association has been established between diet and chronic lifestyle-related conditions, the question of what is the optimal nutritional regimen for humans has been widely debated. Of note is that the anatomic structure and physiological (endocrine) function of humans are consistent with an organism designed for a largely plant-based diet—that is, having hands rather than claws, a particular tooth type and skin type, salivary glands, acidity in the saliva, ptyalin in the saliva, a specific level of hydrochloric acid in the stomach, and an intestinal tract of a certain length.[181]

Cultures that consume a diet based primarily on plants tend to have superior health outcomes. The diets of octogenarians in Asia and of centenarians in general tend to be high in fiber and low in saturated and trans fats, refined sugar, and salt compared with the typical diet of Western people.[182] The Mediterranean diet, which includes plentiful fruits, vegetables, fish, and vegetable oil, has shown health benefits and is associated with lower incidence of chronic disability and premature death compared with the typical Western diet.[87,126] Cultures in the Mediterranean region also tend to have higher activity levels, which influences metabolism and physiological responses to food.

Weight-loss diets are a multibillion-dollar industry in Western cultures. Many of these diets are unsubstantiated or may theoretically work but are not well balanced in terms of the macro- and micronutrients needed daily for optimal health. Low-carbohydrate diets have been popular, but weight loss associated with these diets results from calorie restriction and the duration of the diet rather than from a reduction in carbohydrate consumption.[183] Weight control is achieved by the balance between optimal caloric and nutrient content consumed and optimal energy expenditure. Given the pandemic of obesity in industrialized countries, physical therapists need to understand the normal physiological adaptations to poor food choices and sedentary lifestyles—weight distribution, endocrine changes, cardiovascular and pulmonary changes, and musculoskeletal changes—in order to prescribe the best lifelong management programs.

Overweight and obesity constitute a life-threatening pandemic that warrants management before the manifestation of one or more of its life-threatening consequences, in addition to its associated psychosocial and economic consequences. Along with obesity, glucose intolerance may complicate the picture, or the patient may have subclinical intolerance. Central adiposity, in particular, has been associated with a high incidence of insulin resistance, which may explain the high rates of dyslipidemia, hypertension, and type 2 diabetes mellitus in these individuals.[184] Thus the physical therapist has a primary role in basic nutrition counseling, commensurate with the promotion of optimal health, and in providing information about nutrition (related to exercise energetics and glucose control) to support a prescribed dosage of regular exercise and physical activity. A nutritionist may need to be consulted to provide nutrition counseling beyond fundamental needs, especially in complicated cases.

Nutrition guidelines have been revised by the U.S. Department of Health and Human Services[185] and Health Canada.[186] Compared with previous versions, the revisions appear to be better aligned with the literature than with the interests of lobby groups from the food industry and producers of so-called nutritional supplements. Some authorities have argued that the current pandemic of lifestyle-related conditions reflects adherence to guidelines over which food-industry lobbyists had influence, rather than lack of adherence by consumers. Current consumption of fats, refined foods, and vegetables in North America, for example, has failed to meet the recommended revised guidelines. Diets high in salt, saturated fat, and refined foods, and low in servings of vegetables and fruit have been implicated in lifestyle-related conditions.

The revised guidelines are more evidence based and have been designed to optimize health and reduce the risk for chronic conditions. Earlier guidelines fell short with respect to this objective. Adherence to established dietary guidelines for Americans as assessed by the healthy eating index was only weakly associated with risk for major chronic conditions in men[187] and was not associated at all with risk for major chronic conditions in women.[188] Thus dietary guidelines and the healthy eating index require refining to achieve more favorable outcomes and to allow them to be assessed.

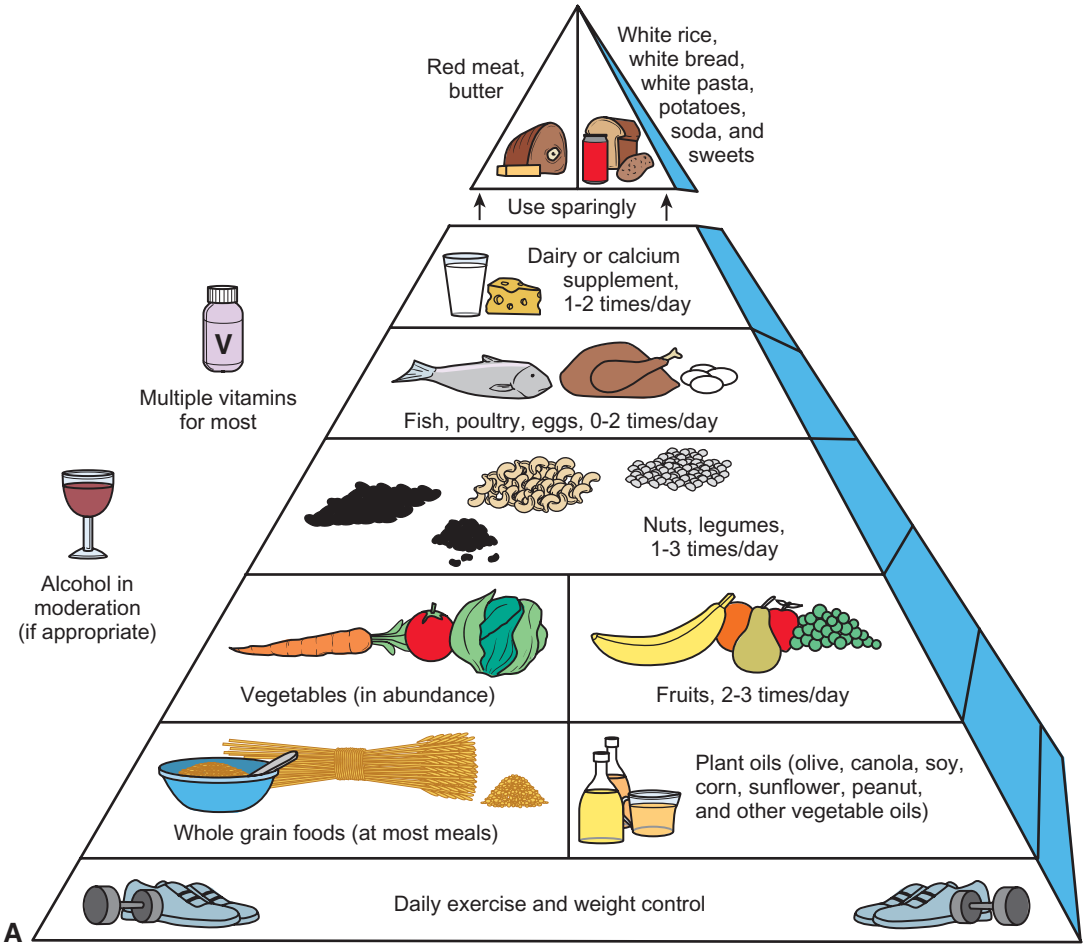
An optimal food pyramid, on which the revised nutrition guidelines are based, is shown in Figure 1-2, *A*. The pyramid illustrates general guidelines for maximizing health in the general public, and these guidelines have been shown to offset lifestyle-related conditions.[189] Each individual's diet should conform with these guidelines for optimal lifelong health. The nutrition food pyramid emphasizes abundant servings of vegetables at the base; followed by vegetable or lean-meat protein sources and dairy; beans, lentils, and whole grains; and low-glycemic foods. Red meat and eggs, positioned at the top of the pyramid, are to be consumed most sparingly. The typical Western diet is short on vegetables, fruits, and fiber (particularly insoluble fiber)[190-192] and includes excess salt, sugar, highly refined foods, and saturated and trans fats.[193] Diets high in grain-based foods are associated with reduced cardiovascular risk, independent of other behaviors.[193,194] The food pyramid has recently been revised as a plate icon where 2-3 servings of vegetables cover half the plate, a quarter carbohydrates (multigrains) and the remaining quarter vegetable protein or animal protein Figure1-2, *B*. Unless a person has an objectively identified deficit, there is no evidence that nutrient supplementation adds benefit to a daily nutritious diet.

Attention to nutrition is important not only in relation to body weight. Cholesterol and triglycerides are risk factors for IHD.[195] To address this major health threat, lipid-lowering drugs have glutted the pharmaceutical market and one-stop coronary cholesterol clinics have been advertised. However, a cardioprotective diet, which has been well described in the literature, should be the goal, in conjunction with lipid-lowering agents in selected cases. Even when medications are used, weaning individuals off them as lipids and cholesterol are lowered by noninvasive means is an important goal of physical therapy, in conjunction with a lifelong program of exercise, good nutrition, no smoking, moderate alcohol consumption, and stress management.

With respect to body mass, risk factors increase as body mass increases beyond a healthy range. Studies recommend that a healthy waist girth (low risk) is <84 cm (33 in) for women and <89 cm (35 in) for men.[196] Further, waist-to-hip ratio has been shown to be a better predictor of myocardial risk than body weight alone.[197] Thus measures of height and weight to calculate body mass index, as well as waist and hip girth, are simple standardized assessment tools and outcomes that can be used diagnostically and as tools to evaluate response to interventions such as dietary education and exercise to achieve optimal weight.

Finally, Western diets have excessive salt content—hence the pandemic of hypertension. Measures need to be taken to legislate the salt added in food production and processing. An overriding simple solution at the individual level is restricting added salt to foods. A one-third reduction of salt intake by the average American (from 3400 mg to 2300 mg daily) would reduce cases of hypertension (the second-leading cause of death in the United States), by 11 million and would lower health care costs by $17.8 billion.[198]

Why Physical Therapists Need to Understand Exercise in the Context of Population Health



The physical activity and exercise pyramid is illustrated in Figure 1-2, *B*. This pyramid shows a physically active lifestyle at the base, followed by aerobic exercise three to five times a week, followed by strengthening exercise and flexibility, with rest and inactivity at the top.

Sedentary behavior has been a recent focus of study with the recognition that reducing sedentary behavior is not necessarily synonymous with increasing physical activity. The literature supports that prolonged periods of being sedentary are associated with greater health risk than multiple short periods of sedentary behavior (i.e., breaks in sedentary time).[199,200] Sedentary activity is common today; people often sit for long periods in front of a television or computer, and children and adolescents are increasingly consumed with screen-based activities. Recommendations for breaks in sedentary behavior are complementary to those for increasing physical activity. Sedentary behavior in early childhood is associated with such behavior in adolescence and adulthood.[201] Encouraging physical activity in adults and children regularly throughout the day requires not only individualized education about exercise, but structuring neighborhoods, transportation systems, recreational facilities, homes, and workplaces that are health promoting.

The physical activity pyramid, like the food pyramid, is a reminder of the importance of lifestyle choices for optimal health.[202] Generally, walking 10,000 steps a day is consistent with an active lifestyle and good health in an adult,[203] whereas fewer than 5000 steps a day would be considered a sedentary lifestyle. Walking 7500 to 9999 steps a day is consistent with a somewhat active lifestyle, and more than 12,500 steps a day would be consistent with a highly active lifestyle.

With increased physical activity, the risks for IHD, stroke, and colon cancer are reduced. The precise dosage-response relationships between physical activity and health and between physical fitness and health have yet to be clarified and may differ among people.[204] Moderate physical activity, which does not have to be strenuous or prolonged, includes leisure activities such as walking and gardening and is associated with marked health benefits.[145] Even light to moderate physical activity in middle and old age confers marked benefit to cardiovascular health and is protective against all-cause mortality.[205] The U.S. Surgeon General recommends 30 minutes of moderately intense exercise on most days, with an accumulated duration of 180 minutes a week.[206]

Exercise has a profound effect on the endothelial function of blood, which has been implicated in atherosclerosis, IHD, cerebrovascular disease, and gastrointestinal conditions, and could explain exercise's multisystem benefits. Moderate levels of physical activity reduce the risk for stroke, independent of other factors.[207] In addition to dietary habits, reduced physical activity has been implicated in most lifestyle-related conditions including osteoporosis, and exercise is recognized as an essential component in the primary prevention of these conditions. Even mild physical activity has an important role in the primary prevention of type 2 diabetes mellitus through its

direct effect on increased tissue sensitivity to insulin.[208] Nonpharmacological interventions for preventing and managing hypertension have been strongly advocated to maximize their therapeutic benefit and minimize the risks associated with medications.[209] Furthermore, in older people, regular physical activity has an important role in preventing chronic conditions and prolonged end-of-life suffering.[210]

Why Physical Therapists Should Promote Smoking Cessation

Smoking is the leading cause of premature death. It results in premature death and higher rates of all-cause death.[50] Although Caucasian Americans have a higher rate of smoking than do African Americans, African Americans and women who smoke have respiratory problems at a younger age, despite having started smoking later and having a lower overall pack-year smoking history.[211] Men with a strong intention to quit have been reported to have a more favorable attitude toward quitting and a stronger sense of perceived control than those with a less strong intention to quit. In addition, men who have a strong intention to quit smoking have greater success.[212] With a view to promoting lifelong health, advocating smoking reduction and cessation is an important responsibility of the physical therapist regardless of the patient's problems.

Over time, smoking cessation can reverse many of the lethal effects of smoking (Table 1-4; also see Table 1-3). For smokers unable to quit, advocating "competing" health strategies has been proposed.[213] Improved diets and increased physical activity and exercise, however, do not counter the negative effects of smoking.[134]

Table 1-4 Health Benefits of Quitting Smoking

	Benefits
Immediate Benefits	Family: Quitting smoking removes harmful environmental tobacco smoke that pollutes nonsmokers' breathing space Individual: Your body starts to heal itself; the levels of carbon monoxide and nicotine in your system decline rapidly; heart rate and blood pressure drop quickly; peripheral circulation improves
Benefits after 1 Year	Increased risk for ischemic heart disease decreases 50%
Benefits after 3 Years	Risk for heart disease declines to levels similar to those of lifelong nonsmokers
Benefits after 5 Years	Risk for cancers of the oral cavity and esophagus reduced by 50% Risk for bladder cancer reduced by about 50% Risk for stroke can return to levels similar to those of nonsmokers Risk for cervical cancer is significantly reduced
Benefits after 10 Years	Risk for lung cancer decreases 50% to 70%
Benefits after 15 Years	Risk for ischemic heart disease is similar to that of lifelong nonsmokers Risk for death is similar to that of lifelong nonsmokers

Why Physical Therapists Need to Understand Ethnic and Cultural Differences

Industrialized countries are becoming increasingly ethnically and culturally diverse as people migrate around the globe, particularly to high-income countries where lifestyle-related conditions are prevalent. With birth rates on the decline in these countries, immigration is being encouraged. Thus it is important to understand the role and impact of ethnicity and culture as important factors influencing health, ill health, use of health care services, the types of health education that are needed, and the ways in which they should be disseminated.[214]

The prevalence of COPD and its associated mortality increase with age, rates being higher in Caucasians than in other ethnic groups in North America.[211] Among people with advanced COPD, however, African Americans and women are more prone than other groups to the adverse effects of tobacco. Cardiovascular disease in Mexican Americans and Native Americans is a particular concern and has implications for optimal care and service delivery.[54,215,216] Obesity, hypertension, and metabolic syndrome are also more prevalent in these groups, so their special needs should be recognized by physical therapists. Currently, Eastern Europe, the Middle East, and Asia have the highest smoking prevalence in the world.

The health advantages that people of other cultures enjoy in their homelands (Asians, for example) are compromised when they immigrate to Western countries and adopt Western dietary and exercise habits.[67,217,218] Although they may benefit from improved health services and access, lifestyle-related conditions exact more of a toll on new immigrants with each passing year. The physical therapist has a unique role as health educator in promoting optimal lifestyle practices in new immigrants, as well as in long-term residents.

People from Utah, 72% of whom are Mormon by faith and follow a strict lifestyle code, have among the best health indexes in the country and some of the lowest rates of chronic disease,[57] but ethnic minorities in Utah are at increased risk for heart disease and stroke, among other conditions. Designing preventive and management strategies requires responding to the needs of different groups. A training program designed specifically for African Americans with stroke and complex comorbidities can be highly effective in improving fitness and reducing risk for further disease and disability.[219] Racial differences have been documented with respect to the interactions of obesity, hypertension, and diabetes between African American and European American women.[220] Greater emphasis needs to be placed on targeting risk factors in various ethnic and cultural groups. For example, alcohol consumption in Caucasian Americans and weight control in African Americans and Caribbean groups are among the targeted priorities.[221] For each individual, the severity of the problem, the risks, and the willingness to change needs to be assessed to

effectively target management strategies. Sensitivity to cultural, as well as to individual, differences when designing health-education strategies is essential to the long-term success of the intervention.

Cultural differences in self-reports of body functioning have been reported.[222] These differences, along with low education status, are thought to explain the overrating of functional status in self-reports as compared with objective measures of performance. These observations support the need for greater cultural sensitivity and awareness in the clinic, particularly when the patient belongs to a minority group and the physical therapist is part of the dominant Caucasian American group. These findings support the need for objective functional assessment in addition to self-reported functional status.

Another important cultural factor in health care is the reporting of exertion, discomfort, and pain, which affect activity and participation. Studies have examined the expression of pain and the responses of health care providers to the pain expressed by people from cultures different from those of the health care provider. In addition to cultural differences in pain expression, patients from cultures that are highly expressive in expressing discomfort and pain have been reported to receive less medication and fewer pain control interventions than individuals who are less expressive, a characteristic consistent with the dominant culture.[223,224]

Physical Therapists as Drivers of Change in Health Behaviors

Direct patient access is fast becoming a reality for physical therapists worldwide. With this trend comes the additional responsibility of knowing whom *not* to treat as well as whom to treat. The physical therapist may be the entry to health care for many patients, so she or he needs to consider the patient's overall health and risk factors in addition to focusing on the specific physical problem that brought the patient to physical therapy. Even if the patient has been referred for physical therapy, the therapist has a responsibility to ensure that the patient's health status is optimal so as to maximize the patient's response to treatment and to address factors contributing to the patient's other complaints, which may be the more serious and important considerations. In a direct-access model of health care delivery, the physical therapist needs to know what is not amenable to noninvasive physical therapy management and, in such cases, have the patient referred to or managed concurrently with an invasive medical care practitioner.

Based on the discordance between the extant knowledge of lifestyle-related conditions and health-promoting lifestyles, health care has failed to significantly reduce the prevalence of these diseases and their risk factors. The issue of why people do not always make appropriate lifestyle choices is of central importance to their health and to the practice of the health care provider. Patients may be more inclined to make follow-up visits to their health care providers than to change their lifestyles.[225] One explanation for the failure of conventional models of health education[226-232] is that traditionally they have been based on a unidirectional model of information delivery—that is, from the health care provider (a dominant person) to the individual or patient (a subordinate person) in the form of brochures, books, videos, magazine articles, and television and radio announcements. These formats typically are not well targeted to a specific demographic or to the needs of the learner. Smoking cessation programs, for example, have been reported to be more effective when targeted to the specific needs of middle-aged men, including resources that promote a perceived sense of control over health behavior.[233] Changes in behavior are effected most successfully in a personal, bidirectional model, including rapport building, trust, commitment, and follow-up. Other important factors include receptivity, susceptibility, beliefs, timing, message delivery, barriers, reinforcers, and external stimulus-control factors.[234] Such a strategy is the so-called AIM approach: *A*ssess the learner, *I*dentify barriers to learning, and *M*otivate the individual to make change.[235]

Cardiovascular disease is the leading cause of death in women, particularly those over 60 years of age. This cohort of women believes they are at low risk for heart attack, yet 82% of coronary events in women are explained by the absence of a low-risk lifestyle.[236] Although women may respond favorably to risk-reduction initiatives, their awareness of risk factors and prevention strategies may be poor.[237] When health information (with respect to a low-fat plant-based diet, exercise, smoking cessation, and stress management) is delivered in a supportive group environment, in innovative multiple formats (e.g., a retreat and group meetings), people make sustainable lifestyle changes that reduce health-risk factors, decrease the need for medication, and improve their quality of life.[238,239] Furthermore, health education is more effective when cultural differences that affect health beliefs, attitudes, and behaviors are considered.[240-242]

Understanding poor adherence to health behavior change is as important as understanding the factors contributing to good adherence. In healthy middle-aged men at risk for IHD, for example, poor adherence to the recommendation to increase dietary fiber is related to smoking, hostility, perception of barriers to diet change, and poor knowledge of risk factors.[243] Poor adherence to following a low-fat diet is related to smoking, young age, and having no family members or friends with IHD. Poor adherence to an exercise program is associated with young age and having young children at home. Such information for various target groups is important in planning effective health-education interventions. The results of studies, however, are based on group outcomes. Individual assessments are needed to determine the barriers to and facilitators of learning for each person. The physical therapist needs to anticipate that these may change for an individual over time.

Education is a common component of the management of every patient with the exception of those who are unconscious, severely mentally challenged, or cognitively incapable of responding to the information. Even in these cases, education of the attending health care providers and caregivers can be the priority. The success of health education reflects the individual's expectations.[244] Most physical therapists and other health care providers have little background in assessing expectations. Physical therapists would benefit from formal education in assessing the learners' needs and wants, expectations, and readiness to learn and implement positive changes in their behaviors. Varying expectations may be particularly important when the patient is from a culture different from that of the physical therapist.

Various theories have been proposed to explain people's health choices and to promote improved choices. One such

theory is that of reasoned action or planned behavior.[245] Based on this theory, an individual's decision to engage in a healthy behavior such as exercise is based on his or her intention. Intention is a function of the person's attitudes, perceived control and self-efficacy, and social factors. The elements of the McEwen model of health motivation are comparable and have been used, for example, to effect positive lifestyle changes in individuals participating in cardiac rehabilitation.[246] The assessment includes the individual's current knowledge, perceived severity, perceived susceptibility, perceived value of action, background variables, internal and external aids and hindrances, and the catalyst factors. Understanding the factors that affect an individual's lifestyle choices is vital for targeting health education so as to produce sustained outcomes.

The transtheoretical model of "readiness to change behavior"[247] outlines several behavioral-change stages, including precontemplative, contemplative, preparation, action, and maintenance. In designing health promotion education programs, this model helps to identify the stage of readiness to change, so that interventions can be tailored to and timed with an individual's readiness to interact with the information, thereby enhancing outcomes. The five stages of change are shown in Box 1-1. Key questions can be asked to establish an individual's stage of readiness to change (Box 1-2).

A study of change in exercise behavior employing the transtheoretical model in sedentary women compared psychological variables and the capacity for a moderate or vigorous exercise program, either at home or at a center, to effect change in their exercise habits over 18 months.[248] Self-efficacy for exercise competence increased as women moved from the contemplative to the action stage and was particularly marked in the groups involved in vigorous exercise. Almost half of the women shifted from the action stage to the maintenance stage. The intervention was effective regardless of the setting and the intensity of the exercise program.

When patients are in the preparation and action stages, the physical therapist can teach a range of self-monitoring skills and recording strategies along with information about circulatory and heart conditions, risk factors, and prevention. Blood pressure self-monitoring can be taught, provided the equipment is calibrated and checked by the physical therapist, standardized procedures are used, and the patient's measurement proficiency is evaluated.[249]

Psychological principles, including cognitive and behavior-modification strategies, are central to behavior change; they include the stimulus environment and events before the behavior, the reinforcement of the behavior, and consequent events.[250] Shaping, feedback, and reinforcement schedules are

Box 1-1 Prochaska's Stages of Readiness to Change*

Precontemplation

- Not currently engaged in the target behavior
- Not seriously thinking of change in the next 6 months
- Unaware of the need to change or denies the need to change

Contemplation

- Not currently engaged in the behavior
- Seriously considering making a change within the next 6 months
- Acknowledges that the behavior is unhealthy
- Seeks out information regarding the pros and cons of changing

Preparation

- Planning to change within the next 30 days
- Has attempted to change in the previous year
- On the verge of taking action to change behavior
- Begins to reevaluate self in light of the new behavior

Action

- Engaged in the desired behavior
- Has implemented the change only in the past 6 months
- Tries the behavior but is at high risk for relapse

Maintenance

- Has maintained the behavior for 6 months

*An individual can be at different stages for different health behaviors.

Box 1-2 Assessing Readiness to Change by Using a Quiz

The Stages of Readiness to Change model is designed to help people adopt new health behaviors. Knowing where you are in the stages of readiness to change helps you to understand the steps you should take to move to subsequent stages to achieve lifelong sustainable health behaviors.

Circle a response to each question using the "Y" or the "N."
Y = Yes, I meet my health objective on this question.
N = For each "N" you circle, circle the readiness-to-change number that applies:
1 = Not thinking about change at this time (precontemplative)
2 = Thinking about change (contemplative)
3 = Preparing to change (preparation)

Readiness to Change Checklist	Response		Readiness to Change		
Do you exercise moderately intensely at least 3 times a week for 20 to 40 minutes?	Y	N	1	2	3
Are you physically active during your average day (walk, walk briskly, take stairs)?	Y	N	1	2	3
Is your weight within normal range?	Y	N	1	2	3
Do you eat at least 5 servings of fruit and vegetables daily?	Y	N	1	2	3
Do you minimize the trans and saturated fats in your diet?	Y	N	1	2	3
Do you minimize highly refined carbohydrates in your diet (sugar and white flour)?	Y	N	1	2	3
Do you drink alcohol less often than 5 times a week?	Y	N	1	2	3
Are you a nonsmoker?	Y	N	1	2	3
Are you generally relaxed during your day and do you feel in control?	Y	N	1	2	3

powerful strategies. Complex behaviors such as lifestyle behaviors may be shaped by the introduction of small, progressive, easily achievable steps toward a larger goal, a process comparable to the integrated stepwise approach used to improve dietary habits.[96] These principles can be incorporated into a model of lifestyle modification that incorporates factors such as culture.[234,250]

Education and effecting change in health behaviors are perhaps the most important components of the physical therapist's expertise because such change dramatically affects the lifelong health of each individual patient. Preventive health messages stated by a health care provider can be powerful, and they are a strong predictor of change in health behaviors.[230,251-253] However, preventive health messages are delivered to a relatively small number of patients by their health care providers. Thus lifestyle recommendations should be delivered as a holistic management priority to every patient, in a structured, conscious manner comparable to the rigor and precision of a prescribed treatment program. The cumulative time the physical therapist spends with each patient over days, weeks, and years translates into numerous teachable moments. Multiplying this time spent annually in teachable moments by the number of physical therapists in the world indicates that the potential for having a societal impact and making a global assault on lifestyle-related conditions is enormous.

Sending a patient home with a brochure on exercise or telling a patient not to smoke has a low probability of producing lasting results—or any results at all. The educational needs of the patient, in terms of receptivity to new information and to the styles of teaching and learning that are being used, need to be established; otherwise, both the clinician and the patient are wasting their time. Educational needs are multifactorial; they include health beliefs, self-efficacy, readiness to change, and motivation. The transtheoretical model[247] of readiness to change (see Boxes 1-1 and 1-2) is valuable in demonstrating how to determine the patient's stage through appropriate questions and how to devise strategies for moving a patient from one stage to the next in a progression toward preparation, action, and maintenance. Self-efficacy is an important determinant of readiness to change and of one's capacity to effect and maintain a behavioral change.[254] If the stage of readiness to change is considered when promoting healthy lifestyles, health coaching can be successful even if brief.[255] The level of importance a person ascribes to a behavior and that person's sense of confidence that she or he can effect the change are the main determinants in whether the person will achieve the threshold level and make the change. Factors that contribute to this decision should be integral components of the assessment; they can be examined systematically, as outlined in Table 1-5. The individual is asked to weigh the benefits and costs of changing a given lifestyle behavior as opposed to not changing that behavior at that point in time. Decision balance analysis involves having the patient identify the benefits and costs of making a lifestyle change *and* of not making the change. This information is useful to the practitioner in directing and planning interventions that will effect changes in health behavior in an individual.

People in need of care such as hospitalized patients are a receptive and captive audience. They present prime opportunities for identifying teachable moments. Even if older, these individuals are motivated to better understand their risk factors and to change their lifestyles.[256]

The impact of the physical therapist as a driver of change may reflect her or his capacity to serve as a role model. Physicians who exercise, for example, are more likely to advise that their patients exercise, as well as to advocate other positive health behaviors.[257,258] Thus as a health care professional, practicing what one preaches may have a powerful effect on patient adherence to lifestyle change and health recommendations.

Evidence-Based Practice

Evidence-based practice has become a major thrust in the physical therapy profession; it ensures that our practice has both a physiological and a scientific basis. An important source of evidence that has shaped cardiovascular and pulmonary physical therapy over the past 50 years has been systematic, methodologically rigorous studies in the physiological and clinical sciences.

Knowledge into Action

With the advent of Sackett's rules of evidence[259] and schemes for grading the quality of scientific studies and critical-appraisal topics,[260] physical therapists have had to learn to be discriminating consumers of research. In addition, systematic reviews and metaanalyses have emerged to examine areas of practice where there are discrepancies in the literature regarding a treatment's effect and to answer specific clinical questions. The levels of evidence and the grading recommendations for the quality of studies are shown in Table 1-6.

In becoming an evidence-based practitioner, the physical therapist needs to know what is *not* known in the field, as well as what is known. The therapist should distinguish this knowledge from what is known inconclusively and from areas in which no studies have been done. The physical therapist needs to be comfortable with uncertainty when applying interventions and receptive to integrating new information as it emerges.

Table 1-6 Basis for Clinical Recommendations Based on Levels of Evidence and Grading of Recommendations

Level of Evidence	Type of Evidence
I	Evidence is obtained from meta-analysis of multiple, well-designed, controlled studies. Randomized trials with low false-positive and low false-negative errors (high power). Evidence is obtained from at least one well-designed experimental study.
II	Randomized trials with high false-positive and/or negative errors (low power).
III	Evidence is obtained from well-designed, quasi-experimental studies, such as nonrandomized, controlled single group, pre-post, cohort, time, or matched case-control series.
IV	Evidence is from well-designed, nonexperimental studies such as comparative and correlational descriptive and case studies.
V	Evidence from case reports and clinical examples.
Grade	**Grading of Recommendations**
A	There is evidence of type I or consistent findings from multiple studies of types II, III, or IV.
B	There is evidence of types II, III, or IV and findings are generally consistent.
C	There is evidence of types II, III, or IV but findings are inconsistent.
D	There is little or no systematic empirical evidence.

From Cook DJ, Guyatt GH, Laupacis A, et al: Rules of evidence and clinical recommendations on the use of antithrombotic agents, *Chest* 102(4 Suppl): 305S–311S, 1992.

The effectiveness of exercise-based interventions in the prevention and remediation of lifestyle-related conditions has been documented for the components of such interventions and at the highest levels of evidence. Physical therapy has to ensure that its practices are based on the literature and that the profession assumes a leadership role in promoting exercise for the development and maintenance of health, for the prevention of disease and disability, and for the remediation of illness and injury.

Physical Therapists as Drivers of Change

Physical therapists are health care professionals well qualified to bridge the gap between knowledge and practice in health care and its delivery. Our role is to increase the number of people at low risk for lifestyle-related conditions rather than focus primarily on high-risk individuals. The biomedical model is being replaced by a broader health model that views the individual in the context of his or her life and culture.

Strategies of behavioral change such as the transtheoretical model[261] are being adopted with increasing frequency for the purpose of promoting healthy lifestyle change. Implementation of such a program in the workplace has been shown to increase physical activity in previously sedentary adults, to reduce the number of reported barriers to such activity, and to increase muscle endurance, predicted $\dot{V}O_2$, and flexibility.[262]

Refocusing and Expanding the Clinical Repertoire of Physical Therapists

Today's health care system is complex, and multiple forces drive the direction of types of services and their delivery. The reductionist perspective of the human body in the biomedical model largely predominates as the model underlying illness care. (Reductionism is the belief that the whole can be understood by the examination of small parts, that is, that treatment focuses on the disease rather than the mind and body as a whole.) Such illness care has been increasingly influenced by economic forces and directed care based on economic factors, such as drug prescription, rapid discharge from the hospital, and focus on process and functional outcomes.[263] The absence of health promotion and wellness initiatives on a patient-by-patient basis before hospital discharge results from economic priorities, yet is a lost window of opportunity at a time when an individual may be receptive to information relating to changes in health behaviors—the teachable moment.[263] Preventive information about nutrition, exercise, smoking cessation, and excessive alcohol consumption is not receiving the attention it deserves from health care providers or from patients.

As noninvasive practitioners, physical therapists are positioned professionally to be leaders in effecting health behavior change. Knowledge of physiology, pathophysiology, and clinical medicine and surgery is not sufficient for the physical therapist to be able to address complex, contemporary, population-wide health problems. To implement effective prevention and interventions with sustainable outcomes, the physical therapist has to consider the interface of treatments and recommendations for each individual. Establishing rapport, exploring the patient's perception of the importance of change in health behavior, building confidence, exchanging information, and reducing resistance are key interpersonal skills needed to promote sustainable health-behavior change.[264-266]

The medical literature abounds with consensus statements of policies and procedures for treating specific conditions. Physical therapy has the expertise to develop parallel guidelines for noninvasive interventions, which in many instances, should be considered before invasive interventions or at least concurrently with them. The medical literature supports invasive care, so often it is not balanced with noninvasive interventions. For example, the report of the Sixth American College of Chest Physicians Consensus Conference on Antithrombotic Therapy has been cited in recommendations for patients following total hip arthroplasty.[267] Physical therapy has a primary perioperative role in the prophylaxis and management of the potentially lethal effects of thrombosis after surgery. This perspective is relatively obscure in the position statement compared with the emphasis on drugs and other options; yet it is highly effective, has an excellent cost-benefit ratio, and results

in minimal side effects compared with the systemic risks of antithrombotic therapy.

The time has come for a call to action within the physical therapy profession concerning the ill health that plagues our village. It is time to take a leadership role in the prevention of lifestyle-related conditions and their reversal, as well as remediation. In the pursuit of health and participation for all, physical therapists have a primary role in health care policy making, including the health of communities and countries, and should become involved in urban and environmental health initiatives, in community health planning,[268-270] and in health and wellness programs, as well as continuing to provide vital one-on-one care to people. Physical therapists can be leaders in promoting community-based programs such as community-based tai chi programs[270] and programs for individuals with physical challenges, including stroke.[271,272] Community-based programs have been shown to be effective if they are well planned and supervised.

Translating sustainable health behavior from the hospital or clinic to the home cannot be assumed; rather, it is a unique skill that should be based on psychosocial teaching and learning factors. Although center- and clinic-based care is convenient for the health care provider, transitioning to home and community is fundamental to the process. The closer-to-home philosophy allows skills to be generalized from one setting to another. Closer-to-home health care delivery has attracted interest largely for economic reasons. However, the fact that better care and longer-lasting sustainable health behaviors may result is also a major reason to promote such care. Cardiac rehabilitation, for example, when initiated in the home environment in low-risk individuals, shows more sustainable physical and psychosocial benefits over time than when initiated in a facility.[273] Community-based programs have to be adapted to the cultural and socioeconomic conditions of that community to promote optimal buy-in from the participants and to maximize their success.[221,274]

Continuing Professional Education

With the ongoing need to be up to date, physical therapists must accrue continuing education credits. With the plethora of opportunities in the open marketplace, courses and workshops need to be stringently evaluated regarding the evidence base of their content and the qualifications of their instructors.

Practice evolves dynamically. Physical therapists can expect that what they learn during their professional education will be challenged and refined over time, with the advancement of knowledge. The practitioner should identify research gaps and help to support research activity, even if not directly engaged in research. Being receptive to changes in practice and serving as a driver of change are characteristics of the contemporary physical therapist. The work of clinicians and scientists should be closely interwoven, and ongoing partnerships must exist between them. Only in this way can clinically important questions be addressed and practice be changed on the basis of advances and discoveries. This approach is subsumed in so-called participatory action research, which aims to unite the needs of the researchers and the stakeholders (patients and clinicians).

Another component of staying up to date through continuing education is reading the professional literature. Knowing what to read and understanding how to read the literature are as important to the clinician as clinical skills, and both skills have to be refined throughout the practitioner's career. Table 1-7 rates the levels of quality of common publications and reading materials accessed by clinicians. Box 1-3 identifies important factors that should be considered when reading in order to enhance professional expertise. Journal clubs in the profession have become a popular means of sharing and discussing published information.

Table 1-7 Sources of Health Information and Quality Rating

Information Source	Quality Rating
Scientific/ Professional	Usually externally peer-reviewed journals (blind or nonblinded); although not infallible, information in journals has the highest probability of containing credible information, compared with other sources
Monographs	May or may not be peer reviewed
Books	Usually not peer reviewed
Professional newsletters	Typically not reviewed
Magazines	Highly variable
Newspapers	Highly variable
Television and radio	Highly variable
Internet	Highly variable

Every Patient Is a Case Study

The randomized controlled clinical trial (RCCT) has become the gold standard for evaluating clinical interventions. Despite the scientific rigor involved, the limitations of the RCCT need to be appreciated by clinicians. Because of these limitations, Simon[275] has argued that the clinical relevance of the RCCT may be overestimated and would be better described as a "silver standard." The designs of RCCTs and their statistical analyses are based on probability theory. Because of this, results can be generalized only to comparable groups, not to an individual—the focus of the clinical situation. The results of RCCTs homogenize the outcomes for individuals who responded to treatment, failed to respond, or had negative outcomes. As clinical practitioners, we are interested in knowing how a particular individual with a given presentation will respond to a given treatment. The clinician needs to exercise a high level of clinical reasoning and judgment in determining the probability of a favorable response to a given treatment regimen in a given individual, based on studies of groups. Thus the physical therapist needs to understand the differences between the responders (favorable and unfavorable) in an RCCT and the nonresponders. This information is seldom detailed in published articles.

Another limitation of RCCTs is that in the real world, individuals seen by physical therapists have multiple comorbidities. In the interest of experimental control, conditions that confound the patient's presentation and treatment response

Box 1-3 Factors to Consider When Reading to Enhance Professional Expertise

Clinical Studies: Extracting Information and Translating the Findings into Practice

- What is the source of the information and its credibility?
- Was the work reviewed objectively by leaders in the field?
- Are the reviewers unbiased and free of any conflict of interest in reviewing the work (no financial or other gain from reviewing the work favorably or unfavorably)?
- Is the information based on a sound study?
- Is the research question derived from the existing literature appropriately?
- Is the study designed appropriately to address the question?
- What type of clinical trial? Is there a control group?
- Are subjects randomly selected and randomly assigned to groups?
- Do the methods control for all confounding variables?
- Are the methods standardized?
- How valid and reliable are the measures?
- Is the statistical analysis appropriate for the research design and research question?
- Is the sample size appropriate?
- Could the outcomes have been influenced by the outcome testers? Are the testers blind to the intervention group that each subject is assigned to?
- Are the results appropriately interpreted (neither over- or understated)?
- Do the results support the hypotheses or answer the research questions?
- Is the interpretation of the results and their clinical implications stated appropriately?

Physiological Studies: Extracting Information and Translating the Findings into Practice

- How sound is the physiological rationale?
- Are the methods rigorous and sound?
- How credible is the generalization to patient populations in the clinical setting?

are selectively eliminated, or the groups are randomized so that they are relatively equivalent in this dimension. Rarely can the findings of a study that compares groups be applied perfectly to a given clinical situation.

The clinical decision-making process is iterative and time limited.[9] Physical therapy diagnoses are derived from detailed histories and assessments. Clinical hypotheses are formulated, and the physical therapist systematically evaluates them to establish the cause of the complaints and factors that contribute to them. The physical therapist selects valid and reliable measures and outcomes and conducts them in a standardized manner. The patient's treatment response and prognosis are predicted so as to establish a timeline for treatment. Based on the assessment, each treatment intervention is prescribed (e.g., with respect to exercise, the type, intensity, duration, frequency, and course). Periodic reevaluation with established standardized outcomes measures are conducted to determine whether the patient has achieved the treatment objective and may be discharged or whether the prescriptions need to be modified and, if so, in what way. The relevant outcomes and outcome measures are identified at the start of treatment, and the treatment responses are evaluated over time until the predetermined outcomes are achieved within the predetermined time frame.

Aligning practice with research requires that the physical therapist apply research tools in practice, or at least have an understanding of them and their impact on drawing conclusions about the effect of treatment. For example, patients often improve spontaneously with time. This phenomenon is called "regression toward the mean." Physical therapy often involves an eclectic treatment approach involving multiple interventions. Because of this, individual treatment effects cannot be isolated. Rather, the physical therapist has to conclude that treatments A, B, and C may have resulted in some improvement; however, the effect of spontaneous improvement with time can be determined only in a controlled clinical trial or on the basis of a prolonged unchanging baseline in the patient's symptoms. Confounding variables such as medications and improvement with time need to be isolated so that it is possible to say that they may have contributed to the outcome, even if they cannot be ruled out. Confounding variables, which result from inadequate experimental control, cloud the interpretation of cardiovascular and pulmonary physical therapy studies.[276] The effect of placebo also plays a major role in treatment outcome. This effect reflects such factors as patient expectancy. Once maligned and considered a characteristic of the hypochondriac, the placebo effect is now known to be a potent and clinically important self-healing effect that warrants being promoted. To date, there is little scientific evidence about how to exploit the power of the placebo effect systematically to promote self-healing.

A typical example of an individual with comorbidities seen by the physical therapist is the person with acute back pain who is also overweight, has high blood pressure, and has a family history of IHD. In such cases, the physical therapist may have to introduce interventions in a stepwise manner. Even though immediate relief needs to be provided for the acute back discomfort, the comorbidities, as well as the low back pain, contribute significantly to the state of the individual's health and well-being at present and figure importantly in the future (with respect to prolonged morbidity and premature death). Thus for maximal and sustainable health, a lifelong health program needs to be implemented. To do this effectively, the practitioner needs a stepwise, paced approach that engages other members of the health care team as needed. The first goal is to provide physical relief of acute pain. Then a weight-reduction and exercise program plan is introduced commensurate with the individual's needs and wants. A nutritionist may need to be consulted not only to assist with weight loss but also to educate the patient about dietary principles to address hypertension (e.g., salt restriction) and minimize the risk for type 2 diabetes mellitus. Weight reduction, improved core and general strength, and aerobic conditioning may eliminate the cause of the low back pain or may attenuate it significantly over the long term. These interventions can also reduce blood pressure and help maintain blood glucose levels within normal limits, considering that the patient is at risk for diabetes. Follow-up is implemented to monitor progress and maintain psychosocial supports so as to ensure the long-term sustainability and success of the lifestyle changes. Such a regimen overcomes the limitations of a conventional course

of analgesia and musculoskeletal physical therapy. Although the latter may produce short-term results, it does not necessarily address the underlying problem or eliminate the likelihood of recurrence of the primary problem and related health-behavior risks over time.

Health promotion practice needs to be modified to the needs of a patient based on his or her cultural background and affiliation. Cultural competence in practice is geared toward augmenting clinical outcomes by adapting communication style, assessments, and treatments. Differences in people with respect to culture, traditions, and religion or faith can affect health, illness, health reporting, beliefs, and expectations about treatment intervention, as well as adherence to the treatment program. For example, the holy month of Ramadan requires creativity in managing the needs of Muslims. During Ramadan, Muslims fast from dawn to dusk, and the fast may include abstinence from water as well as from food. Sedentary people show greater adverse physiological effects during this period, both when at rest and during exercise, than do active people.[277] Body weight drops in a predictable manner. The respiratory exchange ratio decreases during exercise, reflecting increased fat metabolism. Serum iron and platelets decrease, particularly in sedentary people, and fluid balance is better maintained in active people. Exercise, particularly whole-body exercise, may have to be curtailed or modified during fasting. This is especially true when Ramadan falls during the hot summer months.

Adapting lifestyle and treatment recommendations to the needs of the people physical therapists serve is fundamental to a successful outcome. The parameters of exercise prescription for optimal health benefits have been well documented (see Chapter 18). Prolonged adherence to physical activity and exercise programs, however, is poor. Understanding the factors that sustain health behaviors is as critical as the physiological basis for them. One study compared the effects of conventional aerobic training with the effects of a program designed to increase strength, endurance, and mind-body coordination but designed also for "comfort," so that the program would be more appealing to people unused to exercise. After training, participants in the latter group had superior endurance compared with those in the conventional group, and they reported more comfort and less exertion. This preliminary study supported the idea that an exercise program modified for comfort and enjoyment still resulted in a greater capacity to adapt to increased physiological demands. Such programs should be extended so that adherence over time can be evaluated. In addition, readiness to change as described in the transtheoretical model needs to be considered in studies of long-term lifestyle change.[278]

Physical Therapy's Role: Participation in Health Promotion Practice

Healthy lifestyle choices (specifically, not smoking, optimal nutrition, maintaining an optimal weight, not being sedentary, being physically active and exercising regularly, sleeping well and avoiding undue stress) can prevent lifestyle-related conditions. Should the risk factors or manifestations of lifestyle-related conditions emerge, adopting healthy living practices can reverse the risk factors or manifestations in some cases, as well as prevent future signs and symptoms. Given the established prevalence of lifestyle-related conditions, a primary clinical competency of physical therapy in the 21st century is multiple health behavior change.[261,278] In addition to promoting health and wellness one on one, physical therapists need to present a high profile in health promotion and illness prevention by developing and writing physical therapy publications throughout the various levels of their professional associations. They can participate in consensus groups within these associations to issue physical therapy position statements, broadcast television and radio public service announcements, and set up information booths in shopping malls, community centers, and other strategic places within the community. Innovative wellness and prevention programs such as heart camps and retreats should be established.[279] Such active leadership and participation by physical therapists enables them to exploit a range of avenues for effective communication and education strategies directed to the general public in addition to traditional one-on-one contact with patients.

Capitalizing on public health and condition-specific initiatives (e.g., Heart Month and Cancer Month) can reinforce existing community, state or province, national, and global health initiatives. The physical therapist needs to be proactive and function as a role model for health as a community leader by acknowledging these important initiatives and arranging activities to support them. Formal acknowledgment of the initiatives strengthens the profession's identity and its responsibility regarding the conditions being addressed. It also educates the public and reinforces physical therapy's role in the prevention, primary management, and in some cases, reversal of these conditions in the minds of the public, insurers, health care policy makers, health care colleagues, legislators, and others. For example, to address the serious pandemic of type 2 diabetes, the state of Tennessee has initiated statewide action. Schools and communities have been selected as primary prevention targets for the promotion of healthy food choices and activity programs.[280] The initiative is multidisciplinary and multisectorial, and health profession organizations, government, churches, schools, and employers across the state are participating. The World Health Organization has several important annual health markers, including May 31 of each year, which has been designated as World No Tobacco Day. These occasions should be publicized and supported collectively by the physical therapy community globally.

Physical Therapy's Role: Participation in Population-Wide Health Initiatives

As primary health care professionals, physical therapists are uniquely positioned to develop, support, and promote innovative health programs, thereby strengthening the health of communities en masse as well as doing so one person at a time in the clinic. Several excellent resources are available on the subject of building healthy neighborhoods and communities; they are highly recommended to physical therapists as bases for practicing at the levels of the village and community as well as the individual.[281,282]

Multicomponent, multiprofessional wellness and preventive health programs have been proposed to be components of each hospital department, including the emergency department. Hospital-based programs can be successfully implemented in diverse geographic areas and can be focused on each region's needs.[267] Despite the compelling benefits of

home- and community-based care, their effectiveness cannot be assumed. Programs need to be judiciously targeted with due consideration given to the purpose of care, the target population, the congruence of the care and individuals' needs and wants, and outcomes at the individual and societal levels.[283]

The Groningen Active Living Model is an example of a behavior change model that has been developed to encourage sedentary adults to be physically activity.[55] The variables that were examined to determine program success included perceived fitness, social support, self-efficacy, and enjoyment. The outcomes were program adherence and physical activity. With respect to adherence, task self-efficacy was an important mediating variable in this cohort, followed by self-efficacy in overcoming barriers, in social support, and in enjoyment. Perceived physical ability and fitness were relatively less important mediators.

The Hearts for Life community-based program has shown positive outcomes with respect to risk reduction and improvement of knowledge.[284] The Choose to Move physical activity program for women provides an important model for public health and participatory research organizations of targeted, low-cost self-help programs that support the *Healthy People 2020*[285] objectives for physical activity, nutrition, and cardiovascular health.[286] Women who completed the program increased their physical activity, reduced their consumption of high-fat foods, and increased their knowledge and awareness of cardiovascular risk and its symptoms. Schools and workplaces are also sites for innovative health programs in the community. Preventive cardiology programs for children, such as HeartPower!, show some success in nutritional domains.[287] Such programs, however, could benefit from the expertise of a physical therapist with respect to developing, coordinating, integrating, and evaluating a physical activity and an exercise component. Low-income families in particular have an increased risk for inactivity and obesity. A school program for children of low-income families used the Internet, videos, provision of health snacks, and participation in a gym lab to promote exercise and healthy food choices.[288] This program resulted in reduced fat intake and increased physical activity by the children.

One medium through which a physical therapist can assume the role of health coach has been through telerehabilitation. Telerehabilitation has come of age and is a major vehicle that can be exploited by physical therapists for targeted education of patients in the community[289] and for general preventive health. Home-based education about nutrition and exercise has been reported as a means of targeting individuals with obstructive sleep apnea and promoting lifestyle change.[290]

Marketing research methods have been investigated as a means of improving population health outcomes and making their success rates comparable to those that have been well established in business marketing. Mass media promotion has been used to communicate an innovative physical activity and exercise resource called Small Steps.[291] Callers responded to a mass publication campaign to promote Small Steps. People phoned toll free to a call-in center where trained screeners recruited members of the public into a controlled trial, identified their stage of readiness to change based on a few structured questions, and sent out the Small Steps kit, which provided information about being physically active and exercising, along with a workbook. More than 80% of the callers were women. The prospect of making small steps toward improving their health was as compelling for men as for women. At the 3-month follow-up, self-reported current levels of physical activity (main outcome) had changed substantially. Thus the results supported the idea that with the use of mass media, people who are in the preparation stage of being more physically active can shift to the action stage. Long-term studies are needed to establish the long-term benefits of this program and its translation into health outcomes. The reasons given for calling the resource center included the appeal of taking small steps when undertaking health behavior changes, improving nutrition, becoming more active, learning new things, and assisting others to improve their diets and activity levels.

Implications of Epidemiology and Health Care Trends for Physical Therapy Practice

In the 21st century, the impact of noninvasive physical therapy outcomes will be reflected in part by the number of individuals who quit smoking, lose weight, consume healthier foods, exercise, and manage life stress (including moderate use of alcohol), regardless of patients' primary diagnoses. Addressing these priorities first can also alleviate musculoskeletal and neuromuscular problems or at least offset their consequences (such as low back pain). Weight loss, for example, can reduce the energy cost of walking in individuals with stroke, heart disease, or lung disease by optimizing biomechanical efficiency. Furthermore, addressing these priorities reduces the need for use of the health care system (doctor- and hospital-based care) and helps to avoid or minimize the need for drugs and surgery. Such a strategy will enable the profession collectively to address the leading population-wide health priorities of our time one patient at a time—and to affect health globally.

Implications of Epidemiology and Health Care Trends for Physical Therapy Professional Education

Physical therapy professional curricula need to be continuously reviewed with respect to their congruence with epidemiology and health care trends and the provision of evidence-based practice in this context, that is, being informed by epidemiological indicators amenable to noninvasive interventions. Physical therapy in the 21st century requires a high level of expertise in multiple health behavior change, including smoking cessation and counseling for basic nutrition, as well as the prescription of exercise. Patient education needs to be based on the assessment of the patient's learning style and readiness to change. To be effective, health education requires prioritizing goals, delivering health information, evaluating outcomes, and promoting lifelong behavior changes. Physical therapists' capacities to teach and promote learning should be formally evaluated just as are their capacities to prescribe exercise or other physical therapy interventions. A cross-sectional study of health care providers and their provision of health information to patients reported considerable disparities among providers. For instance, the provider's gender and that of the patient influenced whether education was attempted and, if so, what type. Female

providers tend to include health education more often than their male counterparts.

The Magic Bullet and the Fountain of Youth

A "magic bullet" and a "fountain of youth" are not just myths. They exist, but they are not to be found in a pill or in surgery. For almost a century of documented physical therapy practice, education and exercise have been the hallmarks of the profession[292-294] and the elixirs that add years to life and life to years. These "drugs" have been at the core of the practice of the physical therapist, who is distinguished from invasive-medicine practitioners primarily by the use of noninvasive "drugs" as opposed to the invasive interventions of pharmacotherapy and surgery. In addition to providing preventive health benefits, lifestyle changes such as smoking cessation, optimal nutrition, and exercise can enhance the quality of life[295] and increase the probability of long-term health.

Given the epidemiological changes in global health, this is physical therapy's moment on the world health care stage, a time to promote health and wellness in every patient and to prevent, manage, and in some cases, reverse lifestyle-related conditions that are contributing to enormous social and economic burdens globally. The profession is uniquely and strategically positioned to lead the assault on lifestyle-related conditions by integrating health promotion into practice. The benefits of noninvasive strategies such as physical activity and exercise and healthy living are clear. If a drug could offer these same benefits and similarly improve public health, it would be heralded as nothing short of a miracle remedy. Although public perception of the benefits of noninvasive intervention is on the rise, much work remains to be done. The role of health coach for every patient could be one of the most rewarding competencies for physical therapists of the 21st century as they strive to make a positive impact on public health, one patient at a time.

Summary

This chapter describes the pivotal role of the noninvasive practitioner—namely, the physical therapist—within the contemporary framework of health in the 21st century. With the pandemic of lifestyle-related conditions, physical therapists need to consider the underlying risk factors for these conditions in every individual, regardless of the physical therapist's particular specialties or areas of practice and regardless of the patient's primary reasons for the consultation. A patient's low back pain or tennis elbow, for example, may be mere inconvenience compared with his or her smoking, excessive body weight, inactivity, high blood pressure, high cholesterol, or abnormal blood sugar. Physical therapists are uniquely qualified professionally and are strategically well positioned to address the leading health priorities of our time by using the profession's primary "drugs"—education and exercise—in diverse settings, one individual at a time or in groups. In addition, physical therapists need to identify risk factors in all patients, irrespective of presenting problems and diagnoses, so that they can prescribe optimal treatment, including exercise, to address lifestyle risk factors and monitor the patient for therapeutic and safety reasons. Physical therapists pride themselves on their communication skills, which are fundamental to building rapport with people and effecting lifelong behavior change. This expertise can be exploited because physical therapists not only spend more time with people during visits than most health professionals, but also see them over repeated visits. As effective drivers of change, physical therapists can exert considerable influence on their patients over time, given the potential teachable moments through the course of care. In the 21st century, physical therapy's impact will be reflected in outcomes associated with prevention, potential reversal, and management of lifestyle-related conditions, over and above the conventional practice of physical therapists across clinical areas and settings.

Review Questions

1. Describe lifestyle-related conditions.
2. How do lifestyle-related conditions affect every patient seen by the physical therapist? Relate your answer to the World Health Organization's International Classification of Functioning, Disability and Health.
3. Distinguish physical therapy's role in the promotion of health and wellness versus prevention, management, and in some cases, cure.
4. Describe the physical therapist in her or his role as a consumer of research.
5. Describe the concept of evidence-based practice in the context of evidence-informed practice.
6. Describe how you, as a physical therapist, are a driver of change.
7. Describe how the profession of physical therapy is uniquely positioned to assume a leadership role in addressing the leading health problems of our time.
8. You are in dialogue with a physician colleague about a patient who may be a candidate for hip replacement. The patient is obese, has hypertension, and is at high risk for diabetes. How would you describe the power of noninvasive practice as opposed to or in conjunction with invasive practice in effecting maximal health outcomes for the patient?
9. Reference is made in the chapter to the "magic bullet" and the "fountain of youth." Describe these fabled constructs in the context of 21st-century physical therapy practice.

Summary 43
Review Questions 44
References 44

Oxygen transport is essential to life, activity, and participation in life consistent with the International Classification of Functioning, Disability and Health (ICF).[1] Maximizing the efficiency of the oxygen transport pathway promotes optimal mobility and independence, the cornerstones of quality of life and well-being. Attention to oxygen transport—its deficits and threats to it—is the concern of physical therapists, irrespective of the primary clinical area of their practices. This is particularly true given the trend toward physical therapists' direct access to patients and the prevalence of lifestyle-related conditions, all of which affect oxygen transport either directly or indirectly.

Cardiovascular and pulmonary physical therapy consists of noninvasive interventions that can reverse or mitigate insults to oxygen transport. It can eliminate, delay, or reduce the need for medical interventions, such as supplemental oxygen, intubation, mechanical ventilation, suctioning, bronchoscopy, chest tubes, surgery, and medications. To achieve these outcomes, the physical therapist must fully assess oxygen transport and prescribe optimal treatment interventions. This is possible only with a comprehensive understanding of oxygen transport and the factors that determine and influence it.

This chapter details the oxygen transport system (including the pathway and its component steps), which provides a conceptual basis for cardiovascular and pulmonary physical therapy practice. Oxygen transport is the basis of life. Treatment of impaired or threatened oxygen transport (i.e., cardiovascular and pulmonary dysfunction) is a physical therapy priority.

In a healthy person, the oxygen transport system is perturbed by movement and activity, changes in body position, and emotional state. In a person with pathology, disruption of or threat to this system is a medical priority because of the threat to life or the impairment of functional capacity.

The fundamental steps in the oxygen transport pathway, as well as their function and interdependence, are described. Special attention is given to cellular respiration and the body's use of oxygen during metabolism at the cellular level in muscle. The factors that perturb oxygen transport in health are described—namely, gravitational stress secondary to changes in body position, exercise stress secondary to increased oxygen demand of the working muscles, and emotional stress and arousal. A thorough understanding of the effects of those factors that normally perturb oxygen transport is essential in

order to accurately assess and treat deficits in oxygen transport.

Oxygen Transport

Oxygen transport refers to the delivery of fully oxygenated blood to peripheral tissues, cellular uptake of oxygen, use of oxygen within the tissue, and the return of partially desaturated blood to the lungs. The oxygen transport pathway consists of multiple steps ranging from the ambient air to the perfusion of peripheral tissues with oxygenated arterial blood (Figure 2-1). Oxygen transport has become the basis for conceptualizing cardiovascular and pulmonary function and diagnosing and managing cardiovascular and pulmonary dysfunction.[2-8]

Oxygen transport variables include oxygen delivery (DO_2), oxygen consumption ($\dot{V}O_2$), and the oxygen extraction ratio (OER), the utilization coefficient. Oxygen demand is the amount of oxygen required by the cells for aerobic metabolism. Oxygen demand is usually reflected by $\dot{V}O_2$; however, in cases of severe cardiovascular and pulmonary dysfunction and compromise to oxygen transport, $\dot{V}O_2$ can fall short of the demand for oxygen. Oxygen transport variables, including the components of DO_2, $\dot{V}O_2$, and OER, are shown in Figure 2-2. DO_2 is determined by arterial oxygen content and cardiac output, $\dot{V}O_2$ by the arteriovenous oxygen content difference and cardiac output, and oxygen extraction by the ratio of DO_2 to $\dot{V}O_2$.

Measures and indexes of oxygen transport that reflect the function of the component steps of the oxygen transport pathway are shown in Table 2-1.

Energy Transfer and Cellular Oxidation

Cellular metabolism and survival depend on the continuous synthesis and degradation of adenosine triphosphate (ATP), the major source of energy for biological work. Work is

Table 2-1 **Measures and Indexes of the Function of the Steps in the Oxygen Transport Pathway**

Variable	Measure or Index
Control of Ventilation	PO.1 (central drive to breathe) Ventilatory responses of hypoxia and hypercapnia Pa_{O_2} and Sa_{O_2} responses to exercise

performed in biological systems for contraction of skeletal, cardiac, and smooth muscle (e.g., exercise, digestion, glandular secretion, and thermoregulation) and for nerve impulse transmission (Box 2-1). These processes require a continuous supply of ATP, which is made available primarily by aerobic (oxygen-requiring) processes. In the event that oxygen delivery is inadequate, nonaerobic (anaerobic, or non–oxygen-requiring) energy-transferring processes can also supply ATP. Supplying energy anaerobically, however, is more costly metabolically; that is, it is not efficient, is limited, and cannot be sustained because of the disruptive effects of lactate (a cellular byproduct of anaerobic metabolism) on physiological processes. Metabolic acidosis is a consequence of lactate accumulation. In patients who are critically ill, the presence of metabolic acidosis secondary to anaerobic metabolism can be life threatening. Prolonged anaerobic metabolism is lethal in

Box 2-1 Biological Work Requiring Continuous Oxygen Supply

- Active cellular metabolic processes
- Active cellular pumping mechanisms

two respects. First, the patient is increasingly dependent on anaerobic metabolism because of inadequate $D\dot{O}_2$ to peripheral tissues; second, acidosis interferes with normal cellular processes and homeostasis, which require an optimal pH of 7.40.

The ATP molecule consists of an adenine and a ribose molecule with three phosphates attached. The splitting of the terminal phosphate bond or the two terminal phosphate bonds generates a considerable amount of energy. This energy is used to power various chemical reactions associated with metabolism. These metabolic processes take place in specialized organelles in the cells called mitochondria. The primary pathways that are responsible for the formation of ATP are the Krebs cycle and the electron transfer chain.

The Krebs cycle and the electron transfer chain are the biochemical pathways in the mitochondria of the cell responsible for harnessing oxygen for aerobic metabolism and ensuring a continuous supply of oxygen for this process. Initially, glucose is phosphorylated to produce two molecules of ATP (glycolysis). Glucose is oxidized to produce two molecules of pyruvic acid, yielding a net gain of two molecules of ATP per molecule of glucose. The two pyruvate molecules enter the Krebs cycle, where they are oxidized to CO_2 and water. This process yields 30 ATP molecules. Hydrogen ions released in the process are transferred to the electron transfer chain, yielding 4 ATP molecules for cellular metabolism. Electrons are removed from hydrogen and funneled down the electron transport chain by specialized electron carrier molecules, cytochromes 1 to 5. Only the last of these cytochromes, cytochrome oxidase, can reduce molecular oxygen to water. This process is driven by a gradient of high-to-low potential energy. This energy, transferred as electrons, is passed from H_2 to O_2 and is trapped and conserved as high-energy phosphate bonds. Oxygen is involved in these metabolic pathways only at the end of the electron transfer chain, where oxygen is the final electron acceptor and combines with H_2 to form H_2O. More than 90% of ATP synthesis takes place through the electron transfer chain by means of the oxidative reactions associated with oxidative phosphorylation. An individual's peak aerobic capacity is determined by the availability of oxygen at the end of the electron transport chain.

For each molecule of glucose that is metabolized, 36 molecules of ATP are produced: 4 molecules by substrate phosphorylation (anaerobic) and 32 by oxidative phosphorylation (aerobic). The low ATP yield from anaerobic metabolism explains why anaerobic metabolism can serve only as a short-term energy source.

The complex, enzymatically controlled chemical reactions of metabolism are designed to form and conserve energy through the Krebs cycle and the electron transfer chain and then use this energy for biological work.[9,10] Carbohydrates, fats, and proteins ingested from foodstuffs in the diet are oxidized to provide the energy for phosphorylation of adenosine diphosphate (ADP) (i.e., the formation of ATP by combining ADP with phosphate). These substances are broken down, and they access the Krebs cycle at the pyruvic acid or acetyl coenzyme A (CoA) levels (Fig. 2-3). Some amino acids can enter the Krebs cycle directly.

The Krebs cycle degrades acetyl CoA to carbon dioxide (CO_2) and hydrogen (H_2) atoms. The primary purpose of this cycle is to generate hydrogen ions for the electron transfer chain by two principal electron acceptors, nicotinamide adenine dinucleotide (NAD) and flavin adenine dinucleotide (FAD). Many acids catalyze the numerous reactions of the Krebs cycle.

Cellular oxidation, or respiration, refers to the function of the electron transfer chain to release energy in small amounts and to conserve energy in the formation of high-energy bonds. It is this process that ensures a continual energy supply to meet the needs of metabolism (Fig. 2-4).

Three major systems of energy transfer exist to supply energy during all-out exercise over varying durations.[10] Although these systems are discrete, they overlap. Cellular ATP and creatine phosphate (CP) are immediate energy sources for the first 10 seconds of exercise. From 30 to 60 seconds, glycolysis provides a short-term energy source. The ATP-CP system and the glycolytic system are anaerobic processes. As exercise persists for several minutes, the long-term aerobic system predominates. Thus, for sustained physical activity and exercise, energy is provided primarily by aerobic metabolism. For this process, oxygen is provided by the oxygen transport pathway. Carbon compounds that enter the body in the form of carbohydrate, fat, and protein undergo oxidative metabolism in the form of aerobic glycolysis in the mitochondria in the cytoplasm of cells.

Muscle Contraction and Metabolism

The basic mechanism for muscle contraction is excitation contraction coupling.[11,12] Action potentials mediated centrally or through the spinal cord depolarize the muscle cell membrane (the sarcolemma) and stimulate the release of calcium from the lateral sacs of the sarcoplasmic reticulum. The sarcoplasmic reticulum is an extensive network of invaginations and tubular channels encasing the muscle fibers (myofibrils). The calcium floods over the myofilaments of the myofibrils within the sarcomere. Myofilaments consist of thin actin fiber and thick myosin fiber protein, which interdigitate with each other, giving the typical striated appearance to skeletal muscle (Fig. 2-5). Actin is a helical molecule with tropomyosin intertwined along its length. Tropomyosin normally inhibits the interaction of actin and myosin. Calcium causes a conformational change of the tropomyosin molecule that enables troponin, also distributed along the actin molecule, to combine with calcium. The combining of calcium and troponin triggers the interdigitation of actin and myosin (the sliding-filament theory of muscle contraction). Contraction involves myosin heads (cross bridges) attaching to and detaching from actin in a cyclical manner that causes the actin and myosin filaments to slide past each other. In this way, the muscle is shortened without shortening of the myofilaments.

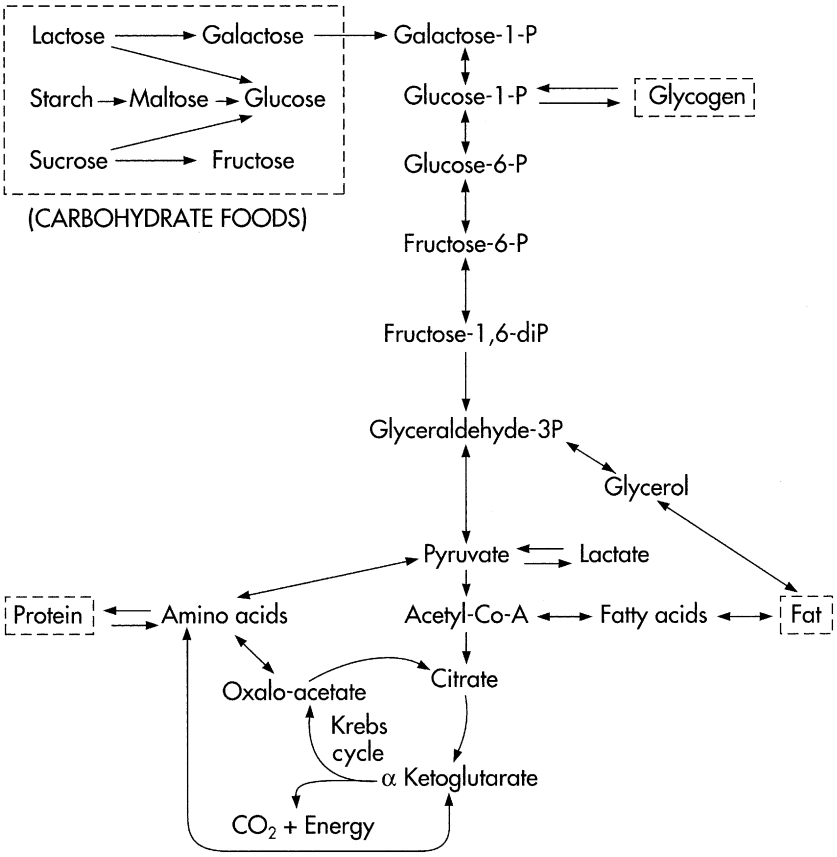

Fig. 2-3 Interrelationships among carbohydrate, fat, and protein metabolism and their points of entry into the Krebs cycle. *(From Mougios V:* Exercise biochemistry, *Champaign, Ill, 2006, Human Kinetics.)*

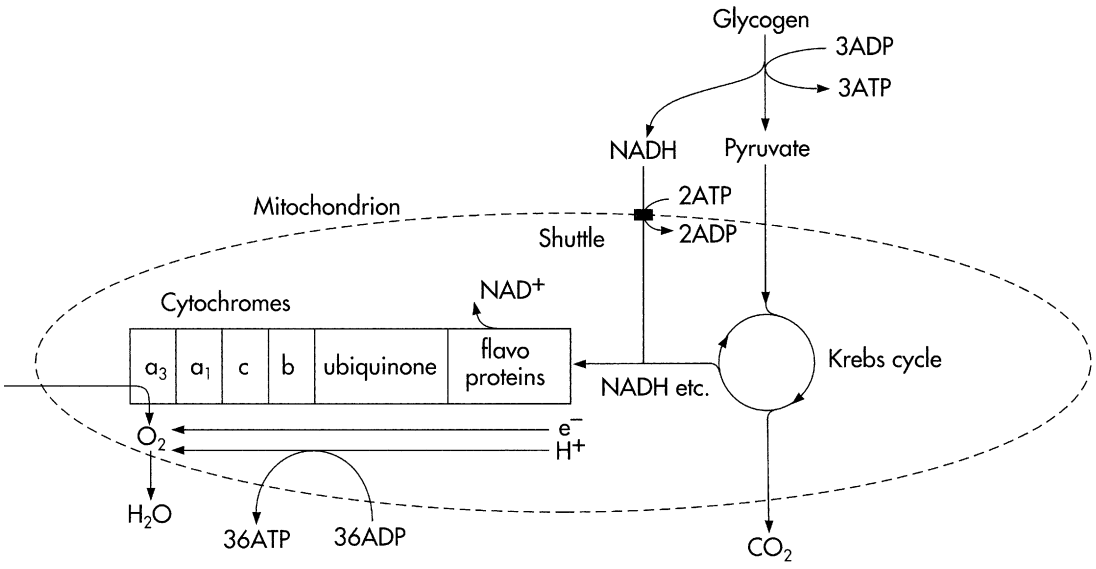

Fig. 2-4 Electron transfer chain and its relationship with the Krebs cycle. *(From Mougios V:* Exercise biochemistry, *Champaign, Ill, 2006, Human Kinetics).*

The energy for muscle contraction in the form of adenosine triphosphate (ATP) is generated within the mitochondria of the myofibrils. Myosin ATPase splits ATP so that the transfer of this energy can be used for muscle contraction. Specifically, the enzyme ATPase is activated when actin and myosin are joined. ATP is then available to bind with the cross bridge, causing it to detach from actin. Relaxation occurs with the cessation of electrical excitation and the rapid removal or sequestration of calcium into the lateral sacs of the sarcoplasmic reticulum.

The specific metabolic properties of muscle depend on the constituent muscle fiber types.[13] The three primary muscle fiber types are fast-twitch fibers, slow-twitch fibers, and intermediate fibers, which have the properties of both fast-twitch

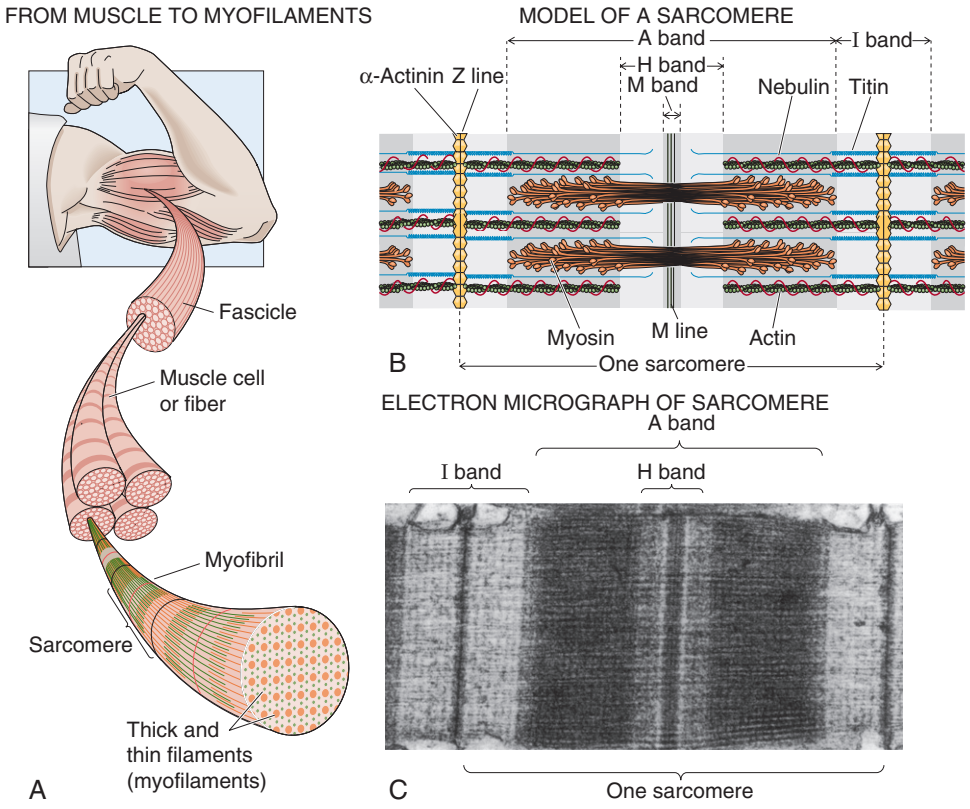

Fig. 2-5 Structure of the sarcomere. *(From Boron WF:* Medical physiology, *St Louis, 2005, Saunders.)*

and slow-twitch fibers. The fast-twitch fibers (fast glycolytic fibers) are recruited during short-term, sprint-type exercise that relies mainly on anaerobic metabolism. These fibers are well adapted for rapid, forceful contractions because they have large amounts of myosin ATPase, rapid calcium release and uptake, and a high rate of cross-bridge cycling. Slow-twitch fibers (slow oxidative fibers) are recruited during prolonged aerobic exercise. These fibers have large amounts of myoglobin, mitochondria, and oxidative enzymes. Compared with the fast-twitch fibers, slow-twitch fibers are fatigue resistant. The intermediate fibers have both anaerobic and aerobic metabolic enzymes, which makes these fibers capable of both types of muscle work. Although the characteristics of the fiber types are distinct, activity and exercise recruit both types of fibers. Depending on the particular activity or exercise, one fiber type may be preferentially recruited over the others.

Principles of Oxygen Transport

Individuals need a continuous supply of oxygen to meet moment-to-moment demands for oxygen commensurate with changing metabolic demands for energy at the cellular level as well as basal metabolic demands.[14,15] Oxygen transport occurs by convection or diffusion. Convection of oxygen refers to the movement of oxygen from the alveoli to the tissue capillaries and is determined primarily by hemoglobin concentration, oxygen saturation, and cardiac output. The diffusion of oxygen refers to the movement of oxygen from the capillaries to the mitochondria and is determined by metabolic rate, vascular resistance, capillary recruitment, and tissue oxygen consumption and extraction.

Normally, D_{O_2} is regulated by tissue metabolism and the overall demand for oxygen. At rest, D_{O_2} is three to four times greater than oxygen demand, and $\dot{V}_{O_2}$ is not directly dependent on D_{O_2}. In a healthy individual, the increased metabolic demands of exercise constitute the greatest challenge to the oxygen transport system; $\dot{V}_{O_2}$ can increase 20 times. In response to increased muscle metabolism, blood flow increases to the peripheral muscles through vasodilation and capillary recruitment, thereby increasing the availability of oxygen to working tissues and its extraction from the arterial blood. As D_{O_2} and $\dot{V}_{O_2}$ increase, venous return, stroke volume, and heart rate also increase, thereby increasing cardiac output (CO). CO can increase by more than five times during strenuous exercise. The capacity to increase CO reflects a person's overall aerobic power.

At rest, regional differences in the proportion of CO normally delivered to the body organs reflect differences in organ functions and are not necessarily matched to the metabolic rate.[16] For example, the distribution of CO to the kidneys is 20%; to the mesenteric, splenic, and portal tissues, 20% to 30%. Comparatively, muscle at rest receives 10% and the brain and myocardium receive less than 5% each.

Oxygen Content of the Blood

The majority of oxygen is transported in arterial blood to the tissues. Oxygen is largely combined with hemoglobin (98%) compared with a relatively minimal amount that is dissolved in the blood (2%). The oxyhemoglobin dissociation curve represents the relationship between the affinity of hemoglobin for oxygen and the arterial oxygen tension. The affinity of

hemoglobin for oxygen depends on the tissues' oxygen demand. In a healthy individual, exercising muscle increases the demand for oxygen. The heat of the working muscles and the acidic environment during exercise result in reduced oxyhemoglobin affinity and increased oxygen release. This is reflected by a shift to the right of the oxyhemoglobin dissociation curve (see Chapter 4). The affinity of hemoglobin and oxygen is increased with the cessation of exercise, which is reflected by a leftward shift of the curve.

Oxygen Delivery to the Tissues

The final steps in oxygen transport involve the dissociation of oxygen from hemoglobin and the diffusion of oxygen from the capillaries to the cells.[17] Diffusion depends on the quantity and rate of blood flow, the difference in capillary and tissue oxygen pressures, the capillary surface area, capillary permeability, and diffusion distance.[18] With increased metabolic demand by the tissues, capillary dilation and recruitment increase capillary surface area and reduce vascular resistance to flow, diffusion distance is decreased, the movement of oxygen into the cell is facilitated, and the tissue oxygen tension is increased.

Two diffusion gradients determine effective oxygen transport: one occurs between the pulmonary capillaries and the alveoli; the other occurs between the peripheral capillaries and the tissue cells. Diffusion of oxygen occurs as the blood moves from the aorta to the arterioles. The mean oxygen tension in the aorta is about 95 mm Hg and in the arterioles is 70 to 80 mm Hg. The oxygen gradient between the arterioles and the cells is the steepest. The mean oxygen pressure is less than 50 mm Hg in the capillaries. The oxygen tension in the capillaries determines the rate of diffusion to the cells. An optimal diffusion gradient maintains the oxygen tension in the cell at between 1 and 10 mm Hg; oxygen tension is less than 0.5 mm Hg in the mitochondria.[16] This decremental Pa_{O_2} profile down the oxygen transport pathway, from the airways to the tissues, is termed the oxygen cascade (Figure 2-6).

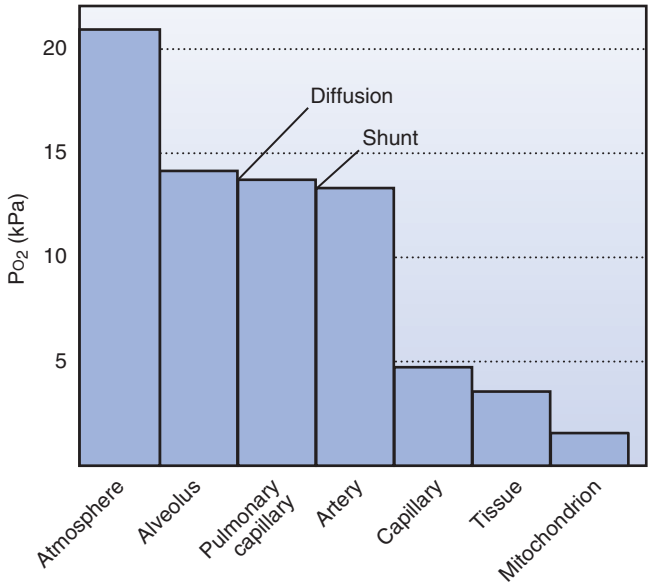

Fig. 2-6 Scheme of oxygen partial pressures from air to tissue. The cascade reflects the removal of oxygen by the pulmonary capillary blood and the tissues. Depressions caused by the effects of diffusion and shunt are also illustrated. *(From Ronco C, Bellomo R, Kellum J:* Critical Care Nephrology, *ed 2, Philadelphia, 2009, Saunders.)*

Cardiac Output

In addition to arterial oxygen content, CO is a primary determinant of D_{O_2}.[14] The transport of oxyhemoglobin to the tissues is dependent on convective blood flow by way of CO. CO is the volume of blood pumped from the right or left ventricle per minute. The components of CO are stroke volume (SV) and heart rate (HR) (i.e., CO = SV × HR). SV is the amount of blood ejected from the left ventricle during each ventricular systole or heartbeat and is determined by the preload, myocardial distensibility, myocardial contractility, and afterload. D_{O_2} is optimized in patients by increasing CO through the therapeutic manipulation of preload, myocardial contractility, afterload, and heart rate.

Preload

Preload is the end-diastolic muscle fiber length of the ventricles before systolic ejection. On the left side it reflects the left ventricular end-diastolic volume (LVEDV). The LVEDV is dependent on venous return, blood volume, and left atrial contraction. An increase in ventricular volume stretches the myocardial fibers and increases the force of myocardial contraction (the Starling effect) and stroke volume. This effect is limited by the physiological limits of distension of the myocardium. Excessive stretching, as in fluid overload of the heart, leads to suboptimal overlap of the actin and myosin filaments, thus impairing rather than enhancing contractility.

Afterload

Afterload is the resistance to the ejection of blood during ventricular systole. Afterload of the left ventricle is determined primarily by four factors: the distensibility of the aorta, the vascular resistance, the patency of the aortic valve, and the viscosity of the blood.

Myocardial Contractility

Myocardial contractility reflects actin-myosin coupling during contraction and is assessed by the ejection fraction, the rate of circumferential muscle fiber shortening, the pressure-volume relationships, and the rate of change of ventricular pressure over time.

Oxygen Debt

Tissue oxygen debt, or recovery oxygen consumption, is the difference between oxygen demand and oxygen consumption. In healthy individuals, oxygen debt can be sustained for short periods during intense exercise. Anaerobic metabolism is stimulated to produce ATP under these conditions. In patients who are critically ill, the degree of oxygen debt is correlated with survival.[19]

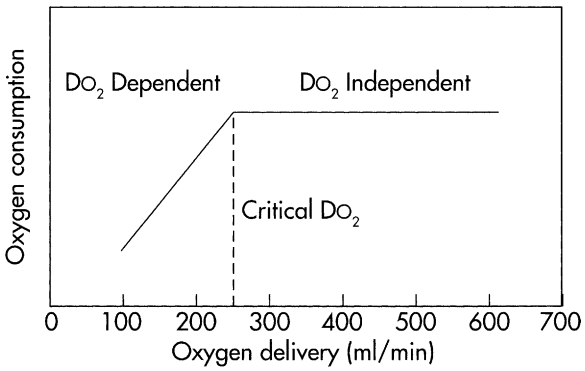

Fig. 2-7 Relationship between oxygen consumption ($\dot{V}O_2$) and oxygen delivery (DO_2). The DO_2-independent phase represents the normal metabolic state. The DO_2-dependent phase represents the dependency of $\dot{V}O_2$ on DO_2 when DO_2 falls below the critical DO_2. *(Modified from Phang PT, Russell JA: When does $\dot{V}O_2$ depend on DO_2?* Respiratory Care *38:618–630, 1993.)*

Oxygen Extraction Ratio or Utilization Coefficient

The oxygen extraction ratio, or utilization coefficient, reflects the proportion of oxygen delivered to that consumed. OER is calculated by dividing $\dot{V}O_2$ by DO_2. Normally, OER is 23% at rest.

Supply-Dependent Oxygen Consumption

Normally, a decrease in DO_2 does not reduce $\dot{V}O_2$.[20] With a decrement in DO_2, the tissues extract a commensurate amount of oxygen from the blood. In patients who are critically ill, DO_2 may be limited to the point where basic metabolic needs for oxygen (300 mL/min/M^2) are not met.[20-23] The critical level at which $\dot{V}O_2$ falls is associated with tissue anaerobic metabolism and the development of lactic acidosis and decreased pH (Fig. 2-7).[19,24] Serum lactates correspondingly increase and provide a valid index of anaerobic metabolism in patients with multiorgan system failure. When oxygen transport data are analyzed, the effect of sedation may suggest a dependency between DO_2 and $\dot{V}O_2$, so the impact of medication in this relationship must be considered.[25]

Oxygen Transport Pathway

Oxygen transport is dependent on several interconnecting steps, ranging from inhalation of oxygen-containing air through the nares to oxygen extraction at the cellular level in response to metabolic demand (see Fig. 2-1). These steps provide the mechanism for ventilatory, cardiovascular, and metabolic coupling. In addition, blood is responsible for transporting oxygen within the body; thus its constituents and consistency directly affect this process.

Quality and Quantity of Blood

Although not considered a discrete step in the oxygen transport pathway, blood is the essential medium for transporting oxygen. To fulfill this function, blood must be delivered in an adequate yet varying amount, proportional to metabolic demands, and must have the appropriate constituents and consistency. Thus consideration of the characteristics of the circulating blood volume is essential to any discussion of oxygen transport.

Blood volume is compartmentalized within the intravascular compartment such that 70% is contained within the venous compartment, 10% in the systemic arteries, 15% in the pulmonary circulation, and 5% in the capillaries.[26] The large volume of blood contained within the venous circulation permits adjustments to be made as CO demand changes. The veins constrict, for example, when CO needs to be increased. When blood volume is normal and body fluids are appropriately distributed between the intravascular and extravascular compartments, fluid balance is considered normal. When they are disrupted, a fluid balance problem exists. In addition, fluid imbalance affects the concentration of electrolytes, particularly sodium, which is present in the highest concentration in the extracellular fluid. Four primary fluid problems that have implications for oxygen transport are water deficit, water excess, sodium deficit, and sodium excess (see Chapter 16). Other ions that are affected often in fluid and electrolyte imbalance deficits include potassium, chloride, calcium, and magnesium. These electrolyte disturbances also contribute to impaired oxygen transport by affecting the electrical and mechanical behavior of the heart and blood vessels, thereby also affecting CO and the distribution of oxygenated arterial blood to the periphery.

Blood is a viscous fluid composed of cells and plasma. Because 99% of blood consists of red blood cells, the white blood cells play almost no role in determining the physical characteristics of blood.

Hematocrit refers to the proportion of red blood cells in the plasma. The normal hematocrit is 38% for women and 42% for men. Blood is several times more viscous than water, which increases the difficulty with which blood is pumped through the heart and flows through vessels; the greater the number of cells, the greater the friction between the layers of blood, which results in increased viscosity. Thus the viscosity of the blood increases significantly with increases in hematocrit. An increase in hematocrit, as in polycythemia, increases blood viscosity several times. The concentration and types of protein in the plasma can also affect viscosity, but to a lesser extent.

In adults, red blood cells are produced in the marrow of the membranous bones, such as the vertebrae, sternum, ribs, and pelvis. The production of red blood cells at these sites diminishes with age. Tissue oxygenation is the basic regulator of red blood cell production. Hypoxemia stimulates red blood cell production through erythropoietin production in bone.[26]

Viscosity of the blood has its greatest effect in the small vessels. Blood flow is considerably reduced in small vessels, which results in aggregates of red blood cells adhering to the vessel walls. This effect is not offset by the tendency of the blood to become less viscous in small vessels (a result of the alignment of the blood cells flowing through these vessels, which minimizes the frictional forces between layers of flowing blood cells). In small capillaries, blood cells can become stuck, particularly where the nuclei of endothelial cells protrude and momentarily obstruct blood flow.

The major function of the red blood cells is to transport hemoglobin, which in turn carries oxygen from the lungs to the tissues. Red blood cells also contain a large quantity of

carbonic anhydrase, which catalyzes the reaction between CO_2 and H_2O. The rapidity of this reaction makes it possible for blood to react with large quantities of CO_2 to transport it from the tissues to the lungs for elimination.

Hemoglobin is contained within red blood cells in a concentration of up to 34 g/dL of cells. Each gram of hemoglobin is capable of combining with 1.34 mL of oxygen (see Figure 2-2). In healthy women, 19 mL of oxygen can be carried in the blood (given that the whole blood of women contains an average of 14 g/100 mL of blood); in healthy men, the blood can carry 21 mL of oxygen (assuming the average concentration in the whole blood of men is 16 g/dL).

The clotting factors of the blood are normally in a proportion that does not promote clotting. Factors that promote coagulation (procoagulants) and factors that inhibit coagulation (anticoagulants) circulate in the blood. In the event of a ruptured blood vessel, prothrombin is converted to thrombin, which catalyzes the transformation of fibrinogen to fibrin threads. This fibrin mesh captures platelets, blood cells, and plasma to form a blood clot.

The extreme example of abnormal clotting is disseminated intravascular coagulation (DIC), when both hemorrhage and coagulation occur simultaneously. The acute form of this syndrome occurs in patients who are critically ill and undergoing multiorgan system failure. The mechanism appears to involve tissue factors, factors that damage the blood vessel walls, and factors that increase platelet aggregation. The chronic form of DIC occurs in chronic conditions such as neoplastic disease.

Plasma is the extracellular fluid of the blood and contains 7% proteins—namely, albumin, globulin, and fibrinogen. The primary function of albumin and, to a lesser extent, globulin and fibrinogen, is to create osmotic pressure at the capillary membrane and to prevent fluid leaking into the interstitial spaces. Globulins transport substances in the blood and provide immunity as the antibodies that fight infection and toxicity. Fibrinogen is fundamental to blood clotting. Most blood proteins, including hemoglobins, are also excellent acid-base buffers and are responsible for 70% of all the buffering power of whole blood.

Blood flow (Q) depends on a pressure gradient (P) and vascular resistance (R) (i.e., $Q = P/R$). Thus blood flow equals the pressure gradient divided by resistance. The length of a given blood vessel and the viscosity of the blood are also determinants of blood flow.

The average blood volume is 5000 mL. Approximately 3000 mL of this is plasma and 2000 mL is red blood cells. These values vary according to gender, weight, and other factors. Normally, changes in blood volume reflect fluid imbalances (deficits and excesses) created by losses through the skin and respiratory tract, as well as through urinary, sweat, and fecal losses. Exercise and hot weather are major challenges to fluid balance in health.

Plasma contains large quantities of sodium and chloride ions and small amounts of potassium, calcium, magnesium, phosphate, sulfate, and organic acid ions. Plasma also contains a large amount of protein. The large ionic constituents of plasma are responsible for regulating intracellular and extracellular fluid volumes, as well as the osmotic factors that cause shifts of fluid between the intracellular and extracellular compartments.

Oxyhemoglobin Dissociation

Demand for oxygen at the cellular level changes from moment to moment. The properties of oxyhemoglobin dissociation ensure that there is a continuous supply of oxygen at the cellular level. Oxygen combines with hemoglobin molecules in the pulmonary circulation and then is released in the tissue capillaries in response to a reduced arterial oxygen tension. The S-shaped oxyhemoglobin dissociation curve (see Chapter 4) shifts to the right in response to reduced tissue pH, increased CO_2, increased temperature, and increased diphosphoglycerate (DPG), a constituent of normal blood cells.

Blood delivery and its ability to transport oxygen effectively are central to all steps in the oxygen transport pathway and must be considered at each stage in clinical problem solving and decision making.

Steps in the Oxygen Transport Pathway

Step One: Inspired Oxygen and Quality of the Ambient Air

In healthy individuals, the concentration of inspired oxygen is relatively constant at 21%. If an individual is at a high altitude, the fraction of inspired oxygen is reduced as elevation increases.

Atmospheric air consists of 79% nitrogen, 20.97% oxygen, and 0.03% CO_2. Because nitrogen is an inert gas and is not absorbed in the lungs, it has a crucial role in keeping the alveoli open. The constituents of the air have become an increasingly important social, environmental, and health issue because of environmental hazards, pollution, and the thinning of the ozone layer, which result in deterioration of air quality, an increase in toxic oxygen-free radicals, and a reduction in atmospheric oxygen pressure.

Many factors influence air quality: geographical region, season, urban versus rural area, high versus low elevation, home environment, work environment, indoor versus outdoor ambience, level of ventilation, presence of air conditioning, buildings that are closed, areas with high levels of particulate matter, areas with gaseous vapors and toxic materials that can be inhaled, and smoke-filled versus smoke-free environments. Poor air quality may overwhelm the filtering ability of the upper respiratory tract and the sensitivity of the airways, causing lung damage, both acutely and over time. Chronic irritation of the lungs by poor air quality can lead to allergies, chronic inflammatory reactions, fibrosis, and alveolar capillary membrane thickening. At the alveolar level, the inspired air is saturated with water vapor. In dry environments, however, the upper respiratory tract may become dehydrated, lose its protective mucous covering, become eroded, and provide a portal for infection even though the air is adequately humidified by the time it reaches the lower airways and alveoli.

Step Two: Airways

The structures of the airways throughout the respiratory tract differ according to their functions. The main airway, the trachea, consists of cartilaginous rings, connective tissue, and small amounts of smooth muscle. This structure is essential to provide a firm and relatively inflexible conduit for air to

pass from the nares through the head and neck to the lungs while avoiding airway collapse. As the airways become smaller and branch throughout the lung tissue, they consist primarily of smooth muscle. Airway narrowing, or obstruction, and the resulting increased resistance to airflow can be caused by a variety of factors, including edema, mucus, foreign objects, calcification, particulate matter, and space-occupying lesions, as well as by hyperreactivity of bronchial smooth muscle. The airways are lined with cilia, which are fine, microscopic, hair-like projections responsible for wafting debris, cells, and microorganisms away from the lungs into larger airways to be removed and evacuated. The airways are also lined with mucus, which consists of two layers, the upper gel layer and the lower sol layer, with which the cilia communicate.

Step Three: Lungs and Chest Wall

Air entry into the lungs depends on the integrity of the respiratory muscles, in particular the diaphragm, the lung parenchyma, and the chest wall. The contraction and descent of the diaphragm generate a negative intrapleural pressure that inflates the lungs. The distribution of ventilation is determined primarily by the negative intrapleural pressure gradient down the lungs. The negative intrapleural pressure gradient results in uneven ventilation down the lungs and in interregional differences (see Chapter 4). There are, however, other factors that contribute to uneven ventilation within regions of the lung. These intraregional differences reflect regional differences in lung compliance and airway resistance.[27] In patients with partially obstructed airways, reduced lung compliance and increased airway resistance increase the time needed for alveolar filling. Gas exchange is compromised if there is inadequate time for alveolar filling or emptying (i.e., increased time constants).[18] Different time constants across lung units contribute to uneven patterns of ventilation during inspiration. A lung unit with a long time constant is slow to fill and empty, and it may continue filling when surrounding units are emptying. Another factor that contributes to uneven ventilation is altered diffusion distance. In diseases in which diffusion distance is increased, ventilation among lung units is uneven.

The lungs and the parietal pleura are richly supplied with thin-walled lymphatic vessels.[16] Lymphatic vessels have some smooth muscle and thus can actively contract to propel lymph fluid forward. This forward motion is augmented by valves along the lymphatic channels. The rise and fall of the pleural pressure during respiration compress lymphatic vessels with each breath, which promotes a continuous flow of lymph. During expiration and increased intrapleural pressure, fluid is forced into the lymphatic vessels. The visceral pleura continuously drains fluid from the lungs. This creates a negative pressure in the pleural space, which keeps the lungs expanded. This pressure exceeds the elastic recoil pressure of the lung parenchyma, which counters the tendency of elastic recoil to collapse the lungs.

The peritoneal cavity of the abdomen consists of a visceral peritoneum containing the viscera and a parietal peritoneum lining the abdominal cavity. Numerous lymphatic channels interconnect the peritoneal cavity and the thoracic duct; some arise from the diaphragm. With cycles of inspiration and expiration, large amounts of lymph are moved from the peritoneal cavity to the thoracic duct of the venous drainage system. High venous pressures and vascular resistance through the liver can interfere with normal fluid balance in the peritoneal cavity. This leads to the transudation of fluid with high protein content into the abdominal cavity. Such an accumulation of fluid is referred to as ascites. Large volumes of fluid can accumulate in the abdominal cavity and compromise cardiovascular and pulmonary function secondary to increased intraabdominal pressure on the underside of the diaphragm.

Optimal diaphragmatic excursion requires a balance between thoracic and intraabdominal pressures. Increases in abdominal pressure secondary to factors such as fluid accumulation can impair diaphragmatic descent and chest wall expansion. Other factors include gas entrapment, gastrointestinal obstruction, space-occupying lesions, and paralytic ileus.

Step Four: Diffusion

Diffusion of oxygen from the alveolar sacs to the pulmonary arterial circulation depends on four factors: the area of the alveolar capillary membrane, the diffusing capacity of the alveolar capillary membrane, the pulmonary capillary blood volume, and the ventilation and perfusion ratio.[9] The transit time of blood at the alveolar capillary membrane is also an important factor that determines diffusion. The blood remains in the pulmonary capillaries for 0.75 second at rest. Within 0.25 second, one-third of that time, the blood is completely saturated. This provides a safety margin during exercise or other conditions in which CO is increased and pulmonary capillary transit time is reduced. The blood can normally be fully oxygenated even with reduced transit time.

Step Five: Perfusion

The distribution of blood perfusing the lungs is primarily gravity dependent, so the dependent lung fields are perfused to a greater extent than are the nondependent lung fields. In upright lungs, the bases are better perfused than the apices (see Chapter 4). Ventilation and perfusion matching is optimal in the midzones of upright lungs.[18] In healthy individuals, the ventilation-to-perfusion ratio is a primary determinant of arterial oxygenation. In upright lungs, this ratio is 0.8 in the midzone.

Step Six: Myocardial Function

Optimal myocardial function and CO depend on the synchronized coupling of electrical excitation of the heart and its mechanical contraction. The sinoatrial node, located in the right atrium, is the normal pacemaker for the heart and elicits the normal sinus rhythm with its multiple-component P-QRS-T configuration (see Chapter 12). This wave of electrical excitation spreads throughout the specialized neural conduction system of the atria, the interventricular septum, and the ventricles and is followed by the contraction of the atria and then of the ventricles. The contraction of the right and left ventricles ejects blood into the pulmonary and systemic circulations, respectively.

CO depends on several factors in addition to the integrity of the conduction system and the adequacy of myocardial depolarization (dromotropic effect). The amount of blood returned to the heart (preload) determines the amount ejected

(the Starling effect). The distensibility of the ventricles to accommodate this blood volume must be optimal—neither too stiff nor too compliant. The force and contractility of the myocardial muscle must be sufficient to eject the blood (inotropic effect and chronotropic effect, respectively). CO is determined by the aortic pressure needed to overcome peripheral vascular resistance and the capacity of the ventricles to eject blood into the pulmonary and systemic circulations (afterload).

The pericardial cavity, like the pleural and peritoneal cavities, is a potential space containing a thin layer of fluid. The space normally has a negative pressure. During expiration, pericardial pressure is increased and fluid is forced out of the space into the mediastinal lymphatic channels. This process is normally facilitated by increased volumes of blood in the heart and each ventricular systole.

Step Seven: Peripheral Circulation

When oxygenated blood is ejected from the heart, the peripheral circulation provides a conduit to supply this blood to metabolically active tissue. Blood vessels throughout the body are arranged both in series and in parallel. The arteries and capillaries are designed to advance blood and thus perfuse the tissues with oxygenated blood. The architecture of the vasculature is such that the proximal large arteries have a higher proportion of connective tissue and elastic elements than do the distal medium and small arteries, which have a progressively higher proportion of smooth muscle. This structure enables the large proximal arteries to withstand high pressure when blood is ejected during ventricular systole. Considerable potential energy is stored within the elastic walls of these blood vessels as the heart contracts. During diastole the forward propulsion of blood is facilitated by the elastic recoil of these large vessels. The thin-walled muscular arterioles serve as the stopcocks of the circulation and regulate blood flow through regional vascular beds (e.g., of the skin, gut, muscle, and organs) and maintain peripheral vascular resistance to regulate systemic blood pressure. Blood flow through these regional vascular beds is determined by neural and humoral stimulation (exogenous) and by local tissue factors (endogenous). Blood pressure control is regulated primarily by neural stimulation of the peripheral circulation and regional vascular beds.

The microcirculation consists of the precapillary arterioles, capillaries, and venules. The Starling effect governs the balance of hydrostatic and oncotic pressures within the capillaries and surrounding tissues. The balance of these pressures is 0.3 mm Hg; its net effect is a small outward filtration of fluid from the microvasculature into the interstitial spaces (see Chapter 4). Any excess fluid or loss of plasma protein is drained into the surrounding lymphatic vessels, which usually have a small negative pressure, as does the interstitium. Integrity of the microcirculation is essential to regulate the diffusion of oxygen across the tissue capillary membrane and removing CO_2 and waste products.

The greater the muscular component of blood vessels, the greater their responsiveness to both exogenous neural stimulation and endogenous stimulation via circulating humoral neurotransmitters, such as catecholamines and local tissue factors. This responsiveness is essential for the moment-to-moment regulation of the peripheral circulation with respect to tissue perfusion and oxygenation, commensurate with tissue metabolic demands and control of total peripheral resistance and systemic blood pressure.

Step Eight: Tissue Extraction and Use of Oxygen

Perfusion of the tissues with oxygenated blood commensurate with metabolic demand is the principal goal of the oxygen transport system.[3] Oxygen is continuously being used by all cells in the body; thus it diffuses rapidly out of the circulation and through cell membranes to meet varying metabolic needs. Diffusion occurs down a gradient from areas of high to low oxygen pressure. The distances between capillaries and cells are variable, so a significant safety factor is required to ensure adequate arterial oxygen tensions. Intracellular P_{O_2} ranges from 5 to 60 mm Hg, with an average of 23 mm Hg.[16] Given that only 3 mm Hg of oxygen pressure is needed to support metabolism, 23 mm Hg of oxygen pressure provides an adequate safety margin. These mechanisms ensure an optimal oxygen supply over a wide range of oxygen demands during healthy functioning and in the event of impaired oxygen delivery because of illness. Normally, the rate of oxygen extraction by the cells is regulated by the oxygen demand of cells (i.e., the rate at which ADP is formed from ATP) rather than by the availability of oxygen.

Adequate quality and quantity of mitochondrial enzymes required for the Krebs cycle and electron transfer chain, along with the availability of myoglobin, may be limiting factors in the oxygen transport pathway secondary to nutritional deficits and muscle enzyme deficiencies. Myoglobin is a protein comparable to hemoglobin and is localized within muscle mitochondria. Myoglobin combines reversibly with oxygen to provide an immediate source of oxygen when there are increased metabolic demands and to facilitate oxygen transfer within the mitochondria.

Normally the amount of oxygen extracted by the tissues at rest is 23% (i.e., the ratio of oxygen consumed to oxygen delivered). This ratio ensures that greater amounts of oxygen can be extracted during periods of increased metabolic demand.

To detect tissue hypoxia, particularly in patients who are critically ill, regional assessments such as gastric mucosal PCO_2 and pH have been proposed as being superior to global assessment of $\dot{V}_{O_2}$ and D_{O_2}.[28] Regional measures of oxygenation could help to enhance the specificity of treatment based on tissue indicators.[29]

Step Nine: Return of Partially Desaturated Blood and CO_2 to the Lungs

Partially desaturated blood and CO_2 are removed from cells via the venous circulation to the right side of the heart and lungs. CO_2 diffuses across the alveolar capillary membrane and is eliminated from the body through the respiratory system, and deoxygenated venous blood is reoxygenated. The oxygen transport cycle is sensitively tuned to adjust to changes in the metabolic demand of the various organ systems, such as digestion in the gastrointestinal system and cardiac and skeletal muscle work during exercise.

Factors that interfere with tissue oxygenation and the capacity of the tissue to use oxygen include abnormal oxygen

demands, reduced hemoglobin and myoglobin levels, edema, and poisoning of the cellular enzymes.[30]

Factors that Normally Perturb Oxygen Transport

Basal metabolic rate (BMR) reflects the rate of metabolism for an individual in a completely rested state: no food intake within several hours, a good night's sleep, no arousing or distressing emotional stimulation, and a comfortable ambient temperature. Normally, the BMR is constant within and among individuals if measured under standardized conditions. BMR reflects the energy expended by the body's cells to maintain resting function and includes the work of breathing; heart, renal, and brain function; and thermoregulation.

Normally, over the course of the day, the human body is exposed to fluctuations in ambient temperature and humidity, ingestion states, activity and exercise levels (exercise stress), body positions and body position changes (gravitational stress), emotional states (emotional stress), and states of arousal. These factors significantly influence $\dot{V}O_2$ and energy expenditure from moment-to-moment and thus increase rate of metabolism.

Several factors related to disease can significantly increase oxygen consumption and metabolic rate over and above the BMR. Such factors include fever, the disease process itself, the process of healing and recovery from injury or disease, thermoregulatory disturbance, reduced arousal, increased arousal resulting from anxiety or pain, sleep loss, medical and surgical interventions, fluid imbalance, and medications.[5] These factors may contribute to a systemic increase in the BMR or may reflect local changes in tissue metabolism. Autoregulation of the regional vascular beds promotes increased regional blood flow in accordance with their local tissue metabolic demand.

Because gravitational stress and exercise stress are fundamental to normal cardiovascular and pulmonary function and oxygen transport, the effects of gravity and exercise are highlighted. These two factors augment arousal through stimulation of the reticular activating system in the brainstem and the autonomic nervous system (ANS), which, when depressed, significantly compromises oxygen transport. Emotional stress also has a marked effect on the stimulation of the ANS (the fight-or-flight response) and hence on oxygen transport. These concepts and their clinical implications are described in detail in Chapters 18 and 19.

Gravitational Stress

Humans are designed to function in a 1-g gravitational field. Given that 60% of the body weight is fluid contained within the intravascular and extravascular compartments and that this fluid has considerable mass, changes in body position result in significant instantaneous fluid shifts that can threaten hemodynamic stability.[6,31] To maintain consciousness and normal body function during changes in body position, the heart and peripheral vasculature are designed to detect these fluid shifts and accommodate quickly to avoid deleterious functional consequences (e.g., reduced SV, CO, circulating blood volume, and cerebral perfusion). Preservation of the fluid-regulating mechanisms is essential to counter the hemodynamic effects of changing body position. This capacity is impaired with recumbency, which has long been associated with bed rest deconditioning in patients and older populations.[32,33] Restoration of adaptation to gravitational stress by upright positioning of a patient is the only means by which these fluid-regulating mechanisms can be maintained and orthostatic intolerance and its short- and long-term sequelae averted.

Exercise Stress

Exercise constitutes the greatest perturbation to homeostasis and oxygen transport in humans. CO can increase by five times to adjust to the metabolic demands of exercise stress. All steps in the oxygen transport pathway are affected by exercise stress. Ventilation is increased, and ventilation and perfusion matching is optimized to maximize oxygenation of blood. Heart rate and stroke volume are increased to effect greater CO of oxygenated blood to the tissues. At the tissue level, oxygen extraction is enhanced.

Emotional Stress

The body responds to emotional stress much as it does to exercise stress—by undergoing the sympathetic stress reaction (the fright-fight-flight reaction). Perceived threat, the basis of emotional stress, can also trigger the fright-fight-flight reaction and a series of sympathetically mediated physiological responses. This reaction, which prepares the body for fight or for flight, includes an increase in circulating stress hormones, heart rate, blood pressure, CO, blood glucose, muscle strength, mental alertness, cellular metabolism, and local blood flow to specific muscle groups, as well as inhibition of involuntary function.

Summary

This chapter describes the oxygen transport system, a system that is essential to life, activity, and social participation. Its component steps and their interdependence are highlighted. This framework provides a conceptual basis for the practice of cardiovascular and pulmonary physical therapy.

The oxygen transport system is designed to deliver oxygen from the ambient air to every cell in the body to support cellular respiration (i.e., metabolic use of oxygen at the cellular level). Blood is the essential medium in which cellular and noncellular components transport oxygen from the cardiovascular and pulmonary unit to the peripheral tissues. The fundamental components in the oxygen transport pathway are described. These components include the quality of the ambient air, the airways, lungs, chest wall, pulmonary circulation, lymphatic circulation, heart, peripheral circulation, and peripheral tissues of the organs of the body.

In healthy individuals, the most significant factors that perturb oxygen transport are changes in gravitational stress secondary to changes in body position, exercise stress secondary to the increased oxygen demand of working muscles, and arousal and emotional stress. A thorough understanding of the normal effects of gravitational and exercise stress and arousal is essential to understanding deficits in oxygen transport. Numerous factors can impair and threaten oxygen

transport, including underlying pathophysiology, restricted mobility, recumbency, factors related to the patient's care, and factors related to the individual (see Chapters 2 and 17). The physical therapist needs a detailed understanding of these concepts to diagnose such threats and deficits, to understand their impact on activity and participation, and to prescribe effective treatments.

Review Questions

1. Describe the clinical implications of limitations of oxygen transport at three levels: structure and function, activity, and participation (consistent with the International Classification of Functioning, Disability and Health).
2. Describe the oxygen transport pathway, its steps and their interdependence.
3. Describe the physiological processes of energy transfer and cellular oxidation.
4. Explain oxygen transport with respect to oxygen delivery, uptake and extraction, and the interrelationship among these processes.
5. Outline the factors that perturb oxygen transport in health.

The heart lies in series with the lungs, constituting the cardiovascular and pulmonary unit, the central component of the oxygen transport pathway.[1,2] Virtually all the blood returned to the right side of the heart passes through the lungs and is delivered to the left side of the heart for ejection into the systemic, coronary, and bronchopulmonary circulations. Because of this interrelationship, changes in lung function can exert changes in heart function and vice versa. A detailed understanding of the anatomy of the heart and lungs and how these organs work synergistically is essential to the practice of cardiovascular and pulmonary physical therapy.

This chapter presents the anatomy of the cardiovascular and pulmonary systems, including the skeletal features of the thoracic cavity; muscles of respiration; anatomy of the tracheobronchial tree; lung parenchyma; basic anatomy of the heart; and peripheral, pulmonary, and lymphatic circulations.[3-11]

Thorax

The bony thorax covers and protects the principal organs of respiration and circulation as well as the liver and the stomach (Fig. 3-1). The anterior surface is formed by the sternum and the costal cartilage. The lateral surfaces are formed by the ribs. The posterior surface is formed by the 12 thoracic vertebrae and the posterior part of the 12 ribs. At birth, the thorax is nearly circular, but during childhood and adolescence it becomes more elliptical. In adulthood, the transverse diameter of the chest wall is greater than the anteroposterior diameter.

Sternum

The sternum, or breastbone, is a flat bone with three parts: manubrium, body, and xiphoid process. The manubrium is the widest and thickest bone of the sternum. Its upper border is scalloped by a central jugular notch, which can be palpated, and by two clavicular notches that house the clavicles. Its lower

border articulates with the upper border of the body at a slight angle, the sternal angle or angle of Louis. This angle, which is easily palpated, is a landmark located between thoracic vertebrae T4 and T5, and is on a level with the second costal cartilages. The bifurcation of the trachea into the right and left main stem bronchi also occurs at the sternal angle. The manubrium and body are joined by fibrocartilage, which may ossify in later life.

The body of the sternum is twice as long as the manubrium. It is a relatively thin bone and can be easily pierced by needles for bone marrow aspirations. The heart is located beneath and to the left of the lower third of the body of the sternum. Although it is attached by cartilage to the ribs, this portion of the sternum is flexible and can be depressed without breaking. This maneuver is used, with care, in closed cardiac massage to artificially circulate blood to the brain and extremities. The lower margin of the body is attached to the xiphoid process by fibrocartilage. This bone is the smallest of the three parts of the sternum and usually fuses with the body of the sternum in later life.

Ribs

A large portion of the bony thoracic cage is formed by 12 ribs located on either side of the sternum. The first seven ribs connect posteriorly with the vertebral column and anteriorly through costal cartilages with the sternum. These are known as the true ribs. The remaining five ribs are known as the false ribs. The first three have their cartilage attached to the cartilage of the rib above. The last two are free or floating ribs. The ribs increase in length from the first to the seventh rib and then decrease to the 12th rib. They also increase in obliquity until the ninth rib and then decrease in obliquity to the 12th rib.

Each rib has a small head and a short neck that articulate with two thoracic vertebrae. The shaft of the rib curves gently from the neck to a sudden sharp bend, the angle of the rib. Fractures often occur at this site. A costal groove is located on the lower border of the shaft of the ribs. This groove houses the intercostal nerves and vessels. Chest tubes and needles are inserted above the ribs to avoid these vessels and nerves. The ribs are separated from each other by the intercostal spaces that contain the intercostal muscles.

Movements of the Thorax

The frequency of movement of the bony thorax joints is greater than that of almost any other combination of joints in the body. Two types of movements have been described: the pump-handle movement and the bucket-handle movement (Fig. 3-2).[12] The upper ribs are limited in their ability to move.

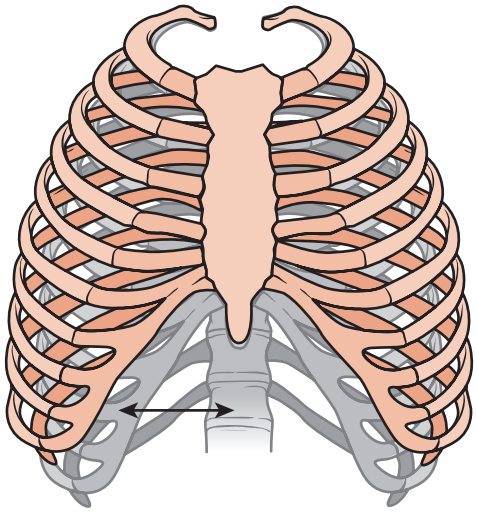

Fig. 3-2 The movements of the ribs. **A,** "Bucket handle," lower rib. **B,** "Pump handle," first rib.

Each pair swings like a pump handle, with elevation thrusting the sternum forward. This forward movement increases the anteroposterior diameter and the depth of the thorax and is called the pump-handle movement. In the lower ribs, there is little anteroposterior movement. During inspiration, the ribs swing outward and upward, each rib helps to elevate the rib above it. This bucket-handle movement increases the transverse diameter of the thoracic cage. Thus during inspiration, the thorax increases its volume by increasing its anteroposterior and transverse diameters.

Muscles of Respiration

Inspiration

Inspiration is an active movement involving the contraction of the diaphragm and intercostal muscles. Additional muscles may come into play during exertion in a healthy person. In disease, the role of these accessory muscles of inspiration may have an important role even at rest. The accessory muscles include the sternocleidomastoids, scalenes, serratus anterior, pectoralis major and minor, trapezius, and erector spinae. The degree to which these accessory muscles are recruited by the patient depends on the severity of cardiovascular and pulmonary distress.

Diaphragm

The diaphragm is the principal muscle of respiration. During quiet breathing, the diaphragm contributes approximately two-thirds of the tidal volume in the sitting or standing positions and approximately three-fourths of the tidal volume in the supine position. Approximately two-thirds of the vital capacity in all positions is contributed by the diaphragm.

The diaphragm is a large, dome-shaped muscle that separates the thoracic and abdominal cavities. Its upper surface supports the pericardium (with which it is partially blended), heart, pleurae, and lungs. Its lower surface is almost completely covered by the peritoneum and overlies the liver, kidneys, suprarenal glands, stomach, and spleen (Fig. 3-3). This large muscle can be divided into right and left halves. Each half is made up of three parts: sternal, lumbar, and costal. These three parts insert into the central tendon, which lies just below the heart. The sternal part arises from the back of the xiphoid process and descends to the central tendon. On each side is a small gap, the sternocostal triangle, which is located between the sternal and costal parts. It transmits the superior epigastric vessels and is often the site of diaphragmatic hernias. The costal parts form the right and left domes. They arise from the inner surfaces of the lower four ribs and the lower six costal cartilages, then interdigitate and transverse the abdomen to insert into the anterolateral part of the central tendon, the central part of the diaphragm. The lumbar part arises from the bodies of the upper lumbar vertebrae and extends upward to the central tendon. The central tendon is a thin, strong aponeurosis situated near the center of the muscle, somewhat closer to the front of the body. It resembles a trefoil leaf, with its three divisions or leaflets. The right leaflet is the largest, the middle is the next largest, and the left leaflet is the smallest.

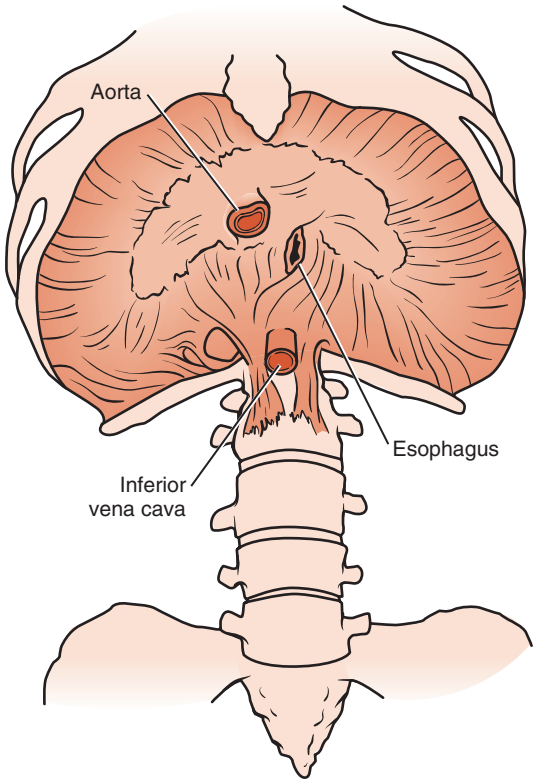

Fig. 3-3 The diaphragm from below.

Major vessels traverse the diaphragm through one of three openings (see Fig. 3-3). The vena caval opening is located to the right of the midline in the central tendon and contains branches of the right phrenic nerve and the inferior vena cava. The esophageal opening is located to the left of the midline and contains the esophagus, the vagal nerve trunks, and branches of the gastric vessels. The aortic opening is located in the midline and contains the aorta, the thoracic duct, and sometimes the azygos vein. The diaphragm is also pierced by branches of the left phrenic nerve, small veins, and lymph vessels.

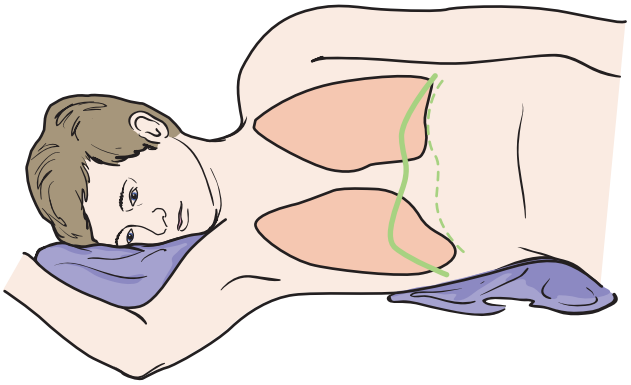

Fig. 3-4 When the patient is lying on his or her side, the dome of the diaphragm on the lower side rises farther in the thorax than the dome on the upper side.

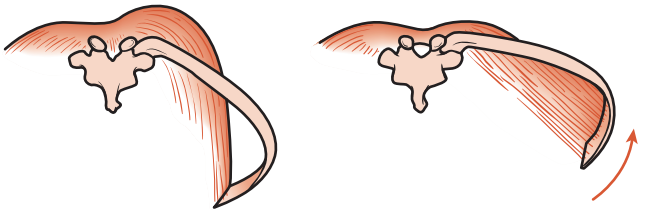

Fig. 3-5 Contraction of the costal fibers of the diaphragm causes rib eversion and elevation.

The position of the diaphragm and its range of movement vary with posture, the degree of distention of the stomach, size of the intestines, size of the liver, and obesity. Average movement of the diaphragm in quiet respiration is 12.5 mm on the right and 12 mm on the left. This can increase to a maximum of 30 mm on the right and 28 mm on the left during increased ventilation. An individual's posture determines the position of the diaphragm. In the supine position, the resting level of the diaphragm rises. The greatest respiratory excursions during normal breathing occur in this position; however, the lung volumes are decreased because of the elevated position of the abdominal organs within the thoracic cavity. In a sitting or upright position, the dome of the diaphragm is pulled down by the abdominal organs, allowing a larger lung volume. For this reason, individuals who are short of breath are more comfortable sitting than reclining. In a side-lying position, the dome of the diaphragm on the lower side rises farther into the thorax than the dome on the upper side (Fig. 3-4). The abdominal organs tend to be displaced forward in a side-lying position, allowing greater excursion of the dome on the lower side. In contrast, the upper side moves little with respiration. On radiograph, the position of the diaphragm can indicate whether the film was taken during inspiration or expiration and may also indicate pathology in the lungs, pleurae, or abdomen.

Each half of the diaphragm is innervated by a separate nerve—the phrenic nerve on that side. Although the halves contract simultaneously, it is possible for half of the muscle to be paralyzed without affecting the other half. Generally, the paralyzed half remains at the normal level during rest. With deep inspiration, however, the paralyzed half is pulled up by the negative pressure in the thorax.

Contraction of the diaphragm increases the thoracic volume vertically and transversely. The central tendon is drawn down by the diaphragm as it contracts. As the dome descends, abdominal organs are pushed forward as far as the abdominal walls will allow. When the dome can descend no farther, the costal fibers of the diaphragm contract to increase the thoracic diameter of the thorax. This occurs because the fibers of the costal part of the diaphragm run vertically from their attachment at the costal margin. Thus contraction of these fibers elevates and everts the ribs (Fig. 3-5). If the diaphragm is in a low position, it will change the angle of pull of the muscle's costal fibers. Contraction of these fibers creates a horizontal pull, which causes the lateral diameter to become smaller as the ribs are pulled in toward the central tendon.

As the diaphragm descends, it compresses the abdominal organs, increasing intraabdominal pressure. At the same time, the intrathoracic pressure decreases as the lung volume is increased by the descending diaphragm. Inspiratory airflow occurs as a result of this decrease in intrathoracic pressure (see Chapter 4). The pressure gradient between the abdominal and thoracic cavities also facilitates the return of blood to the right side of the heart.

Movement of the diaphragm can be controlled voluntarily to some extent. Vocalists spend years learning to manipulate their diaphragms so they can produce controlled sounds when singing. The diaphragm momentarily ceases movement when a person holds his or her breath. The diaphragm is involuntarily involved in parturition, bearing down in bowel movements, and laughing, crying, and vomiting. Hiccups are spasmodic, sharp contractions of the diaphragm that can indicate disease (e.g., a subphrenic abscess) if they persist.

Intercostals

The external intercostals extend down and forward from the tubercles of the ribs (above) to the costochondral junction of the ribs (below), where they become continuous with the anterior intercostal membrane (Fig. 3-6). This membrane extends the muscle forward to the sternum. There are 11 external intercostal muscles on each side of the sternum. They are thicker posteriorly than anteriorly and thicker than the internal intercostal muscles. They are innervated by the intercostal nerves, and contraction draws the lower rib up and out toward the upper rib. This action increases the volume of the thoracic cavity.

There are 11 internal intercostals on each side. These are considered primarily expiratory in function. The intercartilaginous or parasternal portion of the internal intercostals contracts with the external intercostals during inspiration to help elevate the ribs. In addition to their respiratory functions, the intercostal muscles contract to prevent the intercostal spaces from being drawn in or bulged out during respiratory activity.

Sternocleidomastoid

The sternocleidomastoid (SCM) muscles are strong neck muscles arising from two heads, one from the manubrium and one from the medial part of the clavicle (see Fig. 3-6). These two heads fuse into one muscle mass that inserts behind the ear into the mastoid process. It is innervated by the accessory

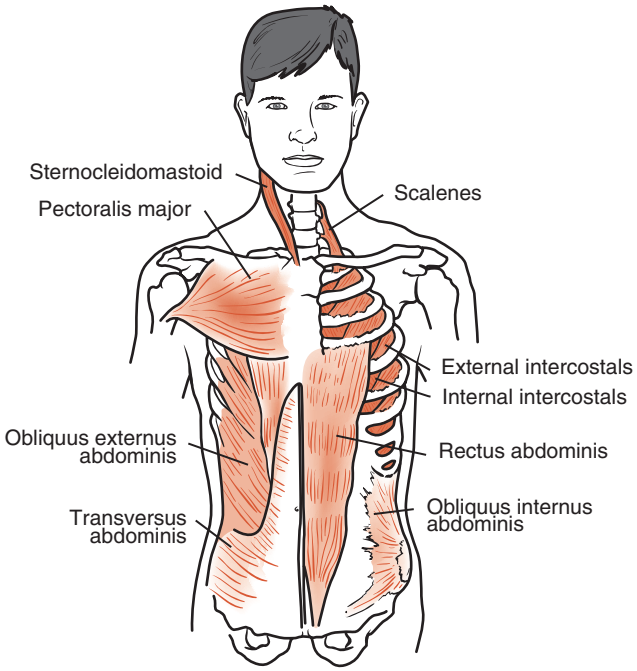

Fig. 3-6 Respiratory muscles (anterior view).

nerve and the second cervical nerve. There are two of these muscles, one on each side of the neck. When one SCM contracts, it tilts the head toward the shoulder of the same side and rotates the face toward the opposite shoulder. If the two SCM muscles contract together, they pull the head forward into flexion. When the head is fixed, the muscles assist in elevating the sternum, increasing the anteroposterior diameter of the thorax.

The SCMs are the most important accessory muscles of inspiration. Their contractions can be observed in all patients during forced inspiration and in all patients who are dyspneic. These muscles become visually predominant in patients who are chronically dyspneic (see Chapter 5).

Scalenes

The anterior, medial, and posterior scalenes are three separate muscles that are considered a functional unit. They are attached superiorly to the transverse processes of the lower five cervical vertebrae and inferiorly to the upper surface of the first two ribs (see Fig. 3-6). They are innervated by their corresponding cervical spinal nerves. These muscles are primarily supportive neck muscles, but they can assist in respiration through reverse action. When their superior attachment is fixed, the scalenes act as accessory respiratory muscles and elevate the first two ribs during inspiration.

Serratus Anterior

The serratus anterior arises from the outer surfaces of the first eight or nine ribs. It curves backward, forming a sheet of muscle that inserts into the medial border of each scapula. It is innervated by the long thoracic nerve (cervical nerves C5, C6, and C7). There are two of these muscles, one on each side of the body. Normally they assist in forward pushing of the arm (as in punching). When the scapulae are fixed, the serratus anterior muscles act as accessory respiratory muscles and elevate the ribs to which they are attached.

Pectoralis Major

The pectoralis major is a large muscle arising from the clavicle, the sternum, and the cartilages of all the true ribs (see Fig. 3-6). This muscle spreads across the anterior chest and inserts into the intertubercular sulcus of the humerus. It is innervated by the lateral and medial pectoral nerves and cervical nerves C5, C6, C7, C8, and T1. There are two of these muscles, one on each side of the body. This muscle rotates the humerus medially and draws the arm across the chest. During climbing and pull-ups, it draws the arms toward the trunk. During forced inspiration when the arms are fixed, it draws the ribs toward the arms, thereby increasing thoracic diameter.

Pectoralis Minor

The pectoralis minor is a thin muscle originating from the outer surfaces of the third, fourth, and fifth ribs near their cartilages. It inserts into the coracoid process of the scapula. It is innervated by the pectoral nerves (cervical nerves C6, C7, and C8). There are two of these muscles, one on each side of the body. They contract with the serratus anterior to draw the scapulae toward the chest. During deep inspiration, they contract to elevate the ribs to which they are attached.

Trapezius

The trapezius consists of two muscles that form an extensive diamond-shaped sheet extending from the head down the back and out to both shoulders (Fig. 3-7). Its upper belly originates from the external occipital protuberance, curves around the side of the neck, and inserts into the posterior border of the clavicle. The middle part of the muscle arises from a thin diamond-shaped tendinous sheet, the supraspinous ligaments, and the spines of the upper thoracic region; it then runs horizontally and inserts into the spine of the scapula. Its lower belly arises from the supraspinous ligaments and the spines of the lower thoracic region, runs upward, and inserts into the lower border of the spine of the scapula. This large muscle is innervated by the external or spinal part of the accessory nerve and cervical nerves C3 and C4. Its main function is to rotate the scapulae during arm elevation and control gravitational descent of the arms. It also braces the scapulae and raises them, as when shrugging the shoulders. Its ability to stabilize the scapulae makes it an important accessory muscle in respiration. This stabilization enables the serratus anterior and pectoralis minor to elevate the ribs.

Erector Spinae

The erector spinae is a large muscle extending from the sacrum to the skull (see Figure 3-7). It originates from the sacrum, the iliac crest, and the spines of the lower thoracic and lumbar vertebrae. It separates into a lateral iliocostalis, an intermediate longissimus, and a medial spinalis column. This muscle mass inserts into various ribs and vertebral processes all the way up to the skull. It is innervated by the corresponding spinal nerves. These muscles extend, laterally flex, and rotate

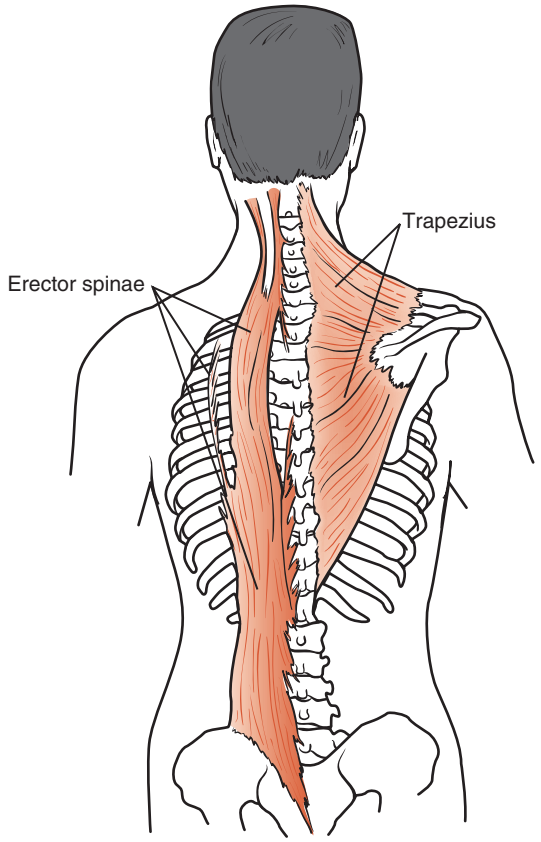

Fig. 3-7 Respiratory muscles (posterior view).

the vertebral column. They are considered accessory respiratory muscles through their extension of the vertebral column. In deep inspiration, these muscles extend the vertebral column, allowing further elevation of the ribs.

Expiration

Expiration is a passive process that occurs when the intercostals and diaphragm relax. Relaxation of the intercostals and diaphragm allows the ribs to drop to their preinspiratory position and the diaphragm to rise. These activities compress the lungs, which then raises intrathoracic pressure above atmospheric pressure and contributes to air flow out of the lungs.

Rectus Abdominis

The rectus abdominis rises from the pubic crest, extends upward, and inserts into the xiphoid process and the costal margin of the fifth, sixth, and seventh costal cartilages (see Fig. 3-6). It is innervated by corresponding spinal nerves and its action is considered within the context of the other abdominal muscles.

Obliquus Externus Abdominis

The obliquus externus abdominis arises in an oblique line from the fifth costal cartilage to the 12th rib (see Fig. 3-6). Its posterior fibers attach in an almost vertical line with the iliac crest. The other fibers extend down and forward and attach to the front of the xiphoid process, the linea alba, and the pubic symphysis. It is innervated by the lower six thoracic spinal nerves.

Obliquus Internus Abdominis

The obliquus internus abdominis originates from the lumbar fascia, the anterior two-thirds of the iliac crest, and the lateral two-thirds of the inguinal ligament (see Fig. 3-6). Its posterior fibers run almost vertically upward and insert into the lower borders of the last three ribs. The other fibers join an aponeurosis attached to the costal margin above, the linea alba in the midline, and the pubic crest below. It is innervated by the lower six thoracic nerves and the first lumbar spinal nerves.

Transversus Abdominis

The transversus abdominis arises from the inner surface of the lower six costal cartilages, the lumbar fascia, the anterior two-thirds of the iliac crest, and the lateral one-third of the inguinal ligament (see Fig. 3-6). It runs across the abdomen horizontally and inserts into the aponeurosis, extending to the linea alba. It is innervated by the lower six thoracic nerves and the first lumbar spinal nerves.

Action of the Abdominal Muscles

The four muscles of the abdomen work together to provide a firm but flexible wall to keep the abdominal viscera in position. The abdominal muscles exert a compressing force on the abdomen when the thorax and pelvis are fixed. This force can be used in defecation, urination, parturition, and vomiting. In forced expiration, the abdominal muscles help force the diaphragm back to its resting position and thus force air from the lungs. If the pelvis and vertebral column are fixed, the obliquus externus abdominis aids expiration further by depressing and compressing the lower part of the thorax. Patients with chronic obstructive pulmonary disease (COPD) have difficulty in exhalation, which causes them to trap air in their lungs. The continued contraction of the abdominal muscles throughout exhalation helps them force this air from the lungs. The abdominal muscles also play an important role in coughing. First, a large volume of air is inhaled, and the glottis is closed. The abdominal muscles then contract, raising intrathoracic pressure. When the glottis opens, the large difference in intrathoracic and atmospheric pressure causes the air to be expelled forcefully at tremendous flow rates (tussive blast). Individuals with weak abdominal muscles (from neuromuscular diseases, paraplegia, quadriplegia, or extensive abdominal surgery) often have ineffective coughs (see Chapters 6 and 32).

The four abdominal muscles have many other nonrespiratory functions, both individually and as a group; these functions are not discussed here.

Internal Intercostals

There are 11 internal intercostal muscles on each side of the thorax. Each muscle arises from the floor of the costal groove and cartilage, passes inferiorly and posteriorly and inserts on the upper border of the rib below. These internal intercostals extend from the sternum anteriorly, around the thorax to the posterior costal angle. They are generally divided into two

parts: the interosseous portion, located between the sloping parts of the ribs, and the intercartilaginous portions, located between costal cartilages. The intercartilaginous portions are considered inspiratory in function. Contraction of the interosseous portions of the intercostals depresses the ribs and may aid in forceful exhalation. These muscles are innervated by the adjacent intercostal nerves.

Overview of the Process of Breathing

During quiet inspiration, the diaphragm, external intercostals, and intercartilaginous portions of the internal intercostals are the primary muscles that contract. The diaphragm contracts first and then descends, enlarging the thoracic cage vertically. When the abdominal contents prevent further descent of the diaphragm, the costal fibers of the diaphragm contract, which causes the lower ribs to swing up and out to the side (bucket-handle movement). This lateral rib movement is assisted by the external intercostals and the intercartilaginous portion of the internal intercostals. The transverse diameter of the thorax is increased by this bucket-handle movement. Finally, the upper ribs move forward and upward (pump-handle movement), also through contraction of their external intercostals and the intercartilaginous portions of the internal intercostals. This increases the anteroposterior diameter of the thorax. The epigastric area protrudes, then the ribs swing up and out laterally, and finally the upper ribs move forward and upward.

Quiet expiration is passive and involves no muscular contraction, although some electrical activity can be detected with electromyography. The inspiratory muscles relax, which raises intrathoracic pressure as the ribs and diaphragm return to their preinspiratory positions and compress the lungs. This increased pressure allows airflow from the lungs.

During forced inspiration, an additional number of accessory muscles may contract along with the muscles involved in quiet inspiration. The erector spinae contract to extend the vertebral column. This extension permits greater elevation of the ribs during inspiration. Various back muscles (e.g., erector spinae, trapezius, and rhomboids) contract to stabilize the vertebral column, head, neck, and scapulae. This enables accessory respiratory muscles to assist inspiration through reverse action. The SCM raises the sternum. The scalenes elevate the first two ribs. The serratus anterior, pectoralis major, and pectoralis minor assist bilateral elevation of the ribs. All these accessory muscles tend to elevate the ribs, thus increasing the anteroposterior diameter but not the transverse diameter of the thorax. (The transverse diameter does increase slightly as a result of the increased strength of the contraction of the normal inspiratory muscles.) The marked increase in anteroposterior diameter in relation to transverse diameter creates an impression of en bloc breathing in a patient using accessory muscles.

During forced expiration, the interosseous portion of the internal intercostals and the abdominal muscles contract to force air out of the lungs. Forced expiration can be slow and prolonged (as in patients with COPD) or rapid and expulsive (as in a cough). If the abdominal contractions are strong enough, the trunk flexes during exhalation. This flexion further compresses the lungs, forcing more air from them.

Upper Airways

Nose

Noses vary in size and shape among individuals. The nose is composed of bony and cartilaginous parts. The upper one-third is primarily bony and contains the nasal bones, the frontal processes of the maxillae, and the nasal part of the frontal bone. Its lower two-thirds are cartilaginous and contain the septal, lateral, and major and minor alar nasal cartilages. The nasal cavity is divided into right and left halves by the nasal septum. This cavity extends from the nostrils to the posterior apertures of the nose in the nasopharynx. The lateral walls of the cavity are irregular as a result of projecting superior, middle, and inferior nasal chonchae. There is a meatus located beneath or lateral to each choncha through which the sinuses drain. The chonchae increase the surface area of the nose for maximum contact with inspired air. The superior chonchae and adjacent septal wall are referred to as the olfactory region. They are covered with a thin, yellow olfactory mucous membrane consisting of bipolar nerve cells that are olfactory in function. Only a portion of inspired air reaches the olfactory region to provide a sense of smell. When people smell something specific, they sniff. This action lifts the inspired air so that more of it comes into contact with the olfactory region.

The anterior portion (vestibule) of the nasal cavity (Fig. 3-8) is lined with skin and coarse hairs (vibrissae) that entrap inhaled particles. The rest of the cavity and sinuses (with the exception of the olfactory region) are lined with respiratory mucous membrane. This membrane is composed of pseudostratified columnar ciliated epithelium (Fig. 3-9). It contains goblet cells, as well as mucous and serous glands that produce mucus and serous secretions. These secretions entrap foreign particles and bacteria. This mucus is then swept to the nasopharynx by the cilia at a rate of 5 to 15 mm/min, where it is swallowed or expectorated. The mucous membrane is vascular, with arterial blood supplied by branches of the internal and external carotid arteries. Venous drainage occurs through the anterior facial veins. The mucous membrane is thickest over the chonchae. As air is inhaled, it passes around and over the chonchae, whose vascular moist surfaces heat, humidify, and filter the inspired air. The mucous membrane may become swollen and irritated as a result of upper respiratory infections and may secrete copious amounts of mucus. Because this membrane is continuous with sinuses, auditory tubes, and lacrimal canaliculi, people with colds often complain of sinus headaches, watery eyes, earaches, and other symptoms. Secretions can be so copious that the nasal passages become completely blocked.

Pharynx

The pharynx is an oval fibromuscular sac located behind the nasal cavity, mouth, and larynx. It is approximately 12 to 14 cm long and extends from the base of the skull to the esophagus below, at the level of the cricoid cartilage opposite the sixth cervical vertebra. The pharynx has three compartments: the nasal cavity (nasopharynx), mouth (oropharynx), and larynx (laryngopharynx). The pharyngeal walls are lined with ciliated respiratory mucous membrane in the nasal portion and with stratified squamous membrane in the oral and laryngeal parts.

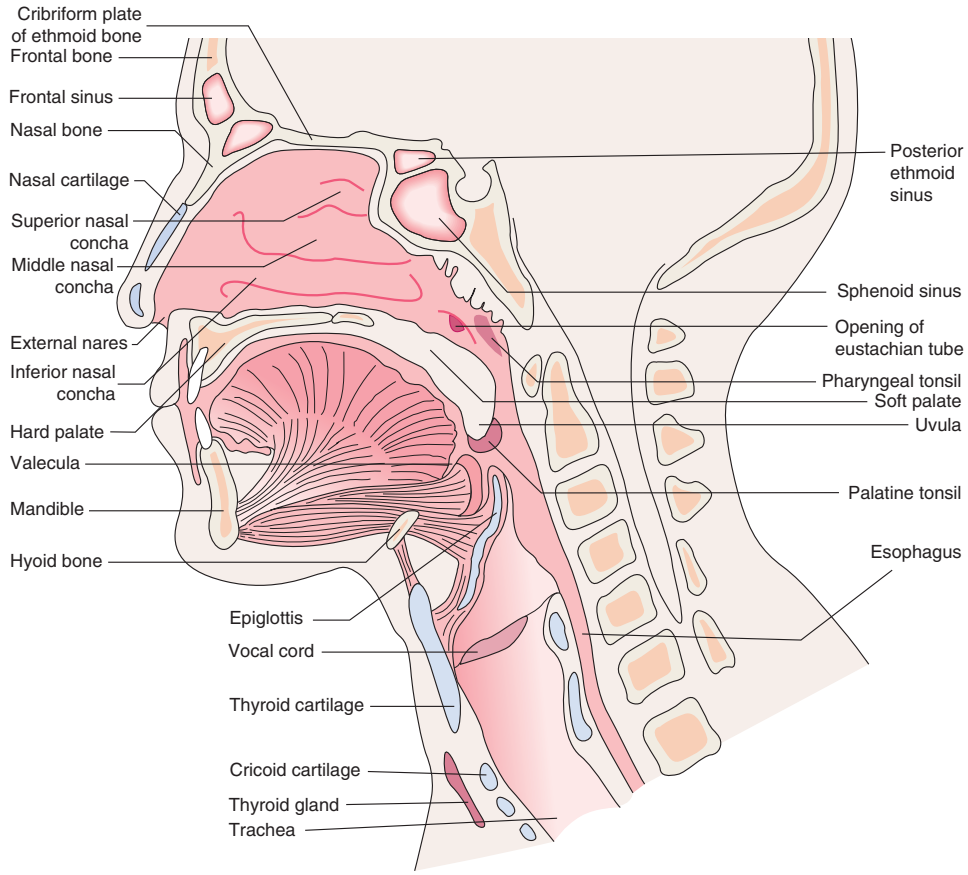

Fig. 3-8 Sagittal section of the head and neck. *(From Hicks GH:* Cardiopulmonary anatomy and physiology, *Philadelphia, 2000, WB Saunders.)*

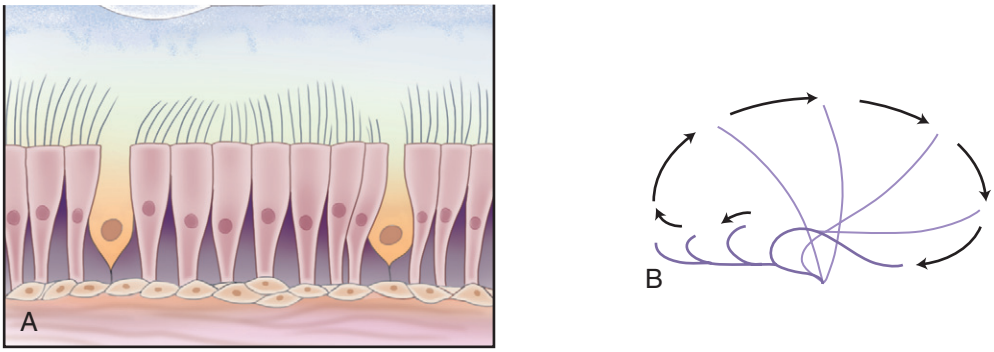

Fig. 3-9 A, Pseudostratified columnar ciliated epithelium. **B,** Normal movements of cilia.

The nasopharynx is a continuation of the nasal cavities (see Fig. 3-8). It lies behind the nose and above the soft palate. With the exception of the soft palate, its walls are immovable, so its cavity is never obliterated as are the oropharynx and laryngopharynx. The nasopharynx communicates with the nasal cavity anteriorly through the posterior apertures of the nose. It communicates with the oropharynx and laryngopharynx through an opening, the pharyngeal isthmus, which is closed by elevations of the soft palate during swallowing.

The oropharynx extends from the soft palate to the epiglottis (see Fig. 3-8). It opens into the mouth anteriorly through the oropharyngeal isthmus. Its posterior walls lie on the bodies of the second and third cervical vertebrae. Laterally, two masses of lymphoid tissue—the palatine tonsils—may be seen. These tonsils form part of a circular band of lymphoid tissue surrounding the opening into the digestive and respiratory tracts.

The laryngopharynx lies behind the larynx and extends from the epiglottis above to the inlet of the esophagus below (see Fig. 3-8). The fourth to sixth cervical vertebrae lie behind the laryngopharynx. In front of the laryngopharynx are the epiglottis, the inlet of the larynx, and the posterior surfaces of the arytenoid and cricoid cartilages.

Larynx

The larynx is a complex structure composed of cartilages and cords moved by sensitive muscles (Fig. 3-10). It is located between the trachea and laryngopharynx, for which it forms an anterior wall. With its rapid closure it acts as a sphincteric valve, preventing food, liquids, and foreign objects from entering the airway. It controls airflow and at times closes so that thoracic pressure may be raised and the upper airways cleared by a propulsive cough when the larynx opens. Expiratory airflow vibrates as it passes over the contracting vocal chords, producing the sounds used for speech. (The larynx is not essential for speech. Humans can speak by learning to dilate the upper part of the esophagus so that air vibrates as it passes over that area; this is called esophageal speech.)

In adult men, the larynx is situated opposite the third, fourth, and fifth cervical vertebrae; it is situated somewhat higher in women and children. The larynx is essentially the same in children, but at puberty, the male larynx increases in size considerably until its anteroposterior diameter has almost doubled. All the cartilages enlarge, and the thyroid cartilage becomes prominent anteriorly.

Vocal cord adductor contraction results in approximation of the vocal cords and narrowing of the glottis. The adductors of the cords are important in protecting the lower airways. Their contraction prevents fluids, food, and other substances from being aspirated. All the intrinsic laryngeal muscles are innervated by the recurrent laryngeal nerve (a branch of the vagus nerve), with the exception of the cricothyroid muscle, which is supplied by the external branch of the superior laryngeal nerve (also a branch of the vagus nerve).

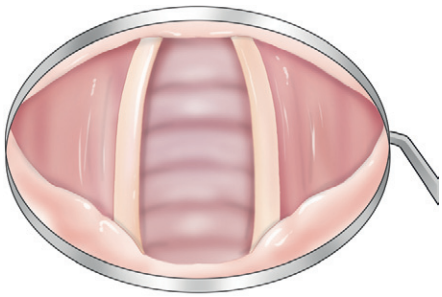

Fig. 3-10 Visualization of the larynx via a laryngoscope.

Lower Airways

Trachea

The trachea is a semirigid cartilaginous tube approximately 10 to 11 cm long and 2.5 cm wide. It lies in front of the esophagus and descends with a slight inclination to the right from the level of the cricoid cartilage (Fig. 3-11; see also Fig. 3-10). It travels behind the sternum into the thorax to the sternal angle (opposite the fifth thoracic vertebra), where it divides to form the right and left main stem bronchi. The tracheal wall is strengthened by 16 to 20 horseshoe-shaped cartilaginous rings. The open parts of the tracheal rings are completed by fibrous and elastic tissue and unstriated transverse muscle. This highly flexible part of the ring is positioned posteriorly. It indents or curves inward during coughing, which increases the velocity of expelled air. The cartilaginous rings lie horizontally one above the other, separated by narrow bands of connective tissue. The trachea is lengthened during hyperextension of the head; during swallowing, which raises the trachea; and during inspiration, when the lungs expand and

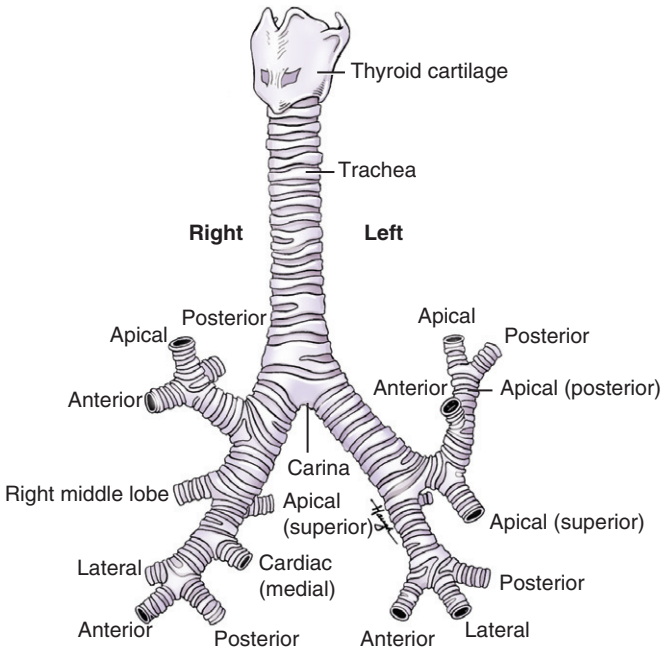

Fig. 3-11 Tracheobronchial tree (a three-quarter view, rotated toward the right side).

pull the trachea downward. Its cross-sectional area becomes smaller with contraction of the unstriated transverse muscle fibers that complete the tracheal rings.

The mucous membrane of the trachea contains columnar ciliated epithelium and goblet cells. Each ciliated epithelial cell contains approximately 275 cilia. These structures beat rapidly in a coordinated and unidirectional manner, propelling a sheet of mucus toward the head, from the lower respiratory tract to the pharynx, where it is swallowed or expectorated. The cilia beat in this layer of mucus with a forceful forward stroke followed by an ineffective backward stroke that returns the cilia to their starting position. Mucociliary escalation propelling of mucus by the cilia toward the upper trachea for clearance, is essential. When cilia are paralyzed by smoking, alcohol, dehydration, anesthesia, starvation, or hypoxia, mucus begins to accumulate in distal, gravity-dependent airways, causing infiltrates and eventually localized areas of lung collapse referred to as atelectasis.

The number of mucus-containing goblet cells is approximately equal to the number of ciliated epithelial cells. Reserve cells lie beneath the ciliated and goblet cells. These reserve cells can differentiate into either goblet cells or ciliated cells. Beneath the reserve cells lie the gland cells. There are approximately 40 times more gland cells than goblet cells. Mucus is composed of 95% water, 2% glycoprotein, 1% carbohydrate, trace amounts of lipid, deoxyribonucleic acid (DNA), dead tissue cells, phagocytes, leukocytes, erythrocytes, and entrapped foreign particles. Mucus lines the airways from the trachea to the alveoli. Two separate layers have been observed: the sol layer, which lies on the mucosal surface and contains high concentrations of water, and the gel layer, which is more superficial and viscous because of its lower concentration of water.

The right main stem bronchus is an extension of the trachea and is wider, shorter, and more vertical than the left main stem bronchus. Greater width and more vertical course cause a majority of aspirated foreign material to pass through the right main stem bronchus. The azygos vein arches over the right main stem bronchus; the right pulmonary artery lies beneath it. The right main stem bronchus divides to form the right upper lobe bronchus, the right middle lobe bronchus, and the right lower lobe bronchus. The right upper lobe divides into three segmental bronchi: apical, posterior, and anterior. The apical bronchus runs almost vertically toward the apex of the lung. The posterior bronchus is directed posteriorly in a horizontal direction, and the anterior bronchus is directed anteriorly in an almost horizontal direction. The right middle lobe bronchus divides about 10 mm below the right upper lobe bronchus and descends anterolaterally. The right lower lobe bronchus divides into five segmental bronchi. The apical or superior bronchus runs almost horizontally, posteriorly. The medial or cardiac bronchus descends medially toward the heart. The anterior basal bronchus descends anteriorly. The lateral basal bronchus descends laterally, and the posterior bronchus descends posteriorly. Each segment describes its anatomic position.

The left main stem bronchus is narrower and runs more horizontally than the right main stem bronchus. The aortic arch passes over it, and the esophagus, descending aorta, and thoracic duct lie behind it. The left pulmonary artery lies anteriorly and above the left main stem bronchus. The left main stem bronchus has two major divisions: the left upper lobe bronchus and the left lower lobe bronchus. The left upper lobe bronchus has three major segmental bronchi. The anterior bronchus ascends at approximately a 45-degree angle. The apical-posterior bronchus has two branches: one runs vertically and the other posteriorly toward the apex of the left lung. The lingular bronchus descends anterolaterally, much the same as does the right middle lobe bronchus of the right lung. The right lower lobe bronchus divides into four segmental bronchi. The superior or apical bronchus runs posteriorly in a horizontal direction. The anterior bronchus descends anteriorly. The lateral bronchus descends laterally, and the posterior bronchus descends posteriorly. The segments describe their anatomic position.

The bronchi of the airways continue to divide until there are approximately 23 generations (Table 3-1). The main, lobar, and segmental bronchi are made up of the first four generations. The walls contain U-shaped cartilage in the main bronchi. This cartilage becomes less well defined and more irregularly shaped as the bronchi continue to divide. In the segmental bronchi, the walls are formed by irregularly shaped helical plates with bands of bronchial muscle. The mucous membrane in these airways is essentially the same as that in the trachea, but the cells become more cuboidal in the lower divisions.

The subsegmental bronchi extend from the fifth to the seventh generation. Although the diameter of these airways becomes progressively smaller, the total cross-sectional area increases because of the increased number of divisions. The mucous membrane is essentially the same, and helical cartilaginous plates and cilia become sparser. These changes continue throughout the 8th to 11th generations, which are referred to as bronchioles.

The terminal bronchioles extend from the 12th to the 16th generation. The diameter of these airways is approximately 1 mm. Cartilage is no longer present to provide structural rigidity. The airways are embedded directly in the lung parenchyma, and it is the elastic properties of this parenchyma that keep these lower airways open. Strong helical muscle bands are present and their contraction forms longitudinal folds in the mucosa that sharply decrease the diameter of the airways. The epithelium of the terminal bronchioles is cuboidal and no longer ciliated. The cross-sectional area of the airways increases sharply at this level. All the airways to this level (generations 1 to 16) are considered conducting airways because their purpose is to transport gas to the respiratory bronchioles and alveoli, where gas exchange occurs. The conducting airways receive their arterial blood from the bronchial circulation (branches of the descending aorta). Airways below this point receive their arterial blood from the pulmonary arteries.

The respiratory bronchioles extend from the 17th to the 19th generation. They are considered a transitional zone between bronchioles and alveoli. Their walls contain cuboidal epithelium interspersed with some alveoli. The number of alveoli increases with each generation. The walls of the bronchioles are also buried in the lung parenchyma. The airways depend on traction of this parenchyma to maintain their lumen. Muscle bands are also present between alveoli.

Alveolar ducts extend from the 20th to the 22nd generation. Their walls are composed entirely of alveoli, which are separated from one another by their septae. Septae contain smooth muscle, elastic and collagen fibers, nerves, and capillaries.

Alveolar sacs make up the 23rd generation of air passages. They are essentially the same as alveolar ducts, except that they

Table 3-1 Structural Characteristics of the Air Passages

	Generation (mean)	Number	Mean Diameter (mm)	Area Supplied	Cartilage	Muscle	Nutrition	Placement	Epithelium
Trachea	0	1	18	Both lungs	U-shaped		From inferior thyroid, thoracic, and branches of bronchial arteries		
Main bronchi	1	2	13	Individual lungs				Within connective tissue sheath alongside arterial vessels	
Lobar bronchi	2 ↓ 3	4 ↓ 8	7 ↓ 5	Lobes	Irregular shape and helical plates	Helical bands	From the bronchial circulation		Columnar, ciliated
Segmental bronchi	4	16	4	Segments					
Small bronchi	5 ↓ 11	32 ↓ 2000	3 ↓ 1	Secondary lobules					
Bronchioles and terminal bronchioles	12 ↓ 16	4000 ↓ 65,000	1 ↓ 0.5			Strong helical muscle bands		Embedded directly in the lung parenchyma	Cuboidal
Respiratory bronchioles	17 ↓ 19	130,000 ↓ 500,000	0.5	Primary lobes		Muscle band between alveolar thin bands in alveolar septa	From the pulmonary circulation		Cuboidal to flat between the alveoli
Alveolar ducts	20 ↓ 22	1,000,000 ↓ 4,000,000	0.3	Alveoli				Lung parenchyma	Alveolar epithelium
Alveolar sacs	23	8,000,000	0.3					Lung parenchyma	Alveolar epithelium

end as blind pouches. Communication occurs between blind pouches in the form of the pores of Kohn, which are channels in alveolar walls, and the Lambert canals, which are communications between bronchioles and alveoli. These communications are thought to be responsible for the rapid spread of lung infection. They also provide collateral ventilation to alveoli whose bronchi are obstructed. Although this ventilation does little to arterialize blood, it does help prevent collapse of these alveoli. Each alveolar sac contains approximately 17 alveoli. There are about 300 million alveoli in an adult man, 85% to 95% of which are covered with pulmonary capillaries. Alveolar epithelium is composed of two cell types. Type I cells, squamous pneumocytes, have broad thin extensions that cover about 95% of the alveolar surface. Type II cells, the granular pneumocytes, are more numerous than type I cells but occupy less than 5% of the alveolar surface. This is because of their small, cuboidal shape. These cells are responsible for the production of surfactant, a phospholipid that lines the alveoli. Surfactant keeps alveoli expanded by lowering their surface tension. Type II cells have been shown to be the primary cells involved in repair of the alveolar epithelium. Type III cells, alveolar brush cells, are rare and found only occasionally in humans.

An additional type of cell, the alveolar macrophage, is found within the alveoli. These cells are thought to originate from stem cell precursors in the bone marrow and reach the lung through the blood stream. They are large, mononuclear, ameboid cells that roam in the alveoli, alveolar ducts, and alveolar sacs. Macrophages contain lysosomes, which are capable of killing engulfed bacteria. They are especially effective in neutralizing inhaled gram-positive organisms. They also engulf foreign matter and are transported to the lymphatic system or migrate to the terminal bronchioles, where they attach themselves to the mucus. Macrophages are carried by the mucus to larger airways and eventually to the pharynx. Because cilia are not present below the 11th generation of air passages, clearance of foreign matter and bacteria from these areas is largely dependent on macrophages.

Other cells located in the distal airways that are important in the defense of the lung are the lymphocytes and polymorphonuclear leukocytes. Immunoglobulins (IgA, IgG, and IgM) in the blood serum enhance the engulfing activity of the macrophages. Two types of lymphocytes are found in the lung: the B lymphocyte and the T lymphocyte. The B lymphocytes produce gamma globulin antibodies to fight lung infections, whereas the T lymphocytes release a substance that attracts macrophages to the site of the infection. The polymorphonuclear leukocytes are important in engulfing and killing blood-borne gram-negative organisms.

Lungs

Two lungs (each covered with its pleurae—the visceral pleura and the parietal pleura), lie within the thoracic cavity. Each lung is attached to the heart and the trachea by its root and the pulmonary ligament. The lungs are otherwise free in the thoracic cavity. The lungs are light, soft, spongy organs whose color darkens with age as they become impregnated with inhaled air pollutants. They are covered with the visceral pleura, a thin, glistening serous membrane that covers all surfaces of the lungs. The visceral pleura extends to the mediastinum and inner thoracic wall, where it becomes known as the parietal pleura. The space between the two pleurae maintains a negative pressure at all times and is therefore termed a potential space. This negative pressure maintains lung inflation. A small amount of pleural fluid lubricates the two pleurae as they slide over each other during breathing. In disease, fluid, tumor cells, or air can invade the pleural space and collapse the underlying lung.

Each lung has an apex, a base, and three surfaces (costal, medial, and diaphragmatic). There are also three borders (anterior, inferior, and posterior). Each lung is divided by fissures into separate lobes. In the right lung, the oblique fissure separates the lower lobe from the middle, whereas the horizontal fissure separates the upper lobe from the middle. The right lung is heavier and wider than the left lung. It is also shorter because of the location of the right lobe of the liver. The left lung is divided into upper and lower lobes by the oblique fissure. It is longer and thinner than the right lung because the heart and pericardium are located in the left thorax. Numerous structures enter the lung at the hilus, or root of the lung, including the main stem bronchus, the pulmonary artery, pulmonary veins, bronchial arteries and veins, nerves, and lymph vessels. The root, or hilus, of the lungs lies opposite the bodies of the fifth, sixth, and seventh thoracic vertebrae. The lungs are connected to the upper airways by the trachea and main stem bronchi.

Surface Markings

Surface markings of the lungs can be outlined on the chest with a basic knowledge of bony landmarks and of the gross anatomy of each lung (Table 3-2 and Fig. 3-12). The apices of both lungs extend 2 or 3 cm above the clavicles at the medial ends. The anteromedial border of the right lung runs from the sternoclavicular joint to the sternal angle and downward to the xiphisternum. The inferior border runs from the xiphisternum laterally to the sixth rib in the midclavicular line, the eighth rib in the midaxillary line, and the 10th rib in the midscapular line. The midscapular line runs downward from the inferior angle of the scapula with the arm at rest. The inferior border joins the posterior medial border of the lung 2 cm lateral to the tenth thoracic vertebra. The posterior medial border runs 2 cm lateral to the vertebral column from the seventh cervical vertebra to the tenth thoracic vertebra.

The left lung is generally smaller than the right and accommodates the position of the heart. The medial border on the anterior aspect runs from the sternoclavicular joint to the middle of the sternal angle, down the midline of the sternum to the fourth costal cartilage. A lateral indentation of about 2 to 3 cm forms the cardiac notch at the level of the fifth and sixth costal cartilages. The courses of the inferior and medial borders on the posterior aspect are similar in the left and right lungs. In the left lung, however, the inferior border crosses at the level of the 10th thoracic vertebra, not the 12th, as is observed in the right lung.

The position of the fissures of the lungs can be outlined over the chest wall. In both lungs, the oblique fissure begins between the second to fourth thoracic vertebrae. This can be roughly estimated by following a line continuous with the medial border of the abducted scapula around the midaxillary line at the fifth rib and terminating at the sixth costal cartilage anteriorly. The horizontal fissure of the right lung originates

Table 3-2 **Anatomic Arrangement of the Bronchopulmonary Segments**

Lobe	Right Lung: Bronchopulmonary Segments	Lobe	Left Lung: Bronchopulmonary Segments
Upper	Apical: Extends above the clavicle anteriorly; smaller area posteriorly Anterior: Occupies area between the clavicle and horizontal fissure Posterior: Remainder of upper lobe on the posterior aspect down to the oblique fissure	Upper	Apical posterior: Extends above the clavicle anteriorly; occupies area comparable to that of the apical and posterior segments of the right lung Anterior: Occupies area between the clavicle and the border of the lingula (line comparable to the horizontal fissure of the right lung)
Middle	Lateral: Extends medially from junction of the two fissures at the third intercostal space to occupy one-third of the anterior surface of the lobe Medial: Occupies the remaining anterior surface of the lobe	(Lingula)‡	Superior: Occupies upper half of the lingula Inferior: Occupies lower half of the lingula
Lower (Base)	Anterior: Occupies basal area beneath the oblique fissure anteriorly Superior: Occupies half the area from the oblique fissure downward* on the posterior aspect Lateral: Extends from the junction of the middle lobe over the midaxillary area to occupy one-third the area inferior to the superior segment on the posterior aspect Posterior: Occupies two-thirds of the area posteriorly beneath the superior segment Medial: Occupies a space on the inner aspect of the right base†	Lower (Base)	Anterior: Occupies area inferior to the oblique fissure anteriorly Superior: Occupies one-third of the basal area posteriorly from the oblique fissure downward Lateral: Occupies the lateral half of the remaining two-thirds of the left lower lobe beneath the superior segment on the posterior aspect Posterior: Occupies the medial portion of the remaining two-thirds of the left lower lobe beneath the superior segment on the posterior aspect

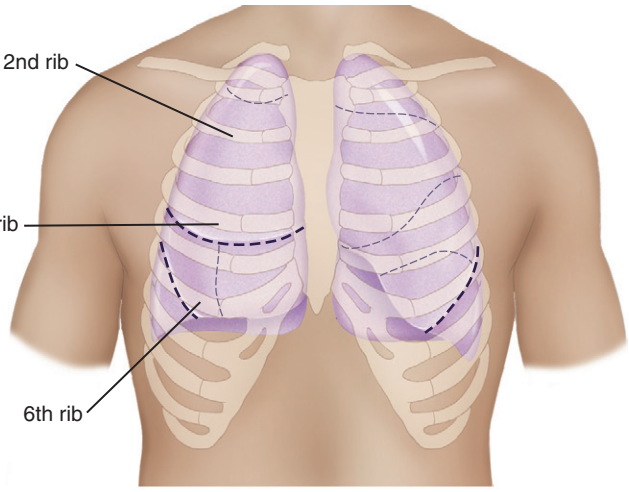
*This segment is best drained when the patient lies prone. Superior segments also called apical segments.

†Medial basal segment has no direct exposure to the chest wall; therefore it cannot be directly auscultated. This segment is best drained when the patient is positioned for the left lateral basal segment because of the comparable angle of its bronchus.

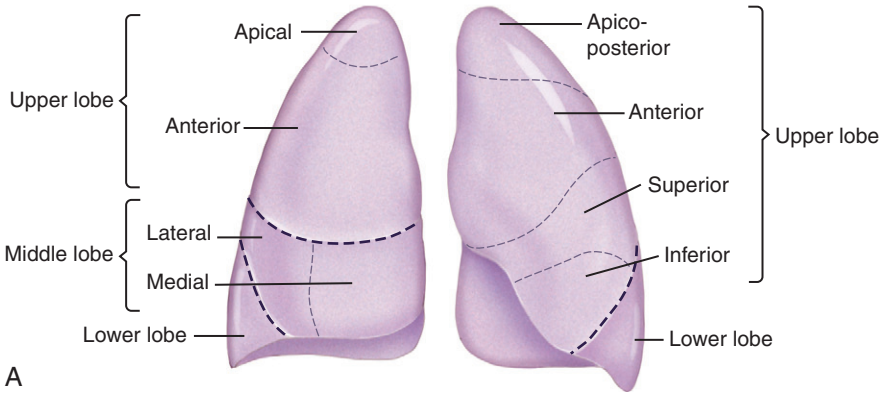
‡Lingula is not an area that is anatomically distinct from the right middle lobe; rather, it is anatomically part of the left upper lobe.

from the oblique fissure at the level of about the fourth intercostal space in the midaxillary line and courses medially and slightly upward over the fourth rib anteriorly. The left lung has no horizontal fissure.

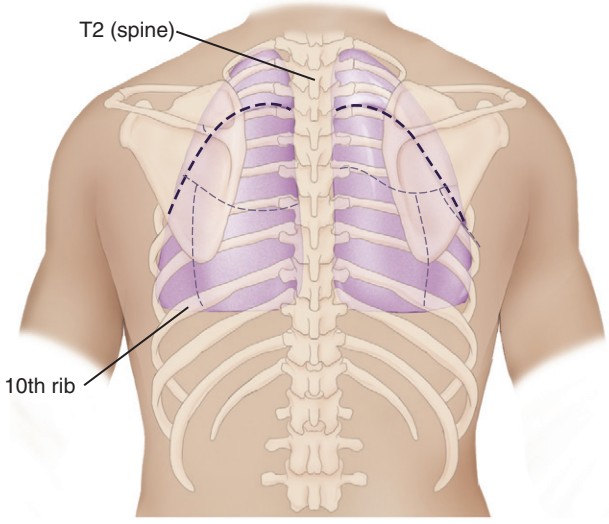
Bronchopulmonary Segments



The bronchopulmonary segments lie within the three lobes of the right lung and the two lobes of the left lung. There are 10 bronchopulmonary segments on the right and 8 on the left. Brief anatomic descriptions of the position of each lobe are provided in Table 3-2. Figure 3-12, *A*, illustrates the surface markings on the anterior view of the lungs and the position of the various bronchopulmonary segments within the major anatomic divisions provided by the fissures. Figure 3-12, *B*, shows some of these features from the lateral views. Figure 3-12, *C*, illustrates the surface markings and bronchopulmonary segments of the posterior aspect of the lungs.



Heart



The heart is a conical, hollow muscular pump enclosed in a fibroserous sac, the pericardium. Its size is closely related to body size and corresponds remarkably to the size of an individual's clenched fist. It is positioned in the center of the chest behind the lower half of the sternum. The largest portion of the heart lies to the left of the midsternal line; the apex is found approximately 9 cm to the left, in the fifth intercostal space.

The surface markings of the heart can be traced by joining four points over the anterior chest wall. On the right, the heart extends from the third to the sixth costal cartilage at a distance of about 10 to 15 mm from the sternum. On the left, the heart extends from the second costal cartilage to the fifth intercostal space, 12 to 15 mm and 9 cm from the left sternal border, respectively. Joining the two points on the left side outlines the left atrium and ventricle. The heart is rotated to the left in the chest, so the right side of the heart is foremost. Joining the two uppermost points outlines the level of the atria, and joining the two lower points represents the margin of the right ventricle.

The heart as a whole is freely movable within the pericardial cavity and changes position during both contraction and respiration. During contraction, the apex moves forward, strikes the chest and imparts the chest-and-apex beat, which may be felt and seen. Abnormal positioning of the apex beat can indicate cardiac enlargement or displacement. During breathing, the movements of the diaphragm determine the position of the heart. This is because of the attachment of the central tendon of the diaphragm to the pericardium. Changes in position during quiet breathing are hardly noticeable, but with deep inspirations, the downward excursion of the diaphragm causes the heart to descend and rotate to the right. The opposite occurs during expiration. Pathology of the lungs can also change the position of the heart. Atelectasis shifts the heart to

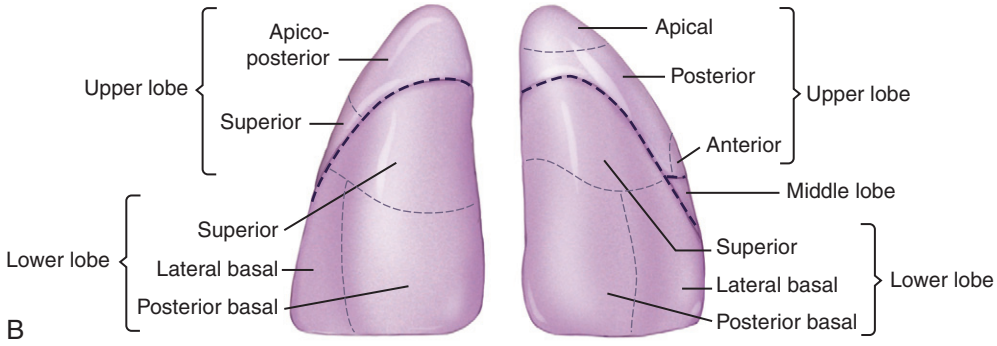


Fig. 3-12 Surface markings of the lungs (anterior **[A],** posterior **[B],** and lateral **[C]** aspects). The underlying bronchopulmonary segments are also shown. *(Modified from Cherniak RM, Cherniack L*: Respiration in health and disease, *ed 3, Philadelphia, 1983, WB Saunders.)*

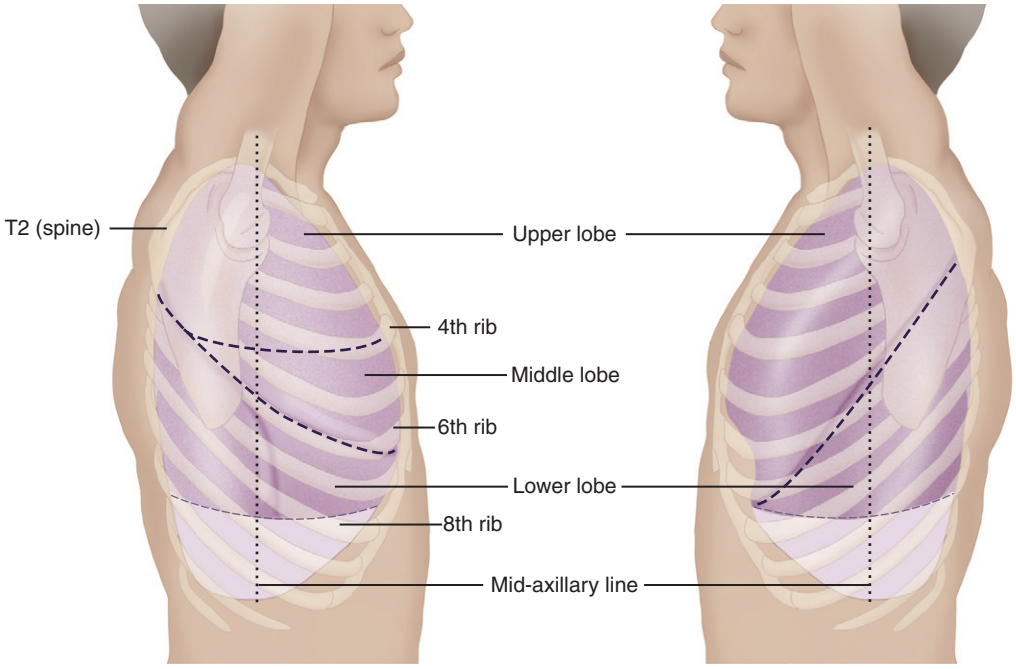

Fig. 3-12, cont'd

the same side. In tension pneumothorax, where air enters the chest (usually through an opening in the chest wall) and cannot escape, the positive pressure shifts the heart away from the side of the pathology.

The heart is enclosed by the pericardium, whose two surfaces can be visualized by visualizing the heart as a fist plunged into a large balloon. The outer surface, a tough fibrous membrane, is called the fibrous pericardium. It encases the heart as well as the organs and terminations of the great vessels. This membrane is so unyielding that when fluid accumulates rapidly in the pericardial cavity, it can compress the heart and impede venous return. When this occurs often, a window is cut in the pericardium, allowing the fluid to escape. The inner surface, the serous pericardium, is a serous membrane that lines the fibrous pericardium. Between 10 and 20 mL of clear pericardial fluid separates and moistens the two pericardial surfaces. The pericardium, with its fluid, minimizes friction during contraction. It also holds the heart in position and prevents dilation. The serous pericardium consists of an outer layer (the parietal layer) and an inner layer (the visceral layer or epicardium).

The heart is divided into right and left halves by an obliquely placed longitudinal septum (Fig. 3-13, *A*). Each half has two chambers: the atrium, which receives blood from veins, and the ventricle, which ejects blood into the arteries. The superior vena cava, inferior vena cava, and intrinsic veins of the heart deposit venous blood into the right atrium. Blood then passes through the tricuspid valve to the right ventricle. The right ventricle ejects the blood through the pulmonary valve into the pulmonary arteries, which are the only arteries in the body that contain deoxygenated blood. Pulmonary veins return the blood to the left atrium, and from there it passes through the mitral valve to the left ventricle. From the left ventricle it is ejected through the aortic valve into the main artery of the body, the aorta.

The heart is divided into three layers: the epicardium, myocardium, and endocardium. The outermost layer, the epicardium, is visceral pericardium and is often infiltrated with fat. The coronary blood vessels that nourish the heart run in this layer before entering the myocardium. The myocardium consists of cardiac muscle fibers. The thickness of the layers of cardiac muscle fibers is directly proportional to the amount of work they perform. The ventricles do more work than the atria; hence their walls are thicker. The pressure in the aorta is higher than that in the pulmonary trunk. This requires greater work from the left ventricle, so its walls are twice as thick as those of the right ventricle. The innermost layer, the endocardium, is the smooth endothelial lining of the interior of the heart.

Heart Valves

The four valves of the heart, although delicate in appearance, are designed to withstand repetitive closures against high pressures. Normally, they operate properly for more than 80 years without need of repair or replacement. The tricuspid and mitral valves function differently from the other valves of the heart. Being located between the atria and ventricles, they must effect a precise closure within a contracting cavity.

During diastole, the two leaflets or cusps of the mitral valve and the three cusps of the tricuspid valve relax into the cavities of the ventricles, allowing blood to flow between the two chambers. As the ventricular chambers fill with blood, the cusps of the valves are forced up into a closed position. Fibrous cords, the chordae tendinae, are located on the ventricular surfaces of these cusps. These cords connect the cusps of the valve with the papillary muscles of the ventricular walls. As pressure builds in the ventricular chambers, contraction of these muscles prevents the cusps from being forced up into the atria. Dysfunction or rupture of the chordae tendinae or

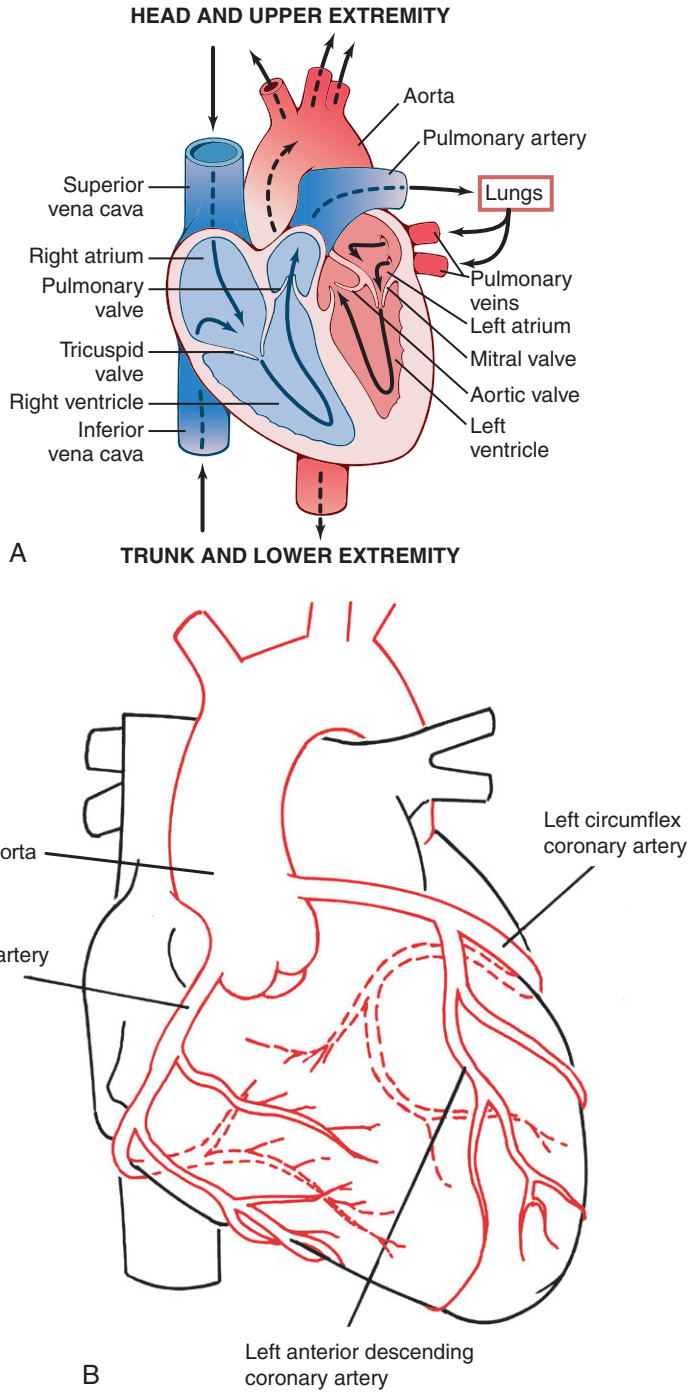

Fig. 3-13 Blood flow through the heart. **A,** The three major coronary arteries that supply blood to the heart. **B,** Blood flow through internal structures. (***A,*** *from Hall J:* Guyton and Hall textbook of medical physiology, *ed 12, Philadelphia, 2011, Saunders.* ***B,*** *from Goldberger:* Clinical electrocardiography: a simplified approach, *ed 7, Philadelphia, 2009, Mosby.)*

the papillary muscles may undermine the support of one or more valve cusps, producing regurgitation from the ventricles to the atria.

The pulmonic and aortic valves are similar in appearance, but the aortic cusps are slightly thicker than the pulmonic cusps. Each valve has three fibrous cusps, the bases of which are firmly attached to the root of the aorta or the pulmonary artery. The free edges of these valves project into the lumen of the vessels. At the end of systole, blood in the aorta and pulmonary artery forces the cusps of the valves shut. These valves are attached in such a manner that they cannot be everted into the ventricles by increased pressure in the vessels. During diastole, the cusps support the column of blood filling the ventricles. Contraction of the ventricles during systole increases pressure within the ventricular chambers, forcing the cusps to open and allow blood flow into the vessels.

The arterial supply of the heart muscle is derived from the right and left coronary arteries, which arise from the aortic

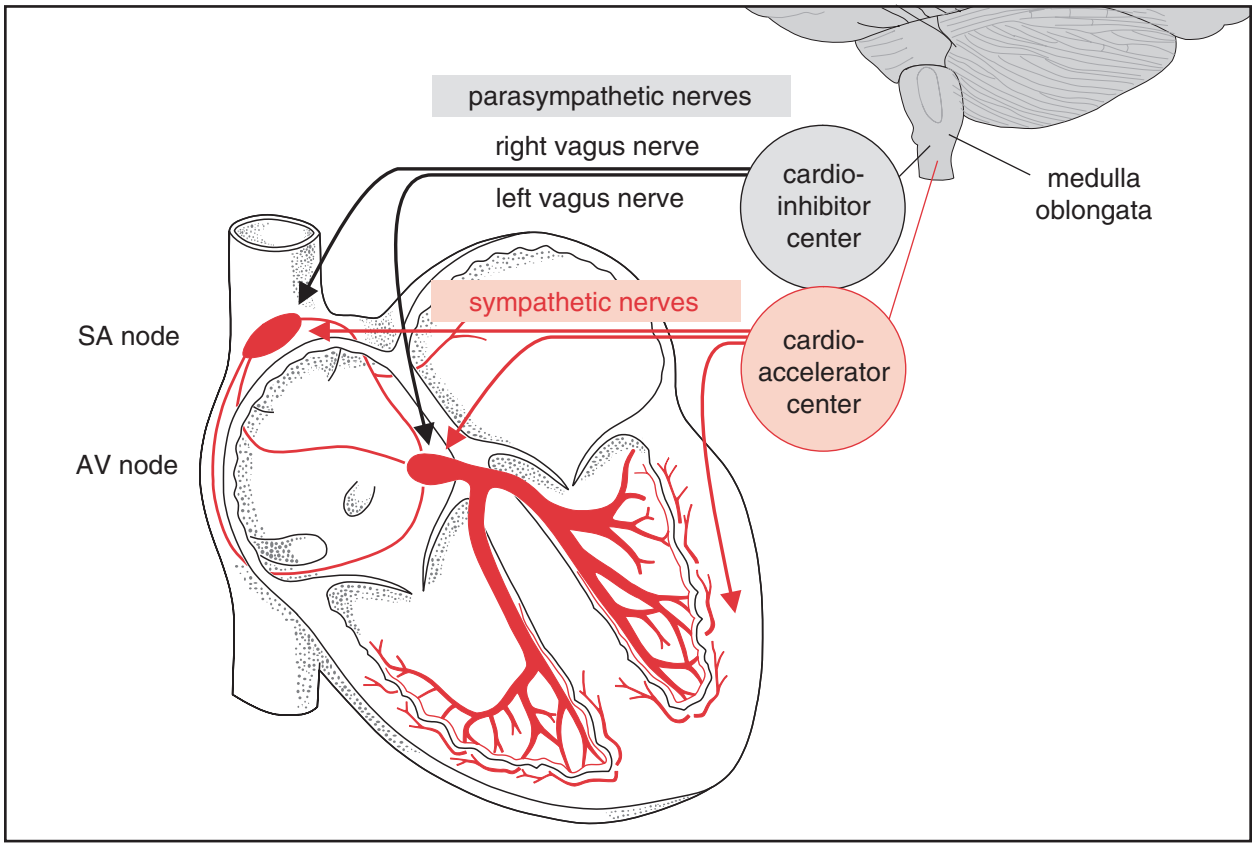

Fig. 3-14 Sympathetic and parasympathetic innervation of the heart. *(From Huszar RJ:* Basic dysrhythmias: interpretation and management*, ed 3, Philadelphia, 2007, Mosby.)*

sinuses (Fig. 3-13, *B*). The left coronary artery (LCA) divides into the anterior descending artery and the left circumflex artery. These arteries supply most of the left ventricle, the left atrium, most of the ventricular septum, and in 45% of people, the sinoatrial (SA) node. The right coronary artery (RCA) supplies most of the right ventricle, the atrioventricular (AV) node, and in 55% of people, the SA node. Infarction of these arteries or their branches can cause interruption or cessation of the conduction system and death of the myocardial muscle in the area supplied by the artery. The severity of the infarction is dependent on the size of the artery and the importance of the area it supplies.

The heart is drained by a number of veins. Most of the veins of the heart enter the coronary sinus, which then empties into the right atrium. A small number of veins, the thebesian veins, empty directly into the right and left ventricles.

Innervation

Innervation of the heart involves a complex balance between its intrinsic automaticity and extrinsic nerves (Fig. 3-14). The SA and AV nodes provide the heart with an inherent ability for spontaneous rhythmic initiation of the cardiac impulse. The rate of this impulse formation is regulated by the autonomic nervous system (ANS), which also influences other phases of the cardiac cycle. It controls the rate of spread of the excitation impulse and the contractility of both atria and ventricles.

The ANS extends its influence to the heart via the vagus nerve (parasympathetic) and upper thoracic nerves (sympathetic). These nerves mingle around the root and arch of the aorta near the tracheal bifurcation, forming the cardiac plexus. Extensions from the cardiac plexus richly supply the SA and AV nodes. They are so well mingled that scientists are unable to determine which nerves supply which parts of the heart. Stimulation of the sympathetic nervous system causes acceleration of the discharge rate in the SA node, an increase in AV nodal conduction, and an increase in the contractile force of both atrial and ventricular muscles. Stimulation of the vagus nerve causes cardiac slowing and decreased AV nodal conduction. Thus the parasympathetic system decelerates heart rate, and the sympathetic system accelerates heart rate.

Intrinsic innervation of the heart centers around the SA node, which lies near the junction of the superior vena cava and the right atrium. It is the normal pacemaker of the heart, sending concentric waves of excitation throughout the atrium. Without neural influence, impulse formation from this node would be greater than 100 beats per minute. Vagal influence, however, decreases the impulse formation to 60 to 90 beats per minute. The SA node paces the heart as long as it generates impulses at a faster rate than any other part of the myocardium and as long as these impulses are rapidly conducted from the atria to the ventricles. Normal impulse formation may be interrupted by vascular lesions (occlusion of the coronary arteries) or by cardiac disease (pericarditis). The SA node is especially susceptible to pericarditis and all other surface

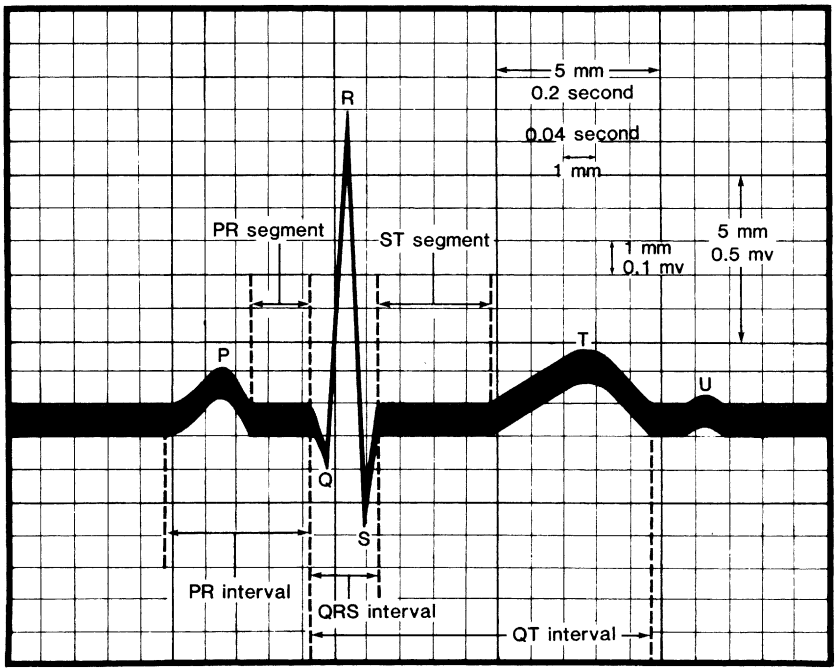

Fig. 3-15 A normal ECG showing characteristic waves, intervals, and segments.

cardiac diseases because of its superficial position immediately beneath the epicardium.

The muscle fibers of the heart are self-excitatory, which enables the heart to contract rhythmically and automatically. The normal pacemaker of the heart, the SA node, is located in the posterior wall of the right atrium. The concentric waves of excitation sent out by the SA node must travel through the AV node to reach the ventricles. This node is located in the floor of the right atrium, just above the insertion of the tricuspid valve. Its main function is to cause a 0.04-second delay in impulse transmission. This delay is beneficial for two reasons: it postpones ventricular excitation until the atria have had time to eject their contents into the ventricles, and it limits the number of signals that can be transmitted by the AV node. The AV node also has its own inherent rhythmicity, firing at a much slower rate than the SA node (40 to 60 beats per minute). Its main pathology is a result of occlusion of the right coronary artery, which supplies the AV node in 90% of cases. From the AV node arises a triangular group of fibers known as the AV bundle, or bundle of His. This bundle divides in the ventricular septum into two branches: the left bundle branch and the right bundle branch. Each of these bundles continues to divide into many fine nerve fibers that spread throughout the ventricles and terminate in the Purkinje fibers, which are continuous with the cardiac muscle. The waves of excitation pass through the bundle of His, down the bundle branches, and through the Purkinje fibers, which permeate the ventricles and cause them to contract. This wave of depolarization gives rise to the normal P-QRS-T configuration of the electrocardiogram (ECG) tracing (Fig. 3-15) (see Chapter 12). The P wave indicates atrial depolarization, the QRS complex indicates ventricular depolarization, and the T wave indicates ventricular repolarization. There is no wave indicating atrial repolarization because atrial repolarization is embedded in the QRS complex[13,15] (see Physiology of the Electrical Excitation of the Heart and ECG Interpretation, Chapter 12).[14,15]

Systemic Circulation

The systemic vascular system is a complex series of branching blood vessels throughout the body. It provides nutrition and oxygen to, and removes waste products from, all tissues of the body. The driving force for this system is the heart. The vascular system has two major components: the peripheral and the pulmonary circulations.[5]

Blood vessels are designed to forward oxygenated blood from the heart during systolic ejection from the left ventricle, perfuse the vascular beds commensurate with their metabolic needs, and remove metabolic waste. Anatomically, the proximal vessels have a higher proportion of connective tissue and elastin so as to withstand high pulse pressures (e.g., the aorta, which carries blood to the head, viscera, and limbs). In addition, potential energy is stored in the walls of the larger vessels during systole. During diastole, the elastic recoil of these vessels maintains the forward motion of the blood between ventricular systoles. The medium-size blood vessels have proportions of connective tissue and elastin comparable to smooth muscle. As the blood vessels become smaller, smooth muscle predominates. The arterioles are primarily smooth muscle, so their diameter can alter significantly. They regulate the blood flow to regional tissue beds and are also responsible for regulating total peripheral resistance and systemic blood pressure. They are called the stopcocks of the circulation. Many factors (e.g., nervous impulses, hormonal stimulation, drugs, oxygen, and carbon dioxide concentrations) determine the degree of contraction of vascular smooth muscle and whether contraction occurs locally or throughout the entire body.

Arterioles branch to form the smallest vessels, capillaries, which consist of a single layer of endothelial cells forming lumen just large enough for red blood cells to pass. The capillary bed is enormous, with a capacity far exceeding 5 L. In active tissue such as muscle and brain, the capillary network

is finer and denser; the network is less dense in less active tissue such as tendon. Gas exchange occurs in the capillary bed, where red blood cells give up their oxygen and blood plasma transudes capillary walls, carrying nutrition to tissue.

The microcirculation specifically consists of the metarterioles, the capillary bed, and the venules. The capillary wall is a semipermeable membrane that is responsible for the transfer of oxygen, nutrients, and waste between the circulation and tissue via the interstitial fluid (see Chapters 2 and 4). The capillary pores selectively allow molecules of different size to pass through them. This is an essential feature that regulates the movement of fluid in and out of the intravascular and extravascular compartments. This process is fundamental to maintaining and regulating normal hemodynamics.

Capillaries give rise to the venules, which are the smallest veins. These veins branch and become increasingly larger. Blood flow through the veins is largely dependent on muscular or visceral action or pressures. These pressures are intermittent and, were it not for double-cusp valves located within the veins, blood would flow backward with fluctuation in the pressure gradient and cessation of flow. In the extremities, muscular contractions move blood into the trunk. In the pelvic and abdominal region, blood flow is dependent on intraabdominal pressure exceeding intrathoracic pressure. Veins in the trunk become increasingly larger until they finally enter the superior and inferior vena cavae.

Pulmonary Circulation

The vena cavae empty directly into the right atrium. Blood flow from the right side of the heart through the lungs is known as pulmonary circulation. The quantity of blood flowing through pulmonary circulation is approximately equal to that flowing through systemic circulation. Blood flows from the right ventricle into the pulmonary artery, which divides into right and left branches 4 cm from the ventricle. These branches then separate, one to each lung, where they continue to divide into smaller arteries. The pulmonary arteries and arterioles are much shorter, have thinner walls and larger diameters, and are more distensible than their systemic counterparts. This gives the pulmonary system compliance as great as that of the systemic arterial system, thereby allowing the pulmonary arteries to accommodate the stroke volume output of the right ventricle. Pulmonary vascular resistance and arterial pressure are one-sixth that of the systemic system (pulmonary arterial pressure is 20/10 mm Hg compared with 120/80 mm Hg systemically).

Pulmonary capillaries are short and arise abruptly from larger arterioles. They form a dense network over the walls of the alveoli to minimize the distance over which gas exchange occurs. The pulmonary veins are also very short but have distensibility characteristics similar to those of veins in the systemic system. Unlike systemic veins, however, pulmonary veins have no valves. Pulmonary veins act as a capacitance vessel, or a blood reservoir, for the left atrium. Contraction of smooth muscle in the veins makes the reservoir constrict. This increases blood volume in relation to the internal volume of the vessels. The pulmonary veins become larger until they converge into two veins from each lung, which then carry oxygenated blood to the left atrium.

Lymphatic Circulation

The lymphatic circulation provides an additional route for fluid to be returned from the interstitium to the systemic circulation and thus has a central role in the regulation of interstitial fluid dynamics. Lymph, the fluid that flows in the lymphatic channels, is interstitial fluid with a composition similar to that of tissue fluid. The vessels of the lymphatic system move excess fluid, large proteins, and other large molecules away from the interstitial spaces. Although relatively little protein leaks from the capillaries into the surrounding tissue, the absence of its immediate removal is life threatening.

Virtually all areas of the body drain into a network of lymphatic channels. From the lower portion of the body and from the left head and neck, excess tissue fluid and protein drain into the thoracic duct, which empties into the venous circulation at the junction of the left internal jugular vein and the subclavian vein. Lymph from the right side of the head, neck, arm, and parts of the right thorax drain into the right lymph duct, which empties into the venous circulation at the junction of the right internal jugular vein and the subclavian vein. Lymph from the lower part of the body drains into the inguinal and abdominal lymphatic channels. The pressure in the lymphatic system is usually slightly negative, which helps to keep the interstitium "dry." The lymph vessels are thin walled and have some smooth muscle, so they can contract to propel their contents. In addition, lymph vessels have valves to facilitate forward motion and minimize retrograde movement of lymph.

Summary

This chapter reviews the anatomy of the cardiovascular and pulmonary systems. The anatomic features of the respiratory pump are described with respect to the structures of the bony thorax, of the muscles of respiration associated with the chest wall, and of the diaphragm. The upper and lower respiratory tracts are described, as is the relationship of the tracheobronchial tree to the lung parenchyma. The lung parenchyma is defined anatomically in terms of discrete bronchopulmonary segments contained within three major divisions of each lung. The specific surface markings defined by the lung fissures and the landmarks of the bronchopulmonary segments are outlined. The basic anatomy of the heart is described. The structures of the peripheral and pulmonary circulations are also presented. Special reference is made to the lymphatic circulation and its central role in the regulation of capillary fluid dynamics. A detailed understanding of cardiovascular and pulmonary anatomy is fundamental to the knowledge base underlying the assessment and management by physical therapists of cardiovascular and pulmonary dysfunction and impaired oxygen transport.

Review Questions

1. Describe the cardiovascular and pulmonary unit and why it is a more useful classification than describing either the heart or lungs separately.
2. Describe the thorax and its movements.

3. Describe the respiratory muscles and their functions.
4. Explain the pathway of oxygen from the atmosphere to the alveolar capillary membrane.
5. Describe the movement of blood returning from the periphery through the heart to the pulmonary and peripheral circulations.
6. Describe the movement of deoxygenated blood from the periphery back to the heart.
7. Explain the role of the lymphatic circulation and its physiological significance.
8. Describe the interdependence between the lungs and the heart in relation to its clinical implications.

This chapter reviews basic cardiovascular and pulmonary physiology. A thorough understanding of normal physiology provides a basis for understanding the deficits in cardiovascular and pulmonary function (in the context of limitation of activity and social participation, as well as structure and function) and the adaptations to changing physiological and pathophysiological demands. This knowledge provides the foundation for conducting a thorough assessment and prescribing treatment.[1-8]

Cardiovascular Physiology

Control of the Heart

The mechanical activity of the heart is precisely regulated in accordance with the electrical activity of the heart to effect optimal cardiac output to the organs of the body.[9,10] The electrical activity of the heart, based on electrocardiography, in both health and pathology, is described in detail in Chapter 12. The electrical and mechanical events of the cardiac cycle and their coupling (electromechanical coupling) are summarized in Figure 4-1. These events include the spread of the wave of electrical excitation throughout the myocardium; the resulting sequence of contraction of the atria and ventricles, followed by dynamic changes in blood pressure and volume in the heart chambers; the heart sounds; and the timing of these events. The cardiac cycle takes 0.8 second in a heart beating at 75 beats per minute. Ventricular systole or ejection takes about one-third of this time. Its onset and termination are marked, respectively, by the closing and opening of the atrioventricular valves (mitral and tricuspid). Diastole, or the period between successive ventricular systoles, in which the ventricles fill with blood, takes two-thirds of the 0.8 second of each cardiac cycle.

Phases of Systole and Diastole

Ventricular systole normally has three phases: the isovolumetric contraction period, the rapid ejection period, and the slower ejection period. Ventricular diastole also has three phases: the passive rapid-filling phase, the slower filling phase (diastasis), and the active rapid-filling phase.

Note the relationship between ventricular pressure and volume: *a,* closure of the atrioventricular valves; *b,* opening of the semilunar valves; *c,* closure of the semilunar valves; *d,* opening of the atrioventricular valves.

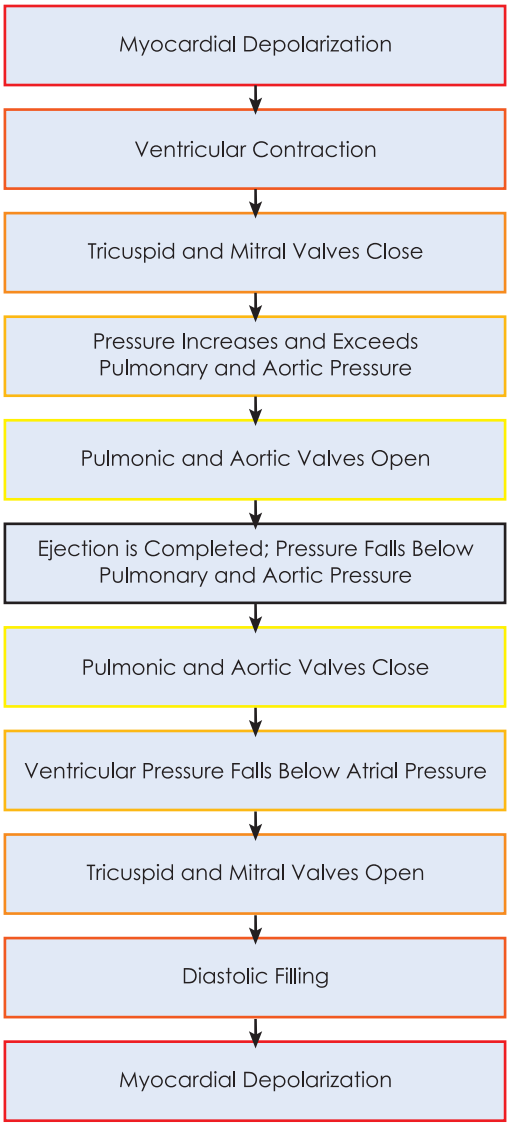

Fig. 4-2 The sequence of pressure changes in the heart during the cardiac cycle.

Cardiac Reflexes

The heart behaves automatically and is therefore termed a functional syncytium. Three primary reflexes enable the heart to increase stroke volume and cardiac output with moment-to-moment changes in myocardial demand.

The first reflex is the Starling effect, which refers to the increased force of contraction that occurs with increased venous return (preload). The second reflex, the Anrep effect, refers to the increase in ventricular contractile force as a result of an increase in aortic pressure (afterload). The third reflex, the Bowdich effect, refers to the corresponding increase in heart rate when myocardial contractile force increases. The integrated function of these three reflexes ensures that cardiac output adjusts as demands on the heart change (i.e., in healthy individuals, primarily in response to exercise, body position, and emotional stress).

Volume and Pressure Changes

Changes in the ventricular volume curve and aortic pressure wave reflect changes in atrial and ventricular pressures during systole and diastole. The sequence of events appears in a flow chart in Figure 4-2. Pressure gradients within the heart are responsible for the opening and closing of the valves. Coordinated valve opening and closure are important to promote the forward movement of blood and prevent mechanical inefficiency of the heart pump resulting from valvular regurgitation of blood during ventricular contraction. Regurgitation of blood in the retrograde direction gives rise to heart murmurs that are audible on auscultation of the heart.

Heart Sounds

The heart sounds are described as a low-pitched, long-duration sound (S_1) followed by a higher pitched, slower duration sound (S_2) that resembles the phonic sounds of LUB-dub. S_1 is associated with the closure of the atrioventricular valves. S_2 is associated with the closure of the semilunar valves. In inspiration, the aortic valve closes several milliseconds before the pulmonic valve, resulting in a splitting of the second heart sound, S_2. During inspiration, intrathoracic pressure becomes more negative, and venous return and right heart volume

increase; hence pulmonary ejection is prolonged in this situation, and closure of the pulmonary valve is delayed. Other variations in splitting of S_2 occur with pathology. The presence of a third (S_3) or fourth (S_4) heart sound is usually considered abnormal. S_3 is usually associated with the passive rapid-filling phase and S_4 with the active rapid-filling phase.

Peripheral Circulation

The purpose of the peripheral circulation, including the microcirculation at the tissue level, is to provide saturated oxygenated blood and remove partially desaturated blood. The microcirculation within each organ regulates the blood flow both exogenously, via the neurological system, and endogenously, via the humoral system, commensurate with the metabolic needs of that tissue bed (see Chapter 3). The four principal factors that determine the movement of fluid in the microcirculation are the following:

1. The capillary hydrostatic pressure from the blood pressure, which tends to move blood across the capillary membrane and out of the circulation into the interstitium
2. The capillary oncotic pressure from the proteins within the blood vessels, which tends to retain fluid in the circulation
3. The interstitial hydrostatic pressure, which tends to move fluid back into the circulation
4. The interstitial oncotic pressure, which tends to draw fluid out of the circulation and into the interstitium

The net forces acting on the capillary fluid are nearly in equilibrium, with a slight tendency for fluid to be filtered out of the systemic circulation into the interstitium. Box 4-1 illustrates the mean pressures that determine normal fluid dynamics across capillary membranes.

Transport of Oxygen

Once oxygen reaches the blood, it rapidly combines with hemoglobin to form oxyhemoglobin. A small proportion of oxygen is dissolved in the plasma. The use of the hemoglobin molecule as an oxygen carrier allows for greater availability and efficiency of oxygen delivery to the tissues in response to metabolic demand. Saturation of the oxygen-carrying sites on the hemoglobin molecule is curvilinearly related to the partial pressure of oxygen in the tissues. This relationship is called the oxyhemoglobin dissociation curve and is a sigmoid, or S-shaped, curve (Fig. 4-3). The hemoglobin of arterial blood is 99%, or almost completely saturated with oxygen. Under normal circumstances, arterial blood is mixed with a small proportion of venous blood from the coronary and pulmonary circulation, resulting in arterial saturation slightly less than 100%. The graph shows a range of partial pressures of oxygen that may exist in the tissues. At relatively high arterial oxygen pressures, the oxygen saturation is high. This reflects high association or low dissociation between oxygen and hemoglobin. Saturation does not fall significantly until the partial pressure of oxygen falls below 80 mm Hg. Even at P_{O_2} levels of 40 to 50 mm Hg, arterial saturation is still 75%. This suggests that the oxyhemoglobin dissociation system has an enormous capacity to meet the varying needs of different tissues without severely compromising arterial saturation. A P_{O_2} of less than 50%, for example, has a profound effect on arterial saturation. This demonstrates an adaptive response of hemoglobin dissociation to respond to low oxygen tissue pressures by greater dissociation of oxygen from hemoglobin as the need arises. As P_{O_2} improves with increased supply of oxygen or decreased demand, the affinity between oxygen and hemoglobin increases, and arterial saturation increases. Thus oxygen is not released unless there is a need for greater oxygen delivery to the tissues.

Various conditions can increase or decrease hemoglobin's affinity for oxygen and thereby cause a shift in the oxyhemoglobin dissociation curve (see Fig. 4-3). A shift to the right results in decreased oxygen affinity and greater dissociation of oxygen and hemoglobin. In this instance, for any given partial pressure of oxygen, there is a lower saturation than normal. This means that there is more oxygen available to the tissues. Shifts in the curve to the right occur with increasing concentration of hydrogen ions (i.e., decreasing pH), increasing P_{CO_2}, increasing temperatures, and increasing levels of 2,3-DPG (diphosphoglycerate), a byproduct of red blood cell metabolism. West suggests that "a simple way to remember these shifts is that an exercising muscle (increased metabolic demand), is acid, hypercapnic and hot, and it benefits from increased unloading of oxygen from its capillaries."[8]

Box 4-1 Balance of Forces Moving Fluid into and out of the Capillary

Mean Forces Moving Fluid out of the Capillary

Mean capillary pressure	17.0 mm Hg
Negative interstitial pressure	6.3 mm Hg
Oncotic interstitial pressure	5.0 mm Hg
Total outward pressure	28.3 mm Hg

Mean Forces Moving Fluid into the Capillary

Plasma oncotic pressure	28.0 mm Hg
Total inward pressure	28.0 mm Hg

Net Outward Pressure

28.3 (outward pressure) – 28.0 (inward pressure) = 0.3 mm Hg

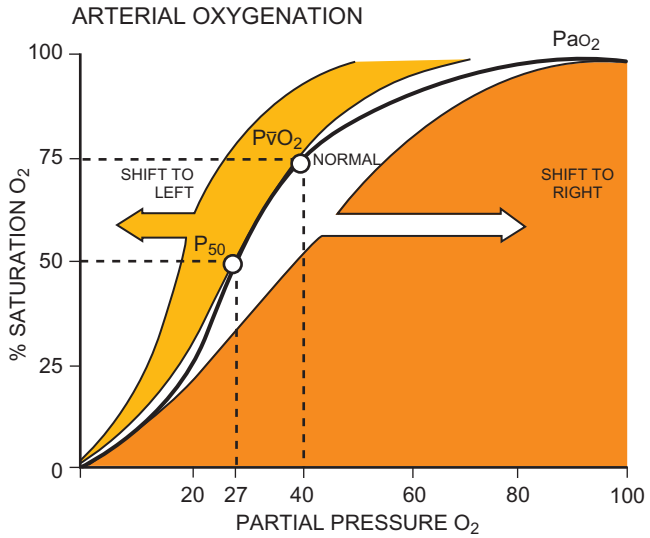

Fig. 4-3 The oxyhemoglobin dissociation curve.

A shift of the curve to the left results in increased oxygen affinity. Thus for any given partial pressure of oxygen, there is a higher saturation than normal. This means that there is less oxygen available to the tissues. This occurs in alkalemia, hypothermia, and decreased 2,3-DPG.

Anemia (reduced red blood cell count and hemoglobin) and polycythemia (excess red blood cell count and hemoglobin) produce changes in the oxygen content of the blood, as well as in its saturation. Anemia shifts the curve to the right and lowers the maximal saturation achievable. Polycythemia has the opposite effect. The curve is shifted to the left, and maximal saturation approaches 100%.

Transport of Carbon Dioxide

Carbon dioxide (CO_2) is an acid produced by cells as a result of cell metabolism. It is carried in various forms by venous blood to the lungs, where it is eliminated. Most of the CO_2 added to plasma diffuses into the red blood cells, where it is buffered and returned to the plasma to be carried to the lungs. The buffering mechanism is so effective that large changes in dissolved CO_2 can occur with small changes in blood pH.

The transport of CO_2 has an important role in the acid-base status of the blood and maintenance of normal homeostasis. The lung excretes 10,000 mEq of carbonic acid per day. (Carbonic acid is broken down into water and CO_2. The CO_2 is buffered and eliminated through the lungs.) The kidney can excrete only 100 mEq of acid per day. Therefore alterations in alveolar ventilation can have profound effects on the body's acid-base status. A decrease in the lung's ability to ventilate causes a sharp rise in P_{CO_2} and a drop in pH. This causes acute respiratory acidosis. If this change occurs gradually, the pH will remain within normal limits while the P_{CO_2} is elevated. This is known as a compensated respiratory acidosis. Hyperventilation or excessive ventilation causes rapid elimination of CO_2 from the blood. This results in a decreased P_{CO_2} and an increased pH and is known as acute respiratory alkalosis. Again, if the change occurs gradually, the pH remains within normal limits, even though the P_{CO_2} is decreased. This is a compensated respiratory alkalosis.

Cardiopulmonary Physiology

Ventilation

Ventilation is the process by which air moves into the lungs. The volume of air inhaled can be measured with a spirometer. The various lung capacities and volumes are defined in Chapter 9.

Regional differences in ventilation exist throughout the lung. Studies using radioactive inert gas with a radiation counter over the chest wall have shown that when the gas is inhaled by an individual in the seated position and measurements are taken, radiation counts are greatest in the lower lung fields, intermediate in the midlung fields, and lowest in the upper lung fields. This effect is position or gravity dependent. In the supine position, the apices and bases are ventilated comparably, and the lowermost lung fields are better ventilated than the uppermost lung fields. Similarly, in the lateral, or side-lying, position, the lower lung fields are preferentially ventilated compared with the upper lung fields (see Chapter 19).

The causes of regional differences in ventilation can be explained in terms of the anatomy of the lung and the mechanics of breathing. An intrapleural pressure gradient exists down the lung. In the upright position, intrapleural pressure tends to be more negative at the top of the lung and becomes progressively less negative toward the bottom of the lung. This pressure gradient is thought to reflect the weight of the suspended lung. The more negative intrapleural pressure at the top of the lung results in relatively greater expansion of that area and a larger resting alveolar volume. The expanding pressure in the bottom of the lung, however, is relatively small, so there is a smaller resting alveolar volume in the bottom. This distinction between the upper and lower lung fields is fundamental to understanding differences in regional ventilation. Regional differences in resting alveolar volume should not be confused with regional differences in ventilation volume. Ventilation refers to volume change as a function of resting volume. The relatively higher resting volume in the upper lung fields renders them stiffer, or less compliant, than the lower lung fields, where there are low lung volumes and greater compliance. The lower lung fields, therefore, exhibit a greater volume change in relation to resting volume, and that effects greater overall ventilation, compared with the upper lung fields. Ventilation is favored in the lowermost lung fields, regardless of body position.

Diffusion

Once air has reached the alveoli, it must cross the alveolar-capillary (A-C) membrane (Fig. 4-4). Gases, specifically oxygen entering the lungs and carbon dioxide leaving the lungs, must cross through the surfactant lining, the alveolar epithelial membrane, and the capillary endothelial membrane. Oxygen then has to travel through a layer of plasma, the erythrocyte membrane, and intracellular fluid in the erythrocyte, until it encounters a hemoglobin molecule. This distance is actually small in normal lungs, but in disease states it may increase. The alveolar wall and the capillary membrane often become thickened. Fluid, edema, or exudate may separate the two membranes. These conditions are often first detected when arterial P_{O_2} becomes chronically lower than normal. Oxygen diffuses slowly through the A-C membrane in comparison to CO_2 diffusion. As a result, patients with diffusion problems frequently have hypoxemia with a normal P_{CO_2}. Sarcoidosis, asbestosis, scleroderma, and pulmonary edema are conditions that decrease the diffusing capacity of the gases. The capacity may also decrease in emphysema because of a decrease in total surface area for gas exchange.

Perfusion

Perfusion of the lungs refers to the blood flow of the pulmonary circulation available for gas exchange. The pulmonary circulation operates at relatively low pressures compared with the systemic circulation. For this reason, the walls of the blood vessels in the pulmonary circulation are thinner than comparable vessels in the systemic circulation. Compared with the systemic circulation, the lungs have little requirement for marked regional differences in perfusion.

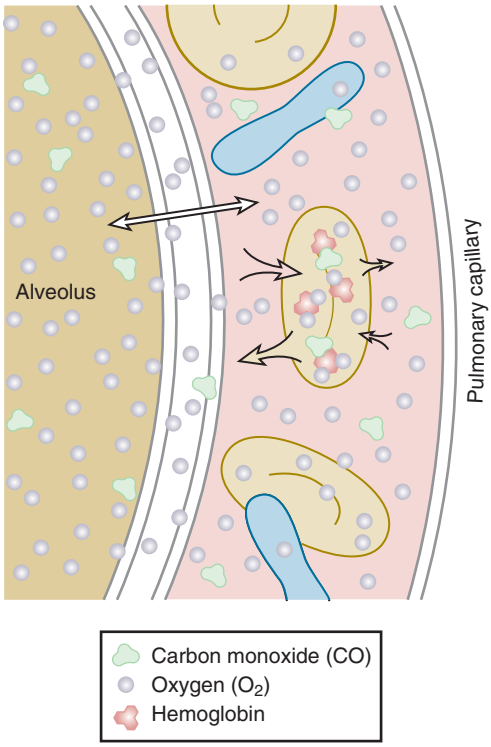

Fig. 4-4 The transfer of carbon monoxide and oxygen molecules across the alveolar-capillary membrane, through plasma, and across the red blood cell membrane. Also represented is the reaction with hemoglobin. *(From Mason RJ, Broaddus VC, Martin T, et al*: Murray and Nadel's textbook of respiratory medicine, *ed 5, Philadelphia, 2011, Saunders.)*

Hydrostatic pressure has a significant effect on the perfusion of the lower lobes. Hydrostatic pressure reflects the effect of gravity on the blood and tends to favor perfusion of the lower lung fields. This fact has been substantiated using radioactive tracers in the pulmonary circulation and measuring radiation counts over the lung fields. The nonuniformity of perfusion reflects the interaction of alveolar, arterial, and venous pressures down the lung. Normally blood flow is determined by the arteriovenous pressure gradient. In the lungs there are regional differences in alveolar pressure that can exert an effect on the arteriovenous pressure gradient. For example, in the upper lung fields, alveolar pressure approximates atmospheric pressure, which overrides the arterial pressure and effectively closes the pulmonary capillaries. In the lower lung fields, the opposite occurs. The relatively low volume of air in the alveoli is overridden by the greater capillary hydrostatic pressure. Thus the capillary pressure effectively overcomes the alveolar pressure.

Pulmonary blood vessels constrict in response to low arterial pressures of oxygen. This is termed hypoxic vasoconstriction. Hypoxic vasoconstriction in the lung is believed to serve as an adaptive mechanism for diverting blood away from underventilated or poorly oxygenated lung areas. Although hypoxic vasoconstriction may have an important role in improving the efficiency of the lungs as a gas exchanger, it may be potentially deleterious to a patient who has reduced arterial oxygen pressure secondary to pulmonary pathology.

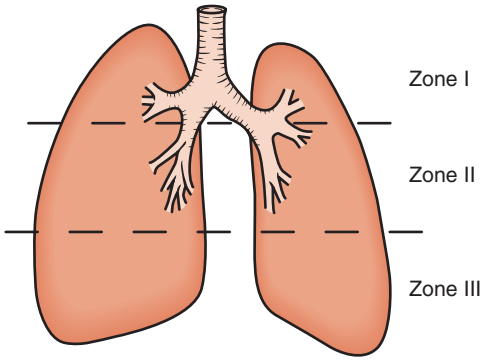

Fig. 4-5 The perfusion of the lungs is dependent on posture. In the upright position, three areas can be seen. Zone III has perfusion in excess of ventilation. In zone II, perfusion and ventilation are fairly equal. In zone I, ventilation occurs in excess of perfusion.

The acid-base balance of the blood also affects pulmonary blood flow. A low blood pH, or acidemia, for example, potentiates pulmonary vasoconstriction. Thus, impaired ventilatory function can disturb blood-gas composition and, in turn, acid-base balance. This effect can be amplified because of the cyclical reaction of pH on pulmonary vasoconstriction. Consideration of these basic physiological mechanisms is paramount to optimize physical therapy intervention.

Ventilation and Perfusion Matching

As discussed previously, gravity tends to pull blood into the dependent positions of the lung (Fig. 4-5). In erect humans, therefore, there is greater blood flow at the bases of the lung. In places, the arterial blood pressure exceeds the alveolar pressure and causes compression or collapse of the airways (Fig. 4-6). Blood flow to the apices is decreased because of gravity. Alveoli in this region are more fully expanded as a result of high transmural pressures and may further decrease blood flow by compressing blood vessels. It follows that the areas of optimal gas exchange occur where there is the greatest amount of perfusion and ventilation. This occurs toward the base of the lungs in erect humans. Changes in posture cause changes in perfusion and ventilation. Generally, greater air exchange occurs toward the gravity-dependent areas. In side-lying, there is greater gas exchange in the dependent lung (Fig. 4-7).

In normal lungs there is an optimal ratio, or matching of gas and blood. This ratio of ventilation to perfusion (V/Q) is 0.8 to maintain normal blood gas values of P_{O_2} and P_{CO_2}. Therefore the lungs must be able to supply four parts ventilation to about five parts perfusion. When the ratio is not uniform throughout the lung, the arterial blood cannot contain normal blood-gas values. Regions with low ratios (perfusion in excess of ventilation) act as shunts, whereas regions with high ratios (ventilation in excess of perfusion) act as dead space (Fig. 4-8). Hypoxemia results if regions of abnormal V/Q predominate. An elevation in arterial P_{CO_2} may also occur unless the patient increases ventilation.

Physical therapists who are positioning patients with cardiovascular and pulmonary pathology may find that their patients experience greater distress when placed in certain positions. Such position-dependent distress can be explained

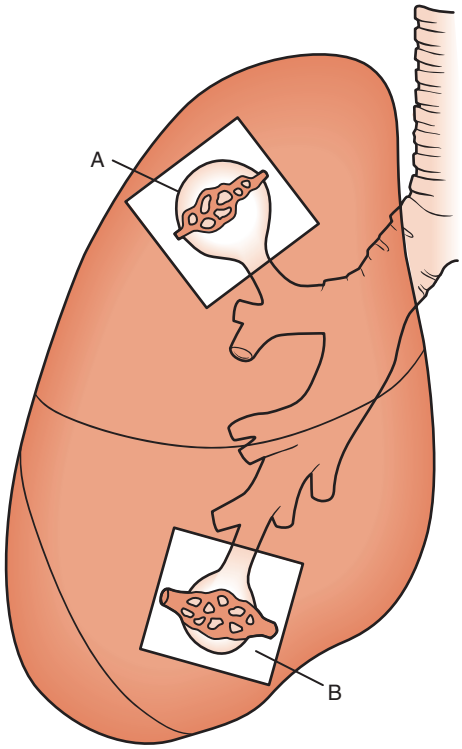

Fig. 4-6 The relationship between the size of the airways and the amount of perfusion in the area when lungs are in the upright position. **A,** Perfusion is decreased in the apices because of gravity. This enables the alveoli to expand fully. This expansion may compress blood vessels and thereby further decrease blood flow. **B,** Perfusion is increased in the bases of the lungs because of gravity. The enlarged vessels prevent full expansion of alveoli and may, in fact, compress them to a smaller size.

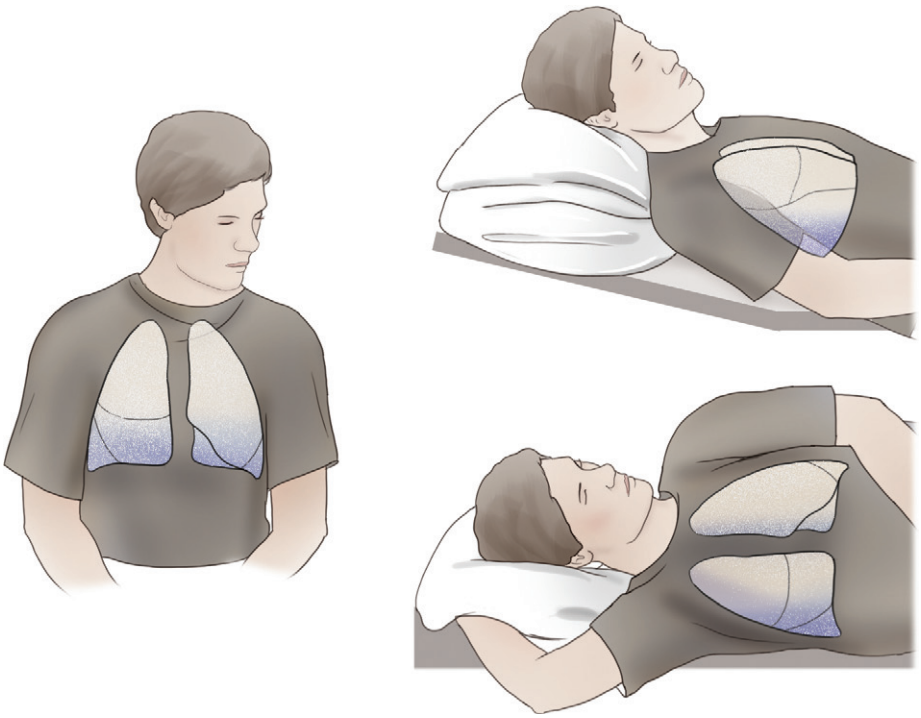
by ventilation-perfusion inequalities that cause poor gas exchange in the dependent lung.

The relationship of ventilation and perfusion in the lung is summarized in the following figures. Figure 4-9 shows increases in ventilation and perfusion down the upright lung. When optimal ventilation and perfusion match, V/Q occurs in the midlung zones. In the upright position, ventilation is in excess of perfusion in the apices, and perfusion is in excess of ventilation in the bases. Figure 4-10 illustrates the effects of shunt and physiological dead space on V/Q matching in the upright lung and shows their effect on alveolar gas. Specifically, Figure 4-10 shows a schematic representation of regional differences in ventilation and perfusion in the upper, middle, and lower zones of the upright lung. These gradients are reflected in the alveolar Po_2 and Pco_2 levels associated with alveolar dead space in the apices, appropriate V/Q matching in the midlung, and shunt in the bases.

Pulmonary Physiology

Control of Breathing

The act of breathing is a natural process to which most of us give little thought. Breathing unconsciously adjusts to varying degrees of activity while maintaining optimum arterial levels of PO_2 and PCO_2, whether we are resting or physically active. Sighing, yawning, hiccoughing, laughing, and vomiting are all involuntary acts that use respiratory muscles. Breathing can also be done under voluntary control. A person can stop breathing momentarily by breath holding or increase breathing by rapidly panting until he or she faints (from cerebral vascular constriction due to a decrease in arterial PCO_2).



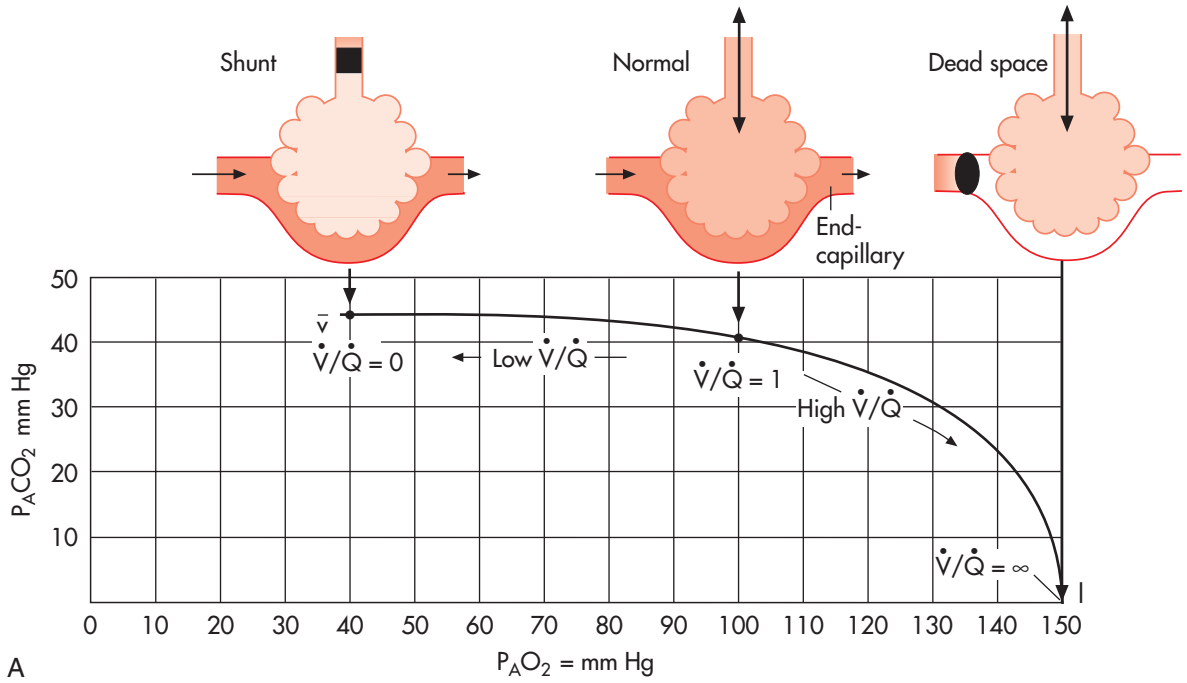


Fig. 4-7 The effect of positioning on the perfusion of the lung. Note that gravity-dependent segments have the greatest amount of perfusion.

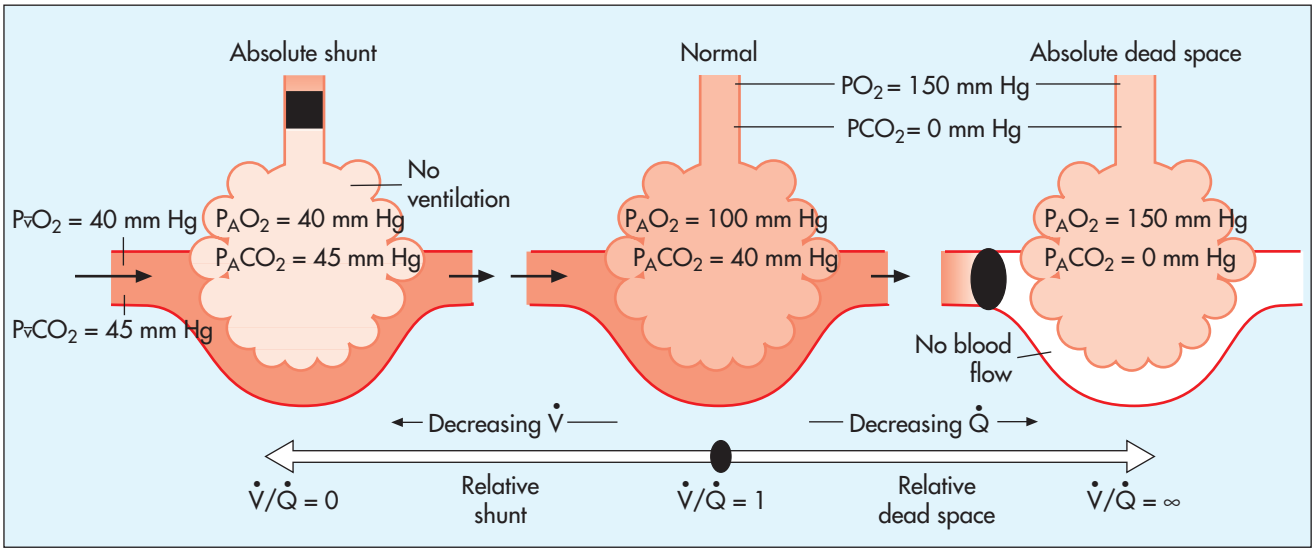

Fig. 4-8 A, The oxygen–carbon dioxide diagram. The diagonal line represents all possible Pa_{O_2}-Pa_{CO_2} combinations from absolute shunt to absolute dead space in a single alveolus. The diagonal line also represents end-capillary P_{O_2} and P_{CO_2} values. $\bar{v}$ represents mixed venous blood composition; ∞ represents inspired gas composition; I represents inspired tracheal gas composition. **B,** The shunt–dead-space continuum. *(From Beachey W:* Respiratory Care Anatomy and Physiology: Foundations for Clinical Practice, *ed 2. Philadelphia, 2008, Mosby.)*

Exhalation is used in singing, speaking, coughing, and blowing, whereas inspiration is used for sniffing and sucking. Parturition, defecation, and the Valsalva maneuver are all performed while voluntarily holding one's breath. These activities are regulated by control centers located in the brain. The centers integrate a multitude of chemical, reflex, and physical stimuli before transmitting impulses to the respiratory muscles. The cerebral hemispheres control voluntary respiratory activity, whereas involuntary respiratory activity is controlled by centers located in the pons and medulla of the midbrain (Fig. 4-11).

Medullary and Pontine Respiratory Centers

The respiratory center in the medulla is in the reticular formation. It contains the minimum number of neurons necessary for the basic sequence of inspiration and expiration. Although this center is capable of maintaining some degree of respiratory activity, these respirations are not normal in character.

The apneustic center is in the middle and lower pons. If uncontrolled by the pneumotaxic center, prolonged inspiratory gasps (apneustic breathing) occur.

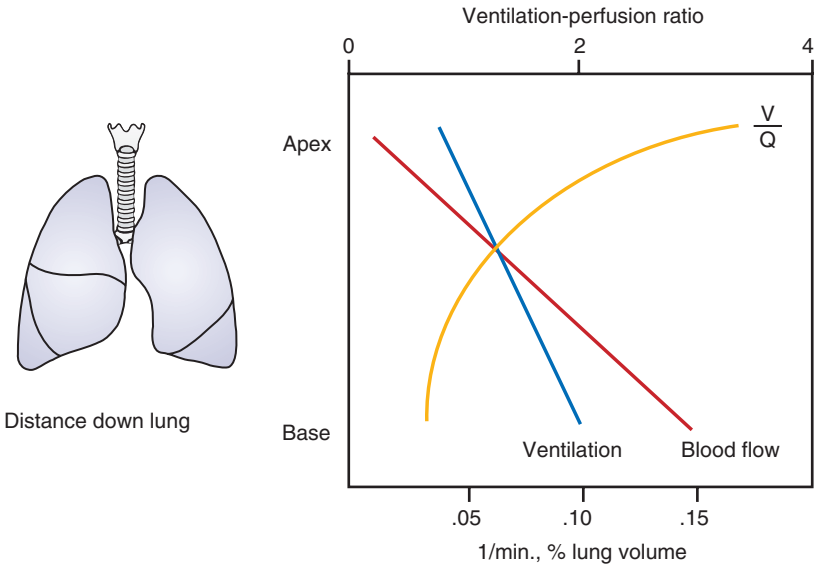

Fig. 4-9 The effect of gravity on ventilation, perfusion, and ventilation-perfusion matching (V/Q ratio).

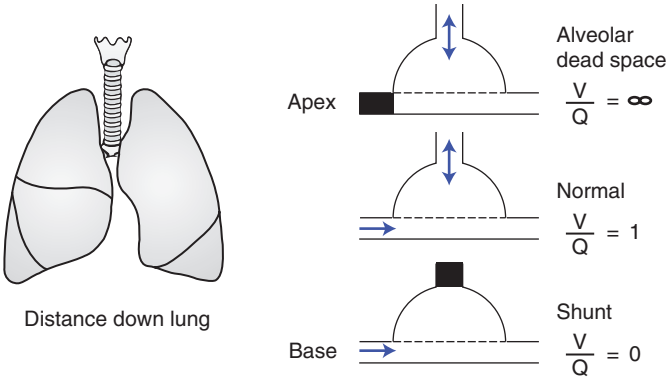

Fig. 4-10 Schemata showing the effect of gravity on ventilation and perfusion down the upright lung.

The pneumotaxic center is in the upper one-third of the pons. It maintains the normal pattern of respiration, balancing inspiration and expiration by inhibiting either the apneustic center or the inspiratory component of the medullary center.

Central Chemoreceptors

Central chemoreceptors are located on the ventral lateral surfaces of the upper medulla. They are bathed in the cerebrospinal fluid (CSF), which is separated from the blood by the blood-brain barrier. Although this barrier is relatively impermeable to hydrogen (H^+) and bicarbonate (HCO_3) ions, carbon dioxide (CO_2) diffuses through the barrier. Increased stimulation of central chemoreceptors by a rising arterial P_{CO_2} results in increased depth and rate of ventilation.

Peripheral Chemoreceptors

Peripheral chemoreceptors are located in the carotid bodies, which lie in the bifurcations of the common carotid artery and the aortic bodies above and below the aortic arch. These bodies receive blood from small branches of the vessels on which they are located. The peripheral chemoreceptors respond to an increase in arterial P_{CO_2} by increasing ventilation, but their response to P_{CO_2} is much less important than that of the central chemoreceptors.

The main role of the peripheral chemoreceptors is to respond to hypoxemia by increasing ventilation. If arterial P_{CO_2} is normal, the P_{O_2} must drop to 50 mm Hg before ventilation increases. A rising P_{CO_2} causes the peripheral chemoreceptors to respond more quickly to a decreasing P_{O_2}. In some patients with severe lung disease, this response to hypoxemia (the hypoxic drive) becomes very important. These patients often have a permanently elevated P_{CO_2} (CO_2 retention). The CSF in these patients compensates for a chronically elevated arterial P_{CO_2} by returning the pH of the CSF to near normal values. When these patients have lost the ability to stimulate ventilation in response to an elevated P_{CO_2}, arterial hypoxemia becomes the major stimulus to ventilation (hypoxic drive).

Reflexes

Hering-Breuer Reflex

In the late 1800s, Hering and Breuer noted that distention of anesthetized animal lungs caused a decrease in the frequency of inspiration and an increase in expiratory time. Receptors for this reflex are thought to lie in the smooth muscle of airways from the trachea to the bronchioles. More than 800 mL of lung volume above functional residual capacity are needed to activate the reflex and delay the next breath.

Cough Reflex

Mechanical or chemical stimuli to the larynx, trachea, carina, and lower bronchi result in a reflex cough and bronchoconstriction. The high velocity created by the cough sweeps mucus and other irritants up toward the pharynx (see Chapter 23).

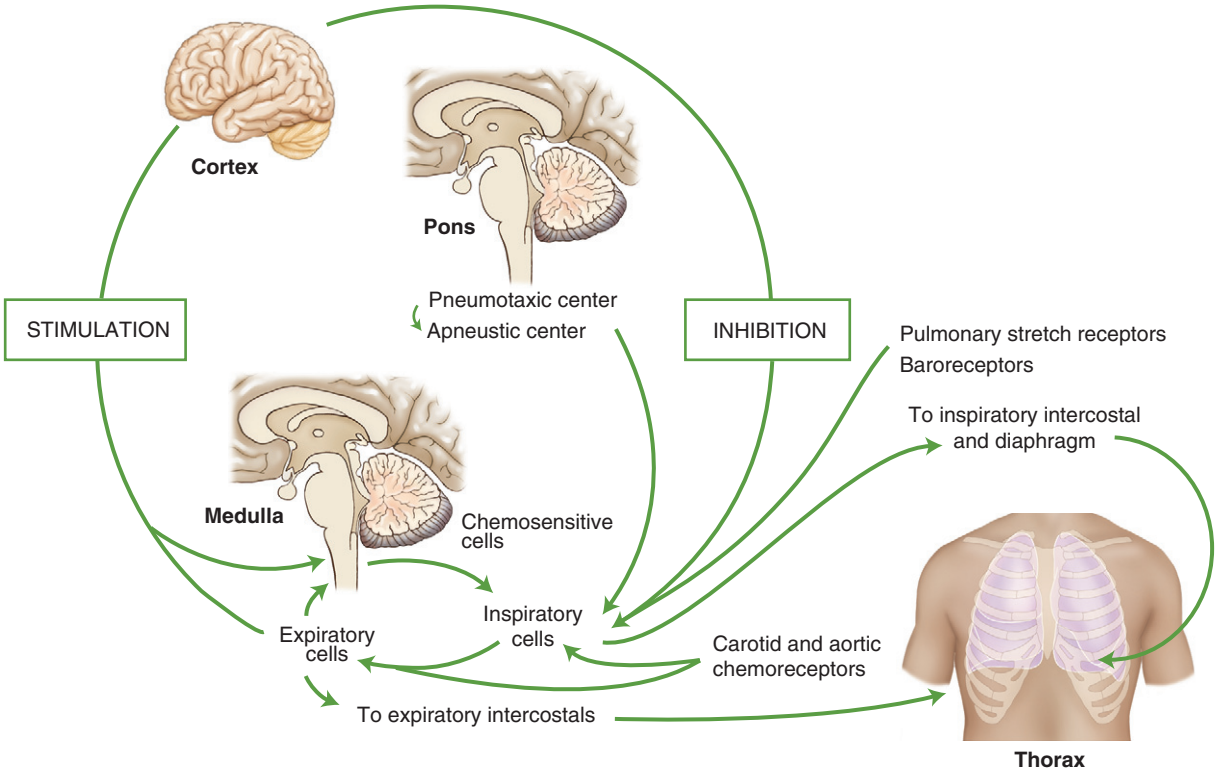

Fig. 4-11 Control of breathing.

Stretch Reflex

The intercostal muscles and the diaphragm contain sensory muscle spindles that respond to elongation. A signal is sent to the spinal cord and anterior horn motor neurons. These neurons signal more muscle fibers to contract (recruitment) and thus increase the strength of the contraction. Theoretically, such a stretch reflex may be useful when there is an increase in airway resistance or a decrease in lung compliance. Stretching the ribs and the diaphragm may activate the stretch reflex and help the patient take a deep breath. The fundamental pathways of the stretch reflex are shown in Figure 4-12. Research is needed, however, to establish the therapeutic role of proprioceptive neurofacilitation techniques based on stretch reflex theory in altering pulmonary function.

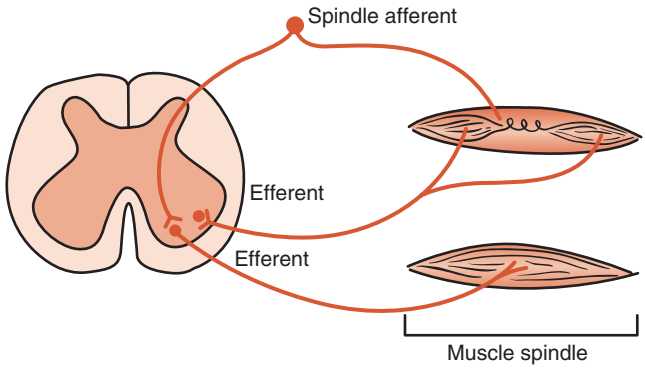

Fig. 4-12 Stretch reflex.

Joint and Muscle Receptors

Peripheral joints and muscles of the limbs are believed to have receptors that respond to movement and enhance ventilation in preparation for activity. Ventilation has also been shown to be stimulated by a similar reflex in humans and anesthetized animals in response to passive movement of the limbs. The precise pathways for these reflexes have not been well established.

Mechanoreceptors

Changes in systemic blood pressure cause corresponding changes in pressure receptors in the carotid and aortic sinuses. Increase in blood pressure causes mechanical distortion of the receptors in these sinuses, producing reflex hypoventilation. Conversely, a reduction in blood pressure can result in hyperventilation.

Mechanical Factors in Breathing

The flow of air into the lungs is a result of pressure differences between the lungs and the atmosphere. In normal breathing, inspiration occurs when alveolar pressure is less than atmospheric pressure. Muscular contraction of the respiratory muscles lowers alveolar pressure and enlarges the thorax. The decreased pressure causes air to flow from the atmosphere into the lungs. Patients who are unable to create adequate negative pressure may have to be mechanically ventilated. The ventilators create a positive pressure (greater than atmospheric pressure) that forces air into the lungs, where there is atmospheric pressure. The iron lung used during the poliomyelitis epidemic of the 1950s assisted ventilation by using cycles of negative pressure to inflate the lungs.

Exhalation occurs when alveolar pressure is greater than atmospheric pressure. At the cessation of inspiration, the respiratory muscles return passively to their resting positions.

The diaphragm rises, compressing the lungs and thereby increasing alveolar pressure. As the intercostals relax, the ribs resume their preinspiratory position, further compressing the lungs and increasing alveolar pressure. The increased alveolar pressure contributes to air flowing from the lungs. Normally, expiration is a passive process reflecting the elastic recoil of the lung parenchyma.

Resistance to Breathing

COMPLIANCE

The inner wall of the thorax, which is lined with parietal pleura, and the parenchyma of the lung, which is enclosed in visceral pleura, lie close to each another. The pleurae are separated by a potential space containing a small amount of pleural fluid. Muscular contraction of the intercostals and the diaphragm mechanically enlarges the thorax. The lungs are enlarged at this time because of their close proximity to the thorax. The healthy lung resists this enlargement and tries to pull away from the chest wall. The ease with which the lungs are inflated during inspiration is known as compliance and is defined as the volume change per unit of pressure change. Normal lungs are very distensible or compliant. They can become more rigid and less compliant as a result of diseases that cause alveolar, interstitial, or pleural fibrosis, or alveolar edema. Compliance increases with age and in emphysema, because of the loss of elastin.

The elastic recoil or compliance of the lung is also dependent on a surface fluid called surfactant, which lines the alveoli. This fluid increases alveolar compliance by lowering the surface tension, thereby reducing the muscular effort necessary to ventilate the lungs and keep them expanded. It is a complex lipoprotein that is produced in type II alveolar cells (see Chapters 2 and 4). A decrease in surfactant causes the alveoli to collapse. Reexpanding these alveoli requires a tremendous amount of work on the part of the patient. The patient may become fatigued and need mechanical ventilation. This occurs in respiratory distress syndrome in premature infants (previously called hyaline membrane disease) and in acute respiratory distress syndrome in adults. In another disease, alveolar proteinosis, there is excessive accumulation of protein in the alveolar spaces. This may be because of excessive production of surfactant or deficient removal of surfactant by alveolar macrophages.

The elastic properties of the lungs tend to collapse them if not counterbalanced by external forces. The tissues of the thoracic wall also have elastic recoil, which causes them to expand considerably if unopposed. These two forces oppose each other, keeping the lungs expanded and the thoracic cage in a neutral position. If these forces are interrupted (as in pneumothorax), the lung collapses and the thoracic wall expands (Fig. 4-13). Similarly, the overinflated, barrel-shaped chest of a patient with chronic obstructive pulmonary disease (COPD) is caused by the elastic tension of the chest wall being unopposed by the usual elastic forces of the lungs, which have been damaged by disease.

Pressure-Volume Relationships

Pressure-volume curves help define the elastic properties of the chest wall and lungs. The elasticity of the respiratory system as a whole is the sum of its two major components, the lungs and the chest wall. The so-called relaxation pressure curve is shown in Figure 4-14. The curve illustrates the static pressure of the lungs and chest wall and the combination of the two measured at given lung volumes. Functional residual capacity (FRC) reflects the balance of elastic forces exerted by the chest wall and the lungs and has significant implications for the clinical presentation and management of patients with cardiovascular and pulmonary dysfunction.

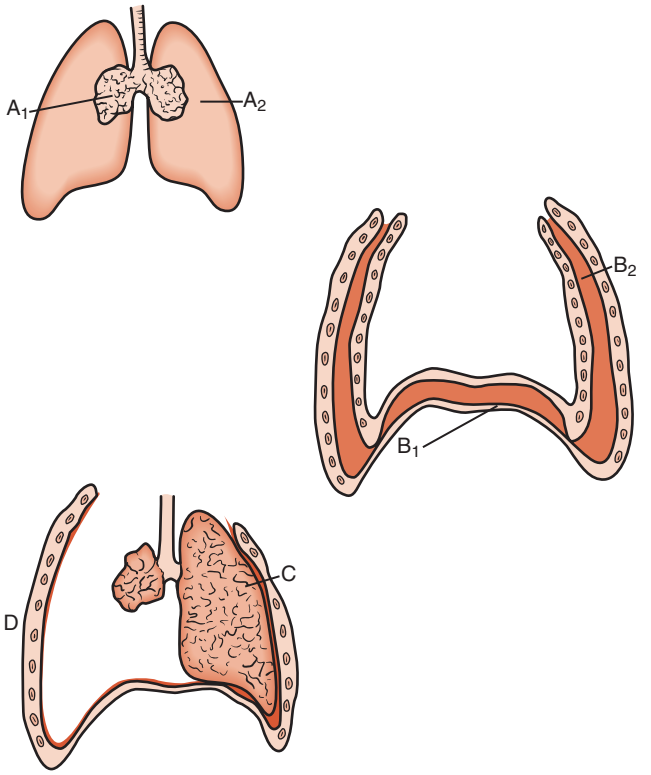

Fig. 4-13 Various relationships between the lungs and the thorax. *A_1,* The size the lungs would assume if they were not acted on by the elastic recoil of the thoracic wall. *A_2,* The normal size of lungs within the thorax. *B_1,* The size the thorax would assume if it were not acted on by the elastic recoil of the lungs. *B_2,* The normal position of the chest wall when acted on by the elastic recoil of the lungs. *C,* The normal relationship of lungs to thorax. *D,* The positions assumed by the lungs and thorax in a tension pneumothorax.

The relaxation pressure curve represents static pressure measurements. This means that the respiratory muscles are inactive, and the volume in the lungs at a given point in the respiratory cycle is determined by the balance of forces between the chest wall and the lungs. The chest wall and lungs exert elastic forces that oppose each other. The chest wall attempts to pull the lung out, and the lungs attempt to recoil and pull the chest wall in. The curves labeled "lung" and "chest wall" (see Fig. 4-14) are theoretical and illustrate the elastic force exerted by each when it is permitted to act unopposed by the other. Normally these two forces are exerted together, producing the pressure-volume relaxation curve. At FRC, these forces are in equilibrium; therefore this capacity constitutes the resting volume of the respiratory system.

In lung disease, the balance between chest wall and lung forces is disrupted.[11] More work and energy are required to sustain the respiratory effort.[12] The patient is less able to rely on normal elastic recoil of the chest wall, lungs, or both.

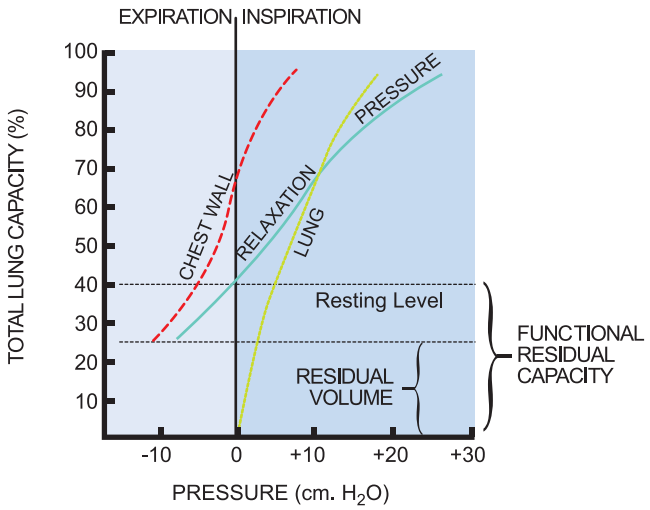

Fig. 4-14 The relaxation pressure curve. The pressure in the lungs at any volume reflects the elastic forces of the lungs and chest wall.

Therefore the patient must expend more energy to effect equivalent respiration. The limits of respiratory excursion are determined by both elastic and muscular forces. At total lung capacity, the elastic forces of the respiratory system are balanced by the inspiratory muscle force. At residual volume, the elastic forces of the chest wall are balanced by the maximum expiratory muscle force. This volume excursion from total lung capacity to residual volume reflects vital capacity.

Although the curves representing the elastic forces of the lungs and chest wall are theoretical, they are helpful in understanding the effect of lung dysfunction on pulmonary function and on the clinical presentation of the patient.[11] For example, in individuals with COPD, the characteristic barrel chest reflects the unopposed elastic forces of the chest wall as it succeeds in increasing the excursion of the chest as a result of reduced elastic recoil of the lungs. At the other extreme is the effect on the chest wall of a puncture wound, which disrupts the intrapleural pressure gradient that normally keeps the lung expanded and the chest wall contained. The result of such a puncture is to produce a pneumothorax in which the lung collapses down to the hilum and the chest wall springs outward (see Fig. 4-13).

AIRWAY RESISTANCE

The flow of air into the lungs depends on pressure differences and on the resistance to flow in the airways. Resistance is defined as the pressure difference required for one unit flow change. The air passages are divided into upper and lower airways (see Chapter 3). The upper airways are responsible for 45% of airway resistance. The resistance to airflow by the lower airways depends on many factors and is therefore difficult to predict. The branching of the lower airways is irregular, and the diameter of the lumen may vary because of external pressures and because of the contraction or relaxation of bronchial or bronchiolar smooth muscle. The lumen diameter may also decrease as a result of edema or mucus. Any of these changes in the airway diameter may cause an increase in airway resistance. Flow of air through these airways can be either laminar or turbulent (Fig. 4-15). Laminar flow is a

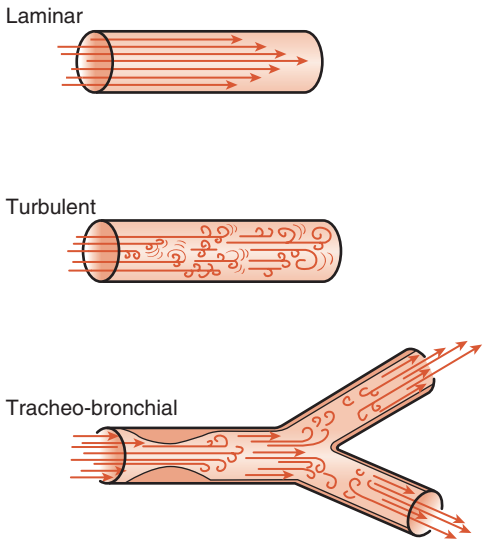

Fig. 4-15 The different types of airflow seen within the tracheobronchial tree.

streamlined flow in which resistance occurs mainly between the sides of the tubes and the air molecules. It tends to be cone shaped, with the molecules in contact with the walls of the tubes moving more slowly than the molecules in the middle of the tube. Turbulent flow occurs when there are frequent molecular collisions in addition to the resistance of the sides of the tubes. This type of flow occurs at high flow rates and in airways where there are irregularities caused by mucus, exudate, tumor, or other obstructions. In normal lungs, airflow is a combination of laminar and turbulent flow and is known as tracheobronchial flow.

The airways are distensible and compressible and thus susceptible to outside pressures. As these pressures compress the airways, they alter airway resistance. Transmural pressure is the difference between pressures in the airways and pressures surrounding the airways. In erect humans, there is a higher transmural pressure at the apices of the lungs than at the bases. This expands the alveoli at the apices relative to those at the

bases. Although the alveoli in the apices have a greater volume at end expiration, the alveoli in the bases are better ventilated. This is because the alveoli in the bases operate at lower transmural pressures and can therefore accommodate a greater volume during inspiration than those at higher pressures.

Airway resistance decreases during inspiration as a result of the widening of the airways. During expiration, airways narrow, which increases resistance. The positive alveolar pressure that occurs during expiration partially compresses the airways. If these airways have lost their structural support as a result of disease, they may collapse and trap air distally (as in emphysema).

Summary

This chapter presents an overview of cardiovascular and pulmonary physiology with respect to breathing control and the central and peripheral mechanisms, such as muscle, joint, and lung and chest wall stretch receptors, involved in the regulation of respiration. The mechanics of breathing, chest wall and lung compliance, and airway resistance are described. The elastic properties of the respiratory system (i.e., chest wall and lungs) are reflected in the pressure-volume relaxation curve. This curve enables the physical therapist to better understand the efficiency and energy requirement of the respiratory system in their patients with cardiopulmonary dysfunction. Ventilation and perfusion matching is the basis of gas exchange and the adequacy of lung function. Many factors in addition to disease, however, can affect ventilation and perfusion matching, including age, body position, exercise, breathing at low lung volumes, and smoking history. The function of the heart is to provide adequate cardiac output, hence, adequate oxygen delivery to the vital organs and peripheral tissues. The optimal coupling of electrical and mechanical events in the heart to effect cardiac output is described.

Arterial Po_2 and Pco_2 are normally maintained within certain prescribed limits. In healthy individuals, oxyhemoglobin dissociation ensures adequate oxygen delivery to the tissues once oxygen has diffused through the alveolar capillary membrane into the circulation. Transport of CO_2 and its buffering mechanisms are central to acid-base balance and normal homeostasis.

Review Questions

1. Describe the control of breathing.
2. Explain the mechanics of breathing with respect to the chest wall and lung compliance.
3. Describe the distributions of ventilation, perfusion, and diffusion.
4. Explain the determinants of ventilation and perfusion matching.
5. Describe electromechanical coupling in the heart.
6. Describe the oxyhemoglobin dissociation curve and its clinical implications.

Because cardiovascular and pulmonary conditions are among the leading causes of morbidity and premature mortality, they often present clinically to the physical therapist as secondary as well as primary diagnoses. In addition, patients commonly have one or more risk factors for one or both of these broad categories of conditions. Thus physical therapists need a thorough understanding of these conditions, their prevention, their presentation, and their management. Lifestyle and environmental factors are primary causes and contributors (see Chapter 1); thus prevention and reversal of symptoms are aimed at modifying these factors wherever possible.

Smoking is a principal contributor to cardiovascular disease and the primary cause of chronic obstructive pulmonary disease (COPD). Abstinence from smoking is the only intervention that can prevent the majority of cases of COPD, and smoking cessation is the only intervention to retard its progression. Thus cessation of smoking is a primary health care goal at the community, societal, and individual levels,[1,2] and it should be a primary intervention by the physical therapist in any patient who smokes (see Chapter 1).

Risk factors for cardiovascular and pulmonary conditions should be assessed in every patient, irrespective of the reason

for physical therapy referral or management. An individual with an overt history of cardiovascular or pulmonary conditions is managed based on the related signs and symptoms. However, if a patient comes to the physical therapist with dysfunction of the musculoskeletal, neuromuscular, or other system and happens to have a secondary diagnosis of a cardiovascular or pulmonary condition, this diagnosis must be considered in overall management and the interventions modified accordingly. Because it is life-threatening, a secondary diagnosis of a cardiovascular or pulmonary condition may be more clinically important for the physical therapist to manage than the primary diagnosis (e.g., low back pain, osteoarthritis, or Parkinson syndrome).

Recent advances in understanding the pathophysiology of cardiovascular and pulmonary conditions have highlighted a common denominator: inflammation of the endothelium of the blood vessels and the epithelium of the airways. With increasing severity of the condition, proteins alter their structure, and repair is required to maintain their essential structure and function with the upregulation of reparative proteins.[3] Activation of this defense system is triggered by ischemia, hypoxemia, and inflammation.

Myopathic changes have been observed in the peripheral muscles of people with chronic cardiovascular conditions and lung conditions (see Chapters 24 and 31). People with COPD, for example, have increased muscle fibrosis compared with age-matched people without the disease, and the cross-sectional area of type IIX muscle fibers is smaller.[4]

Some common causes underlying COPD have been proposed. The Dutch hypothesis explaining the development of both asthma and chronic obstructive lung disease proposes that environmental factors (e.g., smoking and air pollutants) are superimposed upon and interact with allergic and airway hyperresponsiveness components (genetic components). Smoking and airway hyperresponsiveness are the major risk factors for these conditions.[5]

It has been reported that gender plays a role in susceptibility to cardiovascular and pulmonary dysfunction, as well as in the severity of the dysfunction and the response to its management. This is reflected in the finding that women with COPD have an almost three-fold greater death rate than men. Specifically, women are more susceptible to the long-term adverse effects of smoking. Compared with men, they develop pathological changes more readily and have more severe symptomatology for a given long-term exposure to tobacco.[6]

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) has proposed universal guidelines for the classification of COPD[7] on the basis of both spirometry and clinical symptoms to define stage of disease (Table 5-1). Serum or tissue markers are being sought to provide a basis for an objective diagnosis and refine intervention strategies.[8]

Objective measures of limitations of structure and function or impairments associated with cardiovascular and pulmonary conditions are not necessarily closely associated with health-related quality of life. Outcome measures of health-related quality of life and life satisfaction are supplemental to structure and function outcomes and are now being included in the overall clinical assessment of people with these conditions.[9] Thus management programs focus on interprofessional rehabilitation consisting of multiple components to address the complexity of the limitations associated with these conditions rather than traditional primary focus on limitations of functions and structures (see Chapters 1 and 17).[10]

Table 5-1 Universal Guidelines for the Classification of COPD

	Predicted FEV_1/FVC	FEV_1
Mild COPD	<70%	≥80%
Moderate COPD	<70%	<50% to 80%
Severe COPD	<70%	<30%

This chapter describes common pathophysiology of the cardiovascular and pulmonary systems and some common conditions that affect these systems secondarily.

The first part of this chapter describes the pathophysiology of common cardiovascular conditions. CAD is manifested in various clinical syndromes and most commonly results from atherosclerosis in the coronary arteries, which ultimately affects heart performance (i.e., stroke volume and heart rate, hence, cardiac output). The causes of clinical syndromes associated with CAD and the medical management and prognoses are briefly reviewed.

The two classic types of lung pathophysiology (obstructive and restrictive) are then presented. Interdependent pathophysiology of these lung pathologies, which invariably affects the heart as well as the lung, is described in Chapters 6 and 31 (also in Chapters 16, 34, and 36, which are related to critical care). The structure and function of the cardiovascular and pulmonary systems are interdependent (see Chapters 2, 3, 4, 5 and 6).[11] Dysfunction in one system can affect the function of the other.

Obstructive pulmonary conditions are characterized by a reduced expiratory airflow rate due to increased airway resistance. Restrictive pulmonary conditions are marked by the reduced inspiratory capacity of the lungs. Often, however, overlap exists between the two categories.

Coronary Artery Disease

Hypercholesterolemia

Although hypercholesterolemia is a primary risk factor for the development of atherosclerosis, increased cholesterol affects cardiac function independently in the absence of atherosclerosis and primary ischemic heart disease.[12] Elevated cholesterol levels change the structure and function of cell membranes, which in turn, affects myocardial contractility, excitability, and conduction properties. In addition, smooth muscle and endothelial dysfunction occurs, and enzyme activity and cation transporters are disrupted throughout the cardiovascular system. Thus the consequences of hypercholesterolemia are pervasive and warrant assessment even in the absence of overt atherosclerosis and ischemic heart disease.

Atherosclerosis

Pathophysiology

Atherosclerosis is triggered by trauma to the intima of the arterial wall. The trauma may be related to various primary cardiac risk factors, such as high blood pressure and cigarette smoking. Oxidative stress has been identified as the common denominator for atherogenesis, acute myocardial infarction (MI), and heart failure.[13] Healthy endothelium is central to optimal vascular control. High blood pressure has been identified as a trauma inducer because increased pressure and turbulence can damage the endothelial cells of the intima of the blood vessel wall, thus exposing the media to the circulation. The media, which consists primarily of smooth muscle, is thought to be the origin of the atherosclerotic lesion.

Cigarette smoking has also been identified as a potential inducer of trauma in the blood vessel wall. The hypothesized mode of injury appears to be different from that observed with increased blood pressure. Cigarette smoke is high in carbon monoxide and hydrocarbons that are carried by the red blood cells and the plasma. The hydrocarbons and carbon monoxide are thought to bind to the endothelial cells, causing damage to and possibly death of these cells.

Diabetes is another risk factor for cardiovascular disease of the myocardium and of the peripheral arteries.[14] The reduced contractility of the heart in people with diabetes is attributed to reduced calcium handling in the sarcoplasmic reticulum of muscle.

Once the media is exposed to the circulation, the process of atherosclerosis is initiated and this predisposes an individual to thromboembolic events, in even mild cases. Platelets aggregate at the injury site and release substances that induce endothelial and smooth muscle cell replication. It is at this site that fatty streaks and fibrous plaques develop. The cause of fatty-streak development is the deposition of low-density lipoproteins (LDLs) into the smooth muscle of the media. Why this occurs is unknown, but it appears to be related to smooth muscle cell proliferation and perhaps to increased energy demands. The initial fatty streaks are generally raised only slightly and do not impede circulation. When a fibrous plaque develops, however, impingement on the vessel lumen occurs. The plaque is relatively hard and consists of connective scar-like tissue, smooth muscle, and fat. Finally, the plaque may undergo calcification or may lead to hemorrhaging if the vessel wall necroses. The result is decreased blood flow (ischemia) and oxygenation (hypoxia) or complete lack of blood flow and oxygen (anoxia) to the target organ.

Atherothrombosis is a generalized and diffuse progressive process affecting multiple vascular beds.[15,16] The clinical consequences include the acute coronary syndromes, ischemic stroke, and peripheral arterial disease. Thus these conditions can be viewed as diverse manifestations of a common underlying pathology. The time course of these conditions is unpredictable; yet they can be life-threatening.

Thyroid is an important regulator of cardiac function and cardiovascular hemodynamics.[17] The effects of the physiologically active form of thyroid hormone triiodothyronine (T_3) on the systemic vasculature include relaxation of the vascular smooth muscle, hence reduced resistance and diastolic blood pressure. In hypothyroidism, cardiac contractility and cardiac output are decreased and systemic vascular resistance is increased, whereas the opposite occurs in hyperthyroidism. Cardiac dysfunction is associated with low levels of T_3.

Because of the current appreciation and understanding of the involvement of inflammation and endothelial injury in cardiovascular dysfunction, endothelial function biomarkers have been proposed as a sensitive means of evaluating cardiovascular disease.[18,19]

Risk Factors

As described earlier, high blood pressure, cigarette smoking, and hyperlipidemia are direct or primary risk factors for atherosclerosis. Secondary risk factors include age, gender, race, obesity, stress, and activity level. Modifiable risk factors include hypertension, hyperlipidemia, smoking, obesity, abnormal glucose tolerance and diabetes, stress level, and activity level. Homocysteine levels have a strong relationship with atherothrombotic disease and venous thromboembolism, and elevated levels may indicate thrombotic tendencies in individuals, particularly those who are younger, in the absence of other established risk factors.[20] Homocysteine levels can be reduced and regulated through diet by increasing fruit and vegetable intake. Recently, the tendency to panic has been implicated as a risk factor for cardiovascular disease,[21] and depression can result in a worse outcome.[22]

Vascular calcification is an established marker of atherosclerosis, which leads to increased arterial stiffness and reduced compliance and increased pulse pressure. Vascular calcification is highly correlated with mortality resulting from cardiovascular disease, particularly if diabetes or renal disease complicates the clinical presentation.[23,24] The three primary risk factors—diet, hypertension, and smoking—are modifiable by the individual, and altering the diet alone can reduce the probability of CAD five- to ten-fold.[25,26,27]

A proposed and potentially underestimated risk factor for cardiovascular disease is related to circadian rhythms.[28] It has been well established that people with heart failure have a higher rate of mortality in the early morning hours. This probably reflects diurnal variations in neurohumoral factors, including the activity of the sympathetic nervous system. The cardiac circadian clock synchronizes the response of the heart to the diurnal variations in the environment. Impairment of this mechanism could contribute to the pathogenesis of cardiovascular disease.

Aging has been implicated in lowering the threshold for the manifestation of cardiovascular disease.[29] Stiffening of the arteries increases afterload and alters left ventricular architecture. Left ventricular diastolic function changes, whereas systolic function remains unchanged.

Angina Pectoris

Angina pectoris is defined as chest pain that is related to ischemia of the myocardium. Ischemic pain, however, may be referred to the left shoulder, neck, jaw, or between the shoulder blades. In fact, pain anywhere above the umbilicus could be related to coronary ischemia. Angina can be classified as stable, unstable, or variant. People with chest pain but normal coronary arteries on angiography tend to be women, and this presentation is not as benign as previously believed.[30] With the

advent of the ability to assess endothelial function, those at risk may be more readily identified and managed.

Stable Angina

Stable angina generally occurs during physical effort but may be related to stress. The individual is able to describe what type and intensity of activity causes the angina. Stable angina is characterized by substernal, usually nonradiating pain lasting between 5 and 15 minutes after relief from the initiating trigger, such as a given physical or psychological stressor. Sublingual nitrates and cessation of the activity causing the angina are indicated. Usually, the angina subsides completely with treatment. Angina brought about by emotional stress is more difficult to treat because stress cannot be stopped as easily as exercise.

Unstable Angina

Unstable angina occurs during physical exertion or psychological stress. The major difference between stable and unstable angina is the frequency, duration, and intensity of the pain. In unstable angina, the episodes are more frequent and the duration of each event is usually greater than 15 minutes. In addition, the intensity of the pain may be more severe. Unstable angina is usually an indicator of the progression of coronary artery disease. Individuals with unstable angina are at increased risk for MI. Unstable angina is less responsive to treatment with rest and sublingual nitrates. Often the individual needs to be hospitalized and treated with intravenous nitrates.

Variant Angina

Variant angina occurs while the individual is at rest, usually during waking and at the same hour. Exertion does not influence variant angina. This type of angina may benefit from rest and sublingual nitrates. Like unstable angina, the pain is intense and prolonged and can lead to infarction. In addition, dysrhythmias occur more commonly in individuals who have variant angina than in those with exertional angina (i.e., stable and unstable angina). Stable and unstable anginas reflect progressive arterial stenosis and ischemia. Variant angina is caused by a combination of stenosis and coronary artery spasm and is successfully treated with calcium channel blockers.

Prognosis of Angina

Individuals do not die of angina per se. The progression of atherosclerosis of the coronary arteries is reflected in the clinical changes that occur between the experience of angina and an MI. Even though there is no risk of mortality as a result of angina, an individual's lifestyle can change drastically. People with angina may be fearful of being active and may deny that they are having exertional chest pain. Denial, depression, anger, and hostility are common psychosocial correlates.[31] Depression and further reduction in physical activity can be associated with angina (diagnosed or undiagnosed and denied). Although restricted activity is an important component of initial treatment, low levels of activity can modify several risk factors and arrest the progression of atherosclerosis.[32] In addition, diet and exercise have been documented to reverse atherosclerosis.[25,26,33]

Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea (OSA) has a greater incidence in individuals with atherosclerosis, cardiac dysrhythmias, and hypertension than in those without.[34] This has been explained in part by the presence of proinflammatory and prothrombotic factors.[35] OSA is characterized by the repetitive closing and opening of the posterior pharynx that are synchronized with breathing while sleeping, usually when recumbent. Apneic periods and arterial desaturation are also common to the syndrome. Additional pathologies common to OSA and atherosclerosis include endothelial dysfunction, increased C-reactive protein, fibrinogen, reduced fibrinolytic activities, and increased platelet activity and aggregation. OSA is now considered a risk factor for cardiovascular disease. The complications of sleep apnea syndrome are exacerbated by autonomic dysfunction as well. Sleep apnea often coexists undiagnosed in people with cardiovascular disease, activates mechanisms known to aggravate and advance cardiovascular injury, and contributes to resistance to therapeutic interventions.[34]

Myocardial Infarction

MI is defined as necrosis of a portion of the myocardium. The death of the myocardium occurs as a result of ischemia and anoxia. The vessels affected by occlusion are the right and left coronary arteries and their anterior and posterior descending branches. The right coronary artery supplies the posterior section and portions of the inferior section of the left ventricle. The left coronary artery branches and forms the circumflex and anterior descending arteries. The circumflex supplies the lateral portion of the left ventricle, and the anterior descending artery supplies the anterior portion. In addition, the right coronary artery supplies the right atrium atrioventricular bundle and the right ventricle. The left coronary artery supplies the left atrium and the primary portion of the conduction pathway. Generally, the clinical symptoms are similar to those of angina, with emphasis on extreme pressure as well as tightness over the sternal region. In addition, pain can radiate to the jaw, upper back, and shoulders (on the left more often than on the right).

MIs are categorized by location, size, and degree of involvement of the myocardial wall. The terms *small* and *large* are often used to describe MIs. Degrees of complication are also used in conjunction with size. MIs can be described as uncomplicated and complicated, based on the size of the MI and the patient's recovery. Location indicates the area of the heart involved and the coronary artery or branches that are involved. The anatomic areas of the heart are differentiated as anterior, posterior, lateral, and inferior. Finally, MIs are classified by the extent of damage to the wall. A transmural (or full-wall) infarct extends from the endocardium to the epicardium, whereas only some involvement of the ventricle wall may occur, for example, just beneath the epicardium (subepicardial) or just beneath the endocardium (subendocardial).

Silent ischemia is particularly prevalent in patients with high cardiac risk and is associated with a poor outcome.[36] Silent MIs can be detected when a patient has undergone ECG investigation or imaging for other problems.

Uncomplicated Myocardial Infarction

An uncomplicated MI is described as a small infarction with no complications during recovery. Usually the result is full recovery without a significant decrease in cardiac performance at rest and during minimal to moderate activity.[37] Location and the extent of the MI are critical with respect to outcome. MIs located in the inferior portion of the heart are considered the least clinically significant, and partial-wall-thickness MIs are less significant than transmural MIs.

TREATMENT

Initially, the treatment of a patient with an uncomplicated MI is comparable to that of a patient with a complicated MI, so the patient is cared for in a coronary care unit. The medical treatment is designed to decrease myocardial work and oxygen demand. Patients receive supplemental oxygen and are administered coronary vasodilators (nitroglycerin) to increase myocardial blood flow and analgesics to reduce ischemic pain. In addition, calcium channel blockers or beta blockers are administered to reduce the contractility and work of the myocardium. Antidysrhythmia medication may be prescribed if an aberrant cardiac rhythm is present or likely to occur.

Because the clinical course is uncomplicated, a patient's stay in the coronary care unit may be only a couple of days, with a total hospital stay of 3 to 5 days. Once the patient's condition is stabilized, management is oriented toward increasing physical activity and educating the patient and family with respect to risk factor reduction (see Chapters 29, 30, and 31).[38] This process is described as cardiac rehabilitation, phase I (see Chapter 30).

Complicated Myocardial Infarction

A complicated MI is distinct from an uncomplicated case because the patient may have one, a combination, or all four of the following complications: dysrhythmia, heart failure, thrombosis, and damage to heart structures.

DYSRHYTHMIAS

Dysrhythmias occur in 95% of patients with MIs. The type and severity of the dysrhythmia is dependent on the location and extent of the myocardial damage. Imbalance in autonomic regulation has been implicated in dysrhythmogenesis and sudden cardiac death.[39] Blunted heart rate variability has been established as a marker of sympathovagal imbalance and can serve as an indicator of cardiac risk.

The risk for serious or frequent dysrhythmias is lower in a patient with an uncomplicated MI because a small area of the myocardium is involved. Dysrhythmias that are life-threatening include complete AV heart block, ventricular-paced dysrhythmia, and ventricular tachycardia including ventricular flutter and fibrillation. In these conditions, either heart rate (comprising stroke volume, ejection fraction, and overall cardiac output) is too slow and cardiac output is impaired, or heart rate is too fast. Treatment of these conditions is immediate and requires drugs. If refractory to conservative management, cardioversion or electric shock (for flutter and fibrillation) is indicated. If a normal rhythm cannot be restored and maintained by the patient's own inherent pacemaker, an artificial pacemaker may have to be implanted.

Dysrhythmias may be present in the absence of overt myocardial ischemia or heart damage. Common dysrhythmias are presented in Chapter 4, and their clinical implications are presented in Chapter 12. One conduction abnormality that is receiving increasing attention is atrial fibrillation.[40] This dysrhythmia warrants management, given its association with thromboemboli and stroke (see Chapters 6 and 32). Furthermore, atrial fibrillation is the most common dysrhythmia associated with cardiac surgery (25% to 60%), and it leads to increased postoperative morbidity and mortality and to associated health care costs.[41,42] Atrial fibrillation has been reported to be more common in men—and also to be better tolerated by them than by women.[43]

HEART FAILURE

Another complication after MI is cardiac insufficiency and failure. Heart failure is a condition in which the heart is weakened by myocardial damage and is unable to provide cardiac output to meet the body's metabolic needs for oxygen, nutrition, and removal of waste products. When the heart experiences ischemia, the myocardium contracts with less force and conduction abnormalities may alter the mechanics of the contraction. If an area of the heart is infarcted, the affected myocardium does not contract, thus affecting overall cardiac output. Another type of heart failure not directly related to ischemia and infarction is congestive heart failure (described in the next section).

Recent terminology regarding the classification of heart failure differentiates diastolic and systolic heart failure.[44-47] Diastolic heart failure refers to the presence of the symptoms of heart failure in the absence of left ventricular dysfunction, the hallmark of systolic heart failure. Diastolic heart failure in which the left ventricle is stiff (reduced compliance and impaired relaxation resulting in increased end diastolic pressure) has been estimated to account for 40% to 50% of all cases of heart failure.[48] Diastolic dysfunction has been of increasing interest in nonprimary heart disease such as systemic sclerosis, and it appears to be more common than previously thought.[49] The two types of heart failure must be distinguished on the basis of Doppler echocardiography because their signs and symptoms are comparable. Both types are associated with marked morbidity and mortality.

Immediately post-MI, cardiac output is markedly reduced. The compensatory response of the body is to increase sympathetic and renin-angiotensin-aldosterone stimulation, resulting in increased heart rate and myocardial contractility. The result of this compensation is to normalize cardiac output to normal resting values. If myocardial damage is extensive, the kidneys compensate by retaining sodium and water to improve circulatory volume and venous return. Depending on the amount of myocardial tissue death, the individual may survive, but with resulting chronic congestive heart failure through persistent fluid retention and hypotension. If more than 40% of the left ventricle is infarcted, the result is usually cardiogenic shock followed by the death of the individual. Renin-angiotensin-aldosterone activation contributes to left ventricular remodeling, which is further augmented by vascular endothelial dysfunction, resulting in decreased nitric oxide bioavailability.[50]

Diabetic cardiomyopathy leads to heart failure independent of underlying coronary artery disease.[51] Both structural and functional abnormalities associated with diabetic cardiomyopathy have been linked to an underlying metabolic disorder. Other factors include myocardial fibrosis due to an inflammatory process, small blood vessel pathology, cardiac autonomic neuropathy, and insulin resistance.[52]

THROMBOSIS

Deep vein thrombosis (DVT) and related pulmonary emboli are largely preventable clinical complications, and when they do occur, their diagnosis may be missed in hospitalized patients.[53,54] These life-threatening complications are serious and warrant early detection. Mortality resulting from thrombi that migrate to the lungs (pulmonary emboli) is greatest initially after an acute MI. DVTs can be challenging to detect because of the lack of specificity of their clinical presentation. Another complication is increased incidence of thrombosis originating in deep leg veins and in the damaged heart itself. Thrombosis that starts in deep leg veins occurs because of lower limb inactivity and circulatory stasis. This is a complication that can be observed in patients after surgery. Emboli from a deep leg vein thrombus usually cause pulmonary complications. If the emboli are large or numerous, the result can be pulmonary tissue infarction and death. The incidence of pulmonary emboli has been reduced because patients now are usually ambulated soon after a medical event or surgery. Nonetheless, a pulmonary embolus must be considered a distinct possibility in all patients after an MI, surgery, or major trauma.

Heart, or mural wall, thrombosis can lead to an embolus lodging in the brain, intestine, kidney, artery to the extremities, or any location in the systemic arterial circulation. Usually, mural thrombi do not affect the pulmonary system because the small fragments become lodged in the capillaries and fail to access the venous system.

STRUCTURAL DAMAGE

Structural damage to the myocardium is another serious complication of MI. If the neural conduction pathway (bundle branch) located primarily within the septum is damaged, dysrhythmias result. In addition, papillary muscles that regulate heart valve closure can be infarcted. Valve incompetence leads to regurgitation and retrograde flow of blood from the ventricles, thus impeding the forward movement of blood through the heart and decreasing cardiac output. Full-thickness damage to the myocardial wall from atherosclerotic plaques significantly compromises normal cardiac function. Heart wall damage can result in ventricular aneurysms or ventricular wall rupture. Ventricular aneurysm, or the bulging of the weakened ventricular wall, occurs in transmural (full-wall-thickness) infarcts. Ventricular wall rupture, which can occur acutely after transmural infarction but is more common in the first to second week post-MI after an aneurysm, is usually fatal. Therefore, after an MI, it is critical to determine whether an aneurysm has occurred within the myocardium so that appropriate surgical intervention can be performed.

Risk factors for cardiac rupture include being female, being older, having hypertension, and experiencing the first cardiac event.[55] Clinical signs of rupture include syncope, chest pain, and jugular venous distention. In addition, defective ventricular remodeling may predispose the heart to rupturing.

TREATMENT

The treatment of a complicated MI is initially like that of an uncomplicated MI, where the patient is cared for in the coronary care unit. Similarly, medical treatment is designed to decrease myocardial work and oxygen demand. Patients receive supplemental oxygen and coronary vasodilators (nitroglycerin) to increase myocardial blood flow and analgesics to help further reduce ischemic pain. Myocardium calcium channel blockers or beta blockers are administered to reduce contractility. Finally, antidysrhythmia medication is prescribed to stabilize the electrical conduction system of the heart or if an aberrant cardiac rhythm is present.

Patients with complicated MIs require longer stays in the coronary care unit, and their total hospital stay times are longer than those of patients with uncomplicated MIs. The time in coronary care and total hospital stay are dependent on the complications that occur after the MI. Individuals with heart failure, thrombolytic events, or structural damage requiring surgery may be in the coronary care unit for a couple of weeks. Total hospital-stay times for patients with complicated MIs may exceed this length of time. Treatment after discharge from the intensive care unit, however, is similar to that of the patient with an uncomplicated MI; the goal is to increase physical activity and educate the patient and family in risk-factor reduction. The major difference in phase I cardiac rehabilitation for patients with complicated rather than uncomplicated MIs is the intensity, duration, and frequency of the initial exercise workload (i.e., a much lighter workload is prescribed for patients with complicated MI).[56] These patients also require closer monitoring. Progression is more conservative because patients are at higher risk after a complicated MI than after an uncomplicated MI.[56]

Prognosis after a Myocardial Infarction

After an MI, the prognosis depends on many factors. Compared with the patient's premorbid status, cardiovascular performance is reduced, unless the structural damage to the ventricle is minor (as in the case of many patients with uncomplicated MIs). The most important factor is the extent of ventricular damage. With early detection of transmural infarction and improvement in surgical intervention and coronary care, however, the number of acute post-MI deaths has been reduced.[38] Other critical factors include remaining cardiac capacity and cardiac status and risk factors. Even though CAD mortality has declined in the United States, the disease remains the leading cause of death in adults.

Severe infarction can necessitate emergency or elective revascularization surgery. Emergency surgery for an acute MI complicated by cardiogenic shock is associated with satisfactory long-term survival; however, perioperative risk is high.[57]

Congestive Heart Failure

Congestive heart failure (CHF) is a leading cause of hospitalization and death. It is characterized by the inability of the heart to maintain adequate cardiac output. The incidence of

congestive heart failure appears to be increasing because of the prevalence of injurious lifestyle behaviors, aging, and improved survival after acute cardiac episodes.[58]

Almost half of all patients with congestive heart failure are women.[59] Smoking, diabetes, and high blood pressure are stronger risk factors for CHF in women than in men. Peripartum cardiomyopathy, which is unique to women in their childbearing years, occurs either in the late stages of pregnancy or within several months after giving birth.

The causative factors of heart failure are usually ischemia and MI secondary to ischemic heart disease. For the heart to maintain optimal blood flow to the pulmonary and systemic circulations, heart rate and stroke volume must be adequate. If heart rate is regular and within an acceptable range, stroke volume is the critical factor for maintaining adequate cardiac output. Stroke volume is a function of the amount of blood in the left ventricle at the end of diastole (preload); the amount of pressure and resistance the heart must overcome to eject blood into the systemic circulation (afterload); and myocardial contractility, which is the amount of force the left ventricle can apply to the blood within the chamber. If any one of these three variables is adversely affected, cardiac output is reduced. Progressive deterioration of myocardial contractility and dilation and fluid overload precipitate heart failure.

Dyspnea is the primary complaint of people with congestive heart failure. It can be challenging to distinguish between dyspnea resulting from CHF and dyspnea resulting from pulmonary causes. B-type natriuretic peptide (BNP) is synthesized, stored, and released in the ventricular myocardium, and it is stimulated by changes in ventricular wall tension and stretch.[60] The use of BNP holds some promise as a marker for congestive heart failure and a guide to clinical management.

Congestive heart failure is a major contributor to progressive renal dysfunction and anemia.[61] Anemia is observed in one-third of all patients with CHF. Conversely, chronic renal dysfunction can cause severe cardiac injury and is often associated with anemia. Thus congestive heart failure, chronic renal insufficiency, and anemia create a vicious circle that warrants aggressive medical management to attenuate the progression of the three conditions.

Acute Heart Failure

If an individual has a significant MI, the contractility and pumping ability of the heart is immediately reduced. The initial result is decreased cardiac output and the damming of blood in the veins. (The damming of blood in the pulmonary circulation leads to congestive heart failure, as discussed earlier.) The result is increased systemic venous pressure. This acute phase, which may reduce cardiac output to 40% of normal resting values, is short-lived, lasting only a few seconds before the sympathetic nervous system is stimulated, and the parasympathetics become reciprocally inhibited. Sympathetic innervation causes an increase in the contractility of viable myocardial tissue, and the increase in cardiac output may be 100%. In addition, sympathetic innervation increases venous return because the tone of blood vessels is increased. The result is increased systemic filling pressure and, thus, increased preload. The sympathetic reflex after MI becomes maximally operational within 30 seconds; therefore, except for some pain and fainting, individuals experiencing mild MIs may not know they have suffered a heart attack. The sympathetic response can continue if cardiac output is maintained at an adequate level at rest. Ischemic pain, however, may persist and warrants treatment.

Chronic Heart Failure

After an MI, several physiological responses occur along with sympathetic reflex compensation. The kidneys retain fluid almost immediately after an MI. A decrease in glomerular pressure secondary to decreased cardiac output is implicated. In addition, there is an increase in renin output and therefore an increase in angiotensin production. Angiotensin promotes reabsorption of water and salt from the renal tubules. The effect of moderate fluid retention is an increase in blood volume and venous return. This increases preload, hence cardiac output. If the MI was severe, however, the result can be excessive fluid retention. This results in systemic edema and overstretching of the heart due to excessive blood volume and venous return. In the chronic state, this condition is termed chronic heart failure.

Recovery of the damaged myocardium occurs after MI. New collateral arteries are formed to supply the peripheral portions of the infarcted region. This revascularization can assist marginally active cells to become fully functional again. In addition, the unaffected myocardial cells hypertrophy. In a mild to moderate MI, such recovery can result in major improvement in cardiac function and can take 6 weeks to several months, depending on extent of injury.

Gas transfer across the alveolar-capillary membrane is impeded in CHF. This may be explained by the pressure and volume overloading, which injures the alveolar blood-gas barrier, hence impairing the diffusion of blood across it.[62] In the short term these changes may be reversible. If the membrane is chronically challenged, however, the anatomic and physiological integrity of the membrane is remodeled. These changes have been associated with worsened symptoms and exercise tolerance. Further, these changes may be prognostic of patient outcome.

Cardiac remodeling is a central feature of heart-failure progression.[63] Remodeling refers to the alteration of the structure and geometry of the heart in response to myocardial insult or pressure or volume overload. Such remodeling reflects the adaptation that is needed to maintain adequate heart function with changing conditions. Increased muscle mass is one of the primary adaptations, and it usually involves left ventricular hypertrophy.[64] Adaptive hypertrophy of the left ventricle is clinically important in that it is associated with increased morbidity and mortality rates.[65] A further consequence of adaptive cardiac hypertrophy is the potential for reduced responsiveness to the metabolic and functional effects of insulin, which further contributes to the heart's hypoeffectiveness.[66] Pharmacological studies have been conducted to examine the role of drugs on the remodeling process in individuals with heart failure. Studies of the role of nonpharmacological interventions, including exercise, in cardiac remodeling have not been made.

A reciprocal relationship between CHF and diabetes has been well established.[67] People with CHF may be at increased risk for diabetes due to reduced physical activity, cellular metabolic defects, reduced muscle perfusion, and poor nutrition. The increased sympathetic stimulation associated with CHF

increases insulin resistance and decreases insulin release from the beta cells of the pancreas. Both factors contribute to glucose intolerance and diabetes, which in turn lead to hyperglycemia and increased risk for cardiovascular and metabolic complications.

Even in patients with chronic heart failure, regular exercise may be associated with a protective metabolic phenotype.[68] This effect of exercise could explain why fit people have less severe MIs than nonfit people.

Compensated and Decompensated Heart Failure

Compensated heart failure is the final stage after the acute, then chronic, physiological compensation for cardiac dysfunction. In this state the heart can pump blood effectively but at a reduced cardiac output compared with the pre-MI condition. The individual's cardiac reserve, that is, the difference between maximum and resting cardiac output, is greatly reduced. With even small increases in metabolic demand through exercise, symptoms of acute failure reappear because the limits of compensation are exceeded. These symptoms include rapid heart rate, pallor, and diaphoresis.

Decompensated heart failure affects 5 million Americans and is associated with a 5-year mortality rate of almost 50%.[69] Decompensated failure occurs when the heart is so severely damaged or weakened that normal cardiac output cannot be attained. This type of failure is defined as a sustained deterioration of at least one New York Heart Association functional class, usually with evidence of sodium retention.[70] Cardiac output is insufficient to maintain normal renal function. Fluid continues to accumulate so the heart is stretched and weakened further, permitting only moderate to low quantities of blood to be pumped. In unilateral heart failure, the left ventricle may fail while the right ventricle continues to pump vigorously. Blood volume and pulmonary capillary pressure increase. If this occurs, fluid filters into the interstitial spaces of the alveoli, resulting in pulmonary edema, impaired gas exchange, and suffocation. As the heart weakens, not only is systemic blood flow compromised, so is the coronary system. The area most affected is the subendocardial region. As these cells become infarcted, the heart weakens further until other regions of the heart also become ischemic and infarcted.

Prognosis

End-stage cardiac disease without effective pharmaceutical or surgical intervention, including revascularization or heart transplantation, results in death. Intermediate measures to avert deterioration have emerged, including cardiac resynchronization therapy through biventricular pacing.[71] The addition of implantable cardioverter defibrillators may help to minimize the occurrence of sudden death in people with CHF. Left-ventricle assistance devices may be used to support the function of the failing heart until it responds to conservative management or until surgery is scheduled.[72] Surgical ventricular restoration holds some promise for reversing inappropriate remodeling of the myocardium after infarction and restoring its normal elliptical shape.[73] The primary pharmaceutical interventions used to mitigate heart failure include diuretics to reduce fluid overload and cardiac glycosides such as digitalis to improve myocardial contractility. These interventions are combined with modification of salt and fluid intake. Other factors can predict a poor outcome. Sleep apnea syndrome, for example, is common in people with CHF and is associated with a poor prognosis. As ejection fraction is decreased, the risk for thrombus formation and stroke increases.[74]

In cases where the heart has compensated poorly and remains weak and the cardiac output is minimal, heart transplant is the only recourse. Because organ donors are not readily available, the number of individuals who need new hearts far exceeds the available donor organs. Posttransplant prognosis is related to the recipient's surgical suitability and the health of the donor organ. The prognosis will also reflect the amount of cardiac reserve.

Valvular Heart Disease

Heart valve incompetence is classified as being either congenital or acquired (i.e., after a bacterial or viral infection of the heart valves) and can affect any one of the four heart valves. Surgical repair or replacement of defective mitral valves, tricuspid valves, and aortic valves constitutes a significant proportion of cardiac surgeries. Mitral and aortic valve disease is particularly common in people over 65 years of age.[75,76] In this age group, symptoms can be masked by such comorbidities as cardiovascular disease, pulmonary disease, and hypertension. Surgical repair is associated with favorable short- and long-term outcomes. Some valve defects are benign and treatment is not indicated. Some people can tolerate heart valve defects as children, but they become symptomatic with age. Currently, these types of valve defects are often corrected at birth or early in life.

One common valve defect is prolapse of the mitral valve, which is more common in women than in men and may warrant repair.

Cardiac defects may be present as secondary diagnoses in an individual being managed by a physical therapist. Such defects need to be considered in terms of an individual's capacity to respond to exercise, as well as the condition's overall effect on the individual's life. Exercise limitation secondary to heart valve disease may mask limitations due to other causes, or vice versa.

Athletic Heart Syndrome

Although physical fitness is associated with innumerable health benefits (see Chapters 1 and 18), cardiovascular adaptation to intense exercise in athletes (athletic heart syndrome) can mimic disease processes associated with cardiovascular disease.[77] Sudden cardiac death in athletes is often associated with cardiac hypertrophy, dysrhythmias, or both. In addition, cardiac episodes in athletes may reflect the manifestation of congenital abnormalities in electrical activity or mechanical function of the heart. Thus screening athletes for cardiovascular adaptation is warranted. Physical therapists involved with sports teams need to be vigilant regarding risk factors associated with the athletic heart syndrome to detect and avoid untoward events.

Systemic Hypertension

Systemic hypertension, or wide pulse pressure hypertension, has become increasingly prevalent and is implicated in multiorgan dysfunction, not only in cardiac dysfunction and failure (see Chapter 1). Systolic hypertension syndrome refers to a complex of hemodynamic maladaptations, including stiff central arteries, normal peripheral arteries, arteriolar constriction, metabolic abnormalities, cardiac hypertrophy, and increased blood pressure variability.[78] In addition to the conventional measures of hemodynamic status, measures of arterial mechanics, including arterial compliance, elastic modulus, impedance, pulse wave velocity, and pulse pressure amplification, are used for diagnosis and management.

Hypertension is strongly implicated in cardiovascular disease and stroke.[79] When systemic hypertension syndrome advances to heart disease, the prognosis is poor.[80]

Obesity is considered a primary risk factor for hypertension, as well as for heart disease, stroke, and renal dysfunction. Mechanisms that have been proposed for obesity-related hypertension include insulin resistance, hyperinsulinemia, dyslipidemia, increased sympathetic activity, sodium and water retention, cardiac dysfunction, and endothelial dysfunction.[81] To adapt to an increasing workload, the heart enlarges. When it can no longer adequately compensate, the heart begins to fail, and that is usually coupled with respiratory failure. Myocardial hypertrophy is considered an independent risk factor for cardiovascular disease in people who are obese and is a strong predictor of heart failure.

The occurrence and clinical implications of myocardial fibrosis in people with hypertension are well established.[82] The rennin-angiotensin-aldosterone system and contributions of mineralocorticoids and endothelin have been implicated in the development of myocardial fibrosis.

Thyroid hormone has well-documented effects on cardiovascular function, including blood pressure.[17] In hyperthyroidism, pulse pressure is increased, whereas in hypothyroidism, pulse pressure is narrowed. Adaptations of the cardiovascular system alter blood pressure to accommodate new demands on the system. The effects of thyroid hormone on blood pressure, therefore, are mediated both directly and indirectly.

Pulmonary Hypertension

Pulmonary hypertension is increasingly recognized as a pathology that can occur secondary to some other pulmonary condition or with no apparent cause (idiopathic pulmonary hypertension). By definition, pulmonary hypertension exists when the mean pulmonary pressure is greater than 25 mm Hg at rest and greater than 30 mm Hg during exercise.[83] Pulmonary blood pressure can increase in response to increased pulmonary vascular resistance, blood flow, and pulmonary artery wedge pressure. The cause of pulmonary hypertension has shifted from being attributed to vasoconstrictive dysfunction to being attributed to angioproliferative dysfunction.[84] Endothelial dysfunction has been implicated.[85] Although the prognosis is variable, with some people surviving months and others decades, guidelines have been recommended to assess the prognosis for individuals with pulmonary artery hypertension and to institute appropriate intervention expeditiously.[86]

Obstructive Lung Disease

COPD is also known as chronic obstructive lung disease (COLD), chronic obstructive airway disease (COAD), and chronic airway or airflow obstruction (CAO).[87] Exacerbations characterize these conditions and contribute largely to their associated morbidity and mortality.[88] COPD is common worldwide and contributes to major disability, as well as to economic and social burdens.

More than 30 million Americans have COPD.[89] The first part of this chapter describes chronic bronchitis, emphysema, asthma, and bronchiectasis. A patient usually presents with more than one of these conditions. Most people with COPD have a combination of chronic bronchitis, emphysema, and airway hyperactivity. The typical presentation includes episodic wheezing along with a variable degree of chronic bronchitis and emphysema.[90] A radiograph typically shows hyperinflated lungs, flattened diaphragms, and an enlarged right ventricle as a result of hypoxemia and increased pulmonary artery pressure. Other findings vary from patient to patient, depending on the predominant disease process contributing to the COPD.

Inflammation of the bronchial wall is typically present through the course of the disease, with increasing inflammation during exacerbations. In addition to destruction of the lung parenchyma in emphysema, small airways are affected (obstructive bronchiolitis). Chronic inflammation leads to the remodeling and narrowing of the small airways. The destruction of lung parenchyma and the inflammation cause loss of elasticity. The two principal theories about the pathophysiological causes of COPD include oxidative stress and an imbalance between proteinases and antiproteinases. Chronic inflammation of the lung parenchyma associated with COPD can be associated with systemic inflammation and further chronic degenerative dysfunction. Because of the prominence of inflammation in the underlying pathophysiology in COPD, interest in the use of inflammatory markers in clinical assessment is considerable.[91,92]

The symptoms of individuals with COPD can be accentuated during sleep. The mechanisms can originate centrally, as well as peripherally (i.e., in lower airways and the chest wall).[93] Adverse effects include hypoventilation, cardiac dysrhythmias, and pulmonary hypertension, all of which can predispose an individual to nocturnal death. Evaluation of sleep is therefore an essential component of the overall assessment.

Chronic Bronchitis

Chronic bronchitis is a condition associated with chronic swelling and inflammation of the bronchi and bronchioles. The diagnosis is based on report of a cough producing sputum on most days for 3 months during 2 consecutive years when other conditions have been ruled out.[94] The degree of airway narrowing is assessed with spirometry.

Pathologically, an increase in the size of the tracheobronchial mucous glands (increased Reid index) occurs, along with goblet cell hyperplasia.[95] Mucous cell metaplasia of bronchial

epithelium results in a decreased number of cilia. Ciliary dysfunction and disruption of the continuity of the mucous blanket are common. In the peripheral airways, bronchiolitis, bronchiolar narrowing, and increased amounts of mucus are observed.[96]

Chronic bronchitis results from long-term irritation of the tracheobronchial tree. The most common cause of irritation is cigarette smoking.[97] Regular exposure to the inhaled toxic particles and gases in cigarette smoke causes inflammation in the epithelium of the central airways (larger than 4 mm in internal diameter). This inflammatory process is associated with an increased production of mucus by the goblet cells and mucous glands. Smoking inhibits ciliary action and destroys cilia. The hypersecretion of mucus and the loss and impairment of cilia lead to a chronic productive cough. The fact that smokers secrete an abnormal amount of mucus predisposes them to respiratory infection and prolonged recovery from such infection. The irritation of smoke in the tracheobronchial tree causes bronchoconstriction. Although smoking is the most common cause of chronic bronchitis, other triggers include air pollution, bronchial infections, and occupations in which air quality is affected.

Patients with chronic bronchitis often appear blue as a result of hypoxemia. Although many patients have a high arterial partial pressure of carbon dioxide ($PaCO_2$), the pH is normalized by renal retention of bicarbonate (HCO_3). The bone marrow compensates for chronic hypoxemia by increasing the production of red blood cells, leading to polycythemia.[90] Polycythemia increases blood viscosity and the work required by the heart to pump and circulate the blood through the lungs and systemic vasculature. Long-term hypoxemia leads to hypoxic pulmonary vasoconstriction, increased pulmonary artery pressure and, potentially, right ventricular hypertrophy.

Individuals with bronchitis often expectorate mucoid sputum. In an exacerbation, usually from infection, they have an even greater amount of purulent sputum. Ventilation-perfusion abnormalities are common, and they increase hypoxemia and $PaCO_2$ retention. The respiratory rate increases, as does the use of accessory muscles. Oxygen demand by these muscles and production of carbon dioxide (CO_2) increase beyond the capacity of the ventilatory system. The work of breathing increases disproportionately. This contributes to a further decrease in the arterial partial pressure of oxygen (PaO_2) and an increase in $PaCO_2$. The hypoxemia and respiratory acidemia increase pulmonary artery constriction, which further increases pulmonary artery pressure and right ventricular strain. During an exacerbation, these patients are usually treated with intravenous fluids, antibiotics, bronchodilators, and low-flow oxygen. Corticosteroids may be administered. Diuretics and digitalis are used to treat right ventricular failure.

Emphysema

Emphysema is defined as "a condition of the lung characterized by abnormal permanent enlargement of airspaces distal to the terminal bronchiole, accompanied by destruction of their walls."[98] There are two main types of emphysema: centrilobular and panlobular.[99] Centrilobular emphysema is 20 times more common than panlobular emphysema, although both types often coexist in the same patient.

Centrilobular emphysema is characterized by inflammation, edema, thickened bronchiolar walls, and destruction of the respiratory bronchioles. These changes are common and are marked in the upper lobes and the superior segments of the lower lobes.[100] Centrilobular emphysema is more common in men than in women, is rare in nonsmokers, and is common in patients with chronic bronchitis.

Panlobular emphysema, characterized by destructive enlargement of the alveoli, affects primarily the lower lobes (Fig. 5-1). This type of emphysema is characteristic of alpha$_1$-antitripsin deficiency, which involves an imbalance between the elastin and elastase in the lung parenchyma. The emphysematous lung develops secondary to loss of radial traction on the bronchioles and loss of the elastic recoil of the alveoli. When individuals without pulmonary dysfunction inhale, the airways are stretched open by the enlarging elastic lung. In exhalation, the airways are narrowed as a result of the decreasing stretch of the lung. The lungs of people with panlobular emphysema have decreased elasticity because of the destruction of surrounding alveolar walls. Thus the bronchioles lack tethering and support, which exposes them to collapse even during normal exhalation.

Bullae, emphysematous spaces larger than 1 cm in diameter, are commonly present in patients with emphysema (Fig. 5-2).[101,102] Bullae develop from a coalescence of adjacent areas of emphysematous lung or because of an obstruction of the conducting airways that permits the flow of air into the alveoli during inspiration but impedes the outflow of air during expiration. The alveoli become hyperinflated and eventually the walls are damaged, leading to an enlarged air space in the lung parenchyma. These bullae can exceed 10 cm in diameter and they compromise the function of the remaining lung tissue (Fig. 5-3). Surgical intervention to remove bullae may be indicated. Pneumothorax, a serious complication, can result from their rupture.

There are several long-term structural and functional changes in the lungs of people with emphysema. The diagnosis is based on these changes. Chronic airflow obstruction

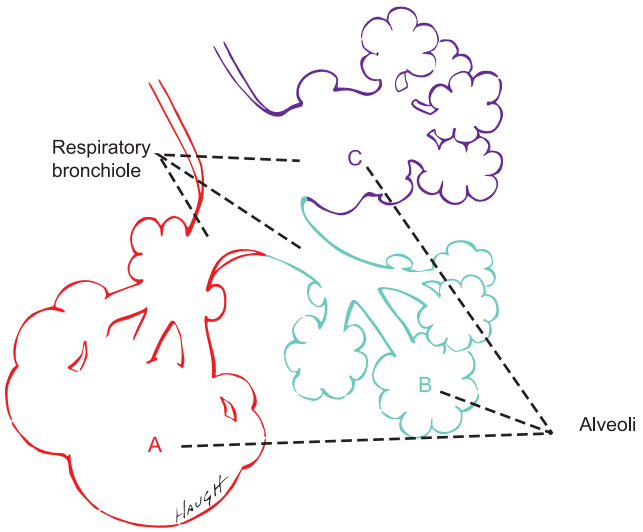

Fig. 5-1 *A,* Panlobular emphysema is characterized by a destructive enlargement of the alveoli. *B,* A normal respiratory bronchiole and alveoli. *C,* Centrilobular emphysema is characterized by a selective enlargement and destruction of the respiratory bronchiole.

reflects both the effect of chronic inflammation of the small airways (contributing to obstructive bronchiolitis) and parenchymal destruction (emphysema). The latter contributes to the loss of alveolar tethering and attachment, resulting in increased lung compliance (reduced elastic recoil) of the affected lung regions. The airways lose their ability to remain open during expiration, which contributes to dynamic airway closure.

Shortness of breath is the most common complaint of a person with emphysema, and it reflects psychological factors, as well as pulmonary impairment.[103] Dyspnea is persistent (present daily) and worsens with exertion and during respiratory infections. These patients appear thin and have elevated shoulders and an increased anteroposterior chest diameter. They tend to breathe with the accessory muscles of respiration. These patients tend to lean forward when distressed, resting their forearms on their knees or sitting with their arms extended at their sides and pushing down against the bed or chair, to elevate their shoulders and improve the efficiency of the accessory muscles to support breathing. They may breathe through pursed lips during the expiratory phase of breathing.

On auscultation, breath sounds are reduced throughout most or all lung fields. Radiographs show overinflated lungs, flattened hemidiaphragms, and elongated hearts (Fig. 5-4). Pulmonary function tests show decreased vital capacity, FEV_1, maximum voluntary ventilation, and diffusing capacity. The total lung capacity increases as a result of greater anatomic

dead space caused by hyperinflation, whereas the residual volume and functional residual capacity increase even more. Arterial blood gases reflect a mildly or moderately low PaO_2, a normal or slightly elevated $PaCO_2$, and a normal pH. At the end stage of disease, these patients develop heart failure (Fig. 5-5).

COPD is often associated with sodium retention, leading to massive edema and the development of right-sided heart failure.[104] Cardiac output can remain remarkably normal, suggesting that the pathology is related to fluid overload. Underfilling of the arterial side of the circulation has been proposed for stimulating the sodium-retaining mechanism in right-sided heart failure.

Exacerbations of the disease are more frequent and severe with increased severity of lung pathology and impairment of baseline pulmonary function.[105] The principal cause of an acute exacerbation of COPD is infection, which may be of viral or bacterial origin. The infection causes an inflammatory response, which causes an increased production of mucus and airflow obstruction. If hospitalization is required, treatment usually includes IV fluids, antibiotics, and low-flow oxygen.[90] Some patients may receive bronchodilators, corticosteroids, diuretics, and digitalis. Theophylline is often prescribed as a bronchodilator in COPD, but it also has other important benefits. Theophylline has been shown to improve respiratory muscle strength and endurance, mucociliary clearance, respiratory drive, and cardiac function.[106,107] Pursed-lip breathing can relieve dyspnea and improve arterial blood gases in some people with COPD.[108] The majority of people with COPD report symptoms consistent with asthma, bronchitis, or both, which explains why inhaled corticosteroids reduce symptoms and improve survival in some patients.[106,109,110]

Individuals with COPD who are hypoxemic when awake become more hypoxemic during sleep, with desaturation most marked during REM sleep.[111] The mechanism is thought to reflect alveolar hypoventilation and ventilation-perfusion mismatch. Diminished ventilation during sleep also increases the risk for cardiac dysrhythmias.[93] If COPD is associated with obstructive sleep apnea, patients have increased risk for respiratory insufficiency and failure. During acute exacerbations, these effects can be augmented, thus contributing to nocturnal death.

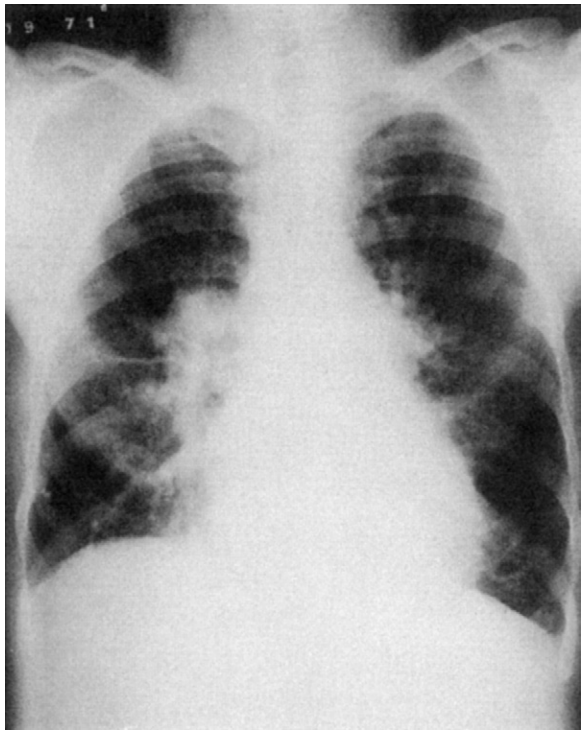

Fig. 5-5 The chest film reveals peripheral emphysematous lucency. The hilar areas are tremendously enlarged by the pulmonary arteries in a typical cor pulmonale configuration. Cardiomegaly is also present. *(Courtesy TH Johnson, MD.)*

Risk factors for emphysema include smoking, a history of chronic bronchitis, and increasing age.[94] The risk for developing COPD is 30 times greater in smokers than in nonsmokers.[99,100] The relatively rare form of inherited emphysema, alpha$_1$-antitrypsin deficiency, develops fairly early in life and is unrelated to smoking history. Repeated lower respiratory tract infections can play a role.

COPD is associated with clinically important extrapulmonary effects, including peripheral skeletal muscle dysfunction, muscle wasting, and osteoporosis.[91] Recent literature supports the theory that chronic lung and heart conditions share a common myopathy (see Chapters 24 and 31).[112-114] Both muscle wasting and altered muscle protein metabolism have been implicated in the muscle adaptation to COPD.[115] This finding has important implications for rehabilitation.

Respiratory muscle weakness and fatigue are associated with the severity of COPD.[116] Muscle weakness results from structural ventilatory impairments, adaptations to the chronic mechanical load imposed by the underlying pathology, and deconditioning. A delicate balance exists between respiratory muscle overload and adaptation. Respiratory muscle strength and endurance are fundamental to assessment, evaluation, treatment prescription, and prognosis.

Venous thromboembolism poses major risk to individuals with COPD, particularly during acute exacerbations, when blood volume may be relatively reduced in the presence of normally elevated hematocrit and, during an exacerbation, these patients are less active.[117] Even though pharmacologic prophylaxis has been advocated for high-risk patients, the physical therapist should institute prophylactic measures for all patients.

For comprehensive evaluation of the functional status of individuals with chronic lung disease, exercise testing provides an integrated perspective of organ-system function and can be used to prescribe physical activity and a structured exercise program (see Chapter 24). Exercise testing data provide supplemental information in the assessment because resting pulmonary function is not necessarily closely associated with functional capacity.

COPD progresses from respiratory insufficiency to failure. The two categories of failure are lung failure, resulting in hypoxemia, and pump failure, resulting in alveolar ventilation and hypercapnia.[118] These two conditions are managed differently based on their underlying pathophysiological mechanisms and varying clinical manifestations.

Prognosis of Chronic Bronchitis and Emphysema

Without cessation of smoking and with chronic respiratory irritation, progressive loss of lung function and worsening of symptoms will progress in people with chronic bronchitis and emphysema.[119]

Smoking cessation is the only effective intervention for preventing or reducing the life-threatening effects of COPD.[120] The decline in pulmonary function (FEV_1) is decelerated, supporting the theory that inflammation and remodeling of the airways are positively affected. Histopathological studies, however, support the idea that inflammation can persist after cessation of smoking. Longitudinal studies are needed to identify the time course and other factors that may contribute to this negative sequela and its remediation.

Individuals with COPD are at risk for tissue catabolism and associated weight loss. Poor nutrition is associated with increased morbidity. Diets are optimized, and nutritional supplements are recommended on the basis of consultation with a nutritionist. The physical therapist pays particular attention to nutrition because interventions that include exercise impose energetic demands. Diet and exercise confer considerable benefits to the functional status of people with COPD that cannot be duplicated by pharmacological interventions.[121]

The life-threatening complications of COPD are associated with prolonged hypoxemia, leading to oxidative stress on the individual, which is manifested by ischemia affecting the organ systems. This causes dysfunction of the brain, heart, kidneys, and lungs. The most common causes of death in patients with COPD are congestive heart failure, respiratory failure, pneumonia, bronchiolitis, and pulmonary embolism. The basic mechanism underlying acute respiratory dysfunction is ventilation-perfusion mismatching with increased anatomical and physiological dead space that leads to hypercapnia and acidosis.[122]

With increasing severity of disease, the load on the heart increases as a result of several factors. COPD leads to sodium retention, volume overload, edema, and right-sided heart dysfunction.[97] Cardiac output, however, can remain relatively normal. Total peripheral vascular resistance falls, with reduced effective circulating blood volume.

An individual with end-stage COPD is severely compromised and may be unable to engage in much meaningful activity. Lung-volume reduction surgery has demonstrable long-term (at least 5 years) objective and subjective benefits in selected patients with disease of the upper lobes and impaired exercise tolerance.[123,124]

Asthma

Asthma is a chronic inflammatory condition of the airways that is characterized by an increased responsiveness of the airway smooth muscle to various stimuli (due to a lowering of the threshold of airway smooth muscle reactivity). It is manifested by widespread narrowing of the airways that reverses either spontaneously or as a result of treatment.[125-127] During an asthma attack, the lumens of the airways are narrowed or occluded by a combination of bronchial smooth muscle spasm, inflammation of the mucosa, and overproduction of viscous mucus.[128-130] Specifically, eosinophilic inflammation is prevalent, and airway remodeling of the bronchial airways occurs over time.[131,132] Clinically, peak expiratory flow rates are sensitive to subtle changes in airway status, which may be detected before the onset of symptoms.[133] This early objective sign can be useful in anticipating an asthma attack.

Asthma is a widespread condition that affects 5% to 10% of the population of the United States.[134] Asthma is prevalent in individuals under 25 years of age, where estimates of prevalence vary from 5% to 15%.[135] Approximately 80% of children with asthma do not have asthma after 10 years of age.

Asthma that begins before the age of 35 is usually allergic or extrinsic. Asthma attacks are precipitated when an individual comes into contact with a substance to which she or he is sensitive, such as pollens or household dust (Box 5-1). Commonly, people with asthma are allergic to multiple allergens.[126]

Box 5-1 Factors That Can Precipitate an Asthma Attack

Allergic or Extrinsic Asthma	Nonallergic or Intrinsic Asthma
Pollen (especially ragweed)	Inhaled irritants
Animals	Cigarette smoke
Feathers	Dust
Molds	Pollution
Household dust	Chemicals
Food	Weather
	High humidity
	Cold air
	Respiratory infections
	Common cold
	Bacterial bronchitis
	Drugs
	Aspirin
	Emotions
	Stress
	Exercise

Fig. 5-6 A patient in respiratory distress during an acute asthma attack. Note the marked use of the sternocleidomastoids and other accessory muscles during inspiration.

Exercise-induced asthma (EIA) is prevalent in school children as well as in competitive athletes. EIA appears to result from hyperosmolar changes or exposure to temperature changes in the airways.[136] The condition can often be well controlled medically.

If a person's first asthma attack occurs after 35 years of age, there is usually evidence of chronic airway obstruction with intermittent episodes of acute bronchospasm. These individuals whose attacks are not triggered by specific substances are referred to as having nonallergic or intrinsic asthma (see Box 5-1). Chronic bronchitis is commonly found in this group, and this type of individual is often seen in the hospital setting.

Individuals with acute asthma attacks often report being awakened at night or early in the morning with one or more symptoms, including cough, dyspnea, wheezing, and chest tightness.[95] Waking at night is so common in the patient with asthma that its absence from the history may cast doubt on its diagnosis. The patient has a rapid rate of breathing and is using the accessory respiratory muscles (Fig. 5-6). The expiratory phase of breathing is prolonged with audible wheezing. As the lungs become increasingly hyperinflated, however, the breath sounds diminish. The patient may cough often, though unproductively, and may complain of chest tightness. Radiologically, the lungs may appear hyperinflated or may show small atelectatic areas caused by retained secretions. Tachypnea, hyperinflation, accessory muscle use, sitting upright, and pulsus paradoxus (difference in systolic blood pressure during inspiration and expiration) are useful guides for determining the severity of airway obstruction present.[129,137] Early in the attack, arterial blood gases reflect slight hypoxemia and a low $PaCO_2$ (from hyperventilation). As the attack progresses, the PaO_2 continues to fall and the $PaCO_2$ increases. As obstruction becomes severe, deterioration of the patient occurs, evidenced by a high $PaCO_2$, a low PaO_2, and a pH below 7.30. Optimal monitoring of the patient's status is based on flow-volume loops and clinical judgment.[138]

The goals of medical management of acute asthma include maintenance of adequate arterial oxygen saturation, relief of airway obstruction, and reduction of airway inflammation.[129] Patients who are hospitalized usually require intravenous fluids, bronchodilators, supplemental oxygen, and corticosteroids.

A severe asthma attack that persists for hours and is unresponsive to medical management is referred to as status asthmaticus. The patient may appear dehydrated, cyanotic, and near exhaustion due to labored breathing. In contrast to the audible wheezing heard early in the attack, the lung sounds can be greatly diminished or absent. Status asthmaticus has a significant death rate, so it is a medical emergency. Bilateral manual lower chest compression can assist expiration and may have value as an emergency treatment of asthma. Patients in respiratory failure require mechanical ventilation. Averting the adverse consequences of dynamic hyperinflation is the goal.[139]

On autopsy, the lungs of people with asthma are hyperinflated and fail to deflate when the thorax is opened.[140] The airway mucosa is inflamed and edematous, and the basement membrane is thickened. The mucous glands are enlarged, and the number of goblet cells is increased. Bronchospasm is evidenced by airway smooth muscle hypertrophy. The lumens of the bronchioles are filled with viscous, sticky mucus, which can precipitate death by asphyxiation (Fig. 5-7). Secretions in the tracheobronchial tree of a patient with asthma are a combination of mucus, secreted by the mucous glands, and an exudate from the dilated capillaries beneath the basement

membrane.[141] Cilia fail to sweep the mucoserous fluid as effectively as they sweep mucus alone. In addition, sheets of ciliated epithelium can be shed into the bronchial lumens, further contributing to airway obstruction. Although the alveoli are overinflated, the permanent destructive changes associated with emphysema are not present.

Prognosis of Asthma

Early detection of an exacerbation of asthma is imperative. Mortality has been attributed to the failure to detect severity early.[129] As a chronic inflammatory condition, asthma may result in irreversible lung damage if untreated.[142] Antiinflammatory medications such as inhaled corticosteroids have a role in controlling mild to moderate cases of asthma. In severe disease that requires heavier doses, the adverse effects of long-term corticosteroid use become prevalent— namely, osteoporosis and glaucoma.[137] Guidelines for the prevention and management of asthma have been well established.[143]

Bronchiectasis

Bronchiectasis is defined as an abnormal dilation of medium-sized bronchi and bronchioles (about the fourth to ninth generations) and generally associated with a previous, chronic necrotizing infection within these airways. Ordinarily, there is sufficient cartilage within the walls of the larger bronchi to protect them from dilation.

The airway deformities can be classified into three types.[90] Cylindrical (or longitudinal) bronchiectasis is the most common type, with a uniform dilation of the airways. Varicose bronchiectasis refers to a greater dilation than in cylindrical bronchiectasis, causing the bronchial walls to resemble varicose veins (Fig. 5-8). Saccular (or cystic) bronchiectasis refers to airways that have intermittent spherical ballooning (Fig. 5-9).

Bronchiectasis is usually localized to a few segments or an entire lobe of one lung and has a predilection for the basal segments of the lower lobes. Some 40% to 50% of cases are bilateral. When the left lower lobe is involved, it is not unusual to find bronchiectasis in the lingula of the left upper lobe as well. It is interesting to note that bronchiectasis of the right middle lobe is relatively common in older adults and can contribute to both hemoptysis and repeated infections of this lobe. Upper lobe bronchiectasis generally involves the apical and posterior segments and is usually caused by tuberculosis or bronchopulmonary aspergillosis.

Pathologically, the mucosa appears edematous and ulcerated. Destruction of the elastic and muscular structures of the airway walls is evident with resultant dilation and fibrosis. The walls are lined with hyperplastic, nonciliated, mucus-secreting cells that have replaced the normal ciliated epithelium. This change is significant because it interrupts the mucociliary

blanket and causes the pooling of infected secretions, which further damages and irritates the bronchial walls.[144]

The cause of bronchiectasis is related to obstruction of the airways and respiratory infections.[90,144] Some 60% of cases of bronchiectasis are preceded by acute respiratory infections. The infection involves the bronchial walls. Portions of the mucosa are destroyed and replaced by fibrous tissue. The radial traction of the lung parenchyma on the damaged bronchi causes the involved airways to become permanently dilated and distorted. These areas, devoid of normal ciliated cells, contain secretions that eventually become chronically infected.

Obstruction can cause bronchiectasis by collapsing lung tissue (atelectasis) distal to the obstruction.[144] The increased negative pressure in the chest (resulting from the collapsed lung) increases the traction on the airways causing them to expand and become distorted. Secretions are retained and, if the obstruction is prolonged, infection may destroy the walls of the bronchi. Infection control with antibiotics has markedly decreased the incidence of bronchiectasis.

Sputum volume during a 24-hour period can be used as an indicator of severity of disease to categorize patients with bronchiectasis. Those producing less than 10 mL per day have been categorized as having mild bronchiectasis, 10 to 150 mL as having moderate bronchiectasis, and more than 150 mL as having severe bronchiectasis.

It is now relatively uncommon for people to have severe, diffuse, long-standing bronchiectasis. Those who do have it appear physically emaciated, and as many as 25% of them may have clubbed fingers. A chronic cough with expectoration of unpleasant-tasting purulent sputum is typical in these patients. Changes in body position while sleeping or on arising often stimulate coughing as secretions drain from the small peripheral to the large central airways. These individuals may have right-sided heart failure due to fibrosis that extends into and involves the pulmonary capillary bed. Patients with widespread bronchiectasis appear dyspneic and must work hard to breathe because of hypoxemia and hypercapnia due to ventilation-perfusion mismatching. Anastomosis of the bronchial and pulmonary vascular systems causes shunting of the systemic blood from the hypertrophied bronchial arteries.[145]

Most patients have a chronic productive cough. Some patients complain of relatively few symptoms except during a respiratory infection, when they have increased cough and sputum production. The amount of sputum expectorated and the severity of the cough vary from patient to patient according to the amount of involvement. Hemoptysis does occur in about half of older patients, evidently because of the erosion of enlarged bronchial arteries that accompany the dilated bronchi. Other common symptoms include dyspnea, wheezing, and pleuritic chest pain.[144]

Pulmonary function tests of patients with localized bronchiectasis show few or no abnormalities. In more widespread disease, however, there is a reduction in the FEV_1, maximum midexpiratory flow rate, maximal voluntary ventilation (MVV), and diffusing capacity and an increase in the residual volume.[90,95]

Prognosis of Bronchiectasis

Before the era of antibiotics, the prognosis for individuals with bronchiectasis was poor. Infection was usually the precipitating cause of death. Today, with advances in medical management, the prognosis for patients is much better.[144] Most patients can lead relatively normal lives. Right-sided heart failure, a complication of diffuse, long-standing bronchiectasis, can lead to death. Pneumonia and hemorrhage are less common causes of death. Repeated bronchopulmonary infections can contribute to worsening pulmonary function and an earlier death. Before the antimicrobial era, most patients with untreated, widespread, severe bronchiectasis died within 25 years. Prognosis depends on the extent of the disease process at the time of diagnosis and on optimal medical management. Patients with moderate, localized disease, with timely intervention, can expect a relatively normal life expectancy.

Restrictive Lung Disease

Environmental factors play a major role in the etiology of primary restrictive lung conditions. Recently, smoking, which has been largely implicated in COPD and has been associated with all-cause cancer, has been reported to have an associated restrictive pulmonary component in some people.[146] Primary restrictive lung disease is characterized by stiffening of the lung parenchyma, which prevents the lungs from expanding fully. Normally, as the diaphragm descends during inspiration, the dimensions of the chest wall increase and the alveoli expand. A decrease in the compliance of the lung parenchyma, as in interstitial fibrosis, sarcoidosis, pneumoconiosis, and scleroderma, can produce this defect. Pleural abnormalities such as pleural effusion due to alveolar compression prevent the lungs from expanding fully. Thoracic changes such as kyphoscoliosis and ankylosing spondylitis restrict lung expansion by restricting chest wall movement. Obesity and ascites restrict lung expansion by limiting diaphragmatic displacement.

The pulmonary function of individuals with interstitial lung dysfunction has characteristic features.[147] Vital capacity, inspiratory capacity, and total lung capacity are reduced. Residual volume can be normal or reduced. If the restriction is pulmonary in origin, the lung compliance and diffusing capacity are reduced. Reduced exercise tolerance is associated with marked arterial desaturation.

Common restrictive lung conditions are described below. Multisystem conditions that can predispose an individual to restrictive lung dysfunction are common and are presented in Chapter 6.

Diffuse Interstitial Pulmonary Fibrosis

Pulmonary fibrosis is a common response to various types of lung injuries.[148] Numerous acute and chronic lung conditions are associated with fibroproliferation, inflammation, or both, predisposing an individual to fibrosis. These are collectively known as interstitial lung disease.

The hypothesis that inflammation causes the development of interstitial pulmonary fibrosis is being challenged by a growing body of evidence suggesting that an abnormal wound-healing response to multiple microscopic sites of acute alveolar injury occurs, progressing to fibrosis.[135,149] The resolution of the fibroproliferation response to irritation and injury is essential to patient survival. More than 130 types of interstitial lung disease have been described. Diffuse interstitial pulmonary fibrosis represents a common histological response to a wide variety of insults.[150] Initially, an insult or injury to the pulmonary parenchyma causes an influx of inflammatory and immune cells, resulting in a diffuse inflammatory process distal to the terminal bronchiole (alveolitis).[151] This can progress to subacute interstitial disease with the presence of acute and chronic inflammatory cells. Chronic disease is manifest by thickened alveolar walls and progression to fibrosis and scarring. A role for circulating cells of hematopoietic origin has been proposed as a causal factor.[150] In addition, apoptosis has been implicated in the pathophysiology of pulmonary fibrosis.[152]

The known causes of pulmonary fibrosis include occupational or environmental exposure to inorganic dusts (e.g., silica and coal), toxic gases, and certain drugs or poisons.[153,154] In addition, interstitial lung disease is associated with rheumatoid arthritis and systemic sclerosis.[155] Twins, siblings, and other family members have been reported to have a higher incidence of diffuse interstitial pulmonary fibrosis, which supports the idea that there is a genetic link. Less commonly, interstitial pulmonary fibrosis has been reported in individuals with Raynaud's phenomenon and ulcerative colitis.

Idiopathic pulmonary fibrosis (IPF), or cryptogenic fibrosing alveolitis, is a chronic, progressive, irreversible disease of unknown cause.[148,149] The median survival time after diagnosis is approximately 3 years. Idiopathic interstitial pneumonia is associated with idiopathic pulmonary fibrosis and is a type of chronic fibrosing interstitial pneumonia with the histiologic appearance of usual interstitial pneumonia (UIP).[87] It is a condition that occurs primarily in individuals over 50 years of age. Risk factors include cigarette smoking, use of antidepressants, chronic aspiration, and exposure to metal and wood dusts.

The most common early symptoms of IPF are fatigue, dyspnea on exertion, and chronic unproductive cough. As the disease progresses, the patient becomes more dyspneic and cyanotic. On auscultation, crackles are noted, chest expansion is reduced, and clubbing of the fingers may be present.

Chest radiograph usually indicates diffuse reticular markings that show prominently in the lower lung fields. High-resolution computerized tomography is often used because it is more sensitive than a radiograph; it usually reveals patchy, predominantly peripheral reticular abnormalities in the bases. It is used to evaluate the extent of parenchymal involvement and to monitor disease progression.

Pulmonary function tests show reduced lung volumes and capacities, maintained flows, and abnormal gas exchange.[156] Compliance is markedly reduced to less than half of the predicted value. Reduced diffusing capacity is the earliest and most consistent change. Initially, arterial Pa_{O_2} may be normal at rest but may decrease markedly with exercise. Pa_{CO_2} is reduced as a result of hyperventilation, and pH is maintained by renal compensation. Later, the Pa_{O_2} is greatly reduced because of the thickened alveolar membrane and ventilation-perfusion mismatching.

Bronchoalveolar lavage (BAL) may be used to assess the amount of inflammation and the accumulation of immune effector cells and proteins in the alveoli.[157] The technique consists of wedging a fiberoptic bronchoscope into a sublobar airway, then infusing 20 to 50 mL aliquots of saline into the peripheral airway. The saline is immediately aspirated by syringe. A total of 150 to 300 mL is instilled and recovered. The fluid and cells are analyzed. High-intensity alveolitis is defined by the presence of 10% or more polymorphonuclear granulocytes (PMNs) in BAL cell differential counts; low-intensity alveolitis consists of 10% PMNs or less.[158]

Lung biopsies that demonstrate an abundance of inflammatory cells suggest early disease, whereas a prevalence of fibrosis is indicative of advanced disease. A distinct category of IPF has been described and may be clinically useful.[154] Desquamous interstitial pneumonitis (DIP) is characterized by the intraalveolar accumulation of mononuclear cells, relatively intact alveolar walls without destruction or fibrinous exudates (numerous inflammatory cells with little or no fibrosis). This pattern has correlated with a more benign course and a better response to corticosteroids. Because a pattern of

DIP is commonly seen with UIP and IPF, DIP may represent an earlier, more easily reversible stage of IPF.

Corticosteroids are the mainstay of treatment for diffuse interstitial pulmonary fibrosis,[154,159] although their efficacy is being questioned for treatment of IPF because the favorable response rate is only 25% to 30% and there is a high incidence of adverse effects.[160,161] Regardless, a trial of immunosuppressive therapy is usually prescribed for a short period. Objective measures such as blood counts, erythrocyte sedimentation rate, pulmonary function testing, exercise tests with measurement of arterial oxygen desaturation and diffusing capacity, BAL fluid analysis, and the patient's symptoms should demonstrate improvement; otherwise, the medication is likely to be discontinued. Individuals who are not responsive to corticosteroids may be placed on antiinflammatory medications such as colchicines[160] or immunosuppressive drugs such as cyclophosphamide, azathioprine, or penicillamine.[148,161,162] Penicillamine is more effective in patients with connective tissue diseases and interstitial fibrosis other than IPF.

Patients should stop smoking. Supplemental oxygen is important, along with exercise, because there is a characteristic significant fall in arterial oxygen tension (Pa_{O_2}).[162] Individuals who require more than a 4-L flow per minute by nasal prongs may prefer direct administration of oxygen into the trachea. In addition to supplying higher concentrations of oxygen to the lungs, many patients prefer not to wear conspicuous nasal prongs.

Patients who have refractory restrictive lung disease may be candidates for single or double lung transplantation. Outcomes of transplantation surgery have been improving (see Chapter 40).

Most individuals with acute interstitial pneumonia and diffuse alveolar damage die within 6 months.[148] Patients with the chronic form who are treated with steroids can survive for years. Untreated, these patients commonly die within 1 to 4 years. The cause of death is usually related to respiratory or heart failure, although some die of adenocarcinoma and undifferentiated or alveolar cell carcinoma of the lung.

Pulmonary Infiltrates with Eosinophilia

Eosinophils are commonly present in lung tissue as part of the body's cellular response to a variety of agents and systemic immunological diseases.[95] They are present in the airways and lung tissue of patients with idiopathic pulmonary fibrosis. In interstitial lung disease that appears to have an allergic component (e.g., hypersensitivity pneumonitis, drug-induced lung syndromes, and sarcoidosis), eosinophils are minor components of the tissue reaction. In certain primary or systemic diseases, however, eosinophils can be the most conspicuous inflammatory cell present in the lung. These conditions can be grouped together and referred to as eosinophilic syndromes. Considerable overlapping exists among these syndromes because their causes and pathogenesis remain poorly understood.[162]

Simple Pulmonary Eosinophilia

Simple pulmonary eosinophilia is a self-limiting disease in which chest radiographs demonstrate migratory, fleeting areas of pulmonary infiltrates located in the periphery of the lungs, along with minimal respiratory symptoms and blood eosinophilia. Certain drugs such as sulfonamides have been implicated as a cause.[162] This disease is also referred to as Loeffler pneumonia and as the PIE syndrome (peripheral infiltrates with blood eosinophilia). If the disease is related to an allergic response to microfilaria, human parasites (e.g., *Ascaris lumbriocoides, Strongyloides stercoralis*), or cat and dog parasites (ascarids) that produce visceral larva migrans, it is termed tropical eosinophilia.

Prolonged Pulmonary Eosinophilia

Prolonged pulmonary eosinophilia is more chronic than the simple form and is associated with a more severe symptom complex. Over time, it can result in a form of diffuse interstitial pulmonary fibrosis that reveals honeycombed lung changes on chest radiograph and a restrictive pattern on pulmonary function tests.

The condition is more common in women. Symptoms include an acute respiratory illness with fever, night sweats, weight loss, and dyspnea. Prolonged pulmonary eosinophilia can be confused with tuberculosis, but patients with prolonged pulmonary eosinophilia deteriorate when treated with antituberculosis drugs. This disease must also be differentiated from eosinophilic granuloma and the desquamative form of idiopathic interstitial pneumonitis. Dense infiltrates located in the periphery of the lung on chest radiographs provide an important clue. Often a lung biopsy is necessary to confirm the diagnosis. Corticosteroids markedly improve the patient's symptoms and the appearance of the chest radiograph within weeks. Months or years of treatment may be required.[154]

Eosinophilic Granuloma

Eosinophilic granuloma (or histiocytosis X) can be either a unifocal disease affecting the lungs only or a multifocal disease involving the bones of the skull, mandible, vertebrae, pelvis, ribs, and extremities. Lung involvement is characterized by an interstitial granuloma composed of moderately large, pale histiocytes and eosinophils, and arteriolitis with eosinophils. The histiocytic process with eosinophils then involves bronchioles, alveolar ducts, and alveolar septae, which leads to their destruction. The proliferative endarteritis causes necrosis.

This disease most commonly affects men in their 30s or 40s. They usually have symptoms of fatigue, malaise, weight loss, a nonproductive cough, dyspnea on exertion, and chest pain, sometimes related to a pneumothorax or rib lesions. The chest radiograph often indicates a diffuse micronodular and interstitial infiltrate initially involving the middle and lower lung fields. In more advanced disease, small cystic areas develop in the infiltrate, producing a honeycomb pattern. Spontaneous pneumothorax is a complication in approximately 25% of cases.

The course of the disease varies.[154] Spontaneous regression with residual symptoms occurs in 10% to 25% of cases. In many patients, the disease stabilizes or "burns out," leaving them with a moderate pulmonary impairment as a result of fibrosis, cystic lung changes, and a restrictive defect on pulmonary function tests. Dyspnea on exertion is common. Some patients have persistent bronchitis. Corticosteroids are not particularly effective. Treatment is mainly symptomatic, with

judicious use of antibiotics and bronchodilators. Occasionally, progressive pulmonary disease leads to right-sided heart failure and respiratory failure.

Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis (PAP) is an uncommon condition of unknown origin that is characterized by alveoli filled with lipid-rich "proteinaceous" material (i.e., surfactant phospholipids) in the absence of defects of the alveolar wall, interstitial spaces, conducting airways, or pleural surfaces. Most commonly, men between the ages of 30 and 50 are affected, although people of all ages and both sexes can be affected. There are three clinical types of PAP. The most common type (>90%) is acquired PAP, which is considered an autoimmune response. Hematopoietic growth factor (granulocyte-macrophage colony-stimulating factor [GM-CSF]) is essential for local regulation of surfactant homeostasis in the lungs. People with acquired PAP have a circulating, neutralizing GM-CSF antibody. The remaining two types are congenital PAP and secondary PAP; the latter is associated with environmental factors, immunological disorders, malignancies, and hematopoietic disorders.[163]

The most common symptoms are progressive dyspnea and weight loss, with cough; hemoptysis and chest pain are reported less frequently. Chest radiographs reveal diffuse bilateral (commonly perihilar) opacities (Fig. 5-10). Physical findings may include fine inspiratory crackles, dullness to percussion, and in the later stages, cyanosis and finger clubbing. Pulmonary function studies show reduced vital capacity, functional residual capacity, and diffusing capacity. Arterial blood gases indicate a low Pa_{O_2}, especially during exercise, with normal Pa_{CO_2}, and pH.[95]

The treatment of choice for patients with moderate to severe dyspnea on exertion due to alveolar proteinosis is whole-lung lavage.[164] In the operating room, after general anesthesia and the placement of a double-lumen tube (which isolates each lung), the patient is positioned in the lateral decubitus position, with the lung that is to be lavaged in the lowermost position. The double-lumen tube enables the patient to be ventilated to functional residual capacity by the uppermost lung while the lower lung is filled with saline. An additional 300 to 500 mL saline is alternately allowed to run in and out of the lung in response to gravity. As the saline flows out, manual percussion is performed over the lavaged lung, which increases the amount of proteinaceous material washed from the affected lung. The effectiveness of mechanical percussion, manual vibration, and manual percussion in removing material from involved lungs has been compared, and manual percussion has been found to be superior.[165,166] In this procedure the affected lung is lavaged with 20 to 70 L saline. The patient may be positioned prone during the administration of the final 10 to 15 L of the lavage. After the procedure, the patient is transported to the recovery room and, once stabilized, to the ward. After a few days, the procedure may be repeated in the opposite lung.

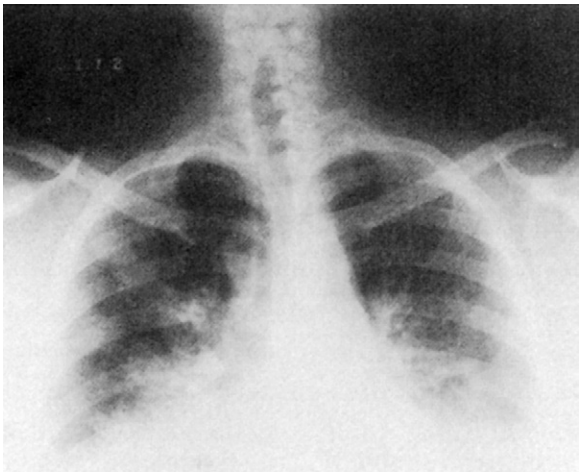

Fig. 5-10 Pulmonary alveolar proteinosis. AP chest film demonstrates an irregular, patchy, poorly defined confluence of acinar shadows that are symmetrical in both lower lung fields. The appearance is very similar to that of pulmonary edema. *(Courtesy TH Johnson, MD.)*

Most patients show significant clinical improvement after whole-lung lavage, including improved Pa_{O_2}, diffusing capacity, and vital capacity.[164,166] Many also show an improved radiograph. After lavage, patients must be followed up, because the material may reaccumulate over time. Some patients do have spontaneous remissions without undergoing lavage.

The use of limited lobar lavage through a bronchoscope has shown some benefit.[167] Half of patients who have acquired PAP with subcutaneous GM-CSF show improvement, but they show a lower rate of improvement than is seen after whole-lung lavage.[164]

Before whole-lung lavage became standard treatment, almost all children with alveolar proteinosis died and 20% to 25% of adults died within a few years, usually because of respiratory failure, right-sided heart failure, or uncontrolled infection. The majority of patients now improve greatly or recover.[164]

Sarcoidosis

Sarcoidosis is one of the most common causes of interstitial pulmonary disease.[95,168] It is a granulomatous disorder of unknown origin that can affect multiple organ systems.[169] Initial findings can include bilateral hilar adenopathy, pulmonary infiltration, and skin or eye lesions.[170] The lungs are the organs most often involved, and in such cases, 20% to 50% of patients seek medical attention because of respiratory symptoms. African Americans are affected 10 to 20 times more often than Caucasians, and women are affected twice as often as men. It usually occurs in the third or fourth decade of life.

The intrathoracic changes can be classified into four stages.[95] In the first stage, the patient is asymptomatic, with the chest radiograph showing bilateral hilar adenopathy and right paratracheal adenopathy (Fig. 5-11, *A*). In the second stage, a diffuse pulmonary infiltration is found, along with the bilateral hilar adenopathy. Interstitial infiltration or fibrosis, without hilar adenopathy, characterizes the third stage (Fig. 5-11, *B*). In the fourth stage, emphysematous changes, cysts, and bullae occur.

About one-third of people with sarcoidosis involving the lungs have spontaneous regressions with some residual fibrosis. The remaining two-thirds have progressive pulmonary impairment, along with a variable degree of impairment to the heart, liver, spleen, lymph nodes, muscles, bones, and central nervous system. Most people with sarcoidosis need no treatment. Corticosteroids, although controversial, have shown benefit.

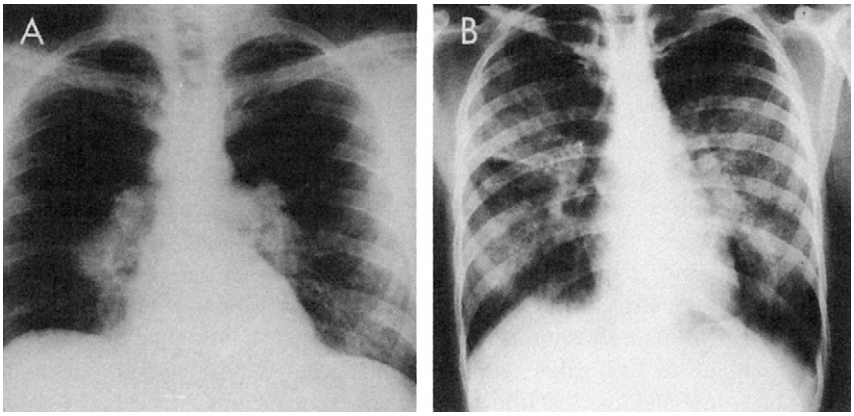

Fig. 5-11 A, Sarcoidosis in its first stage is manifested by bilateral hilar adenopathy. Usually, there are no significant physical symptoms. **B,** Disseminated sarcoidosis (third stage) reveals widespread parenchymal changes with scarring. The hilar adenopathy is usually decreased. *(Courtesy TH Johnson, MD.)*

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a systemic disease that involves the joints but can affect the lungs, pleurae, and heart. The most common thoracic complication in RA is pleuritis, with or without pleural effusions. Although RA occurs twice as often in women, pleuritis has a striking predilection for men.[162] Pleural disease is one manifestation of RA, occasionally causing fibrothorax and restrictive lung disease that requires decortication.

Interstitial lung disease, indicated by abnormal pulmonary function tests demonstrating a restrictive ventilatory impairment and a reduced ventilatory capacity, is evident in about 40% of people with RA. It is also more prevalent in men. The chest radiograph shows diffuse interstitial infiltrates, especially in the lung bases. Pulmonary nodules, which are pathologically identical to the subcutaneous nodules found in RA, may also occur and may cavitate.[155]

Coal miners with RA may have chest radiographs that demonstrate rounded densities that evolve rapidly and undergo cavitation (Caplan syndrome) in contrast to the massive fibrosis found in coal miners' pneumoconiosis.

Systemic Lupus Erythematosus

Although systemic lupus erythematosus (SLE) is a systemic collagen vascular disease, 50% to 90% of patients have pleural or pulmonary involvement. Pleuritic chest pain often signals polyserositis associated with SLE. Pleural effusions are a manifestation of polyserositis and are present in 40% to 60% of individuals with SLE. Often they are bilateral.

Chronic interstitial pneumonitis is found in 3% to 13% of people with SLE, and acute lupus pneumonitis occurs in 1% to 4%.[171] Patients with pulmonary involvement have dyspnea on exertion and a cough productive of mucoid sputum.[155] Although rare, complaints of supine dyspnea suggest diaphragmatic paresis or a diffuse myopathy of the diaphragm.[171] The chest radiograph usually indicates patchy, nonspecific densities, basilar linear or plate-like atelectasis, or both. Pleural effusions and pulmonary infiltrates are common, whereas diffuse interstitial fibrosis is rare. Pulmonary function tests often indicate a restrictive pattern with a decreased diffusing capacity and reduced arterial oxygen saturation.

Progressive Systemic Sclerosis (Scleroderma)

Progressive systemic sclerosis, also called scleroderma, is an uncommon condition that causes thickening and fibrosis of the connective tissue throughout the body and replacement of many elements of the connective tissue by colloidal collagen. Although the skin is most often involved, the lungs, heart, kidney, bones, and other parts of the body can also be affected. Approximately two-thirds of people with progressive systemic sclerosis have pulmonary involvement.[155,162]

Many of these patients with pulmonary involvement are asymptomatic, although symptoms can include weight loss, progressive dyspnea, low-grade fever, and cough (sometimes producing mucoid sputum). Chest radiographs show a characteristic fibrosis of the middle and lower lung fields. Auscultation often reveals bibasilar crackles. Pulmonary function tests reveal a restrictive defect with impaired diffusion.

The form of treatment for pulmonary involvement in patients with progressive systemic sclerosis is controversial, but usually involves corticosteroids, cyclophosphamide, or both.[155]

The prognosis for patients with only skin and joint involvement is much better than for those with involvement of the heart, lungs, and kidneys. Those with kidney involvement have a poor prognosis and a survival rate of only several years. Women have a poorer prognosis than men.

Tuberculosis

Tuberculosis (TB), a highly infectious bacterial disease, was prominent in the first half of the 1900s. With improved sanitation and medical care, TB was largely controlled. A recent resurgence of the disease has been documented, however, probably resulting from the migration patterns of people globally and the poor becoming poorer in high-income countries. TB affects many organ systems, including the lungs, and is more prevalent in people living in poor sanitary conditions with poor health. Mycobacterium tuberculosis is highly contagious but responds well to medication.[87,172] The resurgence of tuberculosis in high-income countries has become a significant public health concern.

Lung Cancer

Lung cancer is by far the leading cause of death due to cancer in both men and women.[173] The growth and division of cells is regulated by the DNA within every cell. When the DNA is damaged, which is estimated to be the result of lifestyle behaviors and environmental factors at least 50% of the time, cell division becomes uncontrolled. Cancer-causing agents, or carcinogens, related to lung disease include oxygen radicals and toxins in cigarette smoke. Although lung cancer is associated primarily with smoking, the occurrence of many other cancers is also higher in smokers. Thus the risk for cancer in general is increased in smokers. A physical therapist needs to understand the pathophysiology of all cancers, particularly lung cancer, and their medical and surgical management, as well as the impact of the natural history of a given cancer and the stage of a particular cancer on an individual's health-related quality of life. Lung cancer, as all cancers, tends to have multisystem consequences that must be understood by the physical therapist and considered during management. The physical therapist has a primary role in cancer prevention, in its early detection (by recognizing the seven warning signs of cancer), and in its management during conservative and surgical phases of care and over the long term.

End-Stage Lung Disease

Lung transplantation may be indicated in end-stage lung disease. Bronchiolitis obliterans syndrome is a serious complication of lung transplantation, but its cause is uncertain.[174]

Anemia

Anemia usually results from blood loss or from acute or chronic dysfunction of red blood cell production. The adaptive responses of the oxygen transport system involve the cardiovascular system and an increase in cardiac output and redistribution of blood flow to favor coronary and cerebral circulations at the expense of the splanchnic vascular beds.[175] These adaptations can maintain tissue oxygenation with hematocrit levels as low as 21%.[176]

Anemia is also commonly seen clinically in patients after orthopedic surgery, in renal failure, and in patients undergoing chemotherapy for cancer. Patients may be treated with blood transfusion or erythropoietin. Mild anemia may be managed by dietary measures and over-the-counter vitamin and mineral tablets alone. Moderate anemia may require mineral supplements. Anemia compromises recovery. Optimal management augments responses to rehabilitation and recovery, reduces fatigue, and improves exercise capacity, muscle strength, and performance of the activities of daily living.[177] Whether there is a critical hemoglobin level that allows for optimal participation and activity performance is unclear. The presence of CAD may mitigate hemodynamic compensation to blood loss and other causes of anemia and may attenuate treatment responses.[178]

Sickle cell anemia is a genetic condition that is common in African Americans and characterized by an abnormal shape of the red blood cell, which impedes its movement through the capillary beds. Patients with sickle cell anemia have a low anaerobic threshold in the presence of a high heart rate reserve, but they have no gas exchange abnormalities.[179] Patients may have restrictive lung pathology, increased alveolar dead space, and hypoxemia. Increased dead space may reflect impaired pulmonary capillary perfusion due to the sickle cells. Exercise hyperventilation is thought to be associated with increased anaerobiosis.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus is increasing in prevalence worldwide (see Chapter 1). Insulin resistance and glucose intolerance result from the additive effect of poor diets and inactivity. Diabetes is a multisystem condition; however, cardiovascular disease is the leading cause of morbidity and mortality in people with diabetes.[180] Organ system dysfunction results from hyperglycemia and the deposition of sorbitol on cell membranes. The toxicity of sorbitol leads to the vascular and neurological complications of this life-threatening condition. Recent evidence supports the theory that the metabolic defects associated with diabetes (impaired glucose tolerance, insulin resistance, and proinflammatory and prothrombotic states) lead to endothelial dysfunction and acceleration of atherosclerosis.[181] Hyperglycemia is associated with changes in the myocardium that lead to diabetic cardiomyopathy and heart failure. These changes can occur even in the absence of hyperglycemia, which has been linked with cardiovascular remodeling.[182] Erectile dysfunction in men has been associated with atherosclerosis and with high fasting blood glucose.[15] A diagnosis of erectile dysfunction can lead to the detection of diabetes. Adequate control of diabetes is essential to minimize these consequences.

Metabolic Syndrome

People with metabolic syndrome are at increased risk for cardiac, pulmonary, and metabolic dysfunction and diabetes. The syndrome results from deleterious body weight, inactive lifestyle, atherogenic diet, or some combination thereof.[183] Assessment is based on elevated triglycerides, low high-density lipoprotein cholesterol, elevated fasting blood glucose, elevated blood pressure, and increased abdominal circumference. At least three of these findings must be present for a diagnosis of metabolic syndrome.

Syncope

Syncope is a syndrome hallmarked by a short period of loss of consciousness resulting from a transient reduction of blood flow to the brain. Although systemic hypotension is the most common cause, it may result from a combination of factors. Syncope occurs mostly in people with cardiovascular dysfunction and in older people. Cardiovascular-related causes include orthostatic factors related to standing upright, cardiac dysrhythmia, and structural cardiac and pulmonary causes.[184] Less common forms of syncope include neurally mediated reflex syncope and syncope resulting from cerebrovascular disorders. A patient complaining of light-headedness,

dizziness, grayouts, blackouts, or fainting episodes needs a thorough multisystem assessment to establish and manage the precise causes.

Cardiac Dysfunction in Noncardiac Conditions

Cardiovascular and pulmonary consequences of noncardiovascular and pulmonary conditions are described in Chapter 6. Although their effects can be subtle, cardiovascular and pulmonary manifestations of these conditions can be serious and even life-threatening. These consequences need to be addressed by the physical therapist during the assessment to guide and modify management. Tools such as ECG are essential in detecting cardiovascular abnormalities at rest and during exercise in patients with noncardiovascular and pulmonary conditions such as electrolyte disturbance, pulmonary embolism, esophageal disorders, drug-related conditions, and neuromuscular conditions.[185]

The connective tissue disorders, including systemic sclerosis, have cardiovascular consequences.[49] Because the heart is significantly involved, scleroderma can manifest as myocardial dysfunction, conduction abnormalities, and pericardial disease. The cardiovascular system can also be involved secondarily because of involvement of the lungs and kidneys.

Myocardial and cardiovascular dysfunction is well recognized as a leading cause of morbidity and mortality in people with neuromuscular conditions, and it can be a major complication in their management.[186,187] Early detection and management of such dysfunction are keys to lifelong health, reduced incidence and severity of associated morbidity, and modification of rehabilitation in this cohort of individuals.

Obesity is an independent risk factor for heart failure.[188] The cellular changes reflect the increased metabolic strain mediated by increased mechanical strain and work of the heart.

Renal disease can lead to heart failure or result from it. In addition, anemia is implicated in both conditions. The triad of these conditions has been termed the cardiorenal anemia syndrome.[189] Anemia increases the severity of CHF and mortality, and renal disease causes anemia. Both renal dysfunction and anemia worsen heart complications. Epoetin (recombinant human erythropoietin), which is used to correct anemia associated with renal dysfunction, also decreases the compensatory increase in left ventricular muscle mass, thereby reducing associated cardiac morbidity and mortality.[190]

Summary

Knowledge of the pathophysiology of primary and secondary cardiovascular and pulmonary dysfunction is essential to the practitioner for relating the underlying pathophysiology to the clinical signs and symptoms and to the appropriate treatment goals and interventions. The cardiovascular and pulmonary systems are interdependent anatomically and physiologically. The physical therapist must distinguish the contribution of cardiovascular or pulmonary pathology to an individual's limitations on participation in life and ability to perform life's requisite activities. In addition, this knowledge is essential in prescribing interventions and appropriately monitoring the patient.

This chapter first distinguishes the pathophysiology related to the structure and function of obstructive and restrictive lung conditions. Obstructive conditions are characterized by decreased airflow during expiration (as a result of increased airway resistance), airway obstruction, and hyperinflation of the lungs. Restrictive conditions are characterized by increased lung stiffness or chest wall rigidity that limits inspiration. Both types of lung pathology progressively limit functional capacity. Second, the essential pathophysiological features of atherosclerosis, ischemic heart disease, coronary artery disease, and related syndromes are described. The pathophysiological consequences of hypertension, diabetes mellitus, anemia, and syncope on oxygen transport are highlighted. Finally, cardiac dysfunction secondary to noncardiac conditions is addressed and linked to discussion of this topic covered in Chapter 6.

Review Questions

1. Describe the role of smoking in the incidence of cardiovascular and pulmonary conditions. Or consider, if smoking had never existed, what would be the epidemiological impact on cardiovascular and pulmonary disease?
2. Describe how lung dysfunction can lead to cardiac dysfunction and provide examples.
3. Describe how cardiac dysfunction can lead to lung dysfunction and provide examples.
4. Distinguish obstructive from restrictive pulmonary pathology and how each manifests clinically.
5. Obstructive and restrictive lung pathology seldom exist alone. Describe how these types of pathology can coexist.
6. Describe tuberculosis and explain why it must be a concern to the contemporary physical therapist.
7. Describe the process of atherosclerosis and the ways in which it is injurious to life.
8. Evaluate the relative contributions of acquired cardiovascular disease and congenital cardiovascular disease to your role as a physical therapist.
9. Describe the pathophysiological progression of cardiac insufficiency to failure and death. Describe how lifestyle changes recommended by the physical therapist as part of comprehensive management could stall such progression.
10. Describe the implications of hypertension, anemia, diabetes mellitus, and syncope on your practice as a physical therapist across clinical settings, including working in the community and working with healthy seniors.
11. What is meant by the term *athletic heart syndrome*? What are the implications in regard to your role as a physical therapist with a sports team?

Acknowledgment

The author gratefully acknowledges the contributions of Willy E. Hammon III to early versions of this chapter.

This chapter describes the cardiovascular and pulmonary consequences of systemic conditions. Systemic conditions can affect oxygen transport, either directly or in combination with primary cardiovascular and pulmonary dysfunction. Although these effects can be as catastrophic as those resulting from primary cardiovascular and pulmonary dysfunction or conditions, their presentation is often subtle and may elude detection until impairment is apparent. The pulmonary and pleural complications of cardiac disease and the cardiac complications of pulmonary disease are described first. The cardiovascular and pulmonary complications of conditions involving the following systems are then described: musculoskeletal, connective tissue, neurological, gastrointestinal (GI), hepatic, renal, hematological, endocrine, and immunological. Finally, the cardiovascular and pulmonary manifestations of nutritional disorders, specifically obesity and starvation (anorexia nervosa), are presented.

To maximize the effectiveness of their treatment prescriptions, physical therapists need to be able to predict the impact of systemic conditions on oxygen transport in a given patient.[1] Complications due to systemic conditions are increasingly prevalent. This may reflect both the aging of the population and the improved survival rate and prognosis of patients with multisystem comorbidity. In addition, it is becoming more common for physical therapists to treat patients without referral, in which case no referring practitioner is alerting the physical therapist about the presence and significance of underlying systemic conditions. In their role as clinical exercise physiologists, physical therapists must be able to identify all factors that compromise or threaten oxygen transport so that treatment interventions can be prescribed effectively and with minimal risk. In addition, untoward exercise responses need to be explained; thus the physical therapist needs a comprehensive understanding of how morbidity affects oxygen transport in general. In some instances, untoward exercise responses may alert the physical therapist to some previously undetected problem warranting referral to the patient's physician.

Diagnosis and Assessment

A comprehensive assessment of all factors that affect or threaten oxygen transport is essential, particularly for patients who are not obviously at risk (i.e., those without overt cardiovascular and pulmonary conditions). The physical therapist must be able to "red-flag" a patient with an underlying problem for which physical therapy may be contraindicated or an untoward treatment response may be anticipated. Alternatively, treatment may have to be modified or treatment responses monitored more often.

Specific diagnosis of the factors that contribute to or threaten cardiovascular and pulmonary dysfunction is paramount to effective treatment across all physical therapy specialties. The overall capacity of the oxygen transport system should be established to ensure that it can adequately respond to changes in metabolic demand (including those imposed by physical therapy treatment—specifically, exercise) and changes in body position in patients who are acutely ill. Even if cardiovascular and pulmonary dysfunction is not a patient's primary condition, it may be a secondary problem, which could seriously limit a patient's response to exercise. Such assessment will establish whether treatment, specifically exercise, should be modified to avert an incident or whether it is contraindicated altogether.

Oxygen transport can be affected by dysfunction of virtually any one of the major organ systems of the body (Box 6-1). The pulmonary and pleural complications of heart disease and the cardiac complications of pulmonary disease are usually predictable and therefore are most readily detected clinically. However, the cardiovascular and pulmonary complications of conditions affecting other organ systems can be more subtle, if not more devastating.

Cardiovascular Conditions

The pulmonary complications of heart disease and the cardiac complications of pulmonary disease have been well documented for several decades.[2] A mechanically inefficient heart disrupts the normal forward propulsion of deoxygenated and oxygenated blood to and from the lungs. Because the right and left sides of the heart function in series, a problem on one side inevitably has some effect, which can lead to a problem, on the other side. For these reasons, the heart and lungs should be thought of as a single functioning unit. Disruption of the cardiovascular and pulmonary circuit leads to the backlogging of blood and an increased volume of blood in the capacitance vessels or the veins. Right heart failure contributes to increased central venous pressure (i.e., right atrial pressure) and, if sufficiently severe, leads to bilateral peripheral edema in the dependent body parts. Because blood is not forwarded to the lungs adequately, hypoxemia can result. In turn, hypoxic vasoconstriction of the pulmonary circulation leads to increased pulmonary vascular resistance and, hence, to increased right ventricular afterload and work.

Left heart failure can result in inadequate forward movement of blood through the left heart, resulting in backlogging in the pulmonary circulation and cardiogenic pulmonary edema. Pulmonary edema alters lung mechanics and lymphatic drainage, and in turn, these effects contribute to an increased risk for infection secondary to impaired macrophage function and bacterial growth. Excess pulmonary fluid around the alveolar capillary membrane creates a diffusion defect. If fluid accumulation is extreme, backlogging may be transmitted to the right side of the heart and to the periphery. Comparable to excess fluid in the lungs, backup of fluid in the peripheral circulation can impair tissue perfusion. Other cardiovascular conditions such as systemic hypertension increase systemic afterload; this, in turn, increases the work of the heart, thereby reducing its mechanical efficiency.

Pulmonary function can be altered in cardiac disease. Left heart failure, for example, is associated with accumulation of fluid in the pulmonary interstitium. This leads to reduced caliber of the airways and early airway closure, air trapping, and increased residual volume. The fluid can produce reflex constriction of bronchial smooth muscle, leading to the syndrome of cardiac asthma. The combination of airway collapse and bronchoconstriction decreases total lung capacity, flow rates, and forced expiratory volumes. Ventilation and perfusion abnormalities are also associated with cardiac disease. Ventilation of underperfused lung zones contributes to increased ventilatory dead space, and perfusion of underventilated lung zones leads to a right-to-left shunt. In left heart failure, reduced lung compliance may contribute to inhomogeneous ventilation and perfusion.

In left heart failure, the normal pattern of increased ventilation to the bases may be reversed (i.e., the apices of the lungs may be better ventilated).[3] If pulmonary edema complicates the clinical picture, the alveoli become flooded, resulting in reduced ventilation and ventilation and perfusion mismatching. The alveolar-arterial oxygen ($A\text{-}aO_2$) gradient is then increased, diffusing capacity is decreased, and arterial partial pressure of oxygen (PaO_2) is decreased. Lung compliance is inversely related to pulmonary artery pressures and interstitial fluid accumulation.[4] The net effect of these abnormalities is both obstructive and restrictive pathophysiological patterns of lung dysfunction (i.e., reduced forced expiratory volumes and vital capacity and an overall increase in the work of breathing).

Pleural effusions can result from heart disease, in particular, congestive heart failure. Changes in intravascular pressures lead to transudative pleural effusions, and cardiac injury leads to exudative effusions. Comparable to fluid balance in other parts of the circulation, fluid balance in the lung is dependent on Starling forces (i.e., hydrostatic and oncotic pressures). In healthy individuals, several liters of fluid a day are absorbed

Box 6-1 Dysfunctions That May Affect the Cardiovascular and Pulmonary Systems and Oxygen Transport

- Musculoskeletal conditions
- Connective tissue (including collagen vascular) conditions
- Neurological conditions (CNS, PNS, or ANS)
- Gastrointestinal conditions
- Hepatic conditions
- Renal conditions
- Hematological conditions
- Endocrinogical conditions
- Immunological conditions

from the pleural space, so when the balance of these forces is disrupted in disease, considerable fluid can accumulate in the pleural space. Impaired alveolar expansion due to pleural effusions is of clinical concern. Small effusions displace rather than compress the lung.

Pulmonary Conditions

Lung conditions can contribute to cardiac dysfunction in several ways. They invariably threaten oxygen transport by their effects on respiratory mechanics and ventilation-perfusion matching. To compensate, the heart attempts to increase cardiac output, which produces a corresponding increase in cardiac work. Overall, ventilation and oxygen transport are less efficient. Hypoxemia secondary to inadequate ventilation-perfusion matching may predispose the patient to cardiac dysrhythmias.

Pleural complications can arise from lung disease as well as from heart disease. Both heart and lung function can be compromised by altered fluid balance in the pleurae. Fluid balance in the pleural space is comparable, in terms of its regulation, to that in the alveolar space. Both are determined by Starling forces. Specifically, hydrostatic pressure pushes fluid into the pleural space while oncotic pressure counters the effect of these forces. The net effect of these filtration and absorption forces is a minimal net filtration pressure. When the balance of these forces is disrupted, heart and lung function can be threatened. Excessive fluid floods the space, usually reflecting both excessive hydrostatic pressure and diminished oncotic pressure. The lymphatic vessels become overwhelmed and are unable to keep the pleural space dry. Pleural fluid accumulates and either displaces lung tissue (in small to moderate effusions) or restricts the opening of adjacent alveolar sacs, causing atelectasis (severe effusions),[5] which, if sufficiently severe, may restrict cardiac filling. Pleural fluid accumulation poses a unique threat to oxygen transport as a result of its direct physical effect on the lungs, heart, or both, so it warrants special attention by physical therapists.

Pulmonary lymphatics control fluid balance within the lung parenchyma. Lymphatic vessels arise within the pleurae and not within the alveolar capillary space. They drain fluid from the interlobular septae and subpleural areas into the hilar vessels and the primary tracheobronchial lymph nodes. Problems arising within the heart or lungs can contribute to imbalances in the major lymphatic inflow and outflow channels. This contributes to fluid accumulation, stagnation, and physical compression of the myocardium and lungs.[6]

Both heart and lung disease can produce deleterious hematological changes to compensate for hypoxemia. Increases in the number of red blood cells raise the hematocrit and viscosity of the blood. This phenomenon increases the work of the heart further. In addition, viscous blood increases the probability of thromboemboli. This risk is superimposed on the existing risk for thromboemboli in hypoeffective hearts.

A thorough understanding of the interrelationship of the heart and lungs is essential for diagnosis and optimal management. In addition, the cardiovascular and pulmonary manifestations of other primary organ systems must be recognized and anticipated, particularly in patients with multisystem conditions.

Musculoskeletal Conditions

Musculoskeletal conditions impact cardiovascular and pulmonary function secondary to their effects on muscle (in particular, the diaphragm, muscles of the chest wall, oropharynx, larynx, and abdomen) and bones and joints (e.g., arthritis, ankylosing spondylitis, kyphoscoliosis, and deformities secondary to neuromuscular diseases and chronic lung diseases) (Table 6-1). Additional effects are imposed by inactivity (i.e., muscle wasting, joint rigidity, and deformity). Increased joint rigidity limits the amount of physical activity a patient may perform, which contributes to cardiovascular and pulmonary compromise, in addition to the local effect of increased chest wall rigidity and compromised bucket-handle and pump-handle motions. The normal three-dimensional movement of the chest wall and normal pulmonary circulation and lymphatic function are compromised (Chapter 23). The cardiovascular and pulmonary manifestations of musculoskeletal conditions are summarized in Table 6-1.

The cardiovascular and pulmonary deficits associated with musculoskeletal disorders of the chest wall include reduced and potentially asymmetric lung volumes consistent with pulmonary restriction, reduced flow rates, reduced inspiratory and expiratory pressures, atelectasis, dynamic airway compression, ventilation-perfusion mismatching, inefficient breathing pattern, impaired cough and gag reflexes, increased risk for aspiration, increased risk for obstruction secondary to

Table 6-1 Cardiovascular and Pulmonary Manifestations of Musculoskeletal Conditions

	Impairment	Factors that Potentially Contribute to Impairment
General Manifestations	Decreased alveolar ventilation	Altered respiratory mechanics Chest wall rigidity Decreased chest wall excursion
	Impaired mucociliary transport	Airflow obstruction Pulmonary restriction Atelectasis Inspissated secretions
	Increased work of breathing	Inefficient breathing pattern
	Increased work of the heart	Inefficient breathing pattern Constrictive pericarditis
	Decreased aerobic capacity	
Manifestations in Specific Conditions	Rheumatoid arthritis	Pleuritis Diffuse interstitial pneumonitis and fibrosis Pulmonary arteritis Bronchiolitis Pleural effusions
	Ankylosing spondylitis	Upper lobe fibrobullous disease Chest wall restriction

impaired mucociliary clearance, restricted mobility, compression of mediastinal structures and heart, and impaired lymphatic drainage, which depends on normal expiratory and inspiratory cycles.[7] Osteoporotic fractures also compromise normal chest wall configuration, hence, pulmonary function.[8]

Autoimmune conditions that have musculoskeletal manifestations can be associated with systemic conditions. Rheumatoid arthritis, for example, is associated with accelerated atherosclerosis.[9]

Connective Tissue Conditions

Connective tissue, or collagen, vascular disorders (e.g., scleroderma, systemic lupus erythematosus, and systemic sclerosis) invariably affect the cardiovascular and pulmonary systems (Box 6-2).[10] Inflammation and tissue injury can affect the airway, lung parenchyma, pulmonary vasculature, pleurae, respiratory muscles, heart, and pericardium. Shrinking-lung syndrome associated with chronic connective tissue changes is a feature of advanced disease and is characterized by loss of alveolar surface area, diffusion capacity, and lung volumes. Fibrotic changes increase the elasticity of the lung parenchyma and reduce lung compliance, thereby increasing the work of breathing. These changes are comparable to those in idiopathic pulmonary fibrosis. Both the electrical conduction system of the heart and its mechanical behavior are adversely affected by systemic connective tissue changes. Furthermore, connective tissue changes in the skin can lead to chest wall restriction. Renal-pulmonary syndrome has been associated with connective tissue conditions.[11] The cardiovascular and pulmonary manifestations of connective tissue conditions are summarized in Box 6-2.

Connective tissue conditions contribute to blood vessel changes and have been implicated in secondary pulmonary arterial hypertension.[12,13]

Neurological Conditions

Cardiovascular and pulmonary consequences of neurological conditions reflect the pathophysiological mechanisms involved.[14] There are three basic patterns of pathology: dysfunction of the central nervous system (CNS), dysfunction of the peripheral nervous system, and dysfunction of the autonomic nervous system. The cardiovascular and pulmonary manifestations of neurological conditions are summarized in Table 6-2.

Box 6-2 Cardiovascular and Pulmonary Manifestations of Connective Tissue/ Collagen Vascular Conditions

General Manifestations	Specific Manifestations in Scleroderma
Acute injury to the alveolar-capillary unit	Restrictive ventilatory impairment
Alveolar hemorrhage	Decreased diffusing capacity
Interstitial pneumonitis	Diaphragmatic dysfunction
Interstitial pulmonary fibrosis	Gastroesophageal reflux and aspiration
Pulmonary hypertension	
Respiratory muscle dysfunction	
Pulmonary edema	
Pulmonary infection	
Abnormal diffusing capacity	
Chest wall restriction	

Dysfunction of the Central Nervous System

The primary centers for breathing control and control of the heart are seated in the midbrain. The generator for breathing control produces a regular respiratory rate through modulation of inspiratory and expiratory inhibitory and excitatory neurons.

Activity of the central generator is affected by arousal and the general alerting reaction of the reticular activating system. In addition, breathing control is influenced by the hypothalamus, orbital cortex, forebrain, and amygdala.[15]

Insult to the CNS can result in cardiovascular responses that precipitate neurogenic pulmonary edema. Such responses include systemic hypertension, pulmonary hypertension, intracranial hypertension, and bradycardia. The medulla may mediate the cardiovascular responses associated with neurogenic pulmonary edema. Marked sympathetic stimulation, catecholamine release, and vagotonia appear to precipitate neurogenic pulmonary edema and the resulting leaking of the alveolar capillary membrane and alveolar flooding.[16]

Cortical disturbances may have a direct effect on cardiovascular and pulmonary function. Among the most common disturbances seen clinically are cortical infarction and seizures. Hemispheric infarction can lead to contralateral weakness of the diaphragm and other respiratory muscles. Epileptic seizures disrupt breathing, which causes hypoxemia, respiratory acidosis, and a metabolic acidosis secondary to extreme muscle contraction and lactate accumulation. The associated increase in sympathetic stimulation can precipitate cardiac dysrhythmias and pulmonary edema.

Demyelinating diseases such as multiple sclerosis result in progressive deterioration of neuromuscular function. The muscles of respiration become increasingly involved, resulting in respiratory insufficiency due to weakness.[17,18] In addition, with increasing debility, cardiovascular and pulmonary conditioning is reduced. Weakness of the pharyngeal musculature contributes to loss of airway protection in addition to the loss of cough and gag reflexes. Aspiration is problematic for these patients as the disease advances.

Patients with stroke may have central dysfunction that affects cardiovascular and pulmonary regulation and function, including reduced electrical activity of the respiratory muscles or peripheral dysfunction such that weakness, spasticity, impaired biomechanics, and gait directly affect respiratory muscle function and chest wall excursion. Hemiparesis of the diaphragm on the affected side can occur. Abdominal muscle weakness contributes to impaired cough effectiveness. Pharyngeal weakness contributes to sleep apnea in these patients. The common clinical presentation of unilateral dysfunction leads to a posture characterized by listing to the affected side when recumbent or sitting and during ambulation. This posture impairs ventilation and chest wall expansion on the affected side. Abdominal muscle dysfunction directly affects intraabdominal pressure and the efficiency of diaphragmatic descent during contraction (i.e., should the abdominal muscles

Table 6-2 **Cardiovascular and Pulmonary Manifestations of Neurological Conditions**

Manifestation Type	Impairment	Factors that Potentially Contribute to Impairment
General	Impaired mucociliary transport	Decreased physical mobility Cilia dyskinesia Increased mucus accumulation Decreased cough and gag reflexes Impaired airway protection Increased airway resistance Increased risk for airway obstruction Impaired glottic closure Increased risk for aspiration
	Impaired alveolar ventilation	Decreased lung volumes and capacities, as well as flow rates Weakness of pharyngeal and laryngeal structures Respiratory muscle weakness Decreased respiratory muscle endurance
	Increased work of breathing	
	Decreased aerobic capacity and deconditioning	
Specific	Multiple sclerosis	Respiratory muscle weakness Impaired ventilation secondary to spasm Increased oxygen consumption secondary to spasm Increased oxygen consumption secondary to impaired posture and gait Impaired gag and cough reflexes Ineffective cough
	Cerebral palsy	Increased oxygen consumption secondary to increased muscle tone Decreased mobility and activity Impaired movement economy Impaired swallowing Impaired saliva control Decreased gag and cough reflexes Impaired coordination of thoracic and abdominal motion during respiration Ineffective cough and airway clearance mechanisms
	Stroke	Decreased movement economy Spasticity and increased oxygen demands Flaccidity of respiratory muscles Impaired respiratory muscle strength Impaired pulmonary function Asymmetric chest wall Weak and ineffective cough
	Parkinson syndrome	Increased oxygen consumption secondary to increased muscle tone Decreased movement economy Chest wall restriction and impaired pulmonary function Ineffective cough

become flaccid, the efficiency of diaphragmatic contraction is reduced). Lung volumes and flow rates are reduced proportionately, causing a restrictive pattern of lung function. Muscle spasticity contributes to chest wall restriction and increased metabolic cost. Reduced activity and exercise around the time of the stroke contribute to reduced cardiovascular and pulmonary conditioning and capacity of the oxygen transport system. A high proportion of patients with strokes are hypertensive and older, a population with a higher prevalence of heart disease and atherosclerosis.[19,20]

Cerebral palsy is associated with increased muscle tone, which correspondingly increases basal and exercise oxygen consumption, resulting in increased oxygen demands. Even though the demands are increased in this condition, oxygen delivery is compromised. For example, thoracic deformity and spasm of the muscles of the chest wall and abdomen impair the breathing pattern and its efficiency. Minimizing secondary scoliosis is a priority.[21] The airways of patients with cerebral palsy are vulnerable to obstruction because of poor gag, cough, and swallowing reflexes. In addition, these patients often have poor saliva control, which further increases the risk for aspiration. Mental retardation often complicates the presentation of cerebral palsy and prevents these patients from responding adequately to their hydration needs and being able to cooperate with life-preserving treatments. These patients may harbor numerous microorganisms, adding further to their general risk for infection. Of clinical importance is the fact that pulmonary function can be substantially improved with adaptive seating and postural control.[22]

Patients with Parkinson syndrome also exhibit cardiovascular and pulmonary deficits.[23] Oxygen demand is increased commensurate with increased muscle tone. Patients with Parkinson syndrome have reduced cardiovascular and pulmonary conditioning levels as a result of compromised agility and ability to be independently mobile. These patients have a restrictive pattern of lung disease in which most lung volumes and capacities are reduced. Chest wall rigidity impairs the normal pump-handle and bucket-handle movements, so

breathing efficiency is reduced. The energy cost of breathing is correspondingly increased. Respiratory insufficiency in Parkinson syndrome likely reflects increases in tone of the respiratory muscles, chest wall rigidity, and parasympathetic tone and resulting airway obstruction. Parkinson syndrome can be associated with cardiac sympathetic denervation,[24] which has implications for the assessment, monitoring during exercise, and exercise prescription.

Patients with a history of poliomyelitis, with or without cardiovascular and pulmonary complications at onset, may exhibit pulmonary limitation several decades later.[25,26] These individuals are at risk for developing respiratory insufficiency as a result of respiratory and abdominal muscle weakness, chest wall deformity, minor infection, and periods of relative immobility; or secondary to medical interventions, such as anesthesia and sedation. Further, because of prolonged reduced physical activity, patients with chronic poliomyelitis may be overweight.

Diseases and lesions involving the brainstem can lead to various abnormal breathing patterns. Some common breathing aberrations are Cheyne-Stokes respiration, central neurogenic hyperventilation, apneustic breathing, and ataxic breathing. Cerebellar and basal ganglia lesions may produce respiratory muscle discoordination and dyspnea.

Spinal cord lesions have a variable effect on cardiovascular and pulmonary function, depending on the level of the lesion. Cervical lesions result in a high mortality rate due to cardiovascular and pulmonary complications. All lung volumes are diminished with the exception of total lung capacity (TLC), which over time returns to normal; tidal volume (TV), which is usually preserved (10% of TLC); and residual volume (RV), which is increased.[27] Patients with quadriplegia tend to have a greater diaphragmatic contribution to tidal ventilation than people without such injury. In addition, these patients have impaired cough as a result of the loss of innervation and paresis of the diaphragm, in some cases, and of abdominal and intercostal muscles. The contribution of accessory muscle activity to ventilation varies considerably. In quadriplegia in which only the accessory muscles and diaphragm have been spared, platypnea (increased dyspnea when upright) may occur.[28] In the upright position, the diaphragm is flattened and less efficient when moved downward by reduced abdominal pressures.

Thoracic lesions tend to have less effect on pulmonary function (vital capacity and forced expiratory volumes, in particular) than do cervical lesions, and the significance of this effect is reduced as the level of the lesion is reduced. Lumbar lesions may have minimal or no effect on pulmonary function; however, dysfunction of the abdominal muscles may limit cough effectiveness.

Dysfunction of the Peripheral Nervous System

Disorders of the peripheral nervous system include those of the motor neuron, peripheral nerve, neuromuscular junction, and muscle. Neuromuscular disorders of the larynx, pharynx, and tongue can lead to upper airway obstruction and increased airway resistance and can interfere with maintaining a clear airway. Aspiration is a common and serious problem associated with impaired motor control of the larynx, pharynx, and tongue.

Dysfunction of the Autonomic Nervous System

Cardiovascular and pulmonary consequences of disorders of the autonomic nervous system have been documented. Of those conditions with an autonomic component, autonomic neuropathies, diabetes, and alcoholism have been the most thoroughly studied. Multiple-system atrophy accompanies autonomic failure affecting multiple systems. Because of the anatomic proximity of the autonomic, respiratory, and hypnogenic neurons and the degeneration of these structures in this condition, dysfunction of the respiratory control mechanisms parallels autonomic and somatic dysfunction. The respiratory dysrhythmias that are seen in multiple-system atrophy include central and upper airway obstruction; irregular rate, rhythm, and amplitude of respiration, with or without oxygen desaturation; transient uncoupling of the intercostal and diaphragmatic muscle activity; prolonged periods of apnea; Cheyne-Stokes respiration; inspiratory gasps; and transient sudden respiratory arrest.[29]

Patients with diabetes and autonomic neuropathies exhibit variable cardiovascular and pulmonary dysfunction. Postural hypotension is a complication of diabetic autonomic neuropathy and efferent sympathetic vasomotor denervation. Norepinephrine levels are generally reduced in these patients. The splanchnic and peripheral circulations fail to constrict in response to standing, so cardiac output falls. The postural effect is exacerbated by reduced cardiac acceleration in patients with diabetes. Insulin has been associated with cardiovascular effects, including reduced plasma volume, increased peripheral blood flow secondary to vasodilation, and increased heart rate. In the presence of autonomic neuropathies, insulin can induce postural hypotension. Diabetic diarrhea secondary to abnormal gut motility can contribute to fluid loss and its sequelae. Cardiovascular and pulmonary changes associated with autonomic neuropathy secondary to diabetes include altered ventilatory responses to hypoxia and hypercapnia, altered respiratory pattern and apneic episodes during sleep, altered bronchial reactivity, and impaired cough.[29] Impaired peripheral perfusion and tissue nutrition are also consequences of diabetes and autonomic neuropathies, which will be described later in this chapter (see Endocrine Conditions).

Gastrointestinal Conditions

The cardiovascular and pulmonary manifestations of gastrointestinal (GI) dysfunction are summarized in Table 6-3. Inflammatory bowel disease and pancreatitis are principal examples of GI dysfunction affecting cardiovascular and pulmonary function. Aspiration is a significant cause of morbidity and mortality in patients with GI dysfunction, so it should be prevented or detected early. The pathophysiology, management, and outcome depend on the nature of the aspirate. Several predisposing factors produce aspiration pneumonia, including a decreased level of consciousness, disorders of pharyngeal and esophageal motility, altered anatomy, disorders of gastric and intestinal motility, and iatrogenic factors such as surgery, nasogastric intubation, and general anesthesia.

Inflammatory bowel disease can lead to the following cardiovascular and pulmonary pathologies: vasculitis, fibrosis,

Table 6-3 Cardiovascular and Pulmonary Manifestations of GI Conditions

Impairment	Factors that Potentially Contribute to Impairment
Risk for aspiration	Gastroesophageal reflux
Increased airway resistance	Bronchospasm
Decreased lung volumes	Elevated hemidiaphragms Compression atelectasis
Arterial hypoxemia	Alveolar capillary leak and V/Q mismatch Alveolar hemorrhage and consolidation worsen shunt Increased pulmonary vascular resistance

Box 6-3 Cardiovascular and Pulmonary Manifestations of Liver Conditions

- Intrapulmonary vascular dilation
- Pulmonary hypertension
- Expiratory airflow obstruction

- Pleural effusions
- Panacinar emphysema
- Pleuritis
- Bronchitis
- Bronchiectasis
- Hypoxic vasoconstriction
- Interstitial pneumonitis
- Pulmonary fibrosis

granulomatous disease, and pulmonary thromboembolism. Bronchitis and bronchiectasis have also been associated with inflammatory bowel disease; however, their occurrence is not related to disease severity or therapy. Biopsy specimens have shown basement membrane thickening, thickening of the epithelium, and infiltration of the underlying connective tissue with inflammatory cells.[30]

The pulmonary manifestations of acute pancreatitis are among the most important sequelae of this disease and often the cause of premature death. Problems include elevated hemidiaphragms, particularly on the right side; basal atelectasis; diffuse pulmonary infiltrates that appear more commonly on the right side than on the left side; pleural effusions that occur more commonly on the left side than on the right side; and pneumonitis. These findings are not specific for pancreatitis and are probably secondary to localized peritonitis, subphrenic collections, ascites, pain, and abdominal distension. In chronic pancreatitis, abdominal symptoms may be reduced and thoracic symptoms such as dyspnea, chest pain, and cough may predominate. Chronic effusions may result in pleural thickening.

Hepatic Conditions

Both acute and chronic liver conditions can predispose a patient to cardiovascular and pulmonary and cardiovascular complications (Box 6-3). Hepatic dysfunction can lead to hypoxemia secondary to intrapulmonary vascular dilation and noncardiogenic pulmonary edema. Hepatopulmonary syndrome, hallmarked by intrapulmonary vascular dilation, produces both diffusion and perfusion defects in the lungs and is the principal reason for severe hypoxemia.[31]

Such pulmonary vasodilation is associated with excess perfusion with respect to ventilation.[32] Arterial oxygenation may range from an asymptomatic increase in alveolar-arterial oxygen pressure difference to extreme breathlessness secondary to severe hypoxemia. Of relevance to the physical therapist is that oxygenation in these patients is frequently worse when the patient is standing compared with lying supine (orthodeoxia). In severe cases, pulmonary edema may occur secondarily to hepatic encephalopathy and cerebral edema.[33]

With respect to chronic liver conditions, cardiovascular and pulmonary manifestations have been associated with cirrhosis and hepatitis. The most common pulmonary abnormalities associated with these conditions are intrapulmonary vascular dilation with and without shunt, pulmonary hypertension, airflow obstruction, chest wall deformity, pleural effusions, panacinar emphysema, pleuritis, bronchitis, bronchiectasis, hypoxic vasoconstriction, interstitial pneumonitis, and fibrosis. Hypoxemia results from shunting, ventilation-perfusion mismatching, and diffusion abnormalities.

Pleural effusions and ascites interfere with diaphragm function and present unique problems in a patient with liver disease. Rich lymphatic connections exist between the abdominal and thoracic cavities, so ascitic fluid can flow into the pleural space. This effect is enhanced during inspiration, when the intraabdominal pressure is relatively positive and the intrapleural space is negative.

The liver is a primary organ for the production of procoagulants and anticoagulants in the blood, both of which are carefully regulated to maintain optimal balance. Liver dysfunction can disrupt the production of these complementary agents and lead to a tendency to bleed or clot. Disseminated intravascular coagulation refers to an extreme imbalance between these vasoactive agents in which bleeding and clotting problems occur simultaneously, resulting in serious consequences to the patient. With respect to central dysfunction, recently impaired myocardial contractility has been reported in patients with cirrhosis.[34]

Renal Conditions

Cardiovascular and pulmonary complications can result from renal dysfunction and from the category of disorders referred to as renal-pulmonary syndromes (Box 6-4).[35,36] The pathophysiological characteristics of these disorders include alveolar hemorrhage, interstitial and alveolar inflammation, and dysfunction of the pulmonary vasculature. Pulmonary function testing may detect both obstructive and restrictive abnormalities as a result of bronchial complications and as a result of inflammation and hemorrhage, respectively.

In systemic illness, pathology of the lungs and kidneys often coexist. Physical therapy warrants being aggressive, given the course of the renal-pulmonary syndromes and the potential for relapses and irreversible organ damage. Notwithstanding the serious medical implications of renal dysfunction, even

Box 6-4 Cardiovascular and Pulmonary Manifestations of Renal Conditions

- Alveolar hemorrhage
- Airway obstruction
- Decreased lung volumes
- Decreased diffusing capacity

Box 6-5 Cardiovascular and Pulmonary Manifestations of Hematological Conditions

General Cardiovascular Pulmonary Manifestations	Abnormalities of the Fluid Portion of the Blood	Abnormalities of the Cellular Portion of the Blood
Hemorrhage	Abnormal blood volume	Abnormal red blood cell count
Edema	Abnormal fluid balance (water excesses and deficits)	Abnormal red blood cells
Polycythemia	Abnormal electrolytes	Abnormal deformability of the red blood cells
Anemia	Abnormal plasma proteins	Abnormal hemoglobin
Infection	Abnormal procoagulants and anticoagulants	Abnormal oxyhemoglobin dissociation (e.g., carbon monoxide poisoning)
	Abnormal clotting times	Abnormal white blood cells and antibodies
		Blood dyscrasias

simple measures such as dietary salt restriction need to be advocated, even for patients on dialysis.[37]

Hematological Conditions

Hematological disorders that can manifest cardiovascular and pulmonary symptoms include abnormalities of the fluid and cellular components of the blood, as well as coagulopathies.[38] Cardiovascular and pulmonary manifestations of hematological conditions are summarized in Box 6-5. The primary underlying mechanisms by which these conditions disrupt gas exchange include hemorrhage, infection, edema, anemia, fibrosis, and malignancies.

Abnormalities related to red blood cells and their ability to transport hemoglobin and oxygen may produce signs resembling pulmonary pathology (e.g., tachypnea, dyspnea, and cyanosis). Abnormalities of the deformability of red blood cells alter blood viscosity and pulmonary blood flow. The interstitium can be disrupted by such factors as hemorrhage and malignancies. Coagulopathies disrupt the normal hemostasis and clotting mechanisms of the blood. Pulmonary hemorrhage and hemoptysis are common sequelae. The most common causes of pulmonary hemorrhage include vitamin K deficiency, hemophilia, hepatic failure, and disseminated intravascular coagulation. Pharmacological agents such as platelet inhibitors and anticoagulants can also result in pulmonary hemorrhage. Pulmonary thromboemboli are common events; symptoms include pleuritic chest pain, dyspnea, and hemoptysis.

Of the erythrocyte disorders, sickle cell anemia is probably the most common, and its manifestations largely reflect erythrocyte rigidity and vasoocclusion.[39] Acute chest infection and thrombosis leading to pulmonary infarction may occur with clinical symptoms such as fever, pleuritic chest pain, cough, and pulmonary infiltrates. The pulmonary function of patients with sickle cell anemia is abnormal; there is likely to be a reduction in TLC, vital capacity, diffusing capacity, arterial oxygen tensions, and exercise capacity.

The hematological malignancy disorders that can affect pulmonary function include the leukemias and Hodgkin disease. The three primary mechanisms by which these disorders can affect pulmonary function include direct infiltration, increased risk for opportunistic infection, and secondary effects of treatment, such as interstitial pneumonitis and fibrosis.

Disorders of plasma proteins can have significant effects on the Starling forces that maintain normal fluid balance within the tissue vascular beds. Depending on the amount of plasma protein, particularly albumin, fluid is retained in or lost from circulation. With reduced protein and oncotic pressure within the vasculature, more fluid is filtered out of the circulation into the interstitium. In catabolic states in which protein is broken down in the body, more protein leaks through the capillaries and takes water with it, thus leading to edema.

Endocrine Conditions

Endocrine and metabolic disorders can be associated with cardiovascular and pulmonary complications (Box 6-6).[6,40] Disorders of the thyroid gland, pancreas (diabetes mellitus), and adrenal glands are examples that are often seen clinically. Thyroid hormone influences surfactant synthesis and the central drive to breathe. Hypothyroidism can lead to sleep apnea, pleural effusions secondary to altered capillary permeability, and pericardial effusions. Decreases in vital capacity have also been reported secondary to muscle weakness. Individuals with hypothyroidism have exercise intolerance.[41] Hyperthyroidism increases cellular oxidative metabolism (the metabolic rate), leading to an increase in oxygen consumption and CO_2 production and an overall increase in minute ventilation.[41] Vital capacity, lung compliance, and diffusion capacity can be reduced. In addition, maximal inspiratory and expiratory pressures can be reduced secondary to muscle weakness. In thyroid dysfunction, cardiorespiratory function can be normal at rest, but dysfunction can be unmasked during exercise stress.

Individuals with diabetes may lose their pulmonary reserve capacity.[42] Although this may present as a subclinical finding, such loss can manifest with stress, aging, chronic hypoxia secondary to lung disease, or volume overload secondary to cardiac and renal failure.

People with diabetes are prone to aspiration and respiratory infections. Late complications of diabetic neuropathy include renal failure, which may be accompanied by pleural effusions and pulmonary edema. Autonomic neuropathy may affect vagal activity and airway tone and the vasomotor tone of the blood vessels. Ischemic heart disease and cardiomyopathies

Box 6-6 Cardiovascular and Pulmonary Manifestations of Endocrine Conditions

Thyroid Disorders
Hypothyroidism
Hypometabolism
- Fatigue and excessive sleeping
- Decreased aerobic conditioning
- Decreased vital capacity secondary to muscle weakness
- Sleep apnea
- Decreased heart rate
- Decreased cardiac output
- Decreased blood volume
- Pleural effusions
- Pericardial effusions

Hyperthyroidism
- Hypermetabolism
- Decreased vital capacity and diffusing capacity
- Fluid loss (diarrhea)
- Respiratory muscle weakness
- Fatigue and inability to sleep
- Decreased aerobic conditioning

Pancreatic Disorders (Diabetes)
Increased pulmonary endothelial thickness
Decreased TLC
Decreased vital capacity and forced expiratory volumes
Decreased airway vagal tone
Increased risk for aspiration
Possible reduced elastic recoil
Impaired hypoxic and hypercapnic responses
Impaired ventilatory response to exercise
Defective neutrophil production
Colonization with gram-negative bacilli
Pleural effusions and pulmonary edema with diabetic nephropathy
Increased sensitivity to increases in inspiratory resistive loading
Accelerated atherosclerotic vascular and cardiac changes
Increased ischemic heart disease
Cardiomyopathy
Increased risk for infection

Adrenal Insufficiency
Orthostatic symptoms
Decreased aerobic capacity secondary to anorexia, weakness, and fatigue
Impaired breathing mechanics secondary to GI symptoms
Increased tendency to retain fluid

are common in patients with diabetes and may cause congestive heart failure and cardiogenic pulmonary edema. Patients with diabetes have been reported to have reduced sensitivity to inspiratory loading,[43] which may impair their subjective responses to exercise. Peripheral perfusion can be compromised, resulting in diabetes. Limbs are endangered by reduced perfusion and reduced sensation. Severe cases result in limb ischemia, gangrene, and surgical amputation. Infection rates are high in patients with diabetes.

Adrenal insufficiency can also compromise oxygen transport.[40] Reduced aerobic capacity results from symptoms of weakness and fatigue and associated muscle and joint complaints. Orthostatic intolerance primarily reflects reduced inotropic capacity of the heart and reduced systemic vascular resistance.

Immunological Conditions

Congenital and acquired defects in the immunological status of the lungs lead to cardiovascular and pulmonary dysfunction, including inflammation and infection. Acquired immunodeficiency syndrome (AIDS), an example of a primary disorder of cell-mediated immunity, has reached epidemic proportions over the past 20 years. This syndrome leads to lymphocyte death. The most serious pulmonary infection associated with AIDS is *Pneumocystis carinii* pneumonia.[44] The fact that a patient with the human immunodeficiency virus (HIV) is likely to have recurrent pneumonia suggests that the infecting organisms persist in the lung despite treatment.[45] The clinical presentation includes diffuse pulmonary infiltrates, cough, dyspnea, and hemoptysis. These patients can also have symptoms of upper airway obstruction.

Nutritional Disorders

The two most common nutritional disorders seen in Western countries are obesity and anorexia nervosa, which is akin to starvation. Two-thirds of the U.S. population is now categorized as being overweight and at risk for its sequelae. Obesity contributes in several ways to impaired oxygen transport.[46] Alveolar hypoventilation and impaired Pa_{O_2} and gas exchange result from chest wall restriction. Systemic and pulmonary blood pressures are increased. In addition, large abdomens and abdominal contents impinge on diaphragmatic motion and can restrict diaphragmatic descent. This can lead to compression of the dependent lung fields. Obesity is associated with elevated C-reactive protein, a marker for inflammation and elevated cardiovascular health risk.[47] Recumbency can induce respiratory insufficiency (positional respiratory failure). Individuals who are obese have a higher incidence of snoring and obstructive sleep apnea secondary to weakness and increased compliance of the postpharyngeal structures. In addition, these patients often have weak, ineffectual coughs resulting from expiratory muscle weakness and the mechanical inefficiency of these muscles. The work of breathing is markedly increased. Furthermore, in chronic cases, reactive pulmonary vasoconstriction in response to chronic hypoxemia contributes to right ventricular insufficiency and increased work of the heart and cardiomegaly. Individuals who are obese tend to be less active and aerobically deconditioned, with reduced efficiency of oxygen transport overall and increased risk for thromboemboli. Hypertension is also a serious sequela of obesity.

In addition to the direct effects obesity has on oxygen transport, central obesity has been strongly linked with metabolic syndrome. Additional risk factors include increased blood pressure, dyslipidemia (raised triglycerides and lowered high-density lipoprotein cholesterol), increased fasting glucose and type 2 diabetes mellitus.[48] In any patient who is overweight, these risk factors need to be assessed, not only so that treatment can be prescribed accordingly, but to facilitate referral of the patient to other health care professionals, if necessary. Abdominal fat, although associated with aging, is more closely linked with health risk than subcutaneous fat. Conventional measures of body composition may not estimate health risk sufficiently (e.g., insulin resistance and cardiovascular disease).[49]

The major cardiovascular and pulmonary manifestations of anorexia nervosa relate to generalized weakness and reduced

Box 6-7 Cardiovascular and Pulmonary Manifestations of Nutritional Disorders

Obesity	**Starvation or Anorexia Nervosa**
Alveolar hypoventilation	Generalized weakness, debility, decreased cardiopulmonary conditioning
Obstructive sleep apnea	Impaired mucociliary transport
Decreased outward recoil of the chest wall	Ineffective cough
Increased abdominal contents	Fluid and electrolyte disturbances
Increased mass of the abdominal wall	Cardiac dysrhythmias
Decreased functional residual capacity	Respiratory muscle weakness
Decreased expiratory reserve volume	
Decreased lung volumes, arterial oxygen tension (Pa_{O_2}), and saturation (Sa_{O_2}) in recumbency	
Basal airway closure and resulting decrease in Pa_{O_2}	
Marked pulmonary abnormalities during sleep	
Decreased ventilatory responses to CO_2	
Cardiomegaly	
Rotation and horizontal position of the heart	
Axis deviation on ECG	
Decreased myocardial pumping efficiency	
Decreased aerobic conditioning and oxygen transport reserve capacity	

endurance of all muscles, including the respiratory muscles. Cough effectiveness is correspondingly compromised. Oxygen transport reserve is minimal. Because of poor nutrition and fluid intake, the patient is at risk for anemia, fluid and electrolyte imbalances, and cardiac dysrhythmias.[50] Common manifestations of nutritional disorders are summarized in Box 6-7.

Summary

This chapter describes the cardiovascular and pulmonary consequences of common systemic conditions. Oxygen transport, the purpose of the cardiovascular and pulmonary system, can be significantly affected by dysfunction in virtually all organ systems of the body. The pathophysiological consequences of conditions of the following systems of oxygen transport are presented: cardiac, pulmonary, musculoskeletal, connective tissue/collagen vascular, neurological, gastrointestinal, hepatic, renal, hematological, endocrine, and immunological. In addition, the cardiovascular and pulmonary manifestations of nutritional disorders, including obesity and anorexia nervosa, are described.

Knowledge of these effects is essential to the practice of physical therapy across all specialties because of the prevalence of systemic conditions either singly or in combination. The presentation of the cardiovascular and pulmonary consequences of systemic conditions is often subtle or obscured and is associated with a poor prognosis, so early detection and appropriate management are essential.

Physical therapists must be able to diagnostically distinguish cardiovascular and pulmonary manifestations of systemic conditions in order to appropriately identify indications for physical therapy, contraindications, side effects, and unusual treatment responses. In addition, detailed assessment of the patient's problems ensures that problems amenable to physical therapy are appropriately treated and that those that are not are referred back to a physician. These skills are particularly important given the advent of direct-access practice and the fact that a high proportion of patients being treated by physical therapists have systemic conditions as secondary, as well as primary, diagnoses. Further, cardiovascular and pulmonary manifestations of systemic diseases may not have been previously diagnosed, but may be identified on the physical therapy assessment or manifested by the patient during exercise stress.

Review Questions

Describe (a) the cardiovascular and pulmonary manifestations and (b) the clinical implications for the physical therapists when a patient has one or more of the following types of dysfunction or conditions affecting the associated system:

1. Musculoskeletal dysfunction (chest wall and peripheral)
2. Connective tissue dysfunction; rheumatoid conditions
3. Neurological dysfunction
4. Hepatic dysfunction
5. Renal dysfunction
6. Hematological dysfunction
7. Endocrine dysfunction
8. Obesity
9. Malnutrition (e.g., anorexia nervosa)

Measurement and documentation are critical components in the process of providing patient care. Measurements (numerical or categorical assignments based on testing or measuring) form the basis for deciding intervention strategy and therefore influence patient response to therapeutic interventions.[1] Measurements are also used during treatment sessions to determine rate of progression and appropriateness of exercise prescriptions. Typically, therapists obtain a series of measures and, in combination with those made by other health care professionals, formulate a clinical hypothesis. The hypothesis includes both physical and psychosocial aspects. If parts of the hypothesis are incorrect because of inaccurate measures, interventions may be misdirected, which can result in treatment that is either not effective or unsafe. Consequently, knowledge of the qualities of measurements that relate to the cardiovascular and pulmonary systems is essential for effective patient care.

Documentation, interpretation of measurements, and the patient plan of care are also important for reimbursement and to ensure communication among health care team members. Timely and appropriate sharing of information on physiological responses to activity is often critical for optimal medical management. Documentation must be written clearly and concisely and include objective findings that will facilitate efficient and continuous care from all members of the health care team.

This chapter provides a discussion of types and characteristics of measurements that are common to cardiopulmonary physical therapy, followed by a discussion of the process of selecting and performing tests and measures, and interpreting the results. A discussion of the purposes and recommended terminology for documentation follows, including suggestions for providing objective and outcome-oriented information and supporting skilled and medically necessary physical therapy services in this population.

Characteristics of Measurements and Outcomes

The purpose of performing a measure is to assess or evaluate a characteristic or attribute of an individual. The characteristic to be measured must first be defined, and the purpose of performing each measure must be clear. Therapists can then select the most appropriate method of measuring, given the available resources and their clinical skills.

Levels or Types of Measurements

Measurements can be described according to their type or level of measurement. There are four levels of measurements: nominal, ordinal, interval, and ratio (Table 7-1).[2] Recognizing the level of measurement aids understanding and interpretation of the result.

Nominal

Objects or people are often placed in categories according to specific characteristics. If the categories have no rank or order, then the measurement is considered nominal. An example of a nominal measurement is the classification of patients with pulmonary disease into those with obstructive lung disease, restrictive lung disease, or a combination of obstructive and restrictive disease. The categories are mutually exclusive (i.e., all patients fit into one and only one category). Nominal categories are unranked, in that an individual with obstructive lung disease would not necessarily have a worse prognosis than an individual with restrictive lung disease.

The categories of a nominal measurement scale are defined using objective indicators that are universally understood. For example, the classification of patients with heart failure could be based on the primary cause for the development of the condition (Box 7-1). In each case, the cause would be determined by diagnostic testing such as angiography or echocardiography. Clear descriptions of the criteria for inclusion in each category are necessary to facilitate clinicians' agreement on the assignment of patients to categories. A high percentage of agreement indicates high interrater reliability.

Ordinal

Ordinal measurements are similar to nominal measurements with the exception that the categories are ordered or ranked. The categories in an ordinal scale indicate more or less of a certain attribute. The scale for rating angina is an example of an ordinal scale (Table 7-2). Each category is defined, and a rating of grade 1 angina is less than a rating of grade 4. In an ordinal scale, the differences between consecutive ratings are not necessarily equal. The difference between grade 1 angina and grade 2 is not necessarily the same as between grade 3 and grade 4 angina. Consequently, if numbers are assigned to categories, they can be used to represent rank but cannot be subjected to mathematical operations. Averaging angina scores is incorrect because averaging assumes that there are equal intervals between categories. A group of ordinal data could be reported as a percentage of each response (i.e., 80% of clients reported exercise-induced angina as 3 before a cardiac rehabilitation program.)

Categorical measurements are considered ordinal if being assigned to a specific category is considered better than or worse than being in another category. For example, patients with angina could be classified as having either stable or unstable angina. This measurement would be considered ordinal, because stable angina is considered a better condition to have compared with unstable angina.[3]

Interval

Interval measurements have units on a scale with equal distance between consecutive measurements and are differentiated from ratio measurements because the zero point is arbitrary rather than absolute. An arbitrary zero point is one that does not mean an absence of the characteristic that is being measured. Temperature, for example, can be measured using either an interval or a ratio scale. The Celsius

temperature scale (interval measurement) assigns the zero point to the temperature at which water freezes, whereas the Kelvin scale (ratio measurement) assigns the zero point to an absence of heat.

The original Borg Ratings of Perceived Exertion (RPE) scale is considered an interval level of measurement.[4] This scale, ranging from 6 to 20, has been shown to be linear with oxygen consumption and heart rate.[4]

Measuring force production using an isokinetic dynamometer is an example of an interval measurement commonly used in physical therapy. Patients may generate muscle tension and move an extremity but register a score of zero because they cannot move as fast as the dynamometer. Interval measurements can have negative values and can be subjected to some arithmetic operations. Adding and subtracting values is logical. A patient who generates 10 ft-lb of torque at one session and 20 ft-lb at the following session increased her torque production by 10 ft-lb. However, interval values cannot be subjected to division or multiplication. It cannot be stated that the patient generated twice as much torque on the second session compared with the first session because it cannot be assumed that a reading of zero indicates no torque production.

Ratio

Ratio measurements have scales with units that are equal in size and have a zero point that indicates absence of the attribute being measured. Examples of ratio measurements that are used in cardiopulmonary physical therapy include heart rate, cardiac output, oxygen consumption, and 6-minute walk distance (6-MWD). Ratio measurements are always positive values and can be subjected to all arithmetic operations. For example, an aerobic capacity of 4 L/min is twice as great as an aerobic capacity of 2 L/min. The Borg CR10 scale and visual analogue scales are also examples of ratio level measurements.[4,5] The zero point of these scales is "nothing at all" or no perception of exertion. The CR10 scale may be preferable for use with patients who experience strong symptoms during testing or training.[6]

When deciding whether a measurement is a ratio or interval, the attribute that is being measured is defined. If the zero point indicates absence of the attribute, then the scale would be considered ratio. For example, cardiac output can be defined as the amount of blood in liters ejected from the left ventricle over a 1-minute period. A measurement of zero cardiac output would be absence of the characteristic, or no blood ejected from the left ventricle.

Reliability and Validity of Measurements

For a measurement to be of value to the therapist, the measure should be both reliable (reproducible) and valid (meaningful). When selecting and performing tests and measures, it is important to remember that measures can be reliable but not valid for a specific application.[7]

Reliability

Reliability is defined as the consistency or reproducibility of a measurement. Ideally, when attempting to measure a specific attribute, the value of the measurement should change only when the attribute changes. All measures, however, have some element of error that contributes to the variability of the measurement. When the error is relatively high, the value of the measurement can change even when the attribute does not change. Believing that a change has occurred when it has not can result in an inaccurate clinical decision related to intervention planning or progression.

Many factors contribute to measurement variability. The characteristic being measured may demonstrate a certain degree of variability. Blood pressure and heart rate vary depending on mental and physical factors such as body position, hydration level, anxiety, and time of day. For these attributes, multiple measurements often are used to provide the best estimate of the patient's true heart rate and blood pressure.

Another factor that contributes to the variability of a measurement is a change in the testing instrument. Testing instruments may vary in their readings because of changes in environmental conditions or malfunction of instrument parts. Instruments should be calibrated (i.e., compared with a known standard) on a regular basis to assure accuracy of the readings. Some instruments are relatively easy to calibrate. For example, values obtained using aneroid blood pressure devices can easily be compared with values obtained using mercury manometers. Values obtained using either palpation or a heart rate monitor can be compared with values obtained from electrocardiograph (ECG) recordings. The mercury manometer and the ECG would be considered the instruments that provided the best estimates of the characteristic being measured. Other devices, such as cycle ergometers, are more difficult to calibrate, and the usual approach is to rely on the manufacturer's specifications regarding the accuracy of the work rate readings.

A third factor contributing to measurement variability is the difference in the methods therapists use to obtain measurements. If a measurement is consistent when the same therapist repeats a test, then the measurement is said to have high intrarater reliability. Measurements that are consistent when multiple therapists perform the test under the same conditions are said to have high interrater reliability. Often, measurements have high intrarater reliability but lower interrater reliability because of variations in the specific methods used by therapists to attain the same measurement. Auscultation of breath sounds, a commonly used method of assessing patients in cardiopulmonary settings, has been shown to have only poor to fair interrater reliability.[8] Interrater reliability is important in clinical settings in which a patient may be evaluated and treated by more than one therapist. If the interrater reliability of a measurement is low, changes in the patient over time may not be accurately reflected. Interrater reliability for auscultation of breath sounds can be improved through education of the persons performing the measurements.[8]

Validity

Valid measurements are those that provide meaningful information and accurately reflect the characteristic for which the measure is intended. For a measure to be useful in a clinical setting, it must possess a certain degree of validity. Measurements can be reliable but not valid. For example, the ankle-brachial index (ABI) is reliable but not necessarily valid in all populations.[9]

There are various types of validity. Of importance in clinical practice are concurrent, predictive, and prescriptive validity. Concurrent validity is when a measurement accurately reflects measurements made with an accepted standard. Comparing a measurement made with a heart rate monitor with an ECG recording is an example of determining concurrent validity. In this example, the ECG recording would be considered the gold or accepted standard. Another example is using pulse oximetry during exercise testing. Yamaya and colleagues (2002)[10] compared pulse oximetry versus directly measured arterial oxygen saturation (the gold standard) and reported that a forehead sensor was more valid than a finger sensor. Measurements with predictive validity can be used to estimate the probability of occurrence of a future event. Screening tests often involve measurements that are used to predict future events. For example, identifying people with risk factors for coronary artery disease (CAD) leads to a prediction that their likelihood of developing CAD is higher than normal. Measures with prescriptive validity provide guidance to the direction of treatment. The categorical measurement of determining a person's risk for a future coronary event is a measurement that would need to have prescriptive validity. By classifying patients into high- versus low-risk categories on the basis of results of a diagnostic exercise test, the intensity and rate of progression of treatment is determined.

Sensitivity and Specificity

Accuracy of various types of exercise tests often is described by reporting sensitivity and specificity. Sensitivity is the ability of a measurement to identify individuals who are positive, or who have the characteristic that is being measured. If a test produces a high number of false-positive results, then the sensitivity will be low. A false-positive result means that the test result was positive but the characteristic was absent. Young women often have positive stress test results but do not have coronary artery disease. The consequence of a false-positive test result could be unnecessary treatment or further diagnostic testing. Specificity is the ability of a measurement to identify individuals who are negative, or who do not have the characteristic. A high number of false-negative results would produce a low specificity. A false-negative result has a negative test result even though the disease or characteristic is present. The consequence of a false-negative test result is not receiving treatment when it is indicated. Use of the Homans' sign to screen for deep vein thrombosis (DVT) is no longer advocated because the test lacks both sensitivity and specificity.[11,12]

Objective and Subjective Measurements

Measurements vary in degree of subjectivity versus objectivity. Subjective measurements are those that are affected in some way by the person obtaining the measurement (i.e., the measurer must make a judgment as to the value assigned). The assessment of a patient's breath sounds is influenced by many factors, including the therapist's choice of terminology for describing the findings, perception of normal breath sounds, and hearing acuity. The grading of functional skills may be influenced by the therapist's interpretation of what constitutes minimal versus moderate assistance. Because of the influence of the person performing the measure, subjective measurements usually have lower interrater reliability compared with objective measurements.[2]

Objective measurements are not affected by the person performing the measure (i.e., these measures do not involve judgment of the measurer). Heart rate measured by a computerized ECG system is an example of an objective measurement. Other examples include measuring blood pressure using an intraarterial catheter and oxygen consumption using a metabolic system. Objective measurements are not necessarily accurate but usually have high interrater reliability.[2]

Clinical Decision Making

The Hypothesis-Oriented Algorithm for Clinicians II (HOAC-II) intertwines the examination, evaluation, and diagnosis elements into an organized algorithm for clinical decision making.[13] Using the HOAC-II, initial data collection (e.g., data from the medical record and patient interview) during the examination allows for generation of patient-identified problems (PIPs) and an initial set of hypotheses that will guide the formulation of an examination strategy (i.e., selection and ordering of tests and measures). These initial measurements help refine the hypotheses and additional measurements are obtained to help confirm or deny the initial set of hypotheses, leading to an eventual hypothesis/physical therapy diagnosis (i.e., an idea of the underlying cause of the patient's problem), and/or a decision to consult with other health care practitioners. For instance, early in the examination process the therapist may suspect a proximal DVT; the Wells clinical decision rule can aid in deciding whether or not to refer the patient for further testing.[14]

Selecting Tests and Measures

Many factors influence the therapist's choice, including information obtained from the medical record, patient interview, and knowledge of available treatment options. Selected tests and measures should be relevant as measured by their potential ability to impact the direction of the examination and intervention. Tests and measures should be limited to those that are necessary to establish a clinical hypothesis, make decisions about appropriate interventions, and determine the effectiveness of the intervention. Therapists also must strive for efficiency and not repeat tests that have been performed by other health care professionals. Characteristics or qualities of measurements, such as reliability and validity, also influence the therapist's decision.

Another factor that influences the selection of tests and measures is the risk-benefit ratio. How do the risks of obtaining a measurement relate to the value of the information gained? Subjecting a patient to a symptom-limited graded exercise test during the acute stage of post-myocardial infarction (MI) could provide information to formulate an exercise prescription; however, the risks of performing this procedure at this phase of the recovery period likely outweigh the benefits.

Measurements selected need to be appropriate to the specific health condition (disorder or disease), severity of the condition, and other contextual (i.e., environmental and

personal) factors specific to the patient.[15] Tests and measures that do not help optimize or assess patient-centered outcomes are an inefficient use of the therapist's time and add unnecessary costs to health care.

Performing Tests and Measures

General Principles

When performing tests and measures, therapists must take care to use procedures that can be replicated for future comparisons (i.e., there must be acceptable intrarater/interrater reliability). Time must be taken to ensure that conditions are optimal and that the patient is informed of his or her part in the activity. For example, measuring blood pressure in a noisy treatment area immediately when the patient arrives for an appointment may not provide an accurate measurement of resting blood pressure. Documenting the conditions in which a measure was made is also important. Conditions may include, but are not limited to, time of day, room temperature, recent activities performed by the patient (including medication administration), and type and model of measuring device (e.g., specific treadmill, sphygmomanometer, pulse oximeter, etc.). Also, if the patient needs supplemental oxygen, it is vital to document the oxygen flow rate or fraction of inspired oxygen and the oxygen delivery device (e.g., nasal cannula, Venturi mask, etc.) for proper test interpretation. For example, a patient's walking distance may not have improved, but if the patient used less oxygen, then a meaningful outcome was achieved.

Measures should be made with an objective and open mind (i.e., without anticipating the result of the measurement). A measure that is approached with a preconceived idea of the outcome may be affected by the therapist's expectations. Having confidence in the results of one's measurements is important and develops as clinical skills develop.

In clinics where more than one therapist is likely to evaluate or treat a patient, written procedures for performing measurements are necessary. Therapists also need to review the written procedures on a regular basis and practice performing the measures as a group. Practicing together is especially important for therapists who are new to the clinic. Interrater reliability for commonly used measures can be determined. If the reliability is low, written procedures may need to be revised to ensure optimal consistency of measurement. Many commonly used tests and measures, such as blood pressure and 6-minute walk test, have standardized methodology.[16,17]

Examination

Initial data collection from referral information or the medical record regarding the patient's current medical stability and functional status will help guide the examination strategy. For example, tests and measures will differ for a patient with an acute MI compared to a patient who is 3 weeks post-MI. Other factors to consider include the size of the infarction and associated complications such as dysrhythmias, heart failure, or angina. Other initial data collected during the interview may also guide the examination strategy. For example, if a patient becomes anxious when discussing walking on a treadmill, then perhaps a "field test," such as the 6-minute walk test (6-MWT), would be more prudent.

The examination begins with and is centered on the patient's self-identified problems that may reflect specific impairments, limitations in activity, and/or restrictions in patient-identified roles at home, work, and the community. The patient's goals for physical therapy should be reported. Documentation of examination findings should reflect the physical therapist's clinical reasoning in determining what impairments may underlie the patient's limitation in activity.

The history section may include information related to the current and past medical/surgical diagnoses, previous functional levels, lifestyle choices, living environment, medications, laboratory values, or diagnostic imaging results. The patient's perception of his or her cardiac or pulmonary condition is important, as are descriptions of pain or discomfort that may be associated with either a cardiac event or a pulmonary complication. Other systems, such as the musculoskeletal, neurological, and integumentary systems are briefly examined to identify concerns that may influence the patient's readiness or ability to participate in certain interventions.

Tests can be categorized as measuring impairments, activity limitations, or participation restrictions as defined by the World Health Organization's International Classification of Functioning, Disability and Health (ICF) model,[18] which was recently adopted by the American Physical Therapy Association (APTA).[19] A body function or body structure impairment is an abnormality of physiological function or anatomic structure at the tissue, organ, or body system level.[15] Examples of impairments include pain, dyspnea, decreased muscle strength or range of motion, abnormal heart rate and blood pressure values, and impaired aerobic capacity. Measurements of impairments are important because they assist therapists in deciphering the causes or reasons for limitations in activity. Activity limitations are difficulties an individual has in performing a task or action.[15] Activity limitations can be attributed to physical, social, cognitive, or emotional factors. Examples of activity limitations include the inability to dress, transfer, walk long distances, or climb stairs. Improvements in activity levels usually are of primary interest to patients and families and to those who reimburse for health care. Participation restrictions are those problems that an individual may experience in life situations, such as performing a job requirement or playing a sport.[15] Figure 7-1 illustrates a patient's condition using the ICF model.

When examining patients with cardiopulmonary disorders, therapists often assess responses to activity. Specific information on the activity and on the physiological responses should be included:

- Mode of activity (corridor or track walking, lower extremity cycling)
- Intensity, work level, or rate of activity (mph, percent grade, estimated MET (metabolic equivalent) level)
- Duration of activity at each intensity level

The description of activities should be written clearly so that the workload can be reproduced. Responses to activity include changes in heart rate and rhythm, blood pressure, respiratory rate, oxygen saturation levels, and heart and breath sounds from pre-activity to either during or immediately after activity. Subjective signs of exercise intolerance, such as changes in skin color, decrease in coordination, and sweating,

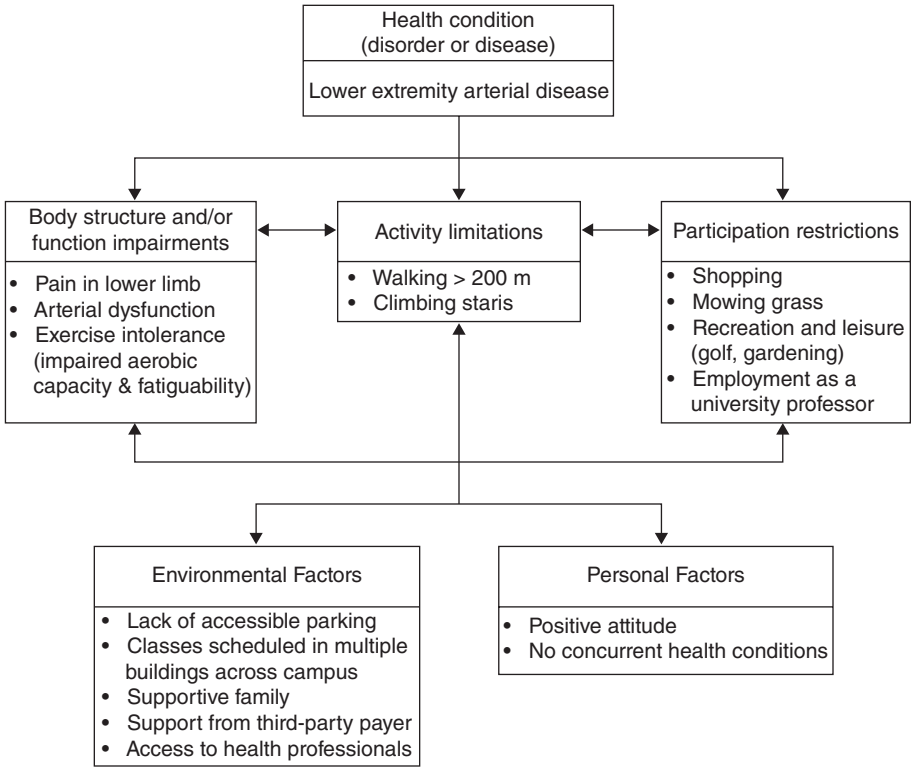

Fig. 7-1 Use of the ICF model to document a patient's condition and demonstrate various levels that need to be measured. The diagram illustrates how a person's health condition and body structure/function impairments affect participation in the community. Contextual factors (i.e., environmental and personal factors) interact at various levels to facilitate or hinder a person's health condition and level of function.

also need to be documented. Whether the patient used oxygen during treatment or required physical assistance should be noted. By objectively recording the activity performed and the physiological responses, therapists can estimate the patient's activity tolerance.

Evaluation and Interpretation of Findings

The evaluation process involves using the results of the examination to make clinical judgments. Therapists state their "clinical hypothesis," or explanation of reasons for activity limitations and/or participation restrictions. Evaluation reports provide the foundational support to confirm why the patient requires the skilled services of a physical therapist and why the services are medically necessary at this time. Examination findings may indicate the need for referral of the patient to other health care professionals or to community services.

Interpreting measurements often is challenging. Usually patients' problems are understood not by reviewing results of a single measure but by viewing relationships between results of several measures. For example, the finding that blood pressure does not increase with activity may not be considered abnormal by itself if the activity level is low or the patient is taking a beta-receptor antagonist medication (e.g., metoprolol); however, the finding of no increase in blood pressure with signs and symptoms of exercise intolerance (e.g., shortness of breath, dizziness, fatigue, etc.) during moderate-level activity in another patient may be indicative of cardiovascular pump dysfunction.

Knowledge of what is "normal" is important to interpret measurements accurately. For some measurements, normal values are well defined. Measurements of resting blood pressure, cholesterol, and blood glucose have defined categories of normal, borderline, and elevated. For other measurements, population normative standards are not specifically defined. For example, what is the normal increase in heart rate when walking at 3.5 mph on a level surface? Values for individuals differ depending on age, medications, fitness level, and walking efficiency. Results must be interpreted by considering these factors and pathological conditions, if present. Each individual has his or her own "normal" or usual response, and variations from this value could be considered abnormal.

Interpreting measurements is similar to putting the pieces of a puzzle together to create a picture of the patient and his or her activity limitations and participation restrictions. Data are collected from several sources, including the medical record, patient interview, and physical therapy examination. Measures performed and interpreted by other health care professionals can be obtained from the medical record; these include measures such as chest radiographs, blood tests, echocardiography, angiography, and ventilation-perfusion scans. During an interview, patients report information about their current and past medical problems and especially specific patient-identified problems. It is important to be sensitive to patient's feelings about their condition, noting their stage of emotional recovery. Detecting attitudes related to changing lifestyle habits is also important. After the interview, the therapist should have a sense of the patient as a person and begin to plan an intervention strategy for improving body structure and function impairments, and optimizing activity and participation.[13]

Measures made during the physical examination may include physiological responses to activity, breathing patterns, ventilatory capacity, and breath sounds. These measurements are integrated with results collected during the chart review and evaluated in the context of the patient-identified problems and the goals for each problem. As therapists refine their

hypothesis, they develop a picture of the severity of the cardiopulmonary condition, stage of recovery, and presence of coexisting conditions. An intervention strategy is developed on the basis of the final clinical hypothesis/diagnosis. The intervention strategy is implemented, and measurements are regularly obtained during treatment sessions to reassess existing problems and goals. Because of the dynamic nature of many of the conditions that affect the cardiovascular and pulmonary systems, each treatment session can be viewed as a reassessment of the hypothesis and progress toward patient goals.

Minimal Clinically Important Difference

To help facilitate evidence-based practice related to interpreting outcome measurements, a minimal clinically important difference (MCID)—that is, "the minimal level of change required in response to an intervention before the outcome would be considered worthwhile in terms of a patient/client's function or quality of life"[20]—has been determined for several endurance/aerobic capacity tests and measures used by physical therapists. Examples include the 6-MWT (54 m[21] or 10% improvement[22]), modified shuttle test (40 m[23]), and the Borg CR10[4] and visual analog scale ratings of dyspnea (1 point and 10-20 mm [Table 7-3], respectively[24]). The MCID for various tests and measures can be used for setting relevant goals, as well as interpreting progress toward outcomes.

Physical Therapy Diagnosis, Prognosis, and Plan of Care

The physical therapy diagnosis serves to drive the selection of interventions. A physical therapy diagnosis may be written in the form of a problem list that may include both impairments and activity limitations. Problems can be listed in order of priority and stated in functional terms. For example, stating "patient unable to climb stairs because of abnormal ECG responses and dizziness," rather than "abnormal ECG response during activity" is recommended. Alternatively, physical therapy–related classification systems such as the Practice Patterns found in the Guide to Physical Therapist Practice[25] may be tailored to reflect the individual's physical therapy diagnosis.

Based on the results from a 6-MWT, or another appropriate test, a tentative physical therapy diagnosis of impaired aerobic capacity/endurance impairment could be made if the measurement falls outside the reference values for healthy adults.[26] Concurrent or complementary measures (e.g., respiratory rate, heart rate and blood pressure response, pulse oximetry, heart and lung sounds, ankle brachial index) could help further refine the hypothesis and determine whether the impaired endurance was more likely due to cardiac, peripheral vascular, or pulmonary impairments.

After identifying the patient's problems and determining a diagnosis for physical therapy, a plan of care that includes prognosis is developed. The plan of care includes goals and anticipated outcomes, specific interventions to be used, and the recommended frequency and duration of the interventions. The prognosis is the predicted level of improvement and the amount of time needed to reach that level. Providing additional data related to positive and/or negative contextual factors to justify prognosis is important to reinforce the skilled nature of services. Positive factors may include family support, previous functional levels, or the acuity of the condition. Negative factors may include the severity or chronicity of the condition, barriers in living environments, or lack of financial resources.

Goals are the outcomes to be achieved by participating in a physical therapy program and are generated by the therapist and patient in collaboration. Goals should have baseline measurements documented from the examination, be related to the identified problems, and be supported by statements in the evaluation section. Goals should highlight cardiovascular and pulmonary impairments that are thought to be linked to the activity limitations. Goals are stated in functional terms and concern what the patient will be able to do at discharge. For example, a goal could be "patient will be able to walk up two flights of stairs with appropriate heart rate and rhythm responses, within 2 weeks." Without documenting the associated cardiovascular and pulmonary impairments, the goal may not support the individual's need for skilled or medically necessary services by physical therapy.

To determine whether a goal has been met, the therapist must be able to observe or measure the activity. Therapists also estimate the time it will take to achieve the outcome. In a discharge or follow-up note, it is stated whether each goal has been met. If a goal has not been achieved, an explanation is provided.

The plan provides a description of the approach that will be taken to assist the patient in achieving the stated goals. The plan may include a description of treatment that can be provided, education for the patient and/or family, and referrals to other services. Descriptions of inpatient, outpatient, or home programs should be included in the plan. The plan of care also includes discharge planning.

Intervention

Interventions are physical therapy procedures and techniques designed to produce changes in the patient's condition. Procedures typically used by therapists treating patients with cardiopulmonary disorders include therapeutic exercise (i.e.,

Table 7-3 MRC Dyspnea Scale

Grade	Degree of Breathlessness Related to Activities
1	Not troubled by breathlessness except on strenuous exertion
2	Short of breath when hurrying on level ground or walking up a slight hill
3	Walks slower than contemporaries on level ground because of breathlessness, or has to stop for breath after ≈1 mile (or after 15 min) when walking at own pace
4	Stops for breath after walking about 100 yards (or after a few minutes) on level ground
5	Too breathless to leave the house, or breathless after dressing or undressing

Modified by permission from BMJ Publishing Group Limited. From Fletcher CM, Elmes PC, Wood CH: The significance of respiratory symptoms and the diagnosis of chronic bronchitis in a working population, *Br Med J* 1:257-266, 1959.

aerobic, resistance, breathing exercises), functional training (i.e., work hardening and work conditioning), and airway clearance techniques. The specific intervention selected by the therapist will be influenced by the severity of the cardiopulmonary disorder and the presence of complications. In some cases, the intervention mode and intensity can be derived from the measurement obtained. For instance, 6-MWD can predict peak VO_2 in patients with COPD[27] and heart failure;[28] with this predicted value, converted to METs, the physical therapist can develop an appropriate exercise prescription and guide the patient in selecting physical activities that would fall within a safe and therapeutic range. In addition, a treadmill or overground walking program could be established on the basis of the mean walking velocity during the 6-MWT.[29] Likewise, physical activity/exercise intensity could be set based on measurements of perceived exertion or dyspnea obtained during an exercise test.

Patient and family and/or caregiver instruction is part of all physical therapy interventions. Communication with other health care disciplines involved in the patient's care is essential to ensure efficient and effective health care. For example, for a patient who is being discharged from the hospital after cardiac surgery, the therapist may need to coordinate with the social worker to ensure that the patient receives home services that he or she needs for assistance with activities of daily living.

Documentation is an essential part of intervention. It is important to record the patient's responses to interventions, including changes in heart rate, blood pressure, and heart and lung sounds, recovery time after exercise, and reports of angina, dyspnea, or fatigue. A description of the intervention is recorded so that another therapist or physical therapist assistant can continue the program. Details related to dosage, such as frequency, intensity, and duration of each intervention should be clearly stated. In addition to the medical record, the therapist also may be required to provide documentation to other sources such as home health or insurance agencies.

Reexamination and Outcomes Assessment

Throughout the course of treatments, therapists routinely perform reexaminations to determine whether patients are progressing. For patients with cardiopulmonary disorders, for example, the therapist may reexamine the patient at every session to determine whether physiological responses to activity are appropriate or whether the patient's lungs are clearing. Results of reexamination are used to modify or redirect interventions. It is important to include documentation of patient progression, including the patient's perception of progression, in each note in order to support the continued justification of skilled services.

As the patient approaches discharge from physical therapy services, the therapist assesses the outcomes of the intervention. The therapist measures the impact of physical therapy services on the patient's impairments, activity limitations, and participation restrictions. Examples of outcome measures often used to assess health-related quality of life in patients with cardiopulmonary disorders include the Chronic Respiratory Questionnaire[30] and Minnesota Living with Heart Failure questionnaire.[31]

The therapist relates the assessment of outcomes to the original goals established by the therapist and patient. As a result of the outcomes assessment, the therapist may refer the patient back to the physician or to another health care professional. A systematic review of medical records from a group of patients with similar diagnoses can be performed to determine program outcomes of selected physical therapy interventions. See Chapter 17 for a discussion of optimizing outcomes.

Purposes of Documentation

To be useful, measurements need to be documented. Measurements that remain in the mind of the evaluator often are forgotten or not remembered accurately. Documentation is important to facilitate and to maximize reimbursement, as well as to ensure efficiency of care through communication among health care professionals. Documentation includes information about results of the examination, assessment of the patient's condition, and the physical therapy diagnosis, prognosis, and plan of care.

Specific reasons for documentation include the following:

- To provide information for other therapists and assistants, who may evaluate and/or treat the patient
- To communicate with the referring physician and other health care professionals
- To provide data to support clinical research, such as treatment effectiveness and efficiency through collection of information on outcomes of various types of care
- To verify and support the skilled nature of physical therapy services provided and to justify reimbursement for those services
- To address legal and risk management issues by documenting the care provided and the individual's response to care

Guidelines for Content and Organization

Writing notes in a clear and concise format is important so that information is conveyed accurately. Examples of unclear notes are those that contain typographical errors, illegible handwriting, or vague statements that can be interpreted in more than one way. Concise notes are more likely to be read by other health care professionals. Most clinicians do not have time in their schedules to read through extensive patient information that may not be relevant. A concise note includes only essential information in a clear communication style free of unnecessary phrases. The APTA's Defensible Documentation Tips include the following[32]:

Use only standard or accepted abbreviations. Facilities have lists of approved abbreviations that are available to those who write, read, and review records.

All notations must include the date and time of service.

Documentation of services rendered must match the billing codes submitted to payers.

Tables, headings, and subheadings can be used to help organize the information in an easy-to-find format. Notes must clearly demonstrate the need for skilled, medically necessary services by the physical therapist and the physical therapist assistant.

Patient progression should be evident, with data and assessments provided to support the individual's achievement of goals or the lack of progression toward set goals.

Communications with the patient, family, health care team, payers, and other related parties involving care should be documented in the chart.

Documentation is essential when an unusual or adverse event occurs. For example, abnormal responses to activity that may appear relatively benign are important to record. Abnormal responses include dizziness, chest pain, or dysrhythmias. An unusually high or low heart rate or blood pressure response also should be noted. Combined with information reported by the patient and findings from other health care professionals, these results may indicate significant changes in the patient's cardiopulmonary status.

HIPAA Guidelines

The Health Insurance Portability and Accountability Act (HIPAA) includes federal guidelines that protect the confidentiality of health information. Personal protected health information (PHI) is to be shared only with persons authorized to view the information (i.e., professionals involved in providing health care). Facilities assume the responsibility of designing systems to ensure that health information is protected and kept confidential. When PHI is stored electronically, controls should be established to ensure only authorized access to information. This may include the use of encryption of laptop computers, memory cards, thumb drives, PDAs, and other portable devices. Therapists must ensure that discussions involving patients' health information occur in private locations. All health care professionals are bound by these guidelines. Further information may be found at the U.S. Department of Health and Human Services website (www.hhs.gov/ocr/hipaa/).

Summary

Measurement and documentation are important components in the process of providing patient care. Therapists select measurements because they reveal information about patient characteristics that is needed to determine appropriate directions for intervention. Performing measurements in a consistent way allows comparison of patient characteristics at varied points in time. The recording, or documentation, of the results of measurements and other information about the patient serves as a legal record. Although documentation formats vary among facilities, information from records can be organized to include the following topics: examination, evaluation, diagnosis, prognosis and plan of care, interventions, and reexamination. Documentation can be viewed as a way to assist therapists to organize their findings, reflect on the significance of the findings, and generate an efficient and comprehensive care plan.

Review Questions

1. Describe and give examples of nominal, ordinal, ratio, and interval measurements.
2. Define sensitivity and specificity of tests.
3. Describe four purposes for documenting the results of patient assessment and responses to interventions.
4. Provide an example of an impairment, activity limitation, and participation restriction that is common in patients with cardiopulmonary disorders.
5. Describe each of the components of patient management: examination, evaluation, diagnosis, prognosis, and plan of care.

Review Questions 135

References 135

The value of a history depends in large part on the skill of the interviewer. When eliciting the history from a patient, the physical therapist must be alert to recognize the symptoms that are indicative of cardiac and pulmonary disease. This information is then used in the decision-making process to select the most appropriate intervention for the individual. This chapter presents a comprehensive approach to history taking. Physical therapists may find part or all of this information applicable, depending on the particular circumstances.

The Interview

Obtaining a thorough and accurate patient history is truly an art. One important goal of history taking is to establish a good patient-therapist rapport. The patient must be allowed to explain the history in his or her own words and at a comfortable pace.[1] If the therapist appears hurried, distracted, preoccupied, irritated, or uncaring; is often interrupted; or fails to be an attentive listener, the patient-therapist relationship will likely suffer.

The interviewer must be careful not to allow personal feelings about the patient's grooming, appearance, demeanor, or behavior during the interview to unduly question the validity of the chief complaints.[2] By the time the patient is referred for physical therapy, he or she may have seen one or more physicians, have been subjected to a number of noninvasive or invasive studies, or have been prescribed oral or inhaled medications with variable or unsatisfactory alleviation of symptoms. The patient is likely to manifest a degree of anxiety and frustration. Therefore, the therapist's approach, history-taking method, and interviewing style are important for gaining the patient's confidence and cooperation.

The patient history interview can be divided into the data-gathering and interpretative sections.[3] The data-gathering

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

segment begins with asking why the patient has sought medical attention and has been referred for physical therapy services. In other words, what is the patient's chief complaint—the symptom that caused the patient to seek help?

Each chief complaint should be carefully explored. Supplementary questions should be nonleading, using words the patient can easily understand. This allows the interviewer to determine the significance of the complaint. An in-depth knowledge of cardiopulmonary pathophysiology allows the therapist to gather data about the patient's symptoms while also interpreting the likely type of cardiopulmonary dysfunction that exists. This in turn serves as a basis for the therapist to begin to select the appropriate assessment and treatment modalities for the individual.

It is important to remember that patient satisfaction is greatest if the patient is allowed to fully express major concerns without being interrupted. In addition, the chance of missing what is really of greatest concern to the patient is reduced if the patient is allowed sufficient time to describe it in his or her own words. Studies have shown that this usually takes only 1 to 3 minutes.

The patient's view of what the problem is and his or her suggestions for addressing the problem should be included in the interview. Patients are more satisfied when they are allowed and encouraged to participate in the interview. Patient involvement in the process also leads to improvement in the establishment of short- and long-term goals.

The depth of the history taken by the physical therapist can vary according to the following factors:

- Whether the individual is an inpatient or an outpatient. Many inpatients have detailed medical records available for the therapist to review. This reduces the amount of information the physical therapist needs to obtain from the patient during an interview. If the information in the chart is scant, or if the individual is an outpatient with only a treatment referral and few or no medical records available, the physical therapist should obtain a more detailed history.
- Whether the treatment order is narrow or broad in scope
- The acuteness of the patient's illness, level of consciousness, and ability to provide accurate information

Smoking History

The patient should be asked about his or her tobacco-smoking history.[3] The number of pack-years of cigarette smoking may be calculated (average number of packs per day multiplied by the number of years smoked) as a relative risk for lung cancer and COPD. Regular smoking of marijuana is more damaging to lung health in the short term as well as potentially long term.[4]

Family History

The family history is useful in evaluating the possibility of hereditary pulmonary diseases, such as alpha$_1$-antitrypsin deficiency, cystic fibrosis, allergic asthma, hereditary hemorrhagic telangiectasia, and others.[5,6] A family history of diabetes, hypertension, coronary artery disease (CAD), or rheumatic fever raises the possibility that these conditions might exist in the patient as well.[7]

Occupational History

Taking an occupational history is particularly important for pulmonary patients who arrive for physical therapy with little or no accompanying medical information. The internal surface of the lung measures 50 to 100 m^3 and is in constant contact with the environment.[5] Jobs that involve exposure to silica or silicates (e.g., miners, sandblasters, foundry workers, stone cutters, brick layers, and quarry workers) or other inorganic substances place workers at risk for combinations of obstructive and restrictive lung disease (e.g., silicosis). Construction workers, shipyard workers, pipefitters, and other industrial workers exposed to asbestos are at increased risk for developing a restrictive lung disease such as asbestosis.[8] Benign pleural plaques may be found on the diaphragmatic pleurae and bilaterally between the 6th and 10th ribs on the anterolateral or posterolateral chest wall. Progressive pleural thickening rarely occurs. These individuals have an increased incidence of malignant neoplastic diseases such as bronchogenic carcinoma and malignant mesothelioma. Some firefighters, iron workers, and other rescuers working at the World Trade Center disaster site following September 11, 2001, have developed respiratory symptoms and disorders.[9,10]

Coal workers are exposed to coal mine dust. About 10% have simple pneumoconiosis, whereas a smaller proportion develop the complicated form of the condition—progressive massive pulmonary fibrosis.[11]

A history of paroxysmal coughing, chest tightness, or dyspnea that is worse during the work week but remits on weekends (or other regular days off work) strongly suggests occupational asthma.[11] This condition is difficult to diagnose because symptoms commonly occur several hours after exposure to the provoking agent. Causal agents include grain dusts, wood dusts, formalin, enzyme detergents, ethanolamines (in spray paints and soldering flux), nickel, and hard metals (e.g., tungsten carbide). Workers exposed to cotton flax and hemp dusts may develop byssinosis, an obstructive lung disease. In the early stages, this condition is reversible, but long-term exposure over a number of years causes chronic irreversible obstructive lung disease.

A history of fever, cough, shortness of breath, and recurrent pneumonias in farmers in the northern United States suggests farmer's lung.[11] This is the most common hypersensitive pneumonitis; it is caused by inhaling fungal agents such as thermophilic actinomycetes. Long-term exposure can lead to pulmonary fibrosis. Numerous occupations expose workers to factors that cause hypersensitive pneumonitis.

Prior Treatment

It is important to determine what treatment(s) the patient has received for his or her condition. Specifically, has the patient ever received physical therapy for this or any other condition? What types of treatments were done? Were they helpful in improving or resolving the condition? In this way, it is possible to determine what treatment modalities have been used, which of them the patient believes may have merit, and which the patient finds objectionable or lacks confidence in, thus avoiding alienating the patient by repeating what he or she believes to be ineffective therapy.

Questionnaires

Questionnaires can be used in a number of ways. Printed symptom or medical questionnaires can be beneficial or detrimental to the patient-therapist relationship, depending on how they are used. Questionnaires can expedite the data-gathering portion of the initial visit by allowing the patient to note in advance all symptoms, medical conditions, surgeries, occupations, medications, and other factors that may influence physical therapy intervention. They can reduce the amount of nontreatment time therapists may otherwise spend inquiring about irrelevant symptoms and conditions. Printed questionnaires also allow patients sufficient time to recall relevant information and respond more accurately than they often do in an interview setting.[5] Used in this way, a printed questionnaire can be a valuable tool for expediting a comprehensive evaluation of cardiopulmonary patients. However, if questionnaires are used improperly, they can depersonalize the history-taking portion of the initial visit.[1] If the physical therapist allows the printed form to become a substitute for interaction with the patient, patient satisfaction will be low and the patient-therapist relationship will suffer.

In addition, questionnaires are being increasingly used as standardized outcome measures to assess activity and participation capacity, as well as quality of life and life satisfaction (see Chapter 17). Many questionnaires have been validated and are reliable when used in the clinical setting.

Dyspnea

Dyspnea, commonly referred to as breathlessness or shortness of breath, can be defined as the sensation of difficulty in breathing.[12] It is one of the most common reasons for patients to seek medical attention. Dyspnea is difficult to quantitate because it is subjective and at times is normal (i.e., at high altitudes and during or following vigorous exercise). Also, patients of different backgrounds use different descriptors for their breathlessness.[13] Dyspnea is a symptom of cardiac and pulmonary diseases, among other conditions.

When a patient complains of shortness of breath or breathlessness, it should be noted that this complaint is often unrelated to the patient's arterial oxygen level (PaO_2). Many times, it appears that altered mechanical factors during breathing contribute to the sensation of breathlessness.[14] Numerous receptors that have a role in sensing dyspnea have been identified; they include vagal receptors (e.g., irritant, stretch, and J-receptors), chemoreceptors, proprioceptive receptors (e.g., tendon organs, muscle spindles, joint and skin receptors), and upper airway receptors.[3]

Analyzing the oxygen transport system (Figure 8-1) can help the physical therapist to determine the likely cause of each patient's dyspnea and the most appropriate physical therapy intervention. The delivery of oxygen from ambient air to the mitochondrion within the cell depends on the intact interaction of the respiratory, cardiovascular, and muscular systems. Also, carbon dioxide (CO_2) is eliminated in the opposite direction. Dyspnea can be caused by dysfunction in any of the systems.

Dyspnea commonly occurs when the body's requirement for breathing (ventilation) exceeds the body's capacity to provide it.[3] In other words, the symptom varies directly with the body's demand for ventilation and, inversely, with the body's ventilatory capacity.

There are three basic causes of dyspnea: [12]

1. An increased awareness of normal breathing
2. An increase in the work of breathing
3. An abnormality in the ventilatory system itself

An increased awareness of normal breathing is usually related to anxiety.[5] The patient commonly complains of "not getting a deep enough breath," a feeling of "smothering," or "not getting air down in the right places."[15] These sensations have been designated as psychogenic dyspnea. The patient's breathing pattern is irregular, with frequent sighs. When severe, it is associated with tingling of the hands and feet, circumoral numbness, and lightheadedness. Coaching the patient to hyperventilate and to reproduce the symptoms may help the patient better understand the cause of these symptoms and how to control them.[5] The hyperventilation syndrome is properly diagnosed only after organic causes have been excluded and pulmonary function tests indicate normal respiratory mechanics and PaO_2.

The second cause of dyspnea is an increase in the work of breathing. Greater inspiratory pressures must be generated by the respiratory muscles to move air in and out of the lungs when the mechanical properties of the lungs have changed. This may be related to an increase in lung water resulting from cardiac disease or the high cardiac output of anemia. A loss of compliance (increased lung stiffness) because of diffuse inflammatory or fibrotic lung disease often causes shortness of breath. Small or large airway obstruction as a result of bronchoconstriction, sputum, inflammation, and other effects commonly produces dyspnea.

The third cause of dyspnea is an abnormality in the ventilatory apparatus or pump. The ventilatory apparatus consists of the thoracic cage, respiratory muscles, and nerves.

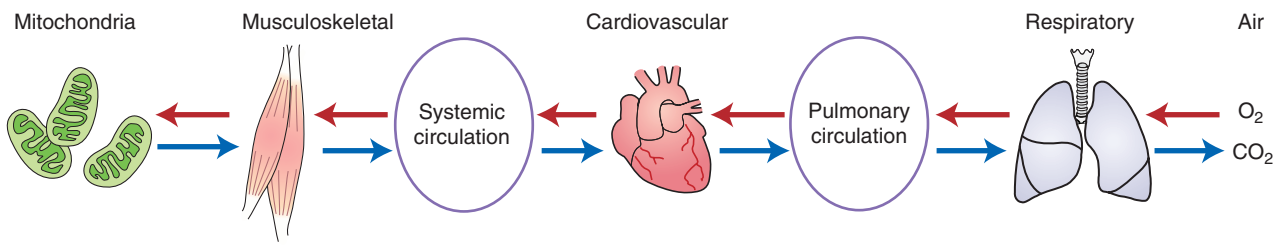

Fig. 8-1 Schematic illustration of the oxygen transport system, which involves the interaction between the respiratory, cardiovascular, and musculoskeletal systems. *(Reprinted with permission from Mahler D: Dyspnea: Diagnosis and management.* Clin Chest Med *8:215-230, 1987.)*

Any of these may become dysfunctional. Thoracic cage abnormalities include kyphoscoliosis, extreme obesity, and large pleural effusions. Diseases of the respiratory muscles include polymyositis and muscular dystrophy. Neurological abnormalities include spinal cord injuries, phrenic nerve injuries, brachial plexus neuropathy, ascending polyneuritis (Guillain-Barré syndrome), myasthenia gravis, amyotrophic lateral sclerosis, poliomyelitis, neurotoxins, and exposure to paralytic agents.

The time course of the appearance and progression of dyspnea should be identified.[6,16] Acute dyspnea is common in pulmonary embolism, pneumothorax, acute asthma, pulmonary congestion related to congestive heart failure (CHF), pneumonia, and upper airway obstruction. Most of these conditions require immediate physician evaluation of the acute problem before physical therapy intervention. Subacute or chronic progression of dyspnea generally presents, over time, as increasingly severe dyspnea with exertion. It occurs with emphysema, restrictive lung disorders such as pulmonary fibrosis, chest wall deformities, respiratory muscle dysfunction, occupational lung diseases, chronic CHF, and large pleural effusions.

Dyspnea may also be related to body position.[16] Therefore, when evaluating dyspnea, the physical therapist should ask whether the patient:

- Has difficulty breathing when reclining horizontally
- Finds it necessary to be propped up on several pillows to sleep at night (orthopnea)
- Has more difficulty breathing when reclining on one side (trepopnea)
- Wakes up at night short of breath and feels the need to sit up or walk around the room to "catch your breath" (paroxysmal nocturnal dyspnea)

Acute Dyspnea

A patient who has acute dyspnea requires a rapid and thorough history and physical assessment. The physical therapist should ask several important questions to address the possible causes of acute dyspnea:[14]

1. Are you short of breath at rest? If the answer is yes, it suggests a severe physiological dysfunction. The patient likely needs prompt evaluation by a physician if this is of recent onset and the patient has not had a medical workup.
2. Do you have chest pain? If so, what part of your chest? Unilateral localized chest pain raises the possibility of spontaneous pneumothorax, pulmonary embolism, or chest trauma.
3. What were you doing immediately before or at the time of the onset of shortness of breath? Approximately 75% of spontaneous pneumothoraces occur during sedentary activity, 20% happen during some strenuous activity, and 5% are related to coughing or sneezing. A history of immobilization of a lower extremity, recent surgery, bed rest, travel requiring prolonged sitting, obesity, CHF, and venous disease of the lower extremities are all risk factors for pulmonary embolism. If the patient's symptoms are related to chest trauma, the fact that a fall, a blow, or an accident occurred can usually be quickly established.
4. Do you have any major medical or surgical conditions? Cystic fibrosis, chronic obstructive pulmonary disease (COPD), interstitial lung disease, and malignancies are important causes of secondary spontaneous pneumothorax.

Acute dyspnea in cardiac patients is difficult to assess because the signs and symptoms are so similar to those caused by pulmonary disease. It is most often due to arrhythmias and acute coronary ischemia with associated left ventricular dysfunction, but it can be caused by any cardiac disorder.[16]

If the therapist strongly suspects pneumothorax, pulmonary emboli, or an acute cardiac disorder on the basis of the history and physical assessment, the patient should be referred for immediate medical evaluation.

Dyspnea on Exertion

Dyspnea on exertion is a common complaint of patients with cardiopulmonary dysfunction. Dyspnea during exercise or exertion usually precedes dyspnea at rest.[17] It most often is a result of chronic pulmonary disease or CHF. Some causes of dyspnea during exertion or exercise are listed in Table 8-1.

It is important to establish the amount of activity required to produce dyspnea. Various scales[18,19] have been developed to categorize the level of dyspnea and impairment present in patients (Figure 8-2 and Table 8-2). The patient should be asked about daily activity and what activities produce breathlessness.[20] Does the patient become short of breath climbing a flight of stairs or walking uphill? Is the patient able to walk and talk simultaneously? Does walking more slowly affect the individual's dyspnea?

In addition, the time at which the patient began to notice an increase in shortness of breath should be noted. A recent onset of dyspnea is more characteristic of heart failure than of chronic lung disease, which has a longer, more insidious onset. Acute pulmonary problems such as pneumothorax, atelectasis, pneumonia, and other conditions superimposed on chronic lung disease can also explain a recent intensification of symptoms.

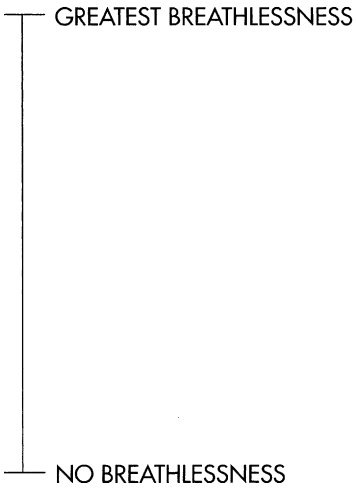

Fig. 8-2 The visual analogue scale is a vertical line 100 mm in length. The patient is asked to make a mark along this line that represents his or her level of breathlessness. The distance of the patient's mark above zero represents the measurement of dyspnea. *(Reprinted with permission from Mahler D: Dyspnea: Diagnosis and management.* Clin Chest Med *8:215-230, 1987.)*

Table 8-1 Disorders Limiting Exercise Tolerance, Pathophysiology, and Discriminating Measures

Disorders	Pathophysiology	Measures That Deviate From Normal
PULMONARY		
Obstructive lung disease	↓ Ventilatory capacity due to airflow limitation, increased ventilatory requirement due to V/Q mismatching, hypoxic stimulation to breathing	↓ VO_2 max, ↑ VD/VT, ↑ $P(a–ET)CO_2$, ↑ $P(A–a)O_2$, ↓ breathing reserve (MVV–VE_2 max), ↓ HR at maximal WR (↑ HR reserve), abnormal (trapezoidal) expiratory flow pattern
Restrictive lung disease	↓ Lung volumes, especially IC and TLC; V/Q mismatching, hypoxemia	↓ VO_2 max, ↑ VT/IC, RR >50 at maximal WR, ↓ breathing reserve, ↑ VD/VT, ↑ $P(a–ET)CO_2$, progressively ↓ PaO_2 and ↑ $P(A–a)O_2$ with ↑ WRs
Chest wall defects	Respiratory pump dysfunction due to muscle weakness or ↓ chest wall compliance	↓ VO_2 max, ↑ VT/IC, ↑ RR at low WRs, nl $\Delta VO_2/\Delta WR$, ↓ breathing reserve, ↓ HR at maximal WR, nl PaO_2
Diseases of pulmonary circulation	↓ Pulmonary perfusion leading to V/Q mismatching	↑ V_E at submaximal WRs, ↑ VD/VT, ↑ $P(a–ET)CO_2$, progressively ↓ PaO_2 and ↑ $P(A–a)O_2$ with ↑ WRs, ↓ VO_2 max, ↓ AT, more shallow $\Delta VO_2/\Delta WR$ as WR is ↑ toward maximum, ↓ O_2 pulse (VO_2 max/HR)
CARDIAC		
Coronary insufficiency	Relative imbalance between myocardial oxygen supply and demand, causing myocardial ischemia	May have chest pain and ischemic ECG changes, ↓ VO_2 max, ↓ AT, ↓ O_2 pulse, more shallow $\Delta VO_2/\Delta WR$ as WR is ↑ toward maximum, ↑ HR/ VO_2, ↑ breathing reserve, metabolic acidosis at low WRs → ↑ WRs→V_E, abnormal BP responses
Valvular	Cardiac output limitation due to ↓ effective SV	↓ VO_2 max, ↓ AT, ↓ O_2 pulse, more shallow ΔVO_2 max/ΔWR as WR is ↑ toward maximum, ↑ HR/ VO_2, ↑ breathing reserve, metabolic acidosis at low WRs → ↑ V_E, abnormal BP responses
Myocardial	Cardiac output limitation due to ↓ EF and SV	
OTHER		
Obesity	↑ Energy cost to move body; if severe, restrictive lung dysfunction and pulmonary insufficiency	↑ VO_2 per workload, nl O_2 pulse when predicted from ht, ↓ VO_2 max/wt and AT/wt but nl VO_2 max/ht and AT/ht (unless extremely obese), ↑ $P(A – a)O_2$ at rest that normalizes during exercise, nl VD/VT
Peripheral arterial disease	Impaired ability to ↑ blood flow to working muscles	Leg pain (claudication), ↓ $\Delta VO_2/\Delta WR$, ↓ VO_2 max, ↓ AT, possible hypertensive BP response
Anemia	↓ Oxygen-carrying capacity	↓ Hemoglobin and hematocrit, ↓ VO_2 max, ↓ AT, ↓ O_2 pulse, nl VD/VT, $P(a – et)CO_2$, and $P(A – a)O_2$
Musculoskeletal disorders	Musculoskeletal coupling inefficiency; inflammation	↓ Mechanical efficiency (VO_2 per workload), ↓ maximal WR; possible pain and abnormal movement patterns
Chronic metabolic acidosis	Due to poorly controlled DM, CRF, CHF, or ingestion of certain drugs	↓ HCO_3^-, steep / VCO_2 relationship, nl $P(a–ET)CO_2$ and $P(A–a)O_2$, nl VD/Vt
Deconditioning	Inactivity or prolonged bed rest leading to loss of ability to effectively redistribute systemic blood flow	↓ VO_2 max, ↓ AT, ↓ O_2 pulse, ↑ breathing reserve, metabolic acidosis at lower WRs → ↑ V_E
Anxiety reaction	Hyperventilation and respiratory alkalosis with precisely regular RR, although possible breath-holding episodes	Abrupt tachypnea that sometimes starts at rest, ↓ $PaCO_2$, respiratory alkalosis
Malingering, poor effort	Very irregular breathing with periods of hyperventilation and hypoventilation	AT not achieved or ↑ compared with VO_2 max, ↑ breathing and HR reserve; often irregular breathing pattern with periods of tachypnea and bradypnea producing wide swings in $PaCO_2$ and $PetCO_2$ unrelated to changes in WR

↓, Decreased; ↑, increased; →, leading to; Δ, change in; AT, anaerobic threshold; BP, blood pressure; CHF, chronic heart failure; CRF, chronic renal failure; DM, diabetes mellitus; ECG, electrocardiogram; EF, ejection fraction; HR, heart rate; ht, height; IC, inspiratory capacity; MVV, maximal voluntary ventilation; nl, normal; $P(A–a)O_2$, alveolar–arterial oxygen difference; $PaCO_2$, partial pressure of arterial carbon dioxide; $P(a–ET)CO_2$, arterial–end-tidal carbon dioxide difference; PaO_2, partial pressure of arterial oxygen; $PetCO_2$, partial pressure of end-tidal carbon dioxide; RR, respiratory rate; SV, stroke volume; TLC, total lung capacity; VCO_2, carbon dioxide production; VD/VT, ratio of dead space volume to tidal volume; V_E, minute ventilation; V_E max, maximal minute ventilation; VO_2, oxygen consumption; VO_2 max, maximal oxygen consumption; V/Q, ventilation–perfusion; WR, work rate; wt, body weight. Table 8-2 American Thoracic Society Dyspnea Scale

Grade	Degree	Description
0	None	Not troubled with breathlessness except with strenuous exercise
1	Slight	Troubled by shortness of breath when hurrying on level ground or walking up a slight hill
2	Moderate	Walks slower than people of the same age on level ground because of breathlessness or has to stop for breath when walking at own pace on level ground
3	Severe	Stops for breath after walking about 100 yards or after a few minutes on level ground
4	Very severe	Too breathless to leave the house or breathless when dressing or undressing

Is wheezing present with the dyspnea on exertion? Has there been an associated weight gain? Does the patient have a positive smoking history and sputum production? If a positive response is received, these suggest that COPD is the primary cause of symptoms.[20]

The basic defect that cardiac diseases produce during exertion is a limited cardiac output, which is caused primarily by a reduced stroke volume.[17] To compensate for the relatively low stroke volume, the patient develops a rapid heart rate and a wide arteriovenous O_2 difference (decreased capillary P_{O_2}) at an inappropriately low work rate. Therefore the exercising muscles (both skeletal and myocardial) have increased difficulty getting an adequate oxygen supply to perform the necessary work: this results in dyspnea, fatigue, or pain. The lactic acidosis that results from the low level of oxygen delivery to the muscles can be measured by either invasive or noninvasive gas-exchange methods during exercise testing. The functional and therapeutic capacity of the patient with heart disease can be estimated on the basis of the history and symptoms (Table 8-3).

Dyspnea in patients with cardiac disorders is usually related to metabolic acidosis-induced hydrogen ion stimulus. Also, increased pressure in the right side of the heart and pulmonary circulation during exertion may stimulate mechanoreceptors that increase ventilation and induce dyspnea.

Diseases that involve the lungs or thoracic cage generally prevent external respiration (ventilation) from keeping pace with internal respiration (in the cells).[17] In other words, patients outwalk or outrun their lungs during activities or exertion. The primary symptom that limits exercise in patients with pulmonary disorders is dyspnea, which occurs because of the difficulty they have eliminating the CO_2 produced by metabolism. Some individuals, such as those with pulmonary fibrosis and some of those with COPD, do experience a decrease in P_{O_2} with exercise. Hence dyspnea on exertion in pulmonary patients is usually related to hypoxic or hypercapnic stimuli.

Dyspnea in Cardiac Patients

The cause of dyspnea in cardiac patients is determined by whether an associated stiffness of the lungs (a loss of compliance) is also present.[15] Dyspnea is the primary symptom of a decompensating left ventricle.[7,16] As the ventricle fails to eject the normal volume of blood, it produces chronic pulmonary venous hypertension, congestion, and pulmonary edema, resulting in stiff or less compliant lungs. This, along with modest hypoxemia that augments the respiratory drive, increases ventilation and the work of breathing. Tachypnea is often seen at rest. Exercise exaggerates the pulmonary congestion and edema and promotes arterial and mixed venous hypoxemia, which also increases the amount of dyspnea and tachypnea manifested. Fatigue, resulting from low cardiac output, also affects the respiratory muscles, further increasing the sensation of breathlessness.

Dyspnea in cardiac patients without stiff lungs is seen primarily during exertion or exercise.[15] In uncomplicated pulmonic stenosis, it is probably related to an inadequate cardiac output during exercise. Patients with tetralogy of Fallot and other forms of cyanotic heart disease experience both dyspnea and fatigue during exercise when the arterial oxyhemoglobin saturation has fallen appreciably below the resting level.

Table 8-3 Functional and Therapeutic Classification of Patients with Heart Disease

Classification	Parameters
FUNCTIONAL CLASSIFICATION	
Class I	Patients with cardiac disease but without resulting limitations of physical activity; ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.
Class II	Patients with cardiac disease resulting in slight limitation of physical activity; they are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
Class III	Patients with cardiac disease resulting in marked limitation of physical activity; they are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.
Class IV	Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort; symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort increases.
THERAPEUTIC CLASSIFICATION	
Class A	Patients with cardiac disease whose physical activity need not be restricted in any way.
Class B	Patients with cardiac disease whose ordinary physical activity need not be restricted but who should be advised against severe or competitive efforts.
Class C	Patients with cardiac disease whose ordinary activity should be moderately restricted and whose more strenuous efforts should be discontinued.
Class D	Patients with cardiac disease whose ordinary activity should be markedly restricted.
Class E	Patients with cardiac disease who should be at complete rest, confined to bed or chair.

Orthopnea

Orthopnea is dyspnea that occurs when the patient is in the recumbent position.[1] The patient may state the need for two or three pillows under the head to rest at night. This symptom is commonly associated with CHF but may also be associated with severe chronic pulmonary disease.

Paroxysmal Nocturnal Dyspnea

Paroxysmal nocturnal dyspnea (PND) is an important type of shortness of breath. This symptom has strong predictive value as a sign of CHF.[1] The patient usually falls asleep in the

recumbent position, and 1 or 2 hours later, awakens from sleep with acute shortness of breath. The patient sits upright on the side of the bed or goes to an open window to breathe "fresh air" and get relief from shortness of breath.

The mechanism of PND is the transfer of fluid from extravascular tissues into the blood stream (or intravascularly) during sleep.[20] The intravascular volume of fluid gradually increases until the compromised left ventricle can no longer manage it. The left atrial pressure rises when the rate of lymphatic drainage from the lungs is unable to keep up with the increased volume of fluid. The increased atrial pressure leads to a sufficiently elevated pulmonary capillary pressure to produce interstitial edema. Patients who are light sleepers awaken early with dyspnea. Deep sleepers may not awaken until they develop alveolar edema.

Classic PND cannot usually be eliminated by only elevating the trunk without lowering the legs. The patient must pool blood in the extravascular tissues of the legs to get adequate relief, which usually takes at least 30 minutes. This is why the patient must sit up or stand up and ambulate.

The patient should be asked about the amount of exercise or work performed during the day before an attack of PND. A true episode of left ventricular failure in PND is more likely to occur after a day of unusual exertion, which causes an increased amount of extravascular fluid to accumulate in the legs. If the patient is participating in an exercise or rehabilitation program, the level of exercise may have to be reduced to prevent PND.

Platypnea

Platypnea is the onset of dyspnea when the patient assumes the sitting position from the supine position.[6,16] This unusual phenomenon is commonly found in patients with basilar pulmonary fibrosis or basilar arteriovenous malformation. It can be related to the redistribution of blood flow to the lung bases when assuming the sitting position and the resultant ventilation-perfusion mismatching and hypoxemia.

Trepopnea

Trepopnea refers to dyspnea in one lateral position but not the other.[3] It is caused by the positional mismatching of ventilation to perfusion in unilateral respiratory system pathology such as lung disease, pleural effusion, or airway obstruction.[16,21,22] It also is commonly seen in patients with mitral stenosis.[20] Occasionally, it may be the result of a fall in blood pressure when the patient is in the left lateral decubitus position. If the patient has ischemic heart disease, the reduction in coronary perfusion can cause either angina or dyspnea.

Functional Dyspnea

Functional dyspnea is defined as shortness of breath at rest but not during exertion.[6] It is most commonly seen in young women who complain of the need to take a deep breath or to sigh, and they interpret this sensation as shortness of breath. The physical examination and pulmonary function tests are negative. Reassurance is usually all that is necessary.

Wheezing

Patients who complain of wheezing associated with dyspnea may have pulmonary or cardiac disease. This symptom, if first reported in patients over the age of 40, is often related to heart failure.[1] When it has been confirmed that the wheezing results from heart disease, the patient is said to have cardiac asthma. Wheezing in cardiac patients is a manifestation of narrowed airways and thickened bronchial walls as a result of pulmonary edema.[15] However, if patients have a history of episodes of wheezing and dyspnea since childhood, COPD or asthma is the likely cause. Other pulmonary conditions, such as eosinophilic pneumonia, bronchopulmonary aspergillosis, allergic granulomatosis, and others can cause wheezing.[5] Wheezing must be differentiated from stridor, which is commonly caused by laryngotracheal narrowing due to a tracheostomy scar, trauma of intubation, laryngeal paralysis, epiglottitis, or tumors. Chronic pulmonary patients may also develop heart conditions, so it is good to remember that patients who complain of wheezing may have both cardiac and pulmonary disease.

Cough

Cough is a common symptom of pulmonary disease. The cough mechanism consists of three phases:[23]

1. Inspiratory phase
2. Compressive phase
3. Expiratory phase

Numerous cough-irritant receptors are located on the mucosa of the larynx, trachea, bronchi, pleura, and external auditory canal. These receptors are most sensitive at the glottis and carina and diminish rapidly beyond the fourth-generation bronchi. A cough follows stimulation of these mucosal receptors by any of a number of factors including inflammation, sputum, foreign bodies, noxious gases or odors, chemical substances, endobronchial tumors, and extrabronchial pressure on the trachea or bronchi.[6]

A productive cough is beneficial for clearing the airways of sputum and foreign material and generally should not be inhibited. However, a dry, hacking cough is usually of no value and can have a self-perpetuating irritant effect on the respiratory mucosa. A dry cough may be the initial symptom of certain interstitial lung diseases such as allergic alveolitis, sarcoidosis, and pulmonary fibrosis. Some causes and characteristics of coughs are listed in Table 8-4.

Cough may be the only presenting symptom of asthma and is a common cause of chronic cough.[24,25] In individuals with asthma, cough is precipitated by inhaling cold air and by exercising, and the cough is dry. Cough can precipitate an asthma attack in sensitive patients; in that instance, it is known as cough-induced bronchospasm.

It is important to determine the length of time cough has been present.[6] The most common cause of an acute cough is a viral respiratory infection, which generally resolves within a few days or 2 to 3 weeks. Exposure to noxious gases also precipitates acute coughing.

A cough that has persisted for more than 3 weeks can be termed chronic.[3] The most common cause of chronic cough is chronic bronchitis, which is present in up to 30% of cigarette smokers. The next most common cause is the postnasal

Table 8-4 Some Causes and Characteristics of Coughs

Cause	Characteristics
ACUTE INFECTIONS OF LUNGS	
Tracheobronchitis	Cough associated with sore throat, running nose and eyes
Lobar pneumonia	Cough often preceded by symptoms of upper respiratory infection; cough dry, painful at first; later becomes productive
Bronchopneumonia	Usually begins as acute bronchitis; dry or productive cough
Mycoplasma and viral pneumonia	Paroxysmal cough, productive of mucoid or blood-stained sputum associated with influenza-like syndrome
Exacerbation of chronic bronchitis	Cough productive of mucoid sputum becomes purulent
CHRONIC INFECTIONS OF LUNGS	
Bronchitis	Cough productive of sputum on most days for more than 3 consecutive months and for more than 2 successive years; sputum mucoid until acute exacerbation, when it becomes mucopurulent
Bronchiectasis	Cough copious, foul, purulent, often since childhood
Tuberculosis or fungus	Persistent cough for weeks to months, often with blood-tinged sputum
PARENCHYMAL INFLAMMATORY PROCESSES	
Interstitial fibrosis and infiltrations	Cough nonproductive, persistent; depends on causes
Smoking	Cough usually associated with injected pharynx; persistent, most marked in morning, usually only slightly productive unless succeeded by chronic bronchitis
TUMORS	
Bronchogenic carcinoma	Nonproductive to productive cough for weeks to months; recurrent small hemoptysis common
Alveolar cell carcinoma	Cough similar to bronchogenic carcinoma, except in occasional instances when large quantities of watery, mucoid sputum are produced
Benign tumor in airways	Cough nonproductive, occasionally hemoptysis
Mediastinal tumor	Cough, often with breathlessness, caused by compression of trachea and bronchi
Aortic aneurysm	Brassy cough
FOREIGN BODIES	
Immediate, while still in upper airway	Cough associated with progressive evidence of asphyxiation
Later, when lodged in lower airway	Nonproductive cough, persistent, associated with localizing wheeze
Left ventricular failure	Cough intensifies while body is supine; aggravation of dyspnea
Pulmonary infarction	Cough associated with hemoptysis, usually with pleural effusion

Reprinted with permission from Szidon J, Fishman A: Approach to the pulmonary patient with respiratory signs and symptoms. In Fishman A, editor: *Pulmonary diseases and disorders.* New York, 1988, McGraw-Hill.

discharge syndrome. Patients describe a sensation of secretions dripping from the back of the nose into the throat, prompting throat clearing or coughing. Gastroesophageal disorders are present in 10% to 40% of patients with chronic cough and may contribute to coughing due to microaspiration or irritation of cough receptors in the lower esophagus.[25-27]

Various cardiac conditions may stimulate receptors in the bronchi and provoke coughing.[28] Because the bronchial veins empty into the pulmonary veins (leading to the left side of the heart), the systemic veins, and the superior vena cava (leading to the right side of the heart), venous congestion and coughing may occur with either right- or left-side CHF. It is more common, however, in left-sided CHF. The onset of a cough in a patient with paroxysmal tachycardia or acute myocardial infarction (MI) is often an early symptom of acute left-side heart failure.

Coughing may be caused by other cardiovascular conditions, such as a large left atrium displacing the left main stem bronchus upward, aortic aneurysms placing pressure on the bronchi, and a double aortic arch compressing the trachea.

A specific diagnosis can be made in 80% of cases of chronic cough by an appropriate history alone.[29] Determining the precipitating causes or the time of onset points the clinician to a probable diagnosis. For example, does the patient cough primarily at night? If so, it points to heart failure, esophageal problems, bronchiectasis, or asthma as the potential cause. An early-morning cough is more common in bronchitis and in individuals with postnasal drip. Cough following meals suggests esophageal disease. Cough precipitated by exertion or deep breathing suggests asthma or interstitial lung disease. Allergens or irritant fumes at home or at work may be a cause of cough. Postviral cough may be present for weeks following a viral illness.

Some medications can elicit coughing. Beta blockers prescribed to treat hypertension, migraine headaches, cardiovascular disease (CVD), or glaucoma may precipitate asthma.

Many drugs, including chemotherapeutic agents, can cause interstitial lung disease and coughing.

Cough and wheezing may result from COPD, asthma, or early left heart failure. Early left heart failure predisposes the patient to respiratory infections and may be responsible for chronic bronchitis.

Cough Complications

One of the more common complications of cough is syncope. Tussive, or cough-induced, syncope, which is more common in men than in women, can be recognized through accurate history taking.[5] It is typically reported by middle-aged men who "smoke hard, eat hard, drink hard, and cough hard." They experience fainting or near-fainting following cough paroxysms. The cause is obscure but may be related to vagus-induced cardiac slowing or vasodilation or to high intrathoracic pressures that impair venous return, decrease cardiac output, increase intracranial pressure, and result in a reduced cerebral blood flow. Cough syncope is often resolved by smoking cessation.

Complications of cough include headache, back pain, muscular tears, hematomas, and rib fractures (along the posterior axillary line). Occasionally, vertebral compression fractures (in osteopenic patients), urinary incontinence (UI) (in women), and inguinal hernias (in men) may occur.[30]

Chest Pain

Taking an accurate history is crucial to the proper evaluation of chest pain.[3] Although the definitive cause of chest pain cannot be fully established without diagnostic medical tests, it is usually possible to determine whether the pain originates in the pleurae, chest wall, or thoracic organs by means of careful history taking.

Pleuritic Chest Pain

Pleuritic chest pain originates from the parietal pleura or endothoracic fascia but not the visceral pleura, which have no pain receptors. The patient can usually identify it as being close to the thoracic cage.[15] Pleuritic chest pain worsens sharply with inspiration as the inflamed parietal pleura are stretched with chest wall motion. Deep breathing, coughing, and laughing are extremely painful, requiring the patient to apply pressure over the involved area to control the pain.

Pleuritic chest pain is ordinarily found in patients who have other signs of respiratory illness, such as cough, fever, chills, and malaise. Inflammation of the central portion of the diaphragmatic pleura produces ipsilateral shoulder pain by way of the phrenic nerve.[5] Outer portions of the diaphragmatic pleura are innervated by the 7th through 12th intercostal nerves. Irritation of these pleura causes referred pain in the lower thorax or upper abdomen.[31]

The onset of pleuritic chest pain varies according to its cause.[3] Sudden severe pleuritic chest pain suggests a spontaneous pneumothorax, pulmonary embolism, or infarct. Pulmonary embolism is usually accompanied by sudden dyspnea, hemoptysis, tachycardia, cyanosis, hypotension, anxiety, and agitation.[7]

Cardiac Chest Pain

Three cardinal features are characteristic of cardiac chest pain. The patient should be asked the following questions:[7]

1. Does the pain have maximal intensity from the onset or does it build up for several seconds? Ischemic cardiac pain, or angina, is caused by the myocardium contracting in the absence of an adequate oxygen supply. The same type of pain can be produced by placing a blood pressure cuff around the upper arm and inflating it until the brachial pulse can no longer be palpated at the wrist. If a patient opens and closes a fist, pain will gradually appear and escalate in the forearm. The causal mechanism of this pain is the same as that of myocardial pain: continuing muscular contraction in the absence of an adequate oxygen supply. This type of pain requires several contractions of the myocardium to reach its maximal intensity. In other words, there is a characteristic buildup, or escalation, of angina pain.
2. Can you point to the area of pain with one finger? Anginal pain is characteristically demonstrated by patients' using their entire hand or closed fist against the anterior chest wall. It is described as a sign of angina because it is so typical.[7] By contrast, any pain that can be localized by pointing with a fingertip is unlikely to be angina.
3. Is the pain deep inside your chest, or does it seem as though it is close to the surface? Anginal pain is visceral pain that may be referred superficially but always has a deep internal component.

Myocardial ischemia may be completely painless (silent ischemia). Angina may, in fact, not be painful but rather may be described as discomfort, pressure, squeezing, a tight band, heaviness, burning, or indigestion. It usually is located substernally and radiates into one or both arms, the neck, the jaw, or the back.

Angina is not limited to patients with CAD.[7] Individuals who have normal coronary arteries but an insufficient oxygen supply for a given cardiac workload can also experience angina. These include individuals with anemia, hypertension, tachycardia, and thyrotoxicosis. Hypertrophic and dilated cardiomyopathy can produce typical angina pain, although the latter tends to be intermittent, usually occurring with episodes of CHF. Aortic valve disease can cause angina as a result of impairment of adequate coronary artery blood flow.

Angina is usually precipitated by exertion, such as walking uphill, against the wind, or in cold weather.[7] It is more likely to be brought on after a meal or by emotional stress. The rapid resolution of chest pain by rest or sublingual nitroglycerin strongly suggests a cardiac origin. The pain produced by MI is longer, persisting more than 20 minutes; it occurs at rest and is accompanied by nausea, diaphoresis, hypotension, and dyspnea.

Pulmonary Hypertension

Chest pain related to pulmonary hypertension may mimic angina pectoris. It is usually found in patients with mitral stenosis or Eisenmenger syndrome (pulmonary hypertension related to an interventricular septal defect, a patent ductus arteriosus, or an atrial septal defect). This type of chest pain usually is absent at rest, occurs during exertion, and is invariably associated with dyspnea.[1] It is believed to result from

dilation of the pulmonary artery or from right ventricular ischemia. The pain is not relieved by nitrates. Primary pulmonary hypertension may be accompanied by syncope and the Raynaud phenomenon.[6]

Pericardial Chest Pain

Pericardial chest pain is also midline, but because of its anatomic relationship with the mediastinal pleura, it has features that suggest pleural involvement.[3] Deep breathing, coughing, swallowing, movement, and lying down may make it worse. If the central tendon of the diaphragm is involved, the pain may be referred to the left shoulder or scapular area.[7] The patient may report that each heartbeat affects the pain. Sitting up and leaning forward or lying on the right side often relieves the pain.

Esophageal Chest Pain

Diffuse esophageal spasm or esophageal colic is a common cause of chest pain. It is often confused with cardiac pain because it is located substernally, has a squeezing or aching quality, and may radiate into one or both arms.[12] Furthermore, diffuse esophageal spasm may be relieved by sublingual nitroglycerin as a result of its generalized function as a smooth-muscle relaxant.

Pain that radiates through the chest to the back, pain that decreases with a change in position from supine to upright, or relief induced by ingesting antacids all suggest an esophageal origin.[3] Also, diffuse esophageal spasm is often associated with pain on swallowing (odynophagia), dysphagia, and regurgitation of stomach contents. Swallowing hot or cold liquids and emotional stress tend to precipitate this type of chest pain.

Chest Wall Pain

Chest wall pain is the most common type of chest pain. Clues in the patient's history to this type of pain include intermittent occurrence, variable intensity, and local tenderness.[5] Because it is commonly located on the anterior chest wall, many patients believe it is heart pain. However, an important differentiation from cardiac pain is that it does not occur during, but rather following, exertion. It may worsen with inspiration, but its association with trunk motions (flexion, extension, rotation) distinguish it from pleuritic chest pain.

Localized anterior chest pain as a result of costochondritis of the second to fourth costosternal articulations (Tietze syndrome) is described as tender to touch.[12] A complaint of rib tenderness, together with a history of trauma, fall, long-term steroid use, coughing, or upper extremity exertion, suggests rib fracture.

Degenerative disk disease and arthritis of the cervical or thoracic spine, thoracic outlet syndrome, spondylitis, fibromyalgia, kyphoscoliosis, and herpes zoster can all produce chest wall pain.[3,5,32-34] Primary lung cancer that invades the adjoining chest wall, ribs, or spine produces severe, persistent, localized pain.[3] Another possible cause of chest wall pain is the Pancoast syndrome (superior sulcus tumor), in which a primary lung tumor located in the extreme apex of the lung invades the brachial plexus and produces pain in the shoulder, scapular region, or medial aspect of the arm and hand.

Chest wall pain may be caused, rarely, by thrombosis of a superficial vein on the chest wall (Mondor's disease). It is a self-limited condition of unknown origin and can last several weeks.[3] The only physical finding is a subcutaneous cord that can be palpated along the lateral chest wall.

Hemoptysis

Hemoptysis is defined as coughing up blood. It can vary in amount from being blood-streaked sputum to being virtually all blood. The bleeding site may be anywhere in the upper or lower respiratory tract.

The timing and frequency of hemoptysis, as determined in the history, can offer clues about its cause. A history of nosebleeds is significant because blood may be aspirated during sleep at night and expectorated the following morning. Intermittent bouts of hemoptysis are characteristic of respiratory infections such as bronchiectasis, tuberculosis, fungus infections, or broncholithiasis.[5] Persistent expectoration of blood-streaked sputum on a daily basis is highly suggestive of bronchogenic neoplasm.

The lung receives its blood supply in two ways: the pulmonary arteries (a low-pressure system) and the bronchial arteries (a high-pressure system) off the aorta.[6] The appearance of hemoptysis may vary according to which blood supply is involved. If the bronchial vessels are the source, there tend to be large amounts of bright-red blood. This is often the site of bleeding in bronchiectasis, because bronchial arteries undergo enlargement and extensive anastomosis with the pulmonary artery system. In mitral stenosis, where there is increased pulmonary vascular resistance, hemoptysis arises from passively engorged submucosal bronchial veins.[15]

Hemoptysis sourced in the low-pressure pulmonary artery system tends to occur in small amounts and is composed of dark or clotted venous blood.[3] It may arise from the pulmonary parenchyma, as in the case of the highly vascular granulation tissue found in the walls of lung abscesses. These abscesses may be caused by infections, such as tuberculosis, anaerobic bacteria, staphylococci, or chronic irritation by a fungus ball in an abscess cavity. If a blood vessel ruptures in an abscess cavity, hemorrhage tends to be massive, even exsanguinating.

Cardiovascular conditions, such as mitral stenosis, pulmonary infarction, Eisenmenger physiology, and aortic aneurysm, are also associated with hemoptysis.[1] Pink frothy sputum is commonly found with acute pulmonary edema. Physical therapists should carefully evaluate complaints of hemoptysis and be certain of its cause before cautiously conducting treatment.

Fatigue and Weakness

There are multiple causes of fatigue and weakness.[1] Physical therapists should not conclude too quickly that they are related to physical inactivity and decreased muscular strength in sedentary cardiopulmonary patients. The most common causes of complaint of fatigue and weakness are depression, anxiety, and emotional stress. They often accompany anemia, hypothyroidism, and chronic disease states.

Fatigue is commonly associated with CHF. In this condition, it is probably related to cardiac output insufficient to

perfuse the entire body adequately, including the skeletal muscles. Generally, fatigue caused by cardiac disease is related to exertion, but fatigue related to anxiety tends to be continuous.[1]

Diuretics used to treat CHF can cause potassium depletion and hypokalemia with resultant weakness. Antihypertensive medications can produce weakness through postural hypotension.

Pedal Edema

CHF is a common cause of bilateral pedal edema.[7] However, 10 to 20 pounds of fluid generally accumulate in the body before foot and ankle swelling is evident. Therefore weight gain is an even earlier indication of fluid retention due to CHF. Occasionally, patients may complain only about an increase in abdominal girth, which results from ascites. When caused by CHF, the onset of ascites virtually always occurs after pedal edema is present. If the amount of ascites is disproportionate to that of pedal edema, restrictive cardiomyopathy or constrictive pericarditis should be a consideration.

It is important to determine whether the patient had dyspnea on exertion before the onset of lower-extremity edema. If the edema is a result of a poorly functioning left ventricle, mitral stenosis, or cor pulmonale, it usually follows dyspnea on exertion.

Patients with CHF and altered renal function commonly report edema of the ankle and lower legs while upright during the day, but indicate a decrease during the night.[1] This is a result of local hydrostatic factors related to the upright position.

Edema may be present in nephrosis or starvation, when the total blood protein falls below 5 g/100 mL (hypoproteinemia). Other causes of pedal edema include liver disease, kidney disease, and anemia. Edema of one leg ordinarily occurs because of local factors such as thrombophlebitis or varicose veins.

Hoarseness

Hoarseness (abnormal vocal cord motion during phonation) is a symptom of laryngeal dysfunction.[5] It is usually associated with upper respiratory tract infections or allergies and resolves in 1 to 2 weeks.[6] Trauma following intubation, laryngeal polyps, or tumors are other common causes of hoarseness. However, this symptom is also related to cardiopulmonary conditions. Because the recurrent laryngeal nerves pass through the upper thorax, intrathoracic pathology that involves one of these nerves can cause unilateral vocal cord paralysis, resulting in hoarseness.[6] These include lung or mediastinal tumors, granulomatous disease, enlarged mediastinal lymph nodes, and pericardial or mediastinal adhesions.

Several cardiovascular conditions can produce hoarseness because the left recurrent laryngeal nerve loops under the arch of the aorta and above the pulmonary artery as it returns to the neck.[1] Therefore an aneurysm of the arch of the aorta, a dilated pulmonary artery or atrium resulting from an atrial septal defect, or mitral stenosis can cause hoarseness.[28]

Hence, if a patient manifests hoarseness, it is necessary to inquire about the length of time it has been present, the patient's smoking history, and any history of cardiac or pulmonary diseases.

Summary

Obtaining an accurate and thorough history is the cornerstone of the physical therapy evaluation process. The probable cause and severity of many cardiopulmonary symptoms can be determined by careful history taking. This information enables therapists to select the most appropriate evaluation and treatment techniques. When properly performed, accurate history taking gains the patient's confidence and cooperation and provides the basis for a good patient-therapist relationship.

Review Questions

1. What are the basic causes of dyspnea?
2. What questions can be asked of a patient with dyspnea in order to determine the likely cause?

Pulmonary function tests are usually ordered when patients go to their primary physician or a pulmonary specialist with complaints of shortness of breath, cough, decreased activity, and dyspnea. When the history is taken, patients' complaints are due to their breathing problem, for example they are short of breath walking up stairs or dressing. As dyspnea begins to affect their daily life more and more, people will often make lifestyle changes, such as selling a two-story house and moving to a ranch house with no stairs or altering the way they dress (e.g., wearing housecoats or jogging pants that are easier to put on and take off). Often, people think that their breathing problems are just part of getting older, and they try to change their lifestyle to accommodate their limitations and avoid doing things that make them short of breath. In many cases, by the time a patient comes to the care provider with these complaints, he or she is already showing signs of moderate to severe chronic obstructive pulmonary disease (COPD). As will be discussed in this chapter, this is a very good reason for considering office spirometry to be a "fifth vital sign." Suggestions have been made that all smokers and any nonsmoker over 40 years of age should have office spirometry. If the values are abnormal, even though patients may not be experiencing noticeable lifestyle changes, the appropriate drug therapy regimen can be implemented and patients who are smokers will have a definite motivation to quit smoking.

Pulmonary function tests (PFTs) help in the evaluation of the mechanical function of the lungs.[1] They are based on researched norms, taking into account sex, height, and age. For example, there are predicted values for a male, age 65, who is 6 feet tall.[2,3] Race and ethnic differences also play roles in the reference values and need to be taken into account for diagnostic and research purposes.[4–6]

When the patient performs the test, actual results (observed) are compared with the predicted value expected of a person of that gender, height, and age to see whether he or she falls within the "normal" range or has a restrictive, obstructive, or a mixed component, based on the tests. If the patient is not within the normal range, a bronchodilator is given, and the test is repeated to see whether there is significant improvement with medication. Basically, the pulmonary function tests are categorized as volume, flow, or diffusion studies. Diagnosis of pulmonary disease or dysfunction and improvement with

treatment are evaluated after interpreting a patient's pulmonary function tests.

Spirometry is the most useful and commonly available test of pulmonary function. Both pulmonologists and primary care physicians commonly use screening spirometry in their offices in order to assess patients and to evaluate the effectiveness of treatment being given to the patient.[7]

Patients with asthma and COPD make up a large portion of the primary care physician's caseload. COPD is often diagnosed in the moderate to severe stage of the disease. The diagnosis of COPD can be made quite easily with spirometry, taking the patient's symptoms and history into account. Smokers can be evaluated for early lung disease, and this can serve as a "teachable moment" for them to quit smoking.[8]

Yawn and colleagues (2007)[9] compared the office spirometry interpretations of pulmonary experts with those of family physicians. They found agreement in 78% of the completed tests. In addition, following spirometry, changes were implemented in the management of 48% of patients. Of interest, there was closer correct interpretation of pulmonary functions between family physicians and pulmonologists in patients who had asthma, versus those with COPD.

Preoperative Pulmonary Evaluation

Preoperative pulmonary evaluation can predict postoperative pulmonary complications.[10–12] As people are living longer lives, more older adults will be candidates for surgery. From 1980 to 1995 the rates of cardiovascular surgical procedures in patients over 65 tripled.[13] In 1997 the performance of 10 of the most common surgical procedures in the United States totaled 1 in 350,0000 operations in the 65- to 84-year-old age group.[14] Considering the comorbidities of an aging population and the concern about complications in older adults, a thorough preoperative pulmonary screening is recommended.[11]

Risk factors that contribute to postoperative complications include smoking, older age, obesity, poor health, and chronic obstructive pulmonary disease.[11] Additional procedure-related risk factors include the site of surgery (abdominal, chest wall versus extremity, duration of surgery, and type of anesthesia or neuromuscular blockage).[15]

Office Spirometry to Improve Early Detection of Chronic Obstructive Pulmonary Disease

The National Lung Health Education Program has recommended that office spirometry be used to screen for subclinical lung disease in adult smokers. For patients who are smokers or for any patients over 40 who have unexplained dyspnea, cough, wheezing, or excessive mucus, spirometric measurements can be considered another vital sign to measure during the routine physical examination, along with blood pressure and cholesterol levels.[16,17]

In a study of 35- to 70-year-old individuals visiting their general practitioners, patients were given a questionnaire on symptoms of obstructive lung disease.[18] Spirometry was performed in patients with positive answers to the questions and in a random sample of 10% of the group. It was found that 42% of the newly diagnosed cases of obstructive disease would not have been detected without spirometry. The researchers concluded that office spirometry is essential in general practice and can be done by general practitioners who have training in the performance and interpretation of the pulmonary function tests. It is essential that there be good quality assurance and good training when these tests are performed in a general practitioner's office. Studies have shown variability between the results of pulmonary function tests done in the office versus those done in a lab, so the results should not be considered interchangeable.[19,20]

Respiration: Effect of Anatomical and Physiological Dead Space

The most important function of the lungs is to supply the body with oxygen and to the remove carbon dioxide (CO_2) that is produced as a waste product of metabolism. As this continuous gas exchange takes place, sufficient ventilation is needed to move the gases to the alveoli. A number of conducting airways in the lungs, from the trachea down to the terminal bronchi, do not participate in respiration but only move the gases to the alveoli. The volume of this series of airways is known as anatomical dead space. Generally, the anatomical dead space is proportional to the adult body weight. For example, in a 150-pound person, there is an anatomical dead space of approximately 150 mL. A normal tidal volume (TV), the breath normally taken, has to be large enough to reach the alveoli well past the anatomical dead space. In a normal adult, the TV is generally 450 to 600 mL. The anatomical dead space would thus represent about one-third of the TV. The rest of the breath would reach the alveoli and be considered "alveolar ventilation." In many neurologically impaired patients who have limited TVs, it is important to note that little alveolar ventilation may be taking place when the patient is breathing in a rapid and shallow pattern. For example, if a patient's TV is 200 mL, 150 mL would be anatomical dead space, and only 50 mL of each breath would be effective alveolar ventilation.

Many diseases and conditions can alter the volume of dead space that requires ventilation. In some cases the dead space decreases—for instance, in a pneumonectomy, when it is physically removed, or in asthma, when bronchospasm may narrow the airways. In other conditions such as pulmonary embolism, dead space increases when ventilated areas of lung cease to be perfused. The alveoli continue to receive fresh gas, but there is no blood available for gas exchange. This type of dead space is known as physiological dead space.

When dead space is increased, a larger percentage of the tidal volume is ventilating the dead space, leaving a smaller percentage for alveolar ventilation. The patient must work harder to get enough air to the functioning alveoli. This causes increased work of breathing and may result in patient fatigue. Work of breathing, or minute ventilation (MV), is defined as the TV times the respiratory rate (RR). The formula for minute ventilation is: $MV = TV \times RR$. For example, an MV of 8 L per minute = 500 mL × 16 breaths per minute. When the ventilatory rate increases, the TV decreases; thus the effective alveolar ventilation decreases.

Neurological and neuromuscular weakness may result in the inability to reach a normal TV. Similarly, surgical

procedures or pain caused by fractured ribs can also compromise a patient's ability to take a breath. Patients given a thoracolumbosacral orthosis (TLSO), or a corset for low back pain, may find their pulmonary function compromised by the restriction of the rib cage and abdomen. As the TV drops, a large percentage of the breath is anatomical dead space. This results in increased work of breathing for the patient and may ultimately result in respiratory failure if the patient is unable to provide effective alveolar ventilation.

Lung Volumes

The lung has four volumes: TV, inspiratory reserve volume (IRV), expiratory reserve volume (ERV), and residual volume (RV) (Figure 9-1).

- TV is the normal breath.
- IRV is the maximum amount of air that can be inhaled above a normal inspiration.
- ERV is the maximum amount of air that can be expired after a normal exhalation.
- RV is the volume of gas that remains in the lungs at the end of a maximum expiration.

Changes in RV can help in the diagnosis of certain medical conditions. An increase in RV means that even with maximum effort, the patient cannot exhale excess air from the lungs. This results in hyperinflated lungs and indicates that certain changes have occurred in the pulmonary tissue, which in time may cause mechanical changes in the chest wall (e.g., increased [AP] diameter, flattened diaphragm). These changes may be reversible in patients with partial bronchial obstruction, such as young patients with asthma, or irreversible, as in patients with advanced emphysema. Restrictive lung disease can cause a decrease in residual volume, as can cancer of the lung, microatelectasis, or musculoskeletal impairment.[21]

Lung Capacities

A lung capacity is two or more volumes added together (see Fig. 9-1). The capacities include total lung capacity (TLC), vital capacity (VC), inspiratory capacity (IC), and functional residual capacity (FRC).

TLC is the amount of gas the lung contains at the end of a maximum inspiration. It is made up of all four lung volumes. An increased TLC is seen with hyperinflation, such as in emphysema. A decrease in TLC may be seen in restrictive lung disease, such as pulmonary fibrosis, atelectasis, neoplasms, pleural effusions, and hemothorax, as well as in restrictive musculoskeletal problems, such as spinal cord injury and kyphoscoliosis. Decreased TLC can also be secondary to morbid obesity or pregnancy.

VC is the maximum amount of gas that can be expelled from the lungs by forceful effort after a maximum inspiration. It contains the IRV, TV, and ERV. A decrease in VC can occur as a result of absolute reduction in distensible lung tissue. This is seen in pneumonectomy, atelectasis, pneumonia, pulmonary congestion, occlusion of a major bronchus by a tumor or foreign object, and restrictive lung disease, due to either a primary cause such as pulmonary fibrosis or a secondary cause such as the application of a TLSO.

A decrease in VC may also be seen without primary lung disease or airway obstruction. In neuromuscular or musculoskeletal dysfunction, VC can be compromised (as in Guillain-Barré syndrome, spinal cord injury, drug overdose, motor vehicle accident with fractured ribs, severe scoliosis, pectus excavatum, and kyphoscoliosis). Additional contributing factors, such as morbid obesity, pregnancy, enlarged heart, and pulmonary effusion, may involve limitation of expansion of the lungs.

IC is the maximum amount of air that can be inspired when starting at the resting expiratory level. It contains the IRV and the TV.

FRC is the volume of air remaining in the lungs at the resting expiratory level. It contains the ERV and the RV. The FRC prevents large fluctuations in PaO_2 with each breath. An increase in FRC represents hyperinflation of the lungs. It causes the thorax to be larger than normal, which results in muscular inefficiency and some mechanical disadvantage. Patients on mechanical ventilators may increase their FRC with positive pressure and by additional modes such as positive end-expiratory pressure (PEEP). Spontaneously breathing patients can also be on continuous positive airway pressures (CPAP and BIPAP), which keep the lungs at a positive airway pressure to improve ventilation and oxygenation.

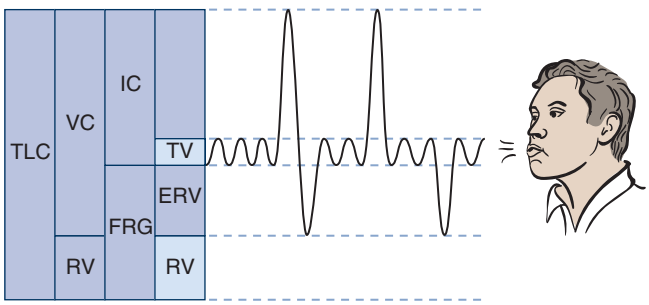

Fig. 9-1 A spirogram (pulmonary function testing).

Air Flow Measurements

Forced Expiration

When a patient performs a VC maneuver, it can either be slow or fast. During exhalation, the amount of air exhaled over time can be measured. In a slow VC, a patient with emphysema can take a great deal of time to empty his or her lungs. In a forced VC, a normal individual can exhale 75% of the VC in the first second of exhalation (FEV_1). Patients with emphysema often have greatly decreased VCs, only 40% of which are predicted. Some pulmonary function laboratories also offer an FEV_6, which measures the flow at six seconds rather than just at 1 second.

Flow Volume Curve

The flow volume curve is helpful in diagnosing lung disease because it is independent of effort. The curve in Figure 9-2 demonstrates that flow rises to a high value and then declines over most of expiration.[22] In restrictive lung disease, the maximum flow rate is reduced, as is the total volume exhaled. In obstructive lung disease, the flow rate is low in relation to

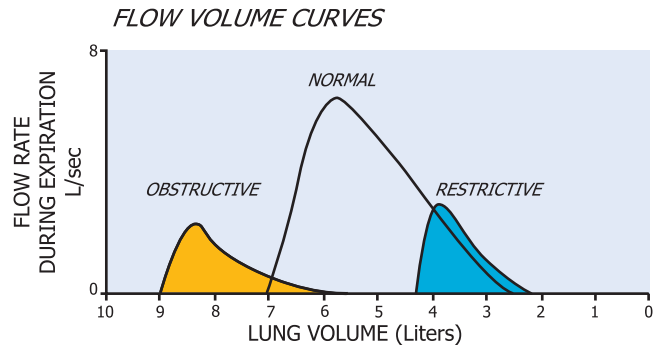

Fig. 9-2 Comparison of flow volume curves in the normal patient and in the patient with obstructive and restrictive lung disease.

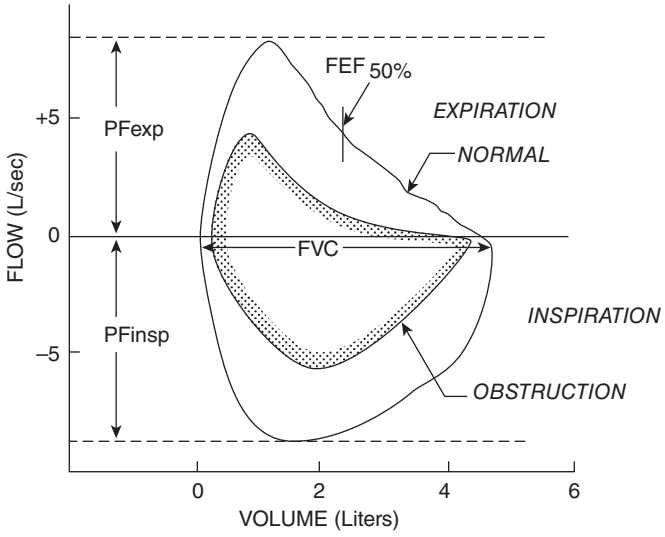

Fig. 9-3 Comparison of flow volume loops in the normal patient and in the patient with obstructive lung disease.

lung volume, and a scooped-out appearance is often seen (see Figure 9-2).

Another diagnostic test that uses forced expiration is the flow volume loop. It is a graphic analysis of the flow generated during a forced expiratory volume maneuver followed by a forced inspiratory volume maneuver (Figure 9-3). This graph offers a pictorial representation of data from many individual tests (e.g., peak inspiratory and expiratory flow rates, FVC, and FEV). The shape of the graph may also be helpful in diagnosing disease, because again there is a more scooped-out appearance in cases of obstructive disease.

Closing Volume and Airway Closure

The assessment of closing volume is used to help diagnose small-airway disease. A test called the single-breath nitrogen (N_2) washout is used for assessing closing volume and closing capacity of the small airways. In this test, the patient takes a single VC breath of 100% oxygen. During complete exhalation, the N_2 concentration can be measured. The characteristic tracing of N_2 concentration can be measured. The characteristic tracing of N_2 concentration versus lung volume reflects the sequential emptying of differentially ventilated lung units,

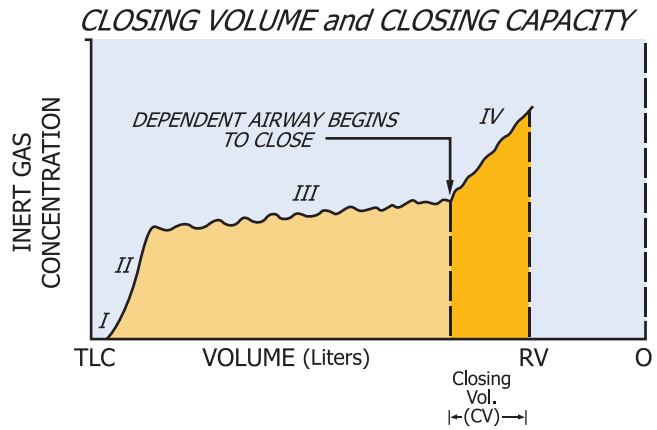

Fig. 9-4 The single-breath nitrogen washout test to assess airway closure.

resulting in different expiratory concentrations of N_2. Four phases can be identified (Figure 9-4). Phase I contains pure dead space and virtually none of the potential N_2 from the RV. Phase II is associated with an increasing N_2 concentration of a mixture of gas from the dead space and alveoli. The plateau in N_2 concentration observed in phase III reflects pure alveolar gas emanating from the base and middle lung zones. Phase IV occurs toward the end of expiration and is characterized by an abrupt increase in N_2 concentration. This high N_2 concentration reflects the closure of airways at the base of the lungs and the expiration of gas from the upper lung zones, because in the single breath of 100% oxygen, less oxygen was initially directed to this area.

Closing volume is the lung volume at which the inflection of phase IV, the marked increase in N_2 concentration after the plateau, is observed. Closing capacity refers to closing volume and RV. The same characteristic tracing of the single-breath nitrogen washout test can be obtained by the inhalation of a bolus of tracer gas (e.g., argon, helium, xenon 133).

The closing volume is 10% of the vital capacity in young, healthy individuals. It increases with age and is 40% of the vital capacity at age 65. Closing volume is used as an aid in the diagnosis of small-airway disease and as a means of evaluating treatment and drug response.

Maximum Voluntary Ventilation

Maximum voluntary ventilation measures the maximum breathing capacity of the patient. It reflects strength and endurance of the respiratory muscles. The patient is asked to pant for 15 seconds into the spirometer tubing. The results are commonly examined preoperatively with the other results to determine a patient's prognosis for success after surgery, such as his or her ability to cough, to take deep breaths, and to enhance airway clearance.

Diagnosis of Restrictive and Obstructive Lung Disease

Physicians use the results of pulmonary function tests to diagnose lung disease or characteristic components of lung disease such as bronchospasm. A restrictive component describes

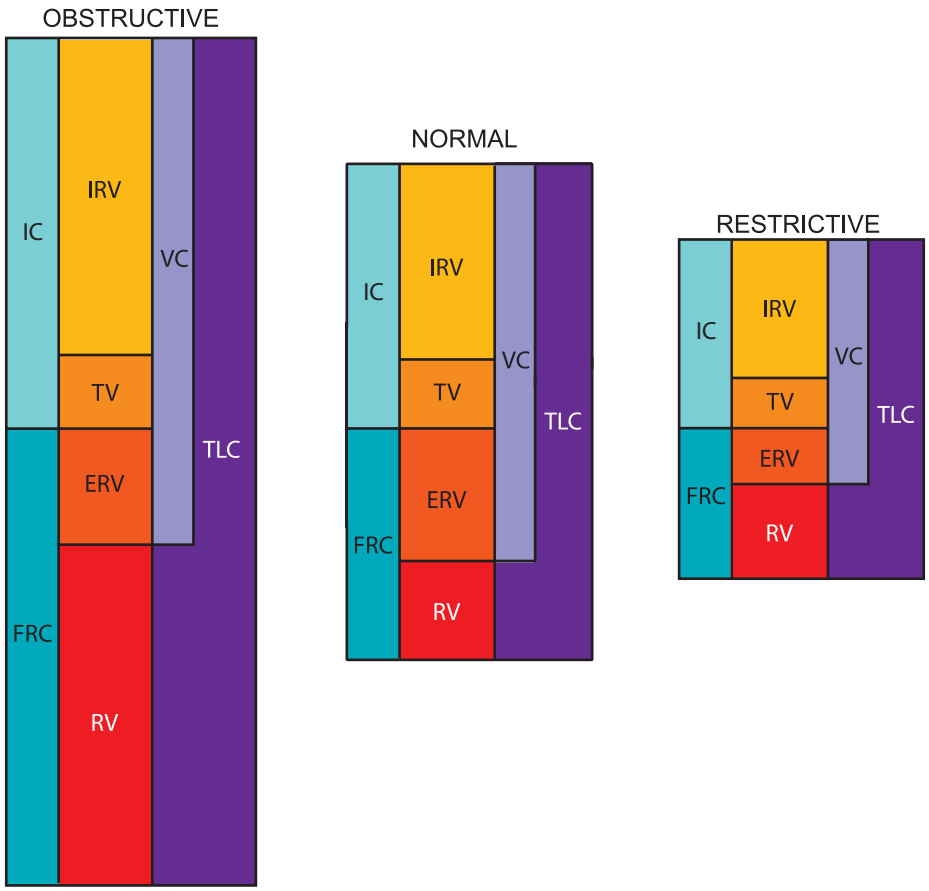

Fig. 9-5 Examples of proportional changes in lung volumes and capacities characteristic of obstructive and restrictive lung diseases.

conditions that limit the amount of volume coming into the lungs (restriction to inspiration). An obstructive component generally relates to problems in exhalation air flows and characteristic patterns of obstruction, such as in the first second of expiration FEV_1 measurement. Patients do not commonly have only one primary disease process but may have overlapping lung conditions.[23] A diagnosis may read, "PFTs consistent with moderate emphysema with bronchospastic component; good response to bronchodilators." A patient with an abnormal PFT is given a bronchodilator and retested. If there is a 15% to 20% increase in the PFT after bronchodilators are administered, they will be a recommended part of the patient's medications. However, some patients are given a trial of bronchodilators, even if there is not such a dramatic response on PFTs.

A pictorial demonstration of the differences in obstructive and restrictive lung disease is shown in Figure 9-5. Disease has a marked effect on pulmonary function; yet TV usually remains 10% of total lung capacity until the disease is relatively severe. Physiological pulmonary reserves in both disease processes are limited and generally affect a patient's response to exercise. Exercise is limited by the ventilatory status rather than by a cardiac end point. As obstructive lung disease progresses, TLC, FRC, and RV are markedly increased. In severe COPD, the increased FRC can compromise the VC. More energy is expended to breathe than that expended by a normal individual. This effect can be disproportionally increased with minimal amounts of activity. In restrictive lung disease, restriction of the chest wall or lung tissue can produce a decrease in TLC. A VC of 80% or less of predicted values for a patient is considered a diagnostic feature. A residual decline in FRC potentiates airway closure.

The phenomenon of closing volume in the lungs is particularly significant to physical therapists who prescribe breathing exercises and body positioning and can thereby alter pulmonary mechanics and gas exchange. These treatment interventions may have pronounced effects on lung volumes and airway closure.[24] At low lung volumes (e.g., breathing at FRC, in the Trendelenberg position, and in lung disease) intrapleural pressures are generally less negative, and the pressure of dependent lung regions may equal or exceed atmospheric pressure. Intrapleural pressure is less negative because the lungs are less expanded and elastic recoil is decreased. As a result, airway closure is potentiated. In young individuals, closure is evident at RV; however, in older individuals, closure is observed at higher lung volumes, such as at FRC. Premature closure of the small airways results in uneven ventilation and impaired gas exchange with a given lung unit. Airway closure occurs more readily in chronic smokers and in patients with lung disease.

Aging has a significant effect on airway closure. With aging, a loss of pulmonary elastic recoil results in a loss of intrapleural negative pressure. In older individuals, therefore, airway closure occurs at higher lung volumes. For example, closure has been reported to occur at the age of 65 in the upright lung during normal breathing. In the supine position, where FRC

is reduced, closure occurs at a significantly younger age (about age 44). In addition to the often compounding effect of age, the lung volume at which airway closure occurs increases with chronic smoking and lung disease and is changed with alterations in body position.[25,26]

Summary

Pulmonary functions change as a patient's condition gets better or worse.[27,28] There are normal declines in volumes and flows with aging, as well as with disease processes. Basic bedside spirometry is often done to assess a patient's breathing mechanical ability and screen preoperatively to predict possible postoperative complications, especially in high-risk patients. Bedside screening can detect improvement or decline in a clinical status. In a patient with Guillain-Barré syndrome, as breathing becomes labored, the VC is monitored to determine whether a ventilator is needed. On the other hand, in a patient with obstructed airways, such as with cystic fibrosis, the pulmonary function tests will improve.[29] In a patient with spinal cord injury or neuromuscular weakness, as strength improves, vital capacity increases. However, because of the lack of abdominal muscles, the flows may be reduced.

Review Questions

1. What effect will an obstructive or restrictive component have on exercise performance?
2. Why is it important to compare the patient's predicted values with the actual observed values in a pulmonary function test?
3. What response should you assess to determine whether bronchodilators have a positive effect on pulmonary function?
4. How can pulmonary function tests be used to assess patient improvement or decline over a period of time?
5. What is the value of using pulmonary function tests as another vital sign?

An arterial blood gas is a physiological assessment tool that measures a patient's acid-base balance, alveolar ventilation, and oxygenation status.[1] It is a valuable resource for obtaining information from respiratory monitoring in the intensive care unit, for conducting follow-up of outpatients, and for evaluating the treatment and the progress of their diseases. There has been a trend toward finding more noninvasive techniques to serve these purposes. This trend has been motivated by the desire to spare patients from being "stuck" so frequently and to avoid the risk for infection posed by indwelling cannulas in patients who already are ill and have weakened immune systems. Physical therapists frequently use oxygen saturation for assessment, but this is insufficient in many patients. When a patient has been thoroughly examined and it is determined that the arterial blood gas values are relatively stable, the physical therapist should compare those values to subsequent readings on the oximeter. Therapists need to consider the blood gas trends, acid/base status, and alveolar ventilation and then correlate those findings to the patient's signs and symptoms, the physiological monitoring of HR, BP, and RR, and the perceived exertion with exercise. In many cases we need to consider a multisystem approach without examination and evaluation. Oximetry readings are important but must be evaluated in light of all body systems, not just the oximetry readings.

Arterial blood gas evaluation and interpretation can be confusing. The purpose of this chapter is to provide the background needed to understand what the arterial blood gas measures and how it can be applied clinically to improve the evaluation and assessment of patients. It cannot be overemphasized that the arterial blood gas is an essential part of the total examination and evaluation. In the case of a complex patient who has both respiratory and metabolic issues and there is no straightforward or "easy" interpretation, interdisciplinary team members often collaborate to evaluate the patient's arterial blood gases. It is extremely valuable for a new physical therapist to make ward rounds with the pulmonary physicians, nurses, and respiratory care practitioners, learning about physiological assessment through discussions and questioning during these rounds.

A further goal of this chapter is to help the clinician evaluate and interpret arterial blood gases more effectively and to integrate the information into treatment planning and the patient's overall progress. However, it is important to remember that

blood gases provide a single, static picture of a patient's condition at a given time; as such, they are important in the management of acutely ill, unstable patients. As a patient's condition changes, new arterial blood gas results must be obtained and evaluated to determine whether the patient is improving or declining.

Noninvasive Monitoring

Noninvasive monitoring has become more readily available and is used to measure expired carbon dioxide (Pet CO_2) and transcutaneous CO_2 (T CO_2) in neonatal and pediatric patients. New studies are showing that a universal pulse oximetry screening of all neonates before they are discharged would improve the detection rate of congenital heart disease. In a survey conducted in the United Kingdom by Kang and colleagues, it was found that 209 (93%) of the 224 units contacted did not use pulse oximetry routinely. In the neonatal units that did use pulse oximetry, if the saturation was abnormal, they also did echocardiography. Two other units obtained not only echocardiogram, but also x-rays and ECG. The conclusion was that this should be used with national guidelines to supplement the postnatal examination.[2]

A similar study was conducted by Arlettaz and colleagues to determine whether pulse oximetry could detect congenital heart disease in newborns. It was noted that about half of all newborns who had congenital heart disease were asymptomatic in the first few days of their life. However, early detection of this condition is important because treatment outcomes are related to the time of the diagnosis, and early identification leads to best outcomes. The authors studied the effectiveness of oximetry on the first day of life for early detection of congenital heart disease in neonates who appeared normal. They also examined whether pulse oximeter screening in addition to the clinical examination of the patient would yield more results in the diagnosis of congenital heart disease than would examination alone. If pulse oximetry was less than 95%, echocardiography was done. Of the 3262 newborns screened, 24 infants had repeated oxygen saturations of less than 95%. Of these neonates, 17 had congenital heart disease and the other 5 had persistent pulmonary hypertension. Arlettaz and colleagues concluded that pulse oximetry screening in the first few days of life is an effective tool to identify cyanotic congenital heart disease in otherwise healthy newborns.[3]

Pulse oximetry has also been used to measure trends in oxygen saturation in patients before, during, and after exercise. For patients who are nervous about exercising, the oximeter can be used to check their saturation level and assure them that they are safe as they exercise. If they are feeling short of breath during exercise, they can stop to look at the value on the oximeter, which will usually return to baseline within a couple of minutes. This gives patients more confidence to exercise. These measures have resulted in fewer invasive arterial sticks and in the ability to monitor patients in an ongoing manner; in addition, they have made it possible to improve the care of patients with cardiovascular and pulmonary illness and to administer the most appropriate ventilation and oxygenation support. Many pulmonary physicians are encouraging patients to obtain a less expensive model that they can carry with them. Such a device will let patients follow their trends and help them to be safer. If more desaturation than normal is measured or anything out of the ordinary occurs, patients are instructed to call their doctor. An early visit may help to prevent exacerbations of their disease.

Partial Pressure of Gases

To better understand blood gases, it is important to remember the properties of gases. The earth's atmosphere consists of gas molecules that have mass and are attracted to the earth's center of gravity. At the surface, this atmospheric weight exerts a pressure that can support a column of mercury 760 mm high.

Dalton's law states that in a mixture of gases, the total pressure is equal to the sum of the partial pressures of the separate gases. Oxygen is 20.9% of the atmosphere, so it has a partial pressure of 159 ($760 \times 20.9\% = 159$). Nitrogen is 79% of the atmosphere; thus it has a partial pressure of 600 ($760 \times 79\% = 600$). Other gases make up 0.1% of the atmosphere.

The diffusion of gases across semipermeable membranes shows gradients from higher concentrations to lower concentrations. Each gas moves independently from the others.

During respiration, oxygen and CO_2 exchange across the alveolar capillary membrane. Special situations may affect the normal progress of respiration and gas exchange.

Normally, alveolar units ventilate and capillary units bring oxygenated blood to the tissues, excreting CO_2 back into the alveoli to be removed through the lungs. Some abnormal situations may occur, however, such as shunts and dead-space units. In a shunt unit, the alveoli have collapsed, but blood flow continues and is unable to pick up oxygen. An example of this is atelectasis, in which a lung segment or part of a segment has retained secretions and lung tissue distal to the mucous plug collapses. Circulation continues but oxygenation does not occur, and the P_{O_2} decreases. On the other hand, a dead-space unit can have ventilation but not perfusion. This occurs with pulmonary embolism, when a blood clot obstructs the circulation. The oxygen is available in the ventilated alveoli, but with no circulation, a dead unit is credited. Figure 10-1 demonstrates the regional differences seen in respiratory units.

Normal Blood Gas Values

The acid-base balance is denoted by the pH scale; it ranges from 1 to 14, where 1 is the most acidic and 14 the most basic. The arterial pH values are normally 7.35 to 7.45. If the pH is below 7.35, the patient is considered to be in a more acidotic state. If the pH is above 7.45, the patient is considered to be in a more alkalotic state.

Alveolar ventilation is reflected in the partial pressure of carbon dioxide (P_{CO_2}). Normal P_{CO_2} values are 35 to 45 mm Hg. If the P_{CO_2} is below 35 mm Hg, the patient is said to be hyperventilating (having increased ventilation, blowing off more CO_2 than normal). If the P_{CO_2} is above 45 mm Hg, the patient is hypoventilating (having decreased alveolar ventilation, not blowing off enough CO_2 to maintain normal alveolar ventilation).

Arterial oxygen is measured as P_{O_2}, the partial pressure of oxygen. Normal values are 80 to 100 mm Hg. If the P_{O_2} is below 80 mm Hg in someone younger than 60 years of age, the patient is hypoxemic. A value of 60 to 80 mm Hg is considered mild hypoxemia; 40 to 60 mm Hg is considered

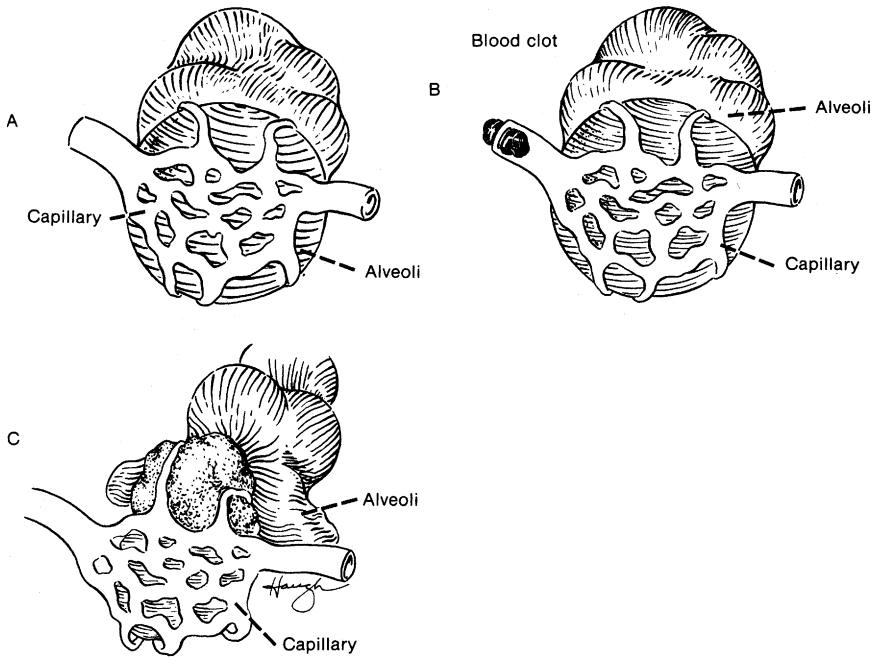

Fig. 10-1 **A,** Normal alveolus. **B,** Dead space. **C,** Shunt.

moderate hypoxemia, and less than 40 mm Hg is severe hypoxemia.[1]

Base Excess/Base Deficit

The blood normally has the capacity to buffer acid metabolites. The normal level of base HCO_3^- in the blood is 22 to 26 millimoles per liter (mmol/L). This buffering capacity diminishes in the presence of acidemia or alkalemia. Acidosis is an abnormal acid-base balance in which the acids dominate. Alkalemia is an abnormal acid-base balance in which the bases dominate. When there is a decrease in HCO_3^-, it is seen in a negative base excess and referred to as a base deficit, which is usually seen as a negative number on the blood gas report, such as −3.

As one looks at the base excess and the base deficit (BE/BD), it is helpful to determine whether the patient's condition is acute or chronic. This state can also be thought of as uncompensated (acute); partially compensated; or completely compensated (chronic). The pH is the key to making this determination. If the pH is not in the normal 7.35 to 7.45 range, the patient is in an acute state. As the balance progresses back toward normal, it may be partially compensated. When a normal pH exists, it is compensated, or chronic. The interpretation comes from looking at the BE/BD and then at the pH. Having a series of arterial blood gases for comparison is helpful, for example, in a patient with respiratory failure and on a ventilator; the patient's improvement can be documented.

Another example is that of a patient in the chronic state who has chronic obstructive pulmonary disease (COPD) and is retaining CO_2 at a level of 55 mm Hg. If the pH reads 7.25, this would be considered an acute state. As the body retains base, the pH will rise back toward normal. If the pH is 7.32 with a PCO_2 of 55 and +3 base excess, the status would be partially compensated. If the pH is within normal limits, with a PCO_2 of 55 and a pH of 7.35, the status would be compensated or chronic. This is a means of identifying people who are chronic CO_2 retainers.

Hemoglobin

Hemoglobin (Hgb) is the main component of the red blood cell. It is crucial for oxygen transport. The normal Hgb range is 12 to 16 g/100 mL blood. In patients who have lost blood through surgical procedures or disease, the decreased hemoglobin can account for their extreme weakness as a result of decreased total oxygen transport capacity. Some of the patients at highest risk are those who have just undergone joint replacement in which there has been much blood loss. Often their Hgb levels are only 8, and because they are considered "orthopedic" patients, it is thought that the low levels can be overlooked. In addition, patients with advanced COPD can at times desaturate (pulse oximetry below 90%) with exercise when the PO_2 is low (i.e., PO_2 55-60). Pulse oximetry is essential for monitoring the exercise of patients with low PO_2, low Hgb, or both.

Cyanosis, the presence of a bluish color to the skin, mucous membranes, and nail beds, is indicative of an abnormal amount of reduced Hgb concentration, usually greater than 5 g of reduced Hgb. The presence of cyanosis suggests a high probability of hypoxemia; however, hypoxemia can occur without cyanosis. Two examples may be cited, one in which an anemic patient with hypoxemia can have little cyanosis, and the other in which a patient with polycythemia can have cyanosis with minimal hypoxemia.

There is a predictable relationship between the arterial oxygen saturation of the Hgb and the PO_2. It is represented in the oxyhemoglobin dissociation curve as follows. When oxygen saturation is monitored during exercise, saturation is kept at or above 90%. As the curve denotes at a level of approximately 60 mm Hg, the saturation is about 90%. As the PO_2 drops at the sharp part of the curve, there is a marked decrease in oxygen saturation for every mm Hg PO_2.[4]

Acid-Base Balance

Normal body metabolism consists of the consumption of nutrients and the excretion of acid metabolites. Acid metabolites must be kept from accumulating in large amounts because the body's cardiovascular and nervous systems operate in a relatively narrow free hydrogen ion (H^+) range (narrow pH). Free H^+ concentration is discussed as pH ($-\log [H^+]$). The maintenance of body systems requires an appropriate acid-base balance.[5]

Approximately 98% of normal metabolites exist in the form of CO_2, which reacts readily with water to form carbonic acid.

$$CO_2 + H_2O \rightarrow H_2CO_3$$

Carbonic acid (H_2CO_3) can exist as either a liquid or a gas. Because carbonic acid can change to CO_2, much of the acid content can be excreted through the lungs during respiration. In this way, the lungs can help regulate the pH of the body.

The Henderson-Hasselbach equation demonstrates how the H^+ concentration results from the dissociation of carbonic acid and the interrelationship of the blood acids, bases, and buffers.

$$H_2O + CO_2 \rightarrow H_2CO_3H^+ + HCO_3^-$$

Renal Buffering Mechanisms

The kidneys are the main route of excretion of the normal metabolic acids. H^+ is excreted in the urine and also resorbed by bicarbonate into the blood. In this manner, the kidneys can respond when there is an acid-base imbalance and return the body to normal homeostasis. Buffering the acid component and holding on to HCO_3^- can bring the pH to a more alkalotic range. The arterial blood gas result includes a comment about base excess/base deficit. Following that number and watching the change in pH is very helpful in monitoring patients to see whether they are improving or declining.

Chemoreceptor Response to Hypoxemia

The peripheral chemoreceptors, the carotid bodies, and the aortic bodies are located at the bifurcation of the internal and external carotid arteries and the arch of the aorta. These receptors are nervous tissue with a high metabolic rate and an abundant oxygen supply. When tissue P_{O_2} decreases, the response of these receptors to the brain is to increase ventilation and cardiac output. When that is not sufficient to effect a normal P_{O_2}, supplemental oxygen or increased mechanical assistance such as continuous positive airway pressure (CPAP) is administered.[6]

Blood Gas Interpretation

Consider the normal values for the arterial blood gas: pH, P_{CO_2}, P_{O_2}, O_2 saturation, and base. With any given patient, there may be a range used (see below) that will be considered in light of the patient's disease, current acute or chronic status, and signs and symptoms. At times, these values will be considered "acceptable ranges," rather than ideal.

Once the norms for the pH, P_{CO_2}, P_{O_2}, and base have been established for a given patient, they should be considered first in the interpretation. Is the current value normal or not? Is the patient acute (uncompensated), partially compensated, or fully compensated (chronic)?

A stepwise interpretation can be helpful. Performing the assessment in the same order each time provides a comprehensive and standard overview.

1. Look at the P_{CO_2} to determine whether there is normal alveolar ventilation.
2. Look at the pH to see whether there is a normal acid-base balance or whether it is acute or chronic.
3. Look at the P_{O_2} to see whether there is normal oxygenation or whether there is hypoxemia and to what degree.
4. Look at the base excess/base deficit BE/BD.

It is important to note additional clinical considerations. Is the patient receiving oxygen or mechanical ventilation? If the patient is on increased inspiratory oxygen (F_{IO_2}) of 40% and the P_{O_2} is not close to acceptable levels, it is more of a concern than if the patient is on a low F_{IO_2} and the P_{O_2} is within normal limits. Similarly, if the patient is on mechanical ventilation, the blood gases should be close to normal. The exception would be a patient who is a chronic CO_2 retainer; that patient would be ventilated to his or her normal level (i.e., at the P_{CO_2} level where the pH becomes closer to normal).

Acceptable Ranges of Arterial Blood Gases

At times, for various medical reasons, an acceptable range of blood gases will be used, rather than trying to get an ideal reading. The following ranges may be acceptable, depending on the physician and the patient's particular circumstances.

- pH 7.30 to 7.50
- P_{CO_2} 30 to 50 mm Hg
- pH 7.45 and above alkalemia
- pH 7.35 and below acidemia

The relationship between the pH and the P_{CO_2} should be noted. In general, as the P_{CO_2} rises, the pH will decrease. There is also predictable change caused by variation in carbonic acid. Some general rules of thumb include:

- For every 20 mm Hg increase in P_{CO_2}, the pH decreases by 0.10 (P_{CO_2} 60, pH 7.25)
- For every 10 mm Hg decrease in P_{CO_2}, the pH increases by 0.10 (P_{CO_2} 25, pH 7.50)

There is also a relationship between the P_{CO_2} and the plasma bicarbonate.

- For every increase of 10 mm Hg in the P_{CO_2}, there is a decrease of 1 mmol/L of plasma bicarbonate
- For every 10 mm Hg P_{CO_2}, there is a decrease in plasma bicarbonate of 2 mmol/L

By knowing these guidelines, the therapist can determine whether the changes in the arterial blood gases are in line with respiratory problems as opposed to metabolic problems such as acidosis due to diabetic ketoacidosis, in which the base deficit can be very low and the pH can be low (acidemic), but the P_{CO_2} can be within normal limits.[5,7]

Potential Causes of Error in Arterial Blood Gas Sampling

The accuracy of arterial blood gas results depends on many factors: proper collection of the arterial sample, the handling of the sample from the patient to the laboratory, and the method by which the sample was analyzed. Possibilities for

error exist all along the pathway. Great care must be taken to create proper protocol for all steps, and laboratories need to remain vigilant to decrease errors. Some of the common problems are nonarterial samples (venous blood versus arterial blood), air bubbles in the syringe, inadequate anticoagulant in the sample, and delayed analysis of a noncooled sample.[8]

Respiratory Failure

Respiratory failure is defined as the inability of the pulmonary system to meet the metabolic demands of the body (i.e., ventilation and oxygenation).[5] The blood gases usually show a pH below 7.30 and a P_{CO_2} above 50. Generally, the patient is also hypoxemic.

During the acute phase, the kidneys have not started to compensate, and the base HCO_3^- is within normal limits. Later, a base excess can be noted as the kidneys try to compensate for the acidotic pH. Chronic respiratory failure can be noted by an increased P_{CO_2}, a pH within normal limits, and a low P_{O_2}.

In assessing the P_{O_2}, the following ranges are used: mild hypoxemia, less than 80 mm Hg; moderate hypoxemia, 60 to 80 mm Hg; and severe hypoxemia, below 40 mm Hg.

Positional changes can affect the oxygenation status. For example, unilateral right lower lobe atelectasis with the patient lying on the right side causes increased blood flow to the right lung, which is collapsed. This causes increased shunting and a decrease in oxygenation (differential shunting). If the patient lies on the left side, the oxygenation will improve. When the patient lies in a supine position, a mixed P_{O_2} can be observed.

When hypoxemia is noted, treatment consists of oxygen therapy, CPAP or biphasic positive airway pressure, and alleviation of the cause of hypoxemia, if possible. This may be achieved by means of airway-clearance techniques or medication, in addition to the oxygen therapy or mechanical ventilation. Oxygen therapy treats the hypoxemia, decreases the patient's work of breathing, and decreases myocardial work.

Factors Affecting Arterial Blood Gases

Many normal causes affect arterial blood gases, such as extremes of age, from neonates to older adults. The neonate has many changes going on in the initial life process; fetal circulation changes dramatically in the first hours and days of life. In the older adult patient, decreases in cardiac output (CO), residual volume (RV) of the lungs, and maximal breathing capacity gradually lower P_{O_2} over the course of the life cycle. It is estimated that after 60 years of age, the P_{O_2} decreases by 1 mm Hg per year of age from 60 to 90 years.

Exercise or any increase in activity above rest may result in significantly increased oxygen consumption in patients with cardiopulmonary dysfunction. In the normal population, the human body compensates by increasing oxygen consumption to meet the workload. Usually, a plateau is reached and a constant oxygen consumption for that activity is achieved. In patients with cardiopulmonary dysfunction, oxygen consumption continues to increase, even at the same workload in untrained patients. It is important to monitor oxygen saturation to prevent desaturation in these patients.[4] During pregnancy, hormonal and mechanical factors may have negative effects on cardiopulmonary function. In the last trimester, women commonly observe shortness of breath and difficulty in taking a deep breath because of hormonal issues and diaphragmatic encroachment.

In a small study by Sunyal and colleagues assessing oxygen saturation in pregnant women to try to evaluate the lung function in pregnancy, 32 women (25 to 35 years old) without any recent respiratory disease were monitored during each trimester. The study compared eight healthy nonpregnant women as an age-matched control group. In the pregnant women, the oxygen saturation levels increased progressively each trimester: first trimester (97.73% ± 0.30), second trimester (98.05% ± 0.54), and third trimester (98.40% ± .30). The oxygen saturation readings were higher in the pregnant women than in the nonpregnant women. The study conclusion was that the increased oxygen saturation during pregnancy was related to increased ventilation and a rising progesterone level, which reaches a peak in the later phases of pregnancy.[9]

During sleep there is a decrease in minute ventilation and a decreased responsiveness to CO_2 and hypoxemia. Many patients who have undergone spinal cord injuries or cerebrovascular accidents, who have COPD, who have significant neuromuscular changes such as kyphoscoliosis, or who are morbidly obese have been noted to have apnea and hypoxemia during sleep. The possibility of these conditions should be considered in any patient with daytime somnolence who complains of difficulty sleeping or staying awake during the day or who has trouble following directions or is mentally confused. Often the patient's spouse or partner will report that the patient is restless in bed and snoring increasingly. Some may actually notice that the patient stops breathing at times during sleep. These patients need to be referred for a sleep study to evaluate their breathing, oxygenation, and oxygen saturation at night. Physical therapists can help by monitoring these patient populations, by understanding and watching for the signs and symptoms listed above, and by communicating with the patient's partner (if the patient has one) to ask about specific details in the patient's sleeping patterns and whether there have been any noticeable changes in function.

Barometric Pressure Can Affect Oxygenation

Low barometric pressure associated with high altitude significantly decreases the amount of oxygen available to an individual. As noted before, the partial pressure of oxygen is dependent on the total atmospheric pressure. When the total pressure is reduced, less O_2 is available. This is particularly important if a patient already has a decreased P_{O_2} and is traveling to an area with lower barometric pressure. Patients on oxygen need an oxygen prescription that is based on the area in which they are living. Dr. Petty, who practiced in Colorado, urged his patients to buy an oximeter to carry with them. His motto was "titrate where you migrate."

Barometric pressure increases, such as in a hyperbaric oxygen chamber with higher barometric pressure, can help deliver increased oxygen for a select group of patients. Wound-healing needs and carbon monoxide poisoning are two such indications. Hyperbaric chambers are not found in all hospitals, but when the need arises, a search can find the one closest for treatment.

Other Factors That Can Influence the Arterial Blood Gas

Increased temperature (a febrile state) can increase metabolism and therefore increase oxygen consumption, decrease P_{O_2}, and consequently, increase alveolar ventilation, which will decrease P_{CO_2}. Decreased temperatures can decrease oxygen consumption, as is seen in patients who have survived for several minutes in cold water and are then resuscitated or in patients who are kept in a state of hypothermia to decrease body functions and preserve oxygen while medical staff members do their best to stabilize the patient.

On the arterial blood gas report it is important to note the status of the patient at the time the blood gas is drawn. Usually, patients are at rest when the blood gas is drawn. If the P_{O_2} is low at rest (60 mm Hg), it is close to the sharp part of the oxyhemoglobin dissociation curve, and the patient may desaturate quickly with an increase in exercise.

If the patient is on supplemental oxygen and the P_{O_2} is only 55 mm Hg, the P_{O_2} is still inadequate because of the additional O_2.[10-12] Any patient on oxygen at rest should be evaluated for appropriate oxygenation with exercise. Most patients' blood gases are drawn at rest, not with exercise. Similarly, if a patient is on mechanical ventilation, the blood gases should be within or near normal limits.

Noninvasive Monitoring

Noninvasive monitoring of respiratory function is convenient, is accurate in showing trends, involves minimal complications, and causes little discomfort for the patient. The modalities are used as part of an ongoing examination, along with clinical monitoring. Noninvasive monitoring tools include pulse oximetry, transcutaneous oxygen (Ptc O_2), transcutaneous P_{CO_2} (Ptc CO_2), and end-tidal CO_2 using capnography.

Pulse Oximetry

Pulse oximetry provides estimates of arterial oxyhemoglobin saturation (Sa_{O_2}) by utilizing selected wavelengths of light to noninvasively determine the saturation of oxyhemoglobin (Sp_{O_2}).[13]

INDICATIONS FOR PULSE OXIMETRY

There are several reasons to perform pulse oximetry.

1. To monitor the adequacy of arterial oxyhemoglobin saturation
2. To evaluate the patient's response to interventions and exercise
3. To meet third-party payers' need to document desaturation and prescribe oxygen in order to meet regulations[14]

PRECAUTIONS FOR PULSE OXIMETRY

If a patient needs ongoing measurement of pH, P_{CO_2}, and total Hgb, the presence of abnormal Hgb may be a "relative" contraindication for pulse oximetry.[13] If the Hgb is low (i.e., 7-8, or virtually half the normal Hgb), the oxygen saturation may be above 90% at rest but as soon as exercise begins, the patient will usually desaturate very quickly. Thus pulse oximeter reading needs to be monitored before, during, and after exercise/activity to have a better overall view of the physiological response to the intervention. The other vital signs need to be evaluated as well.

A probe is attached to the patient's finger, toe, or earlobe, and a measurement is made of the amount of light that is absorbed (i.e., relayed to a microprocessor that calculates Sa_{O_2}). It can be read intermittently or displayed continuously. In addition, a pulse reading is given.

A reading taken at rest as an additional vital sign, along with HR, BP, and RR, provides a baseline before exercise. When an exercise workload is given, the parameters can be compared to see whether the patient has a normal or abnormal response to exercise. The recommendation is to keep the O_2 saturation above 90% during exercise. Supplemental oxygen can be titrated to keep the O_2 saturation within the appropriate range. This is done in conjunction with the physician because it is not in the scope of practice for physical therapists to change F_{IO_2} levels without a consultation and physician's order. Many hospitals that deal with critically ill patients as an interdisciplinary team will have standing orders to cover this situation. The orders may read, for instance, "titrate oxygen to keep the O_2 sats above 90% with exercise." In this case, limits to how high the F_{IO_2} may be raised need to be considered, as well as changing the oxygen delivery system to get a more consistent level of oxygenation, especially during activity.

Situations exist in which pulse oximetry may not yield accurate results: abnormal Hgb, jaundice, anemia, low perfusion (i.e., diabetes), the use of intravascular dye such as methylene blue, deeply pigmented skin, and dark nail polish.[15] In addition, movement artifacts and highly lit fluorescent lights can have an effect on the readings. These concerns must be appreciated by therapists, especially during exercise, to ensure proper readings and correct evaluation of responses to exercise.

Documentation of patients' responses to exercise can be included with vital sign notations: ECG, HR, BP, RR, and Sp_{O_2} may be recorded. The readings taken at rest, during exercise, and at the end point of exercise are important, as well as the time it takes for the patient to recover (to return to baseline). This information documents the physiological response to exercise.

Transcutaneous Oxygenation

To test for transcutaneous oxygenation (Ptc CO_2), a sensor is applied to the skin on the anterior chest or abdomen. The sensor is heated to produce localized erythema. This method is used primarily in the neonatal and pediatric intensive care units. There is an equilibration time of about 10 to 15 minutes, and the sensor must be calibrated to ensure accurate results. Inaccurate measurements may be caused by hypothermia, shock, severe anemia, edema, severe acidosis, and dislodgement of the sensor. Cases of thermal injury have occurred.

Transcutaneous Carbon Dioxide

Transcutaneous carbon dioxide (Tc CO_2) measurements are used in the neonatal ICU, where continuous monitoring is indicated, especially if the baby is not intubated or being mechanically ventilated. The Tc CO_2 has a skin sensor and is most effective in monitoring hemodynamically stable patients. The sensor must be calibrated and must be rotated frequently

to prevent burns. A relatively close correlation exists between arterial P_{CO_2} and Pt $_{CO_2}$, and the latter has the additional benefit of requiring fewer needle sticks.

A study by Sandberg and colleagues performed in the neonatal intensive care unit (NICU) evaluated the accuracy of transcutaneous (Tc) blood gas monitoring in newborn infants, including infants with extremely low birth weights. The measurements were taken under "stable conditions." Some differences were found in arterial measurements versus Tc measurements, related to body weight, postnatal age, and the amount of oxygen each neonate required. Overall, Sandberg and colleagues concluded that there was good agreement between the two methods and that it was clinically acceptable to use Tc in their NICU. They added that although it would not replace the need for doing arterial blood gases, Tc monitoring would be a good supplement to use in assessing neonates.[16]

End Tidal Carbon Dioxide

Capnography uses infrared spectroscopy or mass spectrometry reading of expired CO_2 to analyze CO_2 content in a continuous reading. There is also a wave display of the breath-to-breath readings. The waveform can be divided into segments that represent various phases of the respiratory cycle. In the beginning of a normal exhalation, gas is expelled from the anatomical dead space and has a low CO_2 reading. As more alveoli empty, there is an increasing proportion of alveolar gas in relationship to dead space gas and thus a greater concentration of CO_2. A plateau level is reached when there is a nearly constant CO_2 concentration (alveolar plateau). At the alveolar plateau, the end tidal CO_2 concentrations closely approximate the arterial P_{CO_2}. Then with inspiration, the CO_2 concentration decreases rapidly to baseline.

The end tidal CO_2 readings help monitor changes in the ventilatory status and assist in determining the need for changes in the ventilator settings to improve alveolar ventilation.[17] Most notable is the ability to see trends in these readings and maintain an ongoing monitoring system that can allow for early detection of complications, such as pneumothorax, hypoventilation, pulmonary embolism, or fat embolism (any increase in dead space). The end tidal CO_2 readings have also been used to determine the proper positioning of feeding tubes and endotracheal tubes.[18,19]

Summary

This chapter discusses the normal arterial blood gases and the significance of their values. A guide to the interpretation of blood gases is proposed. The relationships between pH and P_{CO_2}, between P_{CO_2} and HCO_3^-, and between O_2 saturation and P_{O_2} are examined. Predictable changes that are caused by respiratory changes are described. In addition, it is noted that metabolic changes can have marked effects on blood gases. Oxygen therapy and airway-clearance techniques can improve hypoxemia.

Position changes can be detrimental, causing differential shunting, or can improve the P_{O_2} by means of better ventilation-perfusion matching. For example, if the affected lung that has pneumonia is placed down (i.e., lying on the side of the pneumonia), there will be more perfusion passing by the poorly ventilated lung and the P_{O_2} will decrease. If the well ventilating lung is placed down the P_{O_2} will improve.

Noninvasive monitoring has been a great advance; it is now possible to see ongoing trends in a patient and assess complications early so that patients can be moved forward more safely and efficiently. Noninvasive monitoring can also be an adjunct to exercise, as will be discussed in Chapter 43.

Physical therapists must have a thorough understanding of the various respiratory monitors so that they are better equipped to provide comprehensive evaluation and assessment, thus allowing them to safely encourage patients to progress to their optimal rehabilitation outcomes.

Review Questions

1. Which factors may affect arterial blood gases?
2. What effect does an increased temperature in a patient have on the blood gases, and how does this relate clinically to treating a patient with an elevated temperature?
3. How has noninvasive monitoring improved the ability to monitor patients?
4. What parameters of the blood gas reading will guide you in determining whether the patient is a chronic CO_2 retainer?
5. What effect can body position have on blood gases, and how can this knowledge be used therapeutically?
6. What precautions need to be considered for effective reading of arterial blood gases?
7. Which patient diagnoses may pose more chances for error in oxygen saturation readings?
8. What arterial blood gas reading would prompt you to hold physical therapy treatment?
9. What would you follow on the arterial blood gas reading to determine improvement in alveolar ventilation or oxygenation status before increasing activity or exercise?

Wilhelm Roentgen discovered the x-ray in 1895 and won the very first Nobel Prize in physics (1901) for this discovery.[1] Since that time, radiography has been used in medicine to image the chest structures. Ionizing radiation has its disadvantages, however, as Thomas Edison learned when his laboratory assistant, Clarence Daley, became the first scientist to die of radiation exposure in the United States.[1] By the 1940s, ultrasound was being used as a way to image the body using nonionizing radiation.[1] Computed tomography (CT) was developed in the 1970s, and magnetic resonance imaging (MRI) in the 1980s.[1] All these methods have been used to image the chest, and each offers distinct advantages and disadvantages for the patient and the clinician.

Most imaging machines still use film to capture the image, but newer systems are using digital formats. In either case, the basic methods are similar: x-rays are generated when the anode of an x-ray tube is bombarded with electrons from the cathode of the tube. The collision gives off energy in the form of x-radiation, which travels out of the tube and through the patient, then hitting the imaging cassette. The cassette contains film or a digital imaging sensor. The image is then processed by a digital processor or a film developer (Figure 11-1).

The film turns black (is exposed) if the x-rays pass through the patient and reach the film surface. If the x-rays are reflected or absorbed by the patient, they do not reach the film, and the resulting image stays white (unexposed). The patterns and shades of light and dark on the film reflect the differing densities present in the part of the human body being imaged.

The darkest images on a film (also called radiolucent areas) represent pockets of air within the body. Fat is denser than air, and it produces a dark-gray image. Muscle and other soft tissues are more dense and produce a much lighter gray image. Finally, bone is the most dense natural substance in the body and produces a white image. Metallic objects are even more dense (also called radiopaque) than bone and produce a pure white image (Figure 11-2).

Figure 11-2, *A*, demonstrates all the different densities. This lateral view of the knee shows metal from a total knee replacement, along with bone, muscle, fat, and on either side of the patient's knee, air.[2]

The x-ray image is a summation of all the densities that the x-rays have passed through. The different layers of tissue that are on top of one another are flattened into a single two-dimensional image. Sometimes the various densities lie next to one another and are easily distinguished in the image. Other times the two densities overlap one another and are blurred

together in the image. For this reason, the patient is usually positioned so that two or more images can be taken at a right angle to one another. This allows structures that are overlapping in one orientation to be seen side-by-side with the other orientation.[1,3]

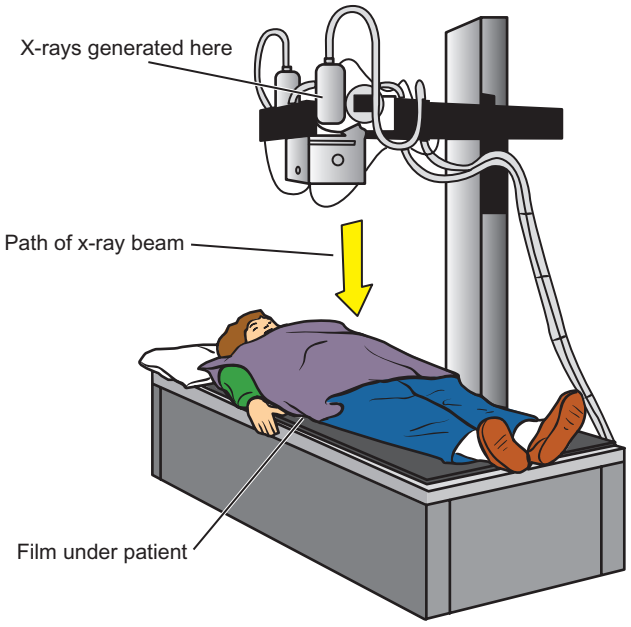

Fig. 11-1 A typical x-ray machine.

The Radiograph and Its Evaluation

The process for evaluating a radiograph can be broken down into several stages. The initial evaluation should verify all of the technical details of the scan; subsequent stages look at various aspects of the anatomy imaged.

Initial Evaluation

The initial stage is when the technical details of the images are noted:

- Correct patient identifying information
- Correct body part imaged
- Body part imaged with two projections
- Quality of the exposure of the film

Before proceeding with any further evaluation, the first step is to check that the information identifying the patient has been properly provided on the image and that the image is indeed of the patient in question. Identifying information usually consists of the patient's full name, date of birth, and if possible, their sex and social security number. Failing to verify this basic information can lead to medical errors in one or multiple patients.

Next, check that the part of the body in question is indeed the part that was imaged and that it was done in at least two projections oriented 90 degrees apart (for example, one view from the front and one from the side). The left and right sides of the patient should be indicated on the films so that they can be viewed in proper orientation. A marker should also indicate the patient's position at the time of the radiograph. For instance, a frontal chest radiograph can be taken with the patient standing, sitting, or lying down.

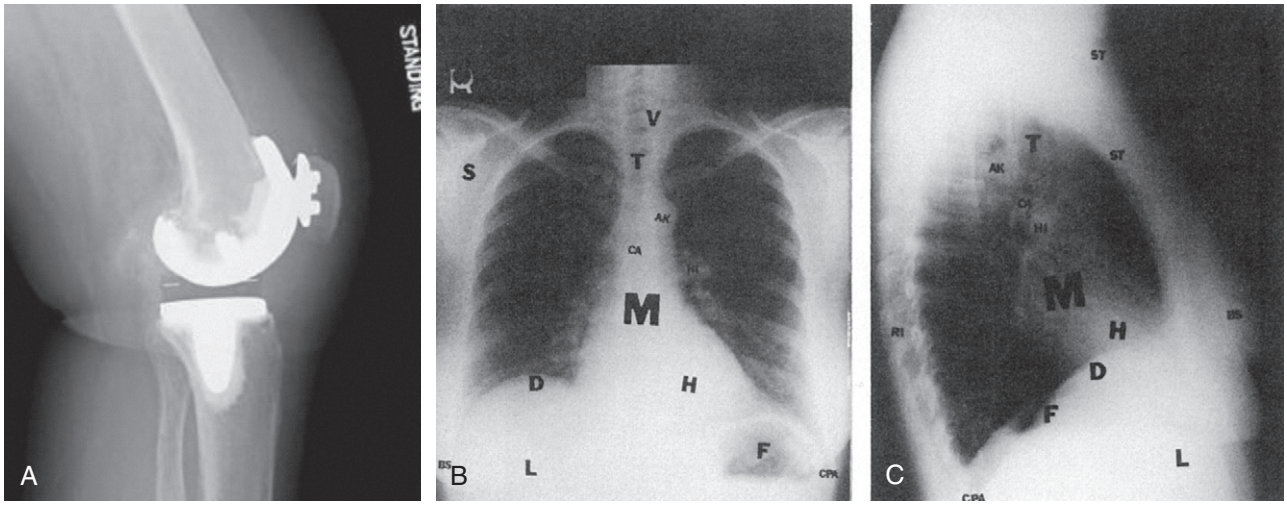

Fig. 11-2 A, This radiograph of a knee with a total joint replacement shows the differences in density among air, fat, muscle, bone, cement, and titanium. **B,** PA radiograph, and **C,** lateral radiograph; these two views anatomically localize the basic structures that must be reviewed during the evaluation of chest radiographs. Some of the structures are seen in both views, whereas others are seen in only one view. During evaluation, the therapist should be able to see and identify the following basic anatomical structures:
Soft tissues and extrathoracic structures: soft tissues (*ST*), breast shadows, (*BS*), diaphragm (*D*), liver (*L*), and fundus of stomach (*F*)
Bony thorax: ribs (*RI*), vertebrae (*V*), scapulae (*S*, seen best on PA), clavicles (*C*, seen best on PA), and sternum (*S*, seen best on lateral)
Mediastinal structures: mediastinum (*M*), trachea (*T*), carina (*CA*), aortic knob (*AK*), heart (*H*), anterior clear space (*ACS*, seen best on lateral), and hilus of lungs (*HI*)
Lung fields: hilus of lungs (*HI*), pulmonary vessels (arise from hilus and branch outward), costophrenic angles (*CPA*), and lung apices (*LA*, seen best on PA) (***A*** *from GE Healthcare.)*

Table 11-1 Standard Radiograph Projections

View	Description
AP (anteroposterior)	Frontal view, taken with the patient facing the x-ray tube, with the back toward the film
PA (posteroanterior)	Looks the same as the AP, but the patient is positioned facing the film
Right lateral	Side view, with the right side against the film
Left lateral	Side view, with the left side against the film
Oblique	A view taken at a 45-degree angle, between the AP and the lateral views

Finally, check the overall exposure of the film. If all the structures are too dark, the film has been overpenetrated. It should be retaken using less radiation. If all the structures are too light, the film has been underpenetrated and should be retaken using more radiation.

Evaluation for Pathology

Overview

After verifying the technical aspects of the images, the diagnostic evaluation can begin. It will help to first review the different projections that have been taken (Table 11-1). There are special views that position the patient in such a way that a particular area of interest is oriented for optimal visualization.

The standard chest radiograph is taken as a posteroanterior (PA) and a left lateral view, with the patient standing. These two views position the heart closest to the film; clinicians use the radiograph to judge the size of the heart, and the farther away from the film the heart is, the more it will appear magnified. This concept is easy to understand if you shine a light on your hand and view the resulting shadow on the wall. The closer your hand is to the wall, the more its shadow's size is true to life. The farther away the hand gets from the wall, the larger and fuzzier the shadow appears. The evaluation of the heart and lungs is most accurate when these structures are positioned close to the film during imaging.

The next step in evaluating a chest radiograph is to do a quick scan of the entire image to look for obvious or life-threatening abnormalities. General anatomy should be identified, including:

- Spine
- Sternum
- Clavicles and ribs
- Right and left diaphragms
- Abdominal organs
- Heart
- Mediastinum and great vessels
- Trachea
- Main bronchi
- Lungs

At this point it is also important to assess the position of the patient by looking at the clavicles to ensure they are aligned. If they are rotated, this could distort images of the lungs, heart, and other important structures. The image should also be scanned for any nonanatomical findings such as pacemakers, tubes, electrical leads, staples, etc. If old films exist in the patient record, it is helpful to compare the current findings with the old. Once this is done, a more thorough evaluation is begun (Table 11-2).

Table 11-2 Summary of Chest X-Ray Evaluation

Focus	Findings
Patient information	Name, date of birth, social security number, sex, existence of any old films.
Nonanatomical findings	Pacemakers, ECG leads, buttons, surgical remnants (e.g., staples), foreign bodies.
General inspection	Check rotation of chest by evaluation of the clavicles. Does anything "jump out" at you? Is everything present that should be there?
Bones	Are the appropriate number present? Are they in normal anatomical position? Any fractures, lesions?
Trachea	Is it midline? Is it narrowed? Are there any foreign bodies?
Lungs	Assess inspiratory effort, diaphragms, lung tissue, full expansion of lungs, opacities, infiltrates.
Heart	Size, borders, shape.
Mediastinum	Is it widened?

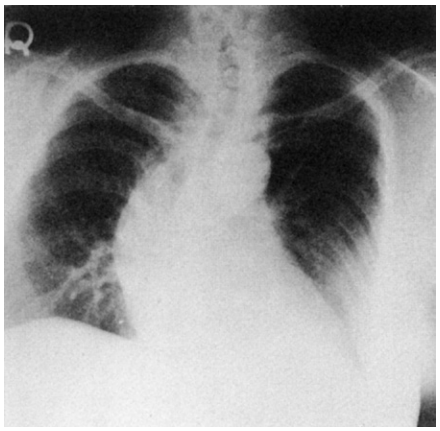

Fig. 11-3 This chest radiograph of a patient with kyphoscoliosis reveals a markedly abnormal, reverse-S–shaped curve of the thoracic spine that is deforming the mediastinal structures and the ribs. This patient is breathing primarily with the diaphragm.

Bony Skeleton

The bony skeleton (Figure 11-3) should be checked for signs of fracture, especially along the margins of the ribs. Fractures are seen as radiolucent lines within the bone or as disruptions of the smooth cortical line at the edges of the bone. Unexplained fragments of bone that are not in a normal anatomical position are another sign of fracture.

Inspiratory Effort

The inspiratory effort should be evaluated. Patients are asked to take a deep breath at the time of the radiograph, and this deep inspiration should make it possible to visualize 10 to 12 ribs within the thoracic cavity. If a radiograph is taken during expiration or during a poor inspiratory effort, the ribs will appear very close together and the lower ribs will be seen below the level of the diaphragm. It is important to take notice of this, as poor inspiratory effort can mask findings in the lungs, or make some findings appear more pronounced than they really are. Inspiratory effort is also important to note because it can provide a quick guide to your patient's respiratory ability.

Position of the Diaphragm

The position of the diaphragm should be noted. Its position, shape, clarity, and the appearance of the costophrenic angles are important, remembering that anatomically, the left (L) diaphragm is usually lower than the right (R) diaphragm. The costophrenic angles are where the diaphragm meets the chest wall. In these thin, pointy areas at the base of the chest cavity, blood or fluid accumulations inside the chest can be seen on an upright film. Such accumulations can affect patient lung capacity and thus oxygenation.

Trachea

Another important structure to evaluate is the trachea, which should be visible at the upper portion of the CXR, with a more radiolucent density, similar to the lung fields. The trachea should be in the midline on the PA view, and the carina (where the trachea branches into the two main stem bronchi) should also be visible. A shift from midline can indicate tension in the chest wall such as that found with some pneumothoraces. Narrowing and/or any foreign objects in the trachea can indicate respiratory distress and must be evaluated immediately.

Lung Fields

Next, the lung fields should be evaluated for uniform density and vascular markings throughout. The hilar area, where the vascular and airway structures converge, is normally more dense and can be an area of importance when looking for masses or tumors. The peripheral lung fields, where the smallest vascular and airway structures are, appear the smoothest and least dense. Comparing them side by side for symmetry helps in the recognition of abnormal areas. Conditions such as pneumonia, tumor, effusion, or other disease processes lead to consolidation of lung tissue, making it more dense than tissue in the rest of the lung fields (Figure 11-4).

Full expansion of the lung fields is also important to evaluate. A pneumothorax causes part of the lung to collapse, creating a less dense empty space in the chest cavity that is devoid of any pulmonary or vascular markings (Figure 11-5). Conversely, a hemothorax or pleural effusion fills the chest cavity with fluid that is denser than normal lung tissue (Figure 11-6). Both of these abnormalities are evident on chest radiographs and can affect oxygenation, as discussed above.

Fig. 11-5 Right-sided pneumothorax. *(From EMBBS. Emergency Medicine and Primary Care Home Page. www.embbs.com.)*

Heart Size

Normally, the heart is about as wide as one-half of the chest cavity. Measuring the cardiac silhouette and then measuring the width of the hemithorax (from the center of the sternum to the outer edge of the ribs) for comparison helps to identify conditions such as cardiac hypertrophy due to chronic or acute heart failure. Next, the shape and the borders of the heart should be examined. For example a "boot shaped" heart

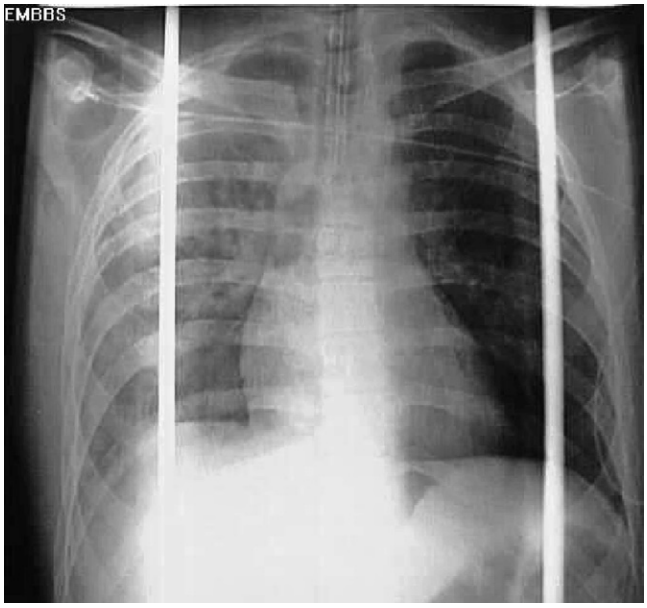

Fig. 11-6 Right rib fractures with right hemothorax. *(From EMBBS. Emergency Medicine and Primary Care Home Page. www.embbs.com.)*

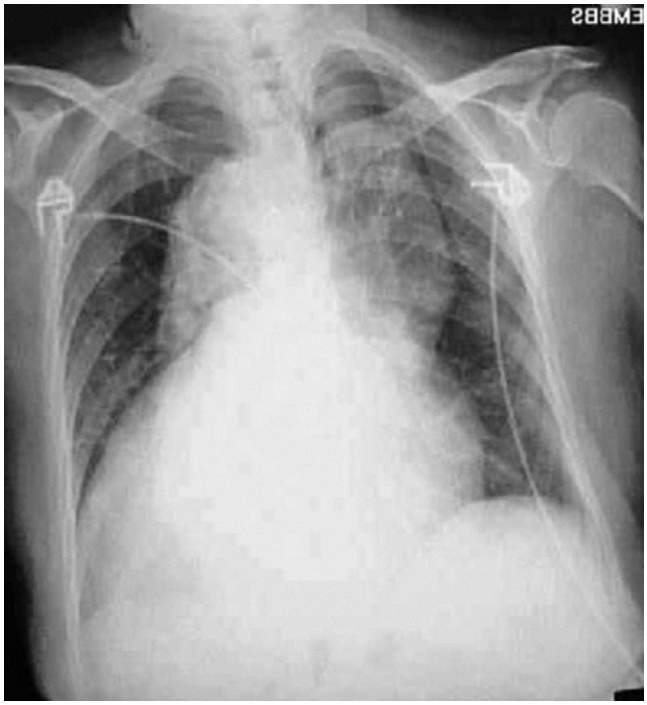

Fig. 11-7 Thoracic aortic aneurism with widened mediastinum. *(From EMBBS. Emergency Medicine and Primary Care Home Page. www.embbs.com.)*

can indicate congenital heart deformities in children, and the loss of a distinct heart border could indicate an infiltrate in the adjacent lung tissue.

Mediastinum

The width of the mediastinum is also important to evaluate. The mediastinal structures should be just wider than the thoracic spine. When the dense structures in this area are much wider than expected, a life-threatening aortic aneurism should be suspected. As the aortic arch widens, it projects a higher-density shadow over the upper left chest cavity that is visible on the radiograph (Figure 11-7).

Other Disease States

Other common disease states can have typical findings on chest radiographs. The hyperinflation caused by an acute asthma attack may present as increased bronchial markings throughout the lung fields, a flattened diaphragm, and a maximally expanded chest cavity. Chronic obstructive pulmonary disease (COPD) causes similar effects, including a barrel-shaped chest (increased anteroposterior [AP] diameter), a flattened diaphragm, and an overall decreased density of the pulmonary markings.

Other Imaging Methods

Computed Tomography

CT scans of the chest can be a useful diagnostic tool for certain diseases (Figure 11-8). Like standard radiographs, CT uses ionizing radiation, but it allows for rapid scanning in much more detail. The CT scan generates pictures that are "slices" through the patient in the axial plane (Figure 11-9). Although bone is visualized much better than soft tissues, a CT scan can still provide excellent images of the lungs, vascular structures,

Fig. 11-8 Computed tomography (CT) scanner.

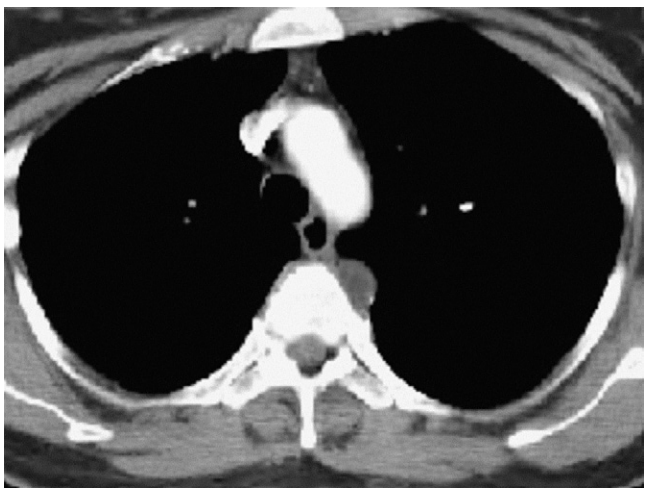

Fig. 11-9 Chest CT showing spine, pulmonary spaces, and aortic arch. *(From GE Healthcare.)*

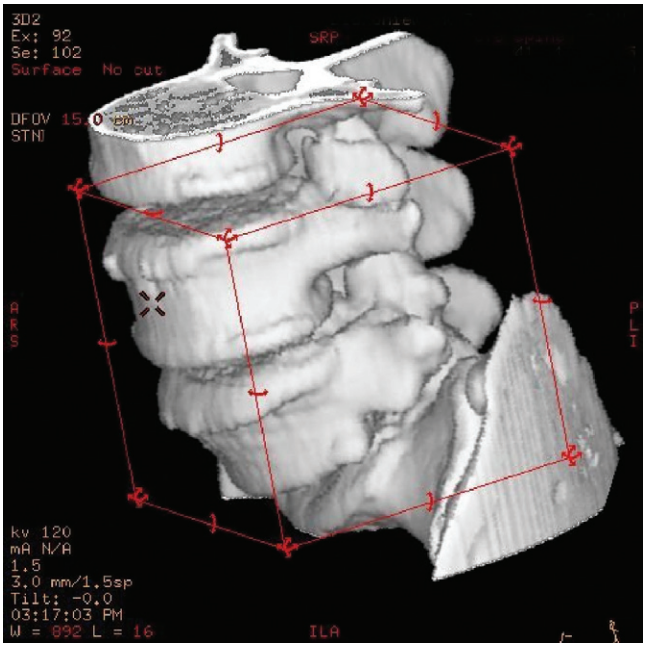

Fig. 11-10 Three-dimensional reconstruction generated by a CT scanner. *(From GE Healthcare.)*

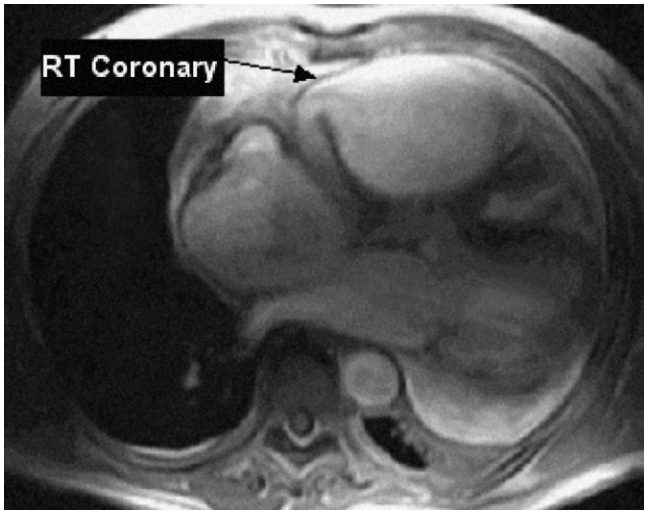

Fig. 11-11 Cardiac MRI evaluating the coronary arteries. *(From GE Healthcare.)*

and heart. New software can produce three-dimensional images that show the anatomy beautifully (Figure 11-10), and the sensitivity of these machines can allow for the detection of very small amounts of calcification in the coronary arteries, which can be an indication of early heart disease. Newer "ultrafast" CT scanners can see more subtle changes in the coronary arteries because they take images so quickly that they seem to "stop" or "freeze" the action and movement of the heart. This results in clearer pictures and the ability to discern small details more accurately.[4] Another modality, called spiral CT scan, provides higher resolution and more rapid images, making it very helpful in the diagnosis of pulmonary embolism, because it can visualize vessels with great precision. In certain cases, an iodine-based dye must be injected intravenously to enhance CT images. This dye can exacerbate renal disorders, and should thus be used with caution.

As CT scans become more and more precise, they are also used more frequently. This increased use raises a concern regarding the radiation exposure of patients undergoing these studies. Although radiation exposure is also a factor with conventional radiography of the chest, the level of exposure with computed tomography has been documented to be much higher. A typical chest CT will expose a patient to the radiation equivalent of 50 to 450 chest x-rays. This increase in radiation exposure had been linked to cancer development later in life, most notably in the pediatric population. Because of this risk, other chest imaging techniques may be considered if appropriate.[5,6]

Magnetic Resonance Imaging

Magnetic resonance imaging of the chest can be performed to evaluate the soft tissues of the chest cavity.[7] MRI has the advantage of using magnetic energy rather than ionizing radiation, so there is no harmful exposure for the patient. MRI scans also provide much higher-quality views of soft tissues than can be achieved by CT scans, but MRI is more expensive and takes nearly an hour to complete. A chest CT can be done in less than a minute, making it a better choice for evaluation of trauma (Figure 11-11). MRI is most useful when evaluating heart function/wall movement, vasculature of the heart and lungs, tumor size and staging, and respiratory movement of the muscles and diaphragm.[4,8]

Radionuclide Ventilation-Perfusion Scan

A radionuclide ventilation-perfusion (VQ) scan can be used to detect conditions that affect blood flow in the lung parenchyma. Radioactive isotopes are injected into the blood stream and are also inhaled into the lungs. Scanning for the location of these isotopes can then determine the extent to which the lungs have been ventilated and perfused. A mismatch (for instance, an area that was perfused with gas but not perfused with blood) would indicate that a blood clot had become caught in the pulmonary vasculature. Research has found, however, that VQ scans produce a high number of indeterminate results, and newer CT images have been found to be more accurate. A pulmonary angiogram is still the definitive test for a pulmonary embolism, but it is an invasive test that must be administered in the cardiac catheterization laboratory and involves injection of dye into the arterial vasculature; thus other imaging methods should be considered when appropriate.

Positron Emission Tomography Scan

Positron emission tomography (PET) scanning is a newer form of radionuclide imaging that helps show the function of organs rather than just their structure. For instance, the amount of radio-labeled glucose taken up by heart muscle cells can help clinicians determine whether the muscles have died after a myocardial infarction or whether they are still alive. This makes the PET scan a crucial decision-making tool: if the post-MI heart muscle cells are alive, they would benefit from bypass surgery, whereas if they are dead, bypass surgery would not be worthwhile. This modality is also very helpful

in the localization of tumors in the chest cavity; these tumors are highly metabolic and have high uptake of the radionuclide, thus "lighting up" on a PET scan.[9]

Ultrasound

Ultrasound is an imaging modality commonly used in the abdomen, but because the sound waves bounce off bone, it is much less useful in the chest cavity. Ultrasound is sometimes used to identify pockets of fluid during thoracocentesis, but a CT scan is more commonly used whenever the precise placement of a needle in the chest is necessary. Ultrasound can also be useful to assess cardiac function via a modality known as transesophageal ultrasound.[10]

Summary

There are a variety of ways to image the chest. The standard chest radiograph is still an important way to gather information quickly, inexpensively, and at low risk for the patient. A physical therapist should be familiar with the basic techniques of reading a chest radiograph and should be able to identify common abnormalities viewable by x-ray, as well as other imaging methods, in order to better adapt their therapy regimen to fit the patient's needs and oxygen demands.

Review Questions

1. What do the differing densities seen on a standard chest radiograph represent?
2. What are the basic steps in reading a chest radiograph?
3. What are the signs, visible on a chest radiograph, of the following disorders: pneumothorax, hemothorax, consolidation, and thoracic aneurism?
4. How does nuclear imaging give the clinician physiological and anatomical information about the patient?

Electrical signaling is a primary method of communication, control, and regulation in the human body, and nowhere is this method employed with greater precision and elegance than in the heart. The rate, rhythm, and conduction of electrical signals are critical to cardiac function; these are the rhythmic electrical impulses that cause the mechanical contraction, or pumping, of the heart muscle. This electrical current is detectable by electrodes that are placed on the surface of the skin. The flow of current during the cardiac cycle is then recorded as the characteristic waveforms of the electrocardiogram (ECG; sometimes also called EKG). Mechanical events such as the contraction and relaxation of the myocardium are inferred from the waveforms produced by the ECG.

The ECG is an essential tool for the diagnosis and medical management of patients with cardiac disease. Information provided by the ECG may also assist the physical therapist in the assessment of a patient's readiness for and response to physical activity. Physical therapists in many different practice environments have access to information afforded by the ECG. For example, in the intensive care unit or acute care setting or during cardiac rehabilitation, a patient's ECG may be continuously monitored via telemetry (a remote monitoring system in which ECG signals are sent via radio waves to a distant receiver) or by a bedside unit. In both the acute and outpatient settings, past significant ECG recordings, as well as an interpretation, may be available in the medical record. Documentation accompanying a referral for outpatient physical therapy may also include a reference to the patient's ECG. It is therefore crucial that all physical therapists have a basic understanding of the uses and limitations of the ECG in their practices.

As an example of how an understanding of ECG interpretation may be useful for physical therapists, consider the following scenario. A physical therapist in a cardiac intensive care unit (CCU) initiates exercise for a patient recovering from open-heart surgery. The patient's ECG has been stable throughout the postoperative recovery phase, but the patient has not yet been challenged with moderate intensity activity or exercise. The therapist gets the patient up and begins an appropriate level of exercise; however, with this greater demand on the heart, the patient develops an exercise-induced dysrhythmia. This abnormal rhythm may be mild and fairly benign, or it could be malignant or life-threatening. If the physical therapist is able to interpret the ECG accurately in this situation, this dysrhythmia may be caught and then

referred to and treated by the physician. If the dysrhythmia is not recognized, a less favorable outcome may occur.

This chapter briefly reviews the basic anatomy and physiology of the myocardial conduction system as it relates to the ECG. The configuration of the normal ECG is presented and discussed, along with several methods of quickly determining heart rate and rhythm from an electrocardiographic record, or ECG "strip." Some of the more common dysrhythmias are examined, as are some other pathological features. Throughout the chapter, the uses and limitations of the ECG in physical therapy practice are highlighted.

Physiology and Anatomy of the Conduction System

Cardiac Action Potential

The cardiac action potential is generated by the flow of ions across myocardial cell membranes; it has a distinctive shape and five phases (phases 0 to 4).[1] In the cell's resting state, a negative membrane potential exists, based on the selective permeability of the cardiac cell membrane and the relative concentrations of sodium (Na^+), calcium (Ca^{2+}), and potassium (K^+) ions in the internal and external cellular environments. The relative time-sensitive ionic currents for each species are color-coded and labeled in Figure 12-1, and the cardiac action potential is superimposed over the individual currents that compose it. At rest, a typical ventricular cardiomyocyte membrane is primarily permeable only to K^+ ions, allowing the movement of K^+ out of the cell until the charge inside is approximately −90 mV, relative to the charge outside. This is the resting membrane potential of the cardiomyocyte and is close to the equilibrium potential for K^+. The membrane potential changes rapidly at the onset of depolarization, with the opening of Na^+ and Ca^{2+} channels, allowing these ions to cross the membrane and enter the cell. Calcium then becomes available for contraction of cardiac muscle myofibrils.

During depolarization, the membrane's potential becomes positive and the cell contracts. As in skeletal muscle, the Na+ channels are fast-opening and fast-closing mechanisms, allowing Na+ to rapidly enter the myocardial cell on depolarization (referred to as phase 0 of the cardiac action potential in Figure 12-1). Unlike skeletal muscle, however, cardiac muscle has a prolonged action potential as a result of the slower and extended opening of the Ca^{2+} channels. After initial depolarization, some K^+ channels remain open while others close, and repolarization begins (phase 1) as a result of outward K^+ current flowing through the open K^+ channels. A plateau phase (phase 2) of the action potential exists, during which the outward flow of K^+ ions is balanced by an inward flow of Ca^{2+} ions. This prolongs depolarization and delays return to the resting membrane potential. Closure of the slow Ca^{2+} channels at onset of repolarization is accompanied by the opening of additional K^+ channels, causing a rapid outflow of K^+, which completes repolarization (phase 3 in Figure 12-1), restoring resting negative membrane potential. During the cell's resting phase (phase 4 of Figure 12-1), Na^+ and Ca^{2+} are actively pumped out of the cell, and K^+ is pumped into the cell, restoring the ionic gradients needed for repolarization.[1,2,3]

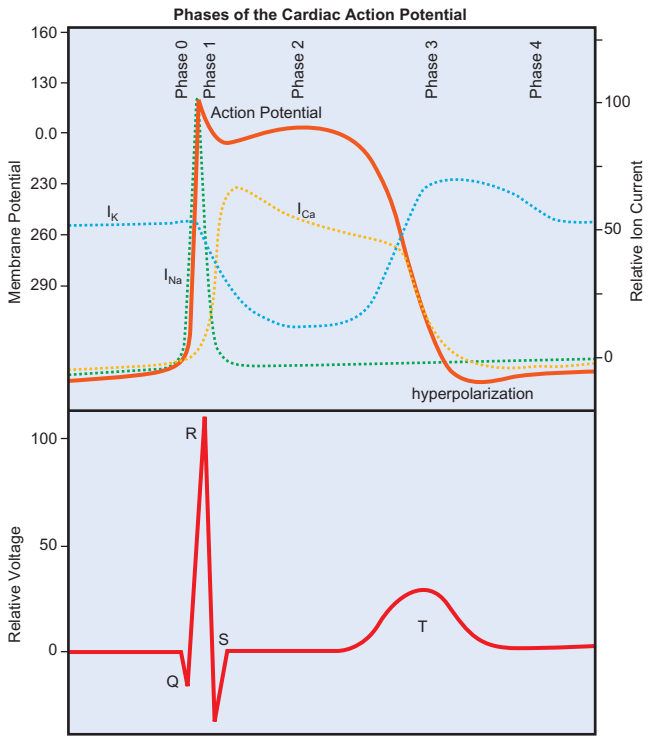

Fig. 12-1 Relationship of an individual ventricular cardiomyocyte action potential to the ECG. **A,** The time-dependent ionic currents (I_K, I_{Na}, and I_{Ca},) of an individual ventricular cardiac cell that determine the shape, amplitude, and duration of the cell's action potential (shown in red). The action potential can be broken down into five distinct phases (0-4). **B,** The QRS complex and T wave of the ECG are temporally related to the cardiac action potential and the phases. However, the ECG also reflects the anatomical orientation of the wave of depolarization through the heart and the location of the recording electrodes.

Each cell has an absolute refractory period during depolarization, meaning that an additional stimulus will not cause an additional depolarization. A brief but important relative refractory period follows depolarization, during which a stimulus of greater than normal intensity is necessary to depolarize the cell again. The refractory period of atrial cells is significantly shorter than that of ventricular cells, allowing a more rapid intrinsic atrial rhythm than intrinsic ventricular rhythm. Therefore atrial rhythms pace the heart, including the ventricles, given intact atrioventricular (AV) conduction.

From Figure 12-1 it can be seen that certain ionic currents contribute to particular phases of the cardiac action potential. The Na^+ current is the predominant factor in the initial depolarization, whereas the Ca^{2+} current is important in the plateau phase, and the K^+ currents are important in the duration of the action potential and in repolarization. Many of the drugs used to treat dysrhythmias work on the channels for one or more of these three ions and affect their permeability. Furthermore, the electrical current produced by these ionic currents is transmitted through the conductive tissues surrounding the heart. The "wave" of depolarization that is propagated through the conduction system and contractile tissue of the heart, as well as repolarization, which takes place in a particular spatial manner, are detectable by the surface electrodes of the ECG.

Conduction System

It is the conduction system that initiates and rapidly transmits impulses to specific locations within the myocardium (the atria, apex, septum, and lateral wall), allowing for effective, coordinated myocardial contraction and pumping. The conduction system is composed of specialized cardiac muscle that contracts minimally because it contains few contractile myofibrils. Any portion of the conduction system is capable of self-excitation and may act as a pacemaker, generating action potentials. However, because of the intrinsically more rapid rate of spontaneous depolarization of the sinoatrial (SA) node, it normally acts as the heart's pacemaker. The rate of depolarization of the SA node determines the heart rate. In the absence of an impulse from the SA node, the AV node depolarizes spontaneously, taking over as pacemaker, with the important difference that the rate of depolarization is lower than that of the SA node.

Figure 12-2 displays the anatomical association of the cardiac electrical conduction system with its components on the ECG. Atrial depolarization is initiated by a spontaneously generated impulse that originates in the SA node. The impulse is then transmitted throughout the atrial muscle, resulting in atrial contraction. The event is recorded as the P wave of the ECG. The impulse is also transmitted, via rapidly conducting internodal pathways, to the AV node. Atrial repolarization is not recorded by the ECG because it occurs during ventricular depolarization.

Impulse conduction slows within the AV node considerably, resulting in a delaying of the impulse before it reaches the ventricular conduction system. The pause in impulse propagation allows the atria to contract and fill the ventricles with blood. The P-R interval of the ECG represents this period between the onset of atrial depolarization and the onset of ventricular depolarization. Normally the P-R interval lasts between 0.12 and 0.20 second.[4]

Following passage through the AV node, the impulse continues to the AV bundle (bundle of His) and then to Purkinje fibers, which transmit the impulse rapidly to the ventricular endocardium. Ventricular depolarization corresponds to

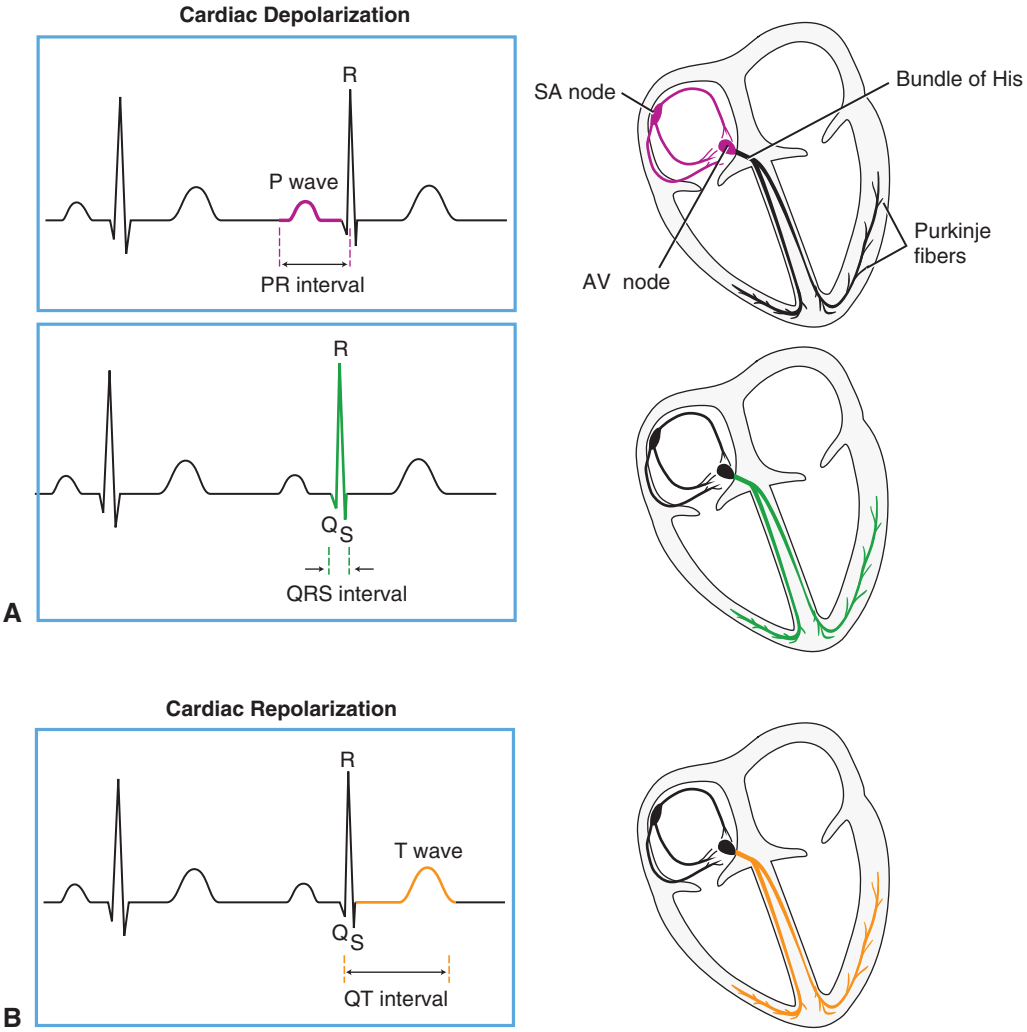

Fig. 12-2 Relationship of ECG complex to conduction pathway. **A,** The sequence of events in depolarization: the wave of depolarization spreads from the SA node through the atria to the AV node. After a delay in the AV node, it travels through the bundle of His to the Purkinje fibers to the ventricular myocardium. The delay at the AV node accounts for the duration of the P-R interval. QRS duration is dependent on normal propagation from the atria and an intact ventricular conduction system. **B,** Ventricular repolarization.

phase 0 of the cardiac action potential (see Figure 12-1) and is represented in the ECG by the QRS complex. The depolarization wave propagates relatively slowly throughout the ventricular myocardium. The span of time elapsing during ventricular depolarization is reflected by the QRS interval, which normally ranges between 0.06 and 0.1 seconds. Ventricular depolarization originates in the interventricular septum, creating the Q wave, which is normally small or absent, depending on the lead. The depolarization wave next spreads to the apex and then to the right and left ventricles, causing the R and S waves. Depolarization also propagates in an endocardial to epicardial direction within the ventricles.[2,3] A normal QRS duration indicates that the impulse originated in the SA node or a region above the AV node (supraventricular). A long QRS interval (≥0.1 second) suggests that the impulse arose from the ventricle or originated abnormally in supraventricular tissue. The normal sequence of depolarization is as follows: SA node to AV node to bundle of His to Purkinje fibers to the ventricular myocardium. When this sequence is followed, the ECG correlates with the mechanical events of the cardiac cycle as shown in Figure 4-13.

After ventricular depolarization, the ECG deflection returns to baseline, and this pause in electrical activity corresponds with the plateau phase (phase 2) of the cardiac action potential. Ventricular repolarization is represented by the T wave and corresponds to phase 3 of the cardiac action potential. The configuration of the S-T segment is an important marker of myocardial ischemia or infarction. Following the T wave, a U wave may also be present. The source of the U wave is not well understood.[5] Although U wave inversion may indicate ischemia involving the left ventricular wall,[6] it is not a unique marker and is not as sensitive as S-T segment changes in predicting ischemia; therefore it is not a useful clinical marker.[7]

Within the ventricle, individual cardiomyocytes are in direct communication with each other via gap junctions. This facilitates rapid spread of the wave of depolarization from cell to cell, allowing the right and left ventricular heart muscle to function as a syncytium, or a single pumping unit.[8] Note that the ventricles remain in a state of contraction until slightly after repolarization. This period of contraction corresponds to the Q-T interval on the ECG. Diastole, therefore, begins subsequent to the end of the T wave and continues until the next ventricular depolarization. Note also that atrial depolarization and contraction occur during diastole.

Electrocardiogram

Recording the Electrocardiogram

Before examining the timing of the wave forms and the rhythms of the ECG, a basic understanding of the principles of electrocardiography is needed. A standard 12-lead configuration is used for the diagnosis and medical management of cardiac conditions (Figure 12-3): six leads record the electrical signals in the frontal plane, and six leads record signals in the transverse plane. The placements of the 10 electrodes for a 12-lead ECG are shown in Figure 12-4 (note that 12 electrodes are not necessary because some leads serve a dual purpose).

The frontal-plane leads include three standard bipolar limb leads, referred to as leads I, II, and III, and three augmented unipolar limb leads, referred to as aVR (right arm), aVL (left arm), and aVF (left leg). These two sets of leads share the same electrodes but view the electrical activity of the heart from different perspectives. The bipolar leads have a single positive and a single negative electrode and record the difference in electrical potential between them. The augmented limb leads have a single positive electrode and derive the negative electrode from the combination of the other electrodes. The standard limb leads form a triangle, known as the Einthoven's triangle, around the heart that allows for advanced calculations related to the net vector of depolarization, or the axis of the heart (an index of the cardiac mass and position). If only a single lead is recorded, standard limb lead II is often chosen because all of the deflections are typically upright.[4]

The transverse-plane leads are referred to as the precordial, or chest, leads. These six leads form a semicircle around the anterior aspect of the heart; their placement is described in Figure 12-4. In addition to the three electrodes for the limb leads and the six electrodes for the chest leads, a 10th electrode that serves as a neutral ground must be used to reduce artifacts and stabilize the baseline. Imagine that each of the 12 leads "views" the heart from a different angle, therefore recording events in different locations of the heart in different ways. By convention, the waveform on the ECG is positive (upward) as current travels toward a positive electrode or lead and is negative (downward) when current travels away from a lead. Other lead configurations may be used for exercise testing.[9] Single-lead monitoring is commonly used during exercise training or in the acute care settings.

Evaluating the ECG Strip

The evaluation of an ECG should be approached in a systematic fashion. The following questions are useful for appreciating the information that is relevant to current clinical practice.[10]

What is the rate and pattern (regularity) of the rhythm? Is the R-R interval (the distance between successive R waves) equal for each beat? This indicates regularity of the beats.

Does a P wave precede every QRS complex? This indicates that the rhythm is atrial.

Is there a QRS complex after every P wave? This indicates conduction of impulses from the atria to the ventricles.

What is the P-R interval? A P-R interval of 0.12 to 0.20 second indicates normal conduction from atria to ventricles. A P-R interval >0.2 seconds indicates a conduction delay or block.

Is the QRS complex of normal duration and morphology (shape)? A QRS complex greater than 0.1 second indicates either that an impulse arose within a ventricle or was conducted abnormally through the ventricular conduction system.

By answering each of these questions, the tendency to "eyeball" the rhythm and make a quick, but inaccurate assessment is avoided.

Determination of Heart Rate

Several quick methods can be used to estimate heart rate. Most printed and displayed ECG recordings indicate a heart rate. This must be interpreted with caution, however, because the presence of artifact (extraneous deflections of the waveform caused by movement or electrical interference) may render an automated heart rate calculation inaccurate. This is a common

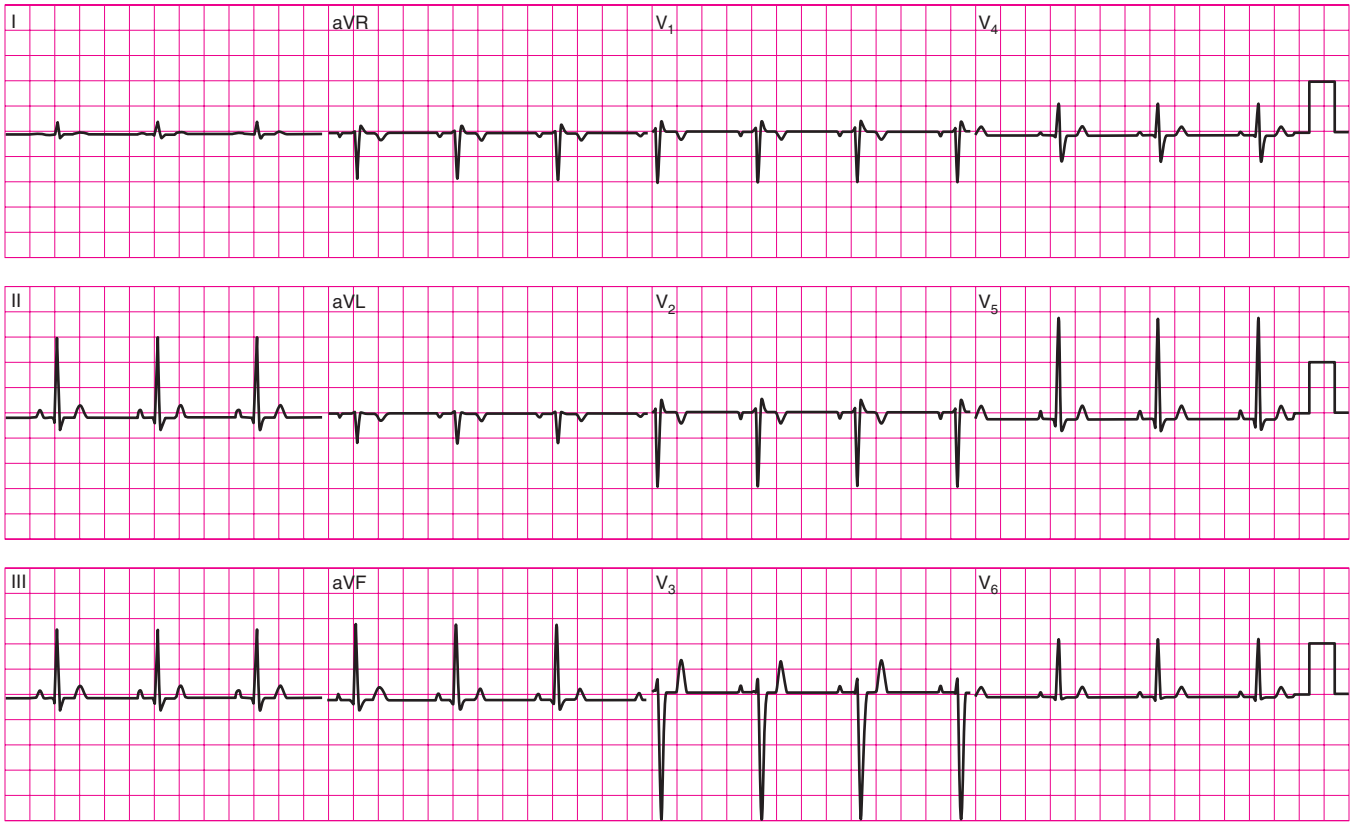

Fig. 12-3 A normal 12-lead ECG.

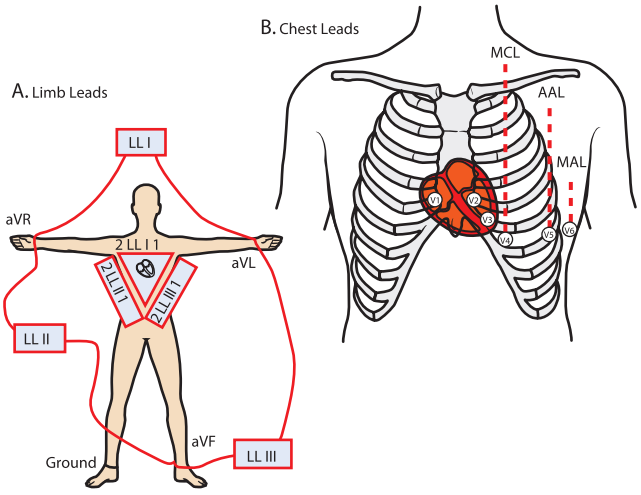

Fig. 12-4 Anatomical placement of the 12-lead electrocardiogram electrodes. **A,** The placement of the electrodes for the three standard limb leads (LL), LL I, LL II, and LL III; and the placement for the augmented limb leads, aVR (right arm), aVL (left arm), and aVF (left leg). The standard limb leads are bipolar leads, whereas the augmented limb leads are unipolar. **B,** The placement of the six chest leads, or precordial leads, V1 to V6. Leads V1 and V2 are placed over the fourth intercostals spaces, on the left and right of the sternum, respectively. Typically, V4 is placed next on the midclavicular line (MCL) at the fifth intercostals space. V3 is placed midway between V2 and V4. V6 is placed next on the midaxillary line (MAL) on the same plane as V4. The V5 lead is placed at a point midway between V4 and V6, at the anterior axillary line (AAL). A 10th electrode must be attached (shown here attached to the right leg) to minimize artifact. Abbreviations: *AAL,* anterior axillary line; *LL,* standard limb lead; *MAL,* midaxillary line; *MCL,* midclavicular line.

problem during activity or exercise, the circumstances during which many physical therapists monitor patients. It is possible to calculate or to estimate a heart rate on the basis of a printed ECG strip because, by convention, the recording paper is divided into 1-mm squares and larger 5-mm squares, which are defined by heavier lines (Figure 12-5). Also by convention, the standard paper speed for an ECG recording is a rate of 25 mm per second, and most recorders mark each 3-second interval. Each millimeter of length then represents $\frac{1}{25}$, or 0.04 second, and each 5-mm block represents $\frac{1}{5}$, or 0.20 second. Some monitor systems, however, place a mark on the recording paper at 25-mm, or 1-second intervals.

There are several methods of estimating heart rate from a printed ECG strip (Figure 12-6). On the strip, find an R wave located on or near a heavy vertical line. Proceeding to the right of that R wave, for each subsequent heavy vertical line, assign the following numbers: 300 for the first heavy line encountered, 150 for the next, followed by 100, 75, 60, 50, and 42 (Figure 12-6, *A*). Stop at the first heavy vertical line following the next R wave that is encountered. The heart rate may be estimated as falling between values to the left and right. In Figure 12-6, the rate would be estimated as falling between 100 and 75, or close to 80 beats per minute.

In many clinics, rulers are available that are calibrated so that heart rate may be estimated quickly by aligning markings on the ruler with features of the ECG strip. For example, after the arrow on the ruler is placed on an R wave, count two R waves to the right and read the number at that position on the ruler. In Figure 12-6, *B,* this method approximates the heart rate as 74 beats per minute. It is important to note that the

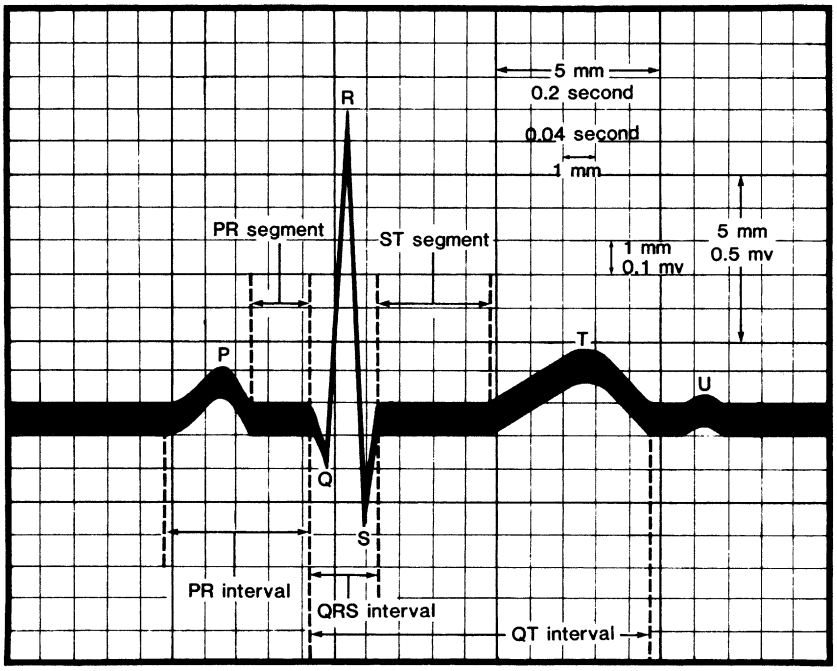

Fig. 12-5 A normal ECG showing characteristic waves, intervals, and segments, and some of the features of the tracing paper.

preceding two methods are useful only if the rhythm of the ECG strip is regular (i.e., the R waves are equally spaced, occurring at consistent intervals). Should the rhythm be irregular, with R waves appearing at varying intervals, another method must be employed to estimate the heart rate.

A common and easy method for estimating the heart rate is to count off the number of R waves in a 6-second strip. Depending on whether the ECG recorder makes a mark every 1, 3, or 6 seconds, count off the appropriate number of seconds to obtain a 6-second strip. The procedure is as follows: Start at the mark corresponding to the beginning of the 6-second period and proceeding from left to right, count the number of R waves within the 6-second recording. Now multiply by 10. That is the estimated heart rate, rounded down to the nearest 10 beats per minute. Several 6-second strips may be analyzed to document the heart rate range of an irregular rhythm. The rate of the irregular rhythm in Figure 12-6, *C*, is estimated at approximately 60 beats per minute.

Evaluation of Rhythms

Electrocardiographic monitoring is an important evaluation tool during the treatment of individuals with a history of, or potential for, acute myocardial infarction (MI) or myocardial ischemia. Most cardiac deaths are a result of lethal dysrhythmias, for which there is increased risk in the presence of infarction or ischemia. Rapid recognition of lethal dysrhythmias, or dysrhythmias that may deteriorate into lethal dysrhythmias, is essential for all health professionals involved in the care of individuals with cardiac disease. The dysrhythmias described in this chapter are those that are either common or dangerous in terms of mortality and morbidity.

Normally, a cardiac impulse is generated by the SA node, causing atrial depolarization. This is followed by a slight delay in the AV node, after which the impulse is conducted to the ventricles, causing ventricular depolarization. These events are shown in Figure 12-7 in their normal spatial and temporal sequence and in normal sinus rhythm. A P wave precedes every QRS complex and every P wave is, in turn, succeeded by a QRS complex. This occurs within an interval of 0.12 to 0.20 second (one large box), as determined by the P-R interval. The QRS complexes occur within a range of 0.04 to 0.12 second, indicating that ventricular impulse conduction and depolarization is occurring in a normal interval. The positively deflected T wave indicates normal ventricular repolarization. Because the SA node spontaneously depolarizes at a rate of between 60 and 100 beats per minute, the rate of normal sinus rhythm must fall within these limits.

The identification of dysrhythmias affects clinical decision making, particularly with regard to a patient's readiness for or response to activity. The clinical significance of dysrhythmias ranges from benign to lethal. The clinical significance of a given dysrhythmia is determined by a number of considerations. Some of these considerations include the following: Is there evidence of hemodynamic compromise? Is the dysrhythmia a new or unusual finding? Might the dysrhythmia be a precursor to a more serious or perhaps lethal dysrhythmia? Is this an acute occurrence or a chronic dysrhythmia pattern? The clinical response to a patient with a dysrhythmia depends on the answers to these questions and the treatment setting.

Dysrhythmia Identification

Supraventricular Dysrhythmias

Supraventricular dysrhythmias arise from an abnormality in impulse generation or conduction "above" the level of the ventricles. A sinus rhythm is any rhythm established by impulses from the SA node. Thus, depending on where the abnormality occurs—in the atria or at the level of the AV junction—a supraventricular dysrhythmia may be categorized as sinus, atrial, or junctional.

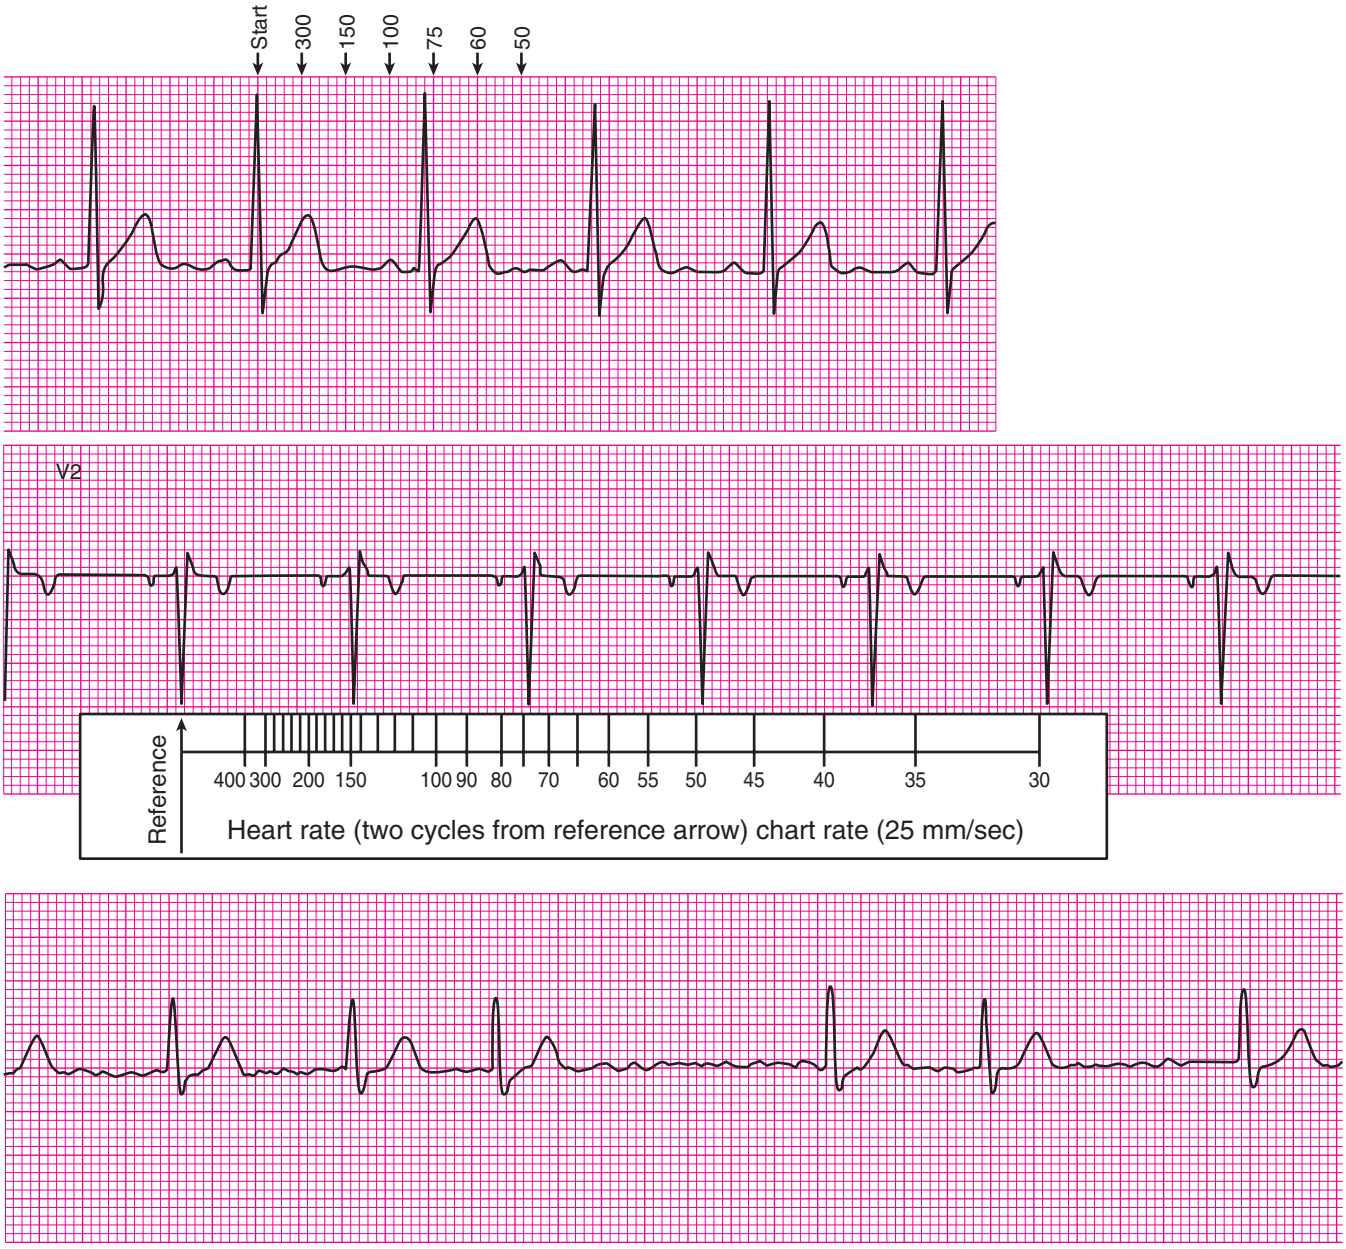

Fig. 12-6 Estimating heart rate. **A,** Count-off method. **B,** Using a rate-ruler. **C,** Heart rate estimation in an irregular rhythm (atrial fibrillation).

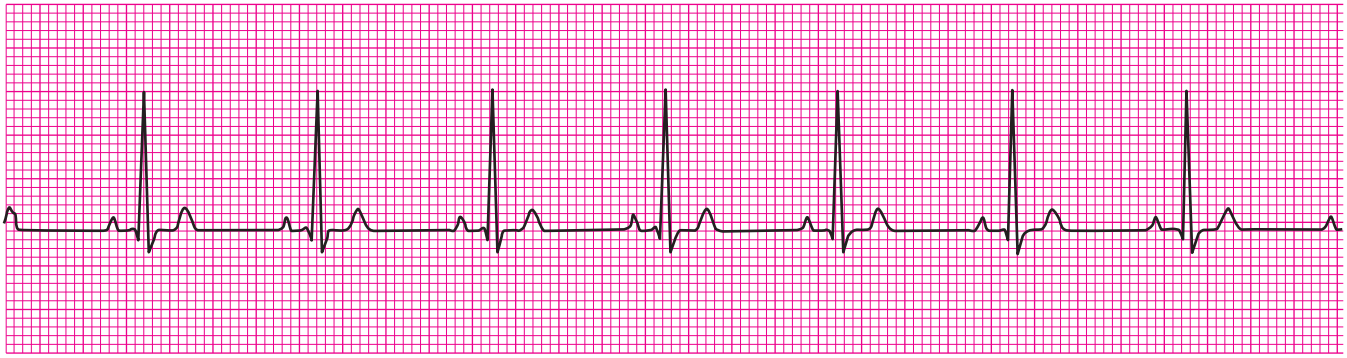

Fig. 12-7 Normal sinus rhythm.

A cardiac dysrhythmia may be a sinus rhythm but with an irregular or abnormally rapid or slow rate (Figure 12-8). Sinus dysrhythmia is an irregular sinus rhythm with varying R-R intervals (Figure 12-8, *A*). This is a normal variant that is associated with the individual's respiratory pattern. Sinus bradycardia is a sinus rhythm occurring at a rate of less than 60 beats per minute (Figure 12-8, *B*). This rhythm may significantly reduce cardiac output, causing hemodynamic compromise, manifested by hypotension or symptoms such as dizziness, lightheadedness, or syncope. On the other hand, individuals taking beta blockers, a group of medications that slow the heart, may exhibit this as their normal rhythm, as might individuals who achieve a high level of physical conditioning. Sinus tachycardia is a sinus rhythm occurring at a rate of greater than 100 beats per minute (Figure 12-8, *C*). Sinus tachycardia, or any other form of tachycardia, increases myocardial oxygen demand, or the workload on the heart. This may initiate or exacerbate ischemia in the presence of coronary artery disease (CAD).

A beat or rhythm that does not originate in the SA node is considered to represent an ectopic focus or pacemaker. One common form of dysrhythmia is a "premature" complex (i.e., a beat that occurs sooner than expected given the established rhythm). A premature atrial complex, or PAC, is an early beat that has an ectopic atrial origin (Figure 12-9). An R wave appears closer to its preceding R wave than the other R waves in the established rhythm. The P wave of the odd beat may have a different shape or may be inverted relative to the normal P waves, indicating that it came from a focus other than the SA node, but the associated QRS complex is always preceded by a P wave, meaning that the impulse first depolarized the atria before being conducted to the ventricles. Sometimes the AV junction may initiate an early beat, causing a premature junctional complex, or PJC. When this occurs, the R wave appears earlier; however, there may be no associated P wave, or there may be an unusual P wave, one that is inverted or follows the QRS complex. An inverted or late P wave indicates that the impulse was conducted in a retrograde

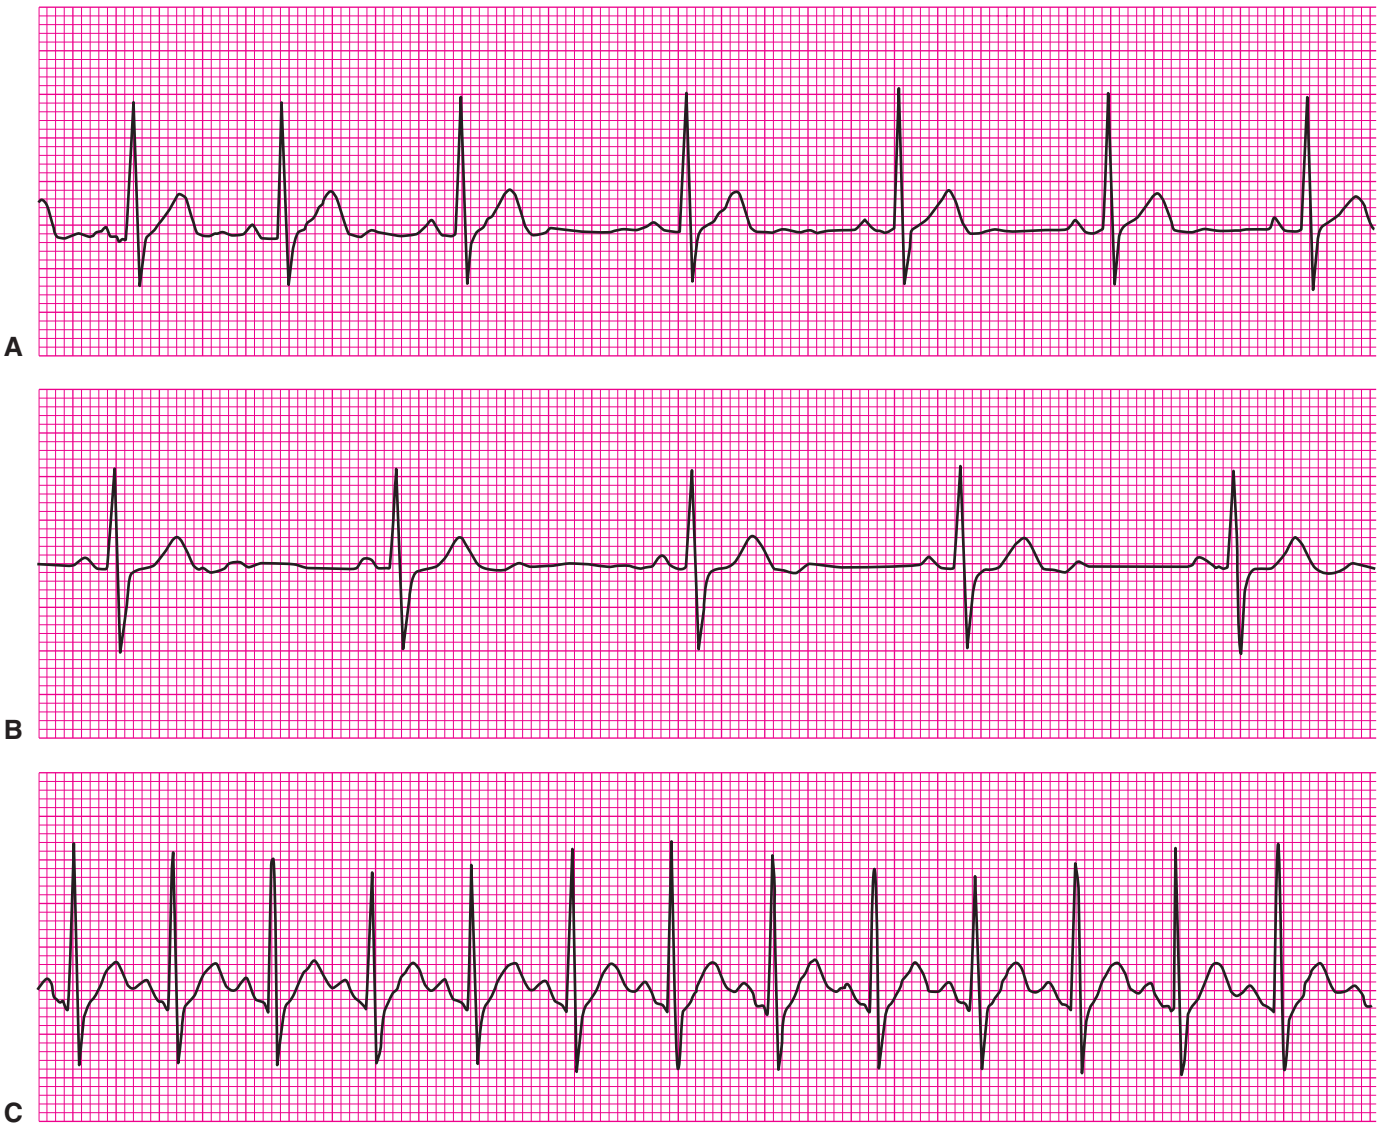

Fig. 12-8 Sinus rhythm but with an irregular or abnormally slow or rapid rate. **A,** Sinus dysrhythmia. **B,** Sinus bradycardia. **C,** Sinus tachycardia.

Fig. 12-9 Premature atrial complex.

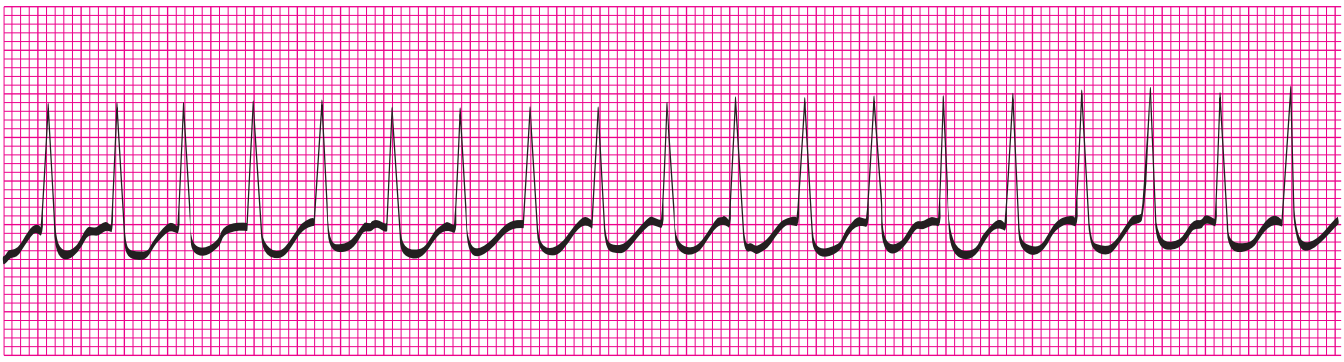

Fig. 12-10 Supraventricular tachycardia.

(backward) fashion. Clinically, a premature atrial or junctional complex may be palpated as a "skipped" or early beat during pulse taking, or the patient may perceive a palpitation or skipped beat. Otherwise, these dysrhythmias are usually of little clinical significance.[4,11]

A more serious supraventricular dysrhythmia is supraventricular tachycardia, or SVT. In this dysrhythmia, the heart rate is rapid, exceeding 150 beats per minute. The tachycardia may be sustained, lasting hours or even days, or it may be "paroxysmal" (PSVT), appearing abruptly and spontaneously reconverting to the previous rhythm within seconds or minutes. The P wave is often not visible, making assessment of atrial or junctional origin difficult. According to the 2005 American Heart Association guidelines, tachycardia is classified on the basis of the width of the QRS complex. So called "narrow-complex tachycardia" refers to a rapid rhythm with a QRS <0.12 seconds. These types of tachycardia originate above the ventricle and are "supraventricular." Wide complex tachycardia (QRS >0.12 seconds) is usually ventricular in origin and is discussed below. Distinguishing between these two types of tachycardia is important since the ventricular form is more serious and a life-threatening condition. The R-R interval in supraventricular tachycardia is markedly shortened. Figure 12-10 demonstrates supraventricular tachycardia at a rate of 190 beats per minute. Other related forms of SVT include paroxysmal atrial tachycardia (PAT) and multifocal atrial tachycardia (MAT). Clinically, patients with SVT may perceive a "racing" heart rate, which may be quite distressing. At very rapid heart rates, for example, greater than 170 beats per minute, diastolic ventricular filling time is markedly reduced, which may cause hemodynamic compromise. Symptoms associated with inadequate cardiac output, such as dizziness, lightheadedness, and syncope may ensue. Some individuals with SVT remain asymptomatic, the rhythm being detected incidentally, for example, during routine pulse or telemetry monitoring.

Atrial fibrillation is the most common clinically encountered dysrhythmia; it is seen in approximately 0.4% of the general population, but in more than 6% of patients over age 80.[12] Atrial fibrillation is characterized by inconsistent, irregular R-R intervals with an absence of true P waves (see Figure 12-6, *C*). P waves may be replaced by multiple, fibrillatory F waves of varying configurations. This dysrhythmia is characterized by the presence of many impulses simultaneously, generated from multiple locations within the atria. The atria, therefore, are not pumping effectively which, in turn, may impair ventricular contraction, resulting in a reduction in cardiac output of up to 25%. This is because of the loss of the additional ventricular filling supplied by atrial contraction. Impulses do conduct through the AV junction to the ventricles; however, this occurs inconsistently and results in the irregular R-R interval. The ventricular response to atrial fibrillation is important. A rapid ventricular response, resulting in tachycardia, may cause hemodynamic compromise with associated symptoms or poor activity tolerance. Of additional clinical significance is the association between atrial fibrillation and embolic cerebrovascular accidents. Stasis of blood within the noncontracting atria may allow for thrombus formation. Figure 12-6, *C* illustrates atrial fibrillation with a "controlled" (i.e., fewer than 100 beats per minute) ventricular response. Pulse monitoring of an individual in atrial fibrillation reveals an irregular pattern.

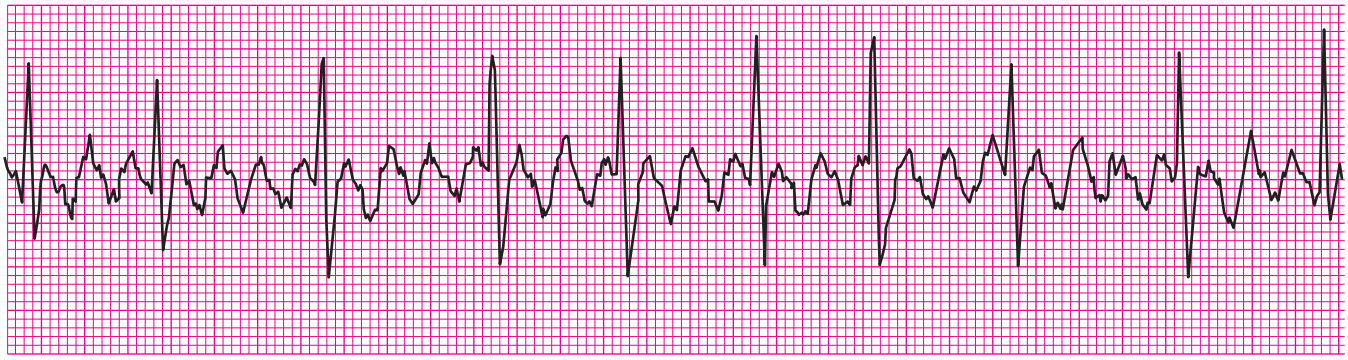

Fig. 12-11 Atrial flutter.

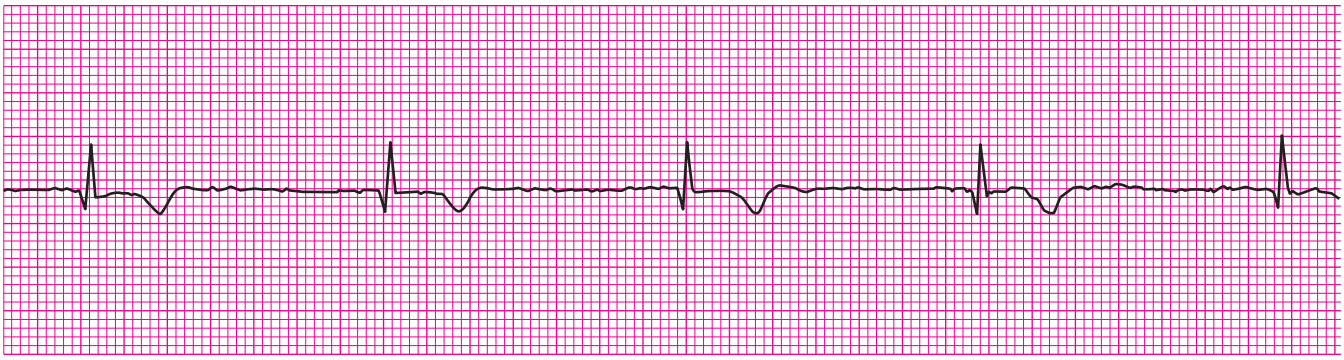

Fig. 12-12 Junctional rhythm.

Another dysrhythmia that is characterized by abnormal atrial activity is atrial flutter (Figure 12-11). In this rhythm, P waves are replaced by F waves that have a distinctive morphology often referred to as a saw-tooth or picket-fence appearance. Of clinical importance is the ratio of atrial to ventricular conduction and whether or not the patient is hemodynamically stable.[4,11]

Because the intrinsic rate of spontaneous depolarization of the AV node is less than that of the SA node, spontaneous AV node depolarization is normally prevented. However, in the absence of an atrial impulse, the AV node depolarizes spontaneously and generates an impulse that then is conducted to the ventricles. Thus in junctional rhythm or nodal rhythm (Figure 12-12), the QRS complex is not preceded by a P wave. The AV node may generate an isolated "escape" beat, or it may take over as the heart's pacemaker. Sustained nodal or junctional rhythm is usually between 40 and 60 beats per minute, corresponding with the inherent rate of spontaneous AV node depolarization.

Ventricular Dysrhythmias

An ectopic pacemaker below the atria and outside the normal conduction system, such as a region in the ventricular myocardium, may give rise to a ventricular dysrhythmia. Ventricular dysrhythmias may be distinguished from supraventricular dysrhythmias in that the QRS duration of a ventricular dysrhythmia is longer than the normal 0.12 second. The appearance of ventricular dysrhythmias may be characterized as being "wide and weird." It is important to point out that not all rhythms with a long QRS result from impulse generation within the ventricles. A disturbance in impulse conduction through the ventricles can also lead to a long QRS.

The reason for the widening of the QRS complex resulting from ventricular impulse conduction disturbance or impulse generation is apparent when one considers the normal conduction of a sinus impulse within the ventricles. An impulse normally is rapidly conducted to ventricular myocardium via the Purkinje fibers. This ensures that the impulse reaches all regions of the ventricular myocardium in a timely fashion, with subsequent coordinated depolarization and contraction. Within the ventricular myocardium itself, however, propagation of the depolarization wave proceeds more slowly as a result of the syncytial arrangement of myocardial cells.

An impulse generated within the ventricles, outside the normal conduction pathways, initially depolarizes surrounding local myocardium. The depolarization wave then spreads outward from that focus, but it is propagated at a slower velocity. Ventricular contraction, in this case, is not coordinated; some regions contract well before the depolarization wave reaches regions remote from the ectopic focus. It follows that the ventricular ejection of blood is reduced during an ectopic beat (Figure 12-13). An ECG rhythm (Figure 12-13, bottom) is recorded simultaneously with the record of arterial blood pressure monitoring (top). The appearance of the wide and weird complex results in significant diminution of the corresponding arterial pressure wave. Ventricular dysrhythmias are strongly associated with serious heart disease, but it is often not clear whether the dysrhythmia is the cause or the result of the heart condition.[13]

The most common form of ventricular dysrhythmia is a premature ventricular complex (PVC). In Figure 12-13 the

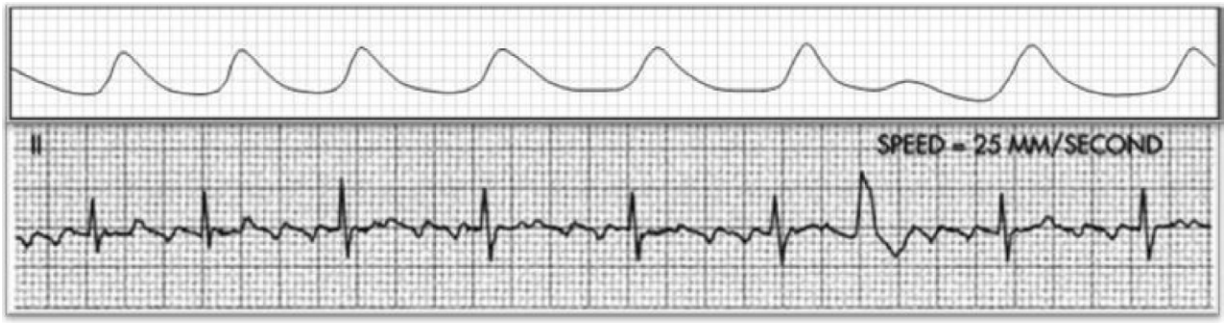

Fig. 12-13 Diminished arterial pressure wave following a PVC.

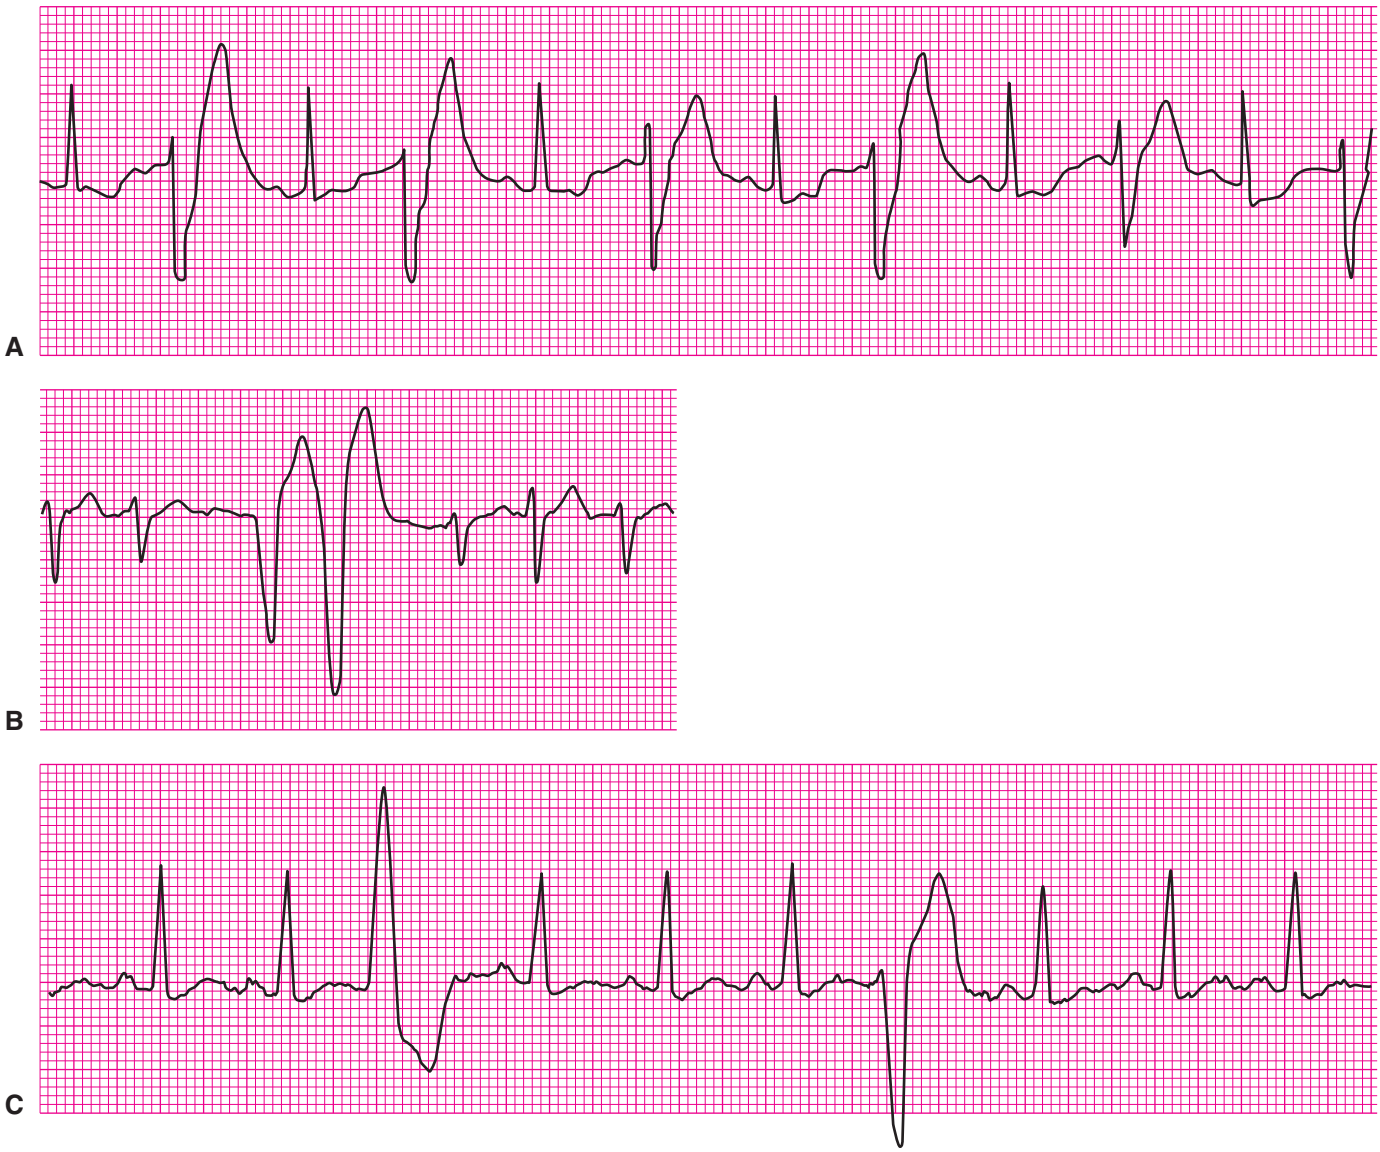

Fig. 12-14 PVC patterns. **A,** Ventricular bigeminy. **B,** Ventricular couplet. **C,** Multifocal PVCs.

QRS complex appears early, interrupting the established rhythm. An electrical pause often follows a PVC, after which the established rhythm resumes. Clinically, a PVC may be perceived by a patient as a skipped beat or a palpitation. If a PVC occurs during pulse monitoring, the examiner will likely sense a skipped, or irregular, beat.

PVCs sometimes happen in patterns, occurring at regular intervals (Figure 12-14). A PVC occurs in ventricular bigeminy on every second beat (Figure 12-14, *A*), in ventricular trigeminy on every third beat, and in ventricular quadrigeminy on every fourth beat. With these rhythms, a regularly irregular pattern may be noted during pulse monitoring.

PVCs may also occur twice in succession as a ventricular couplet, as seen in Figure 12-14, *B*.

PVCs that originate from more than one ectopic focus are termed multifocal PVCs. In this circumstance, the waveforms will have different morphologies according to the locations of the ectopic foci. Remember that the positive or negative deflection of the waveform depends on the direction of depolarization, as viewed by the lead used for monitoring. In Figure 12-14, *C*, the first PVC shown has an initial positive deflection, whereas the second PVC seen has an initial negative deflection. Each of these PVCs comes from a different ectopic focus.

The physical therapist's decision-making process in response to observation of ventricular ectopic beats is complex and may not be grasped easily by the entry-level practitioner. Factors such as the presence or absence of symptoms, the acuity of the patient, and whether the rhythm is a new finding all influence a clinical response. The presence of a pattern such as bigeminy, couplets, or a multifocal pattern is also considered. Further elucidation of clinical responses to most dysrhythmias is beyond the scope of this chapter; however, some dysrhythmias demand an immediate response once they have been observed.

Ventricular tachycardia (V-tach, or VT) (Figure 12-15) is defined as three or more consecutive PVCs at a rate greater than 100 beats per minute.[14,15] This is a serious and potentially lethal dysrhythmia that requires that emergency measures be undertaken. During V-tach all complexes are ventricular in origin. V-tach sometimes occurs in runs of three or more ectopic complexes followed by reversion to the baseline rhythm, or it may be sustained. Effective circulation may be preserved, or it may be seriously compromised or absent in sustained V-tach. A patient may be asymptomatic, particularly if only a brief run of V-tach was experienced. If VT is sustained, the patient may be asymptomatic, symptomatic, or unconscious and pulseless. The physical therapist's response depends on the rhythm (regardless of whether it is sustained) and on whether the patient is symptomatic or conscious. Clinical responses range from cessation of activity, ongoing patient monitoring, and immediate notification of a physician to a full code.

Ventricular fibrillation (V-fib) is a lethal dysrhythmia accompanied by immediate loss of consciousness and loss of circulation (i.e., cardiac arrest). It is characterized by disorganized, simultaneous firing of multiple, ectopic ventricular foci and there is no organized rhythm (Figure 12-16). Effective ventricular contraction ceases and cardiopulmonary resuscitation is indicated until defibrillation is available. Death follows unless defibrillation with an automated external defibrillator (AED) or other device successfully restores an effective rhythm. Conditions that render the myocardium vulnerable to ventricular fibrillation include V-tach, myocardial ischemia or infarction, dilation of the heart, hyperkalemia, and electric shock.[3]

If not successfully treated, V-fib may further degenerate into asystole, which indicates complete absence of ventricular electrical activity (see Figure 12-16). Asystole may also occur as a primary event. This is known colloquially as flat-line rhythm. Like ventricular fibrillation, asystole requires that cardiopulmonary resuscitation begin immediately to save the patient's life.

Care must be taken to distinguish an apparent lethal dysrhythmia from lead disconnection or movement artifact. Unwary therapists have hastily summoned help upon

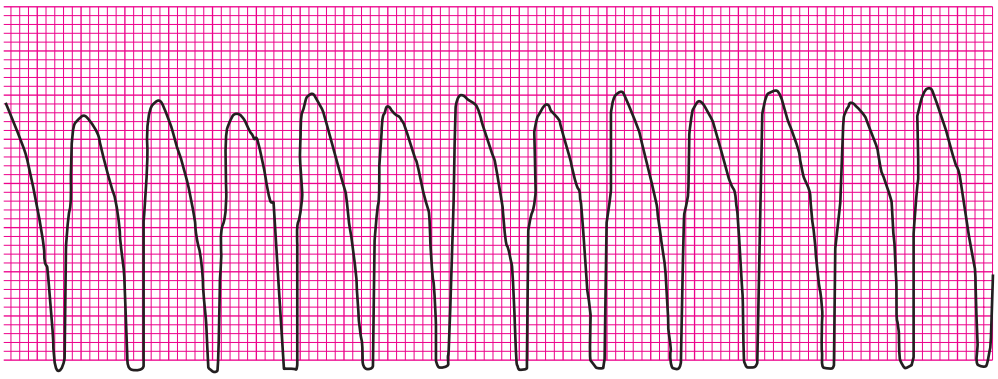

Fig. 12-15 Ventricular tachycardia.

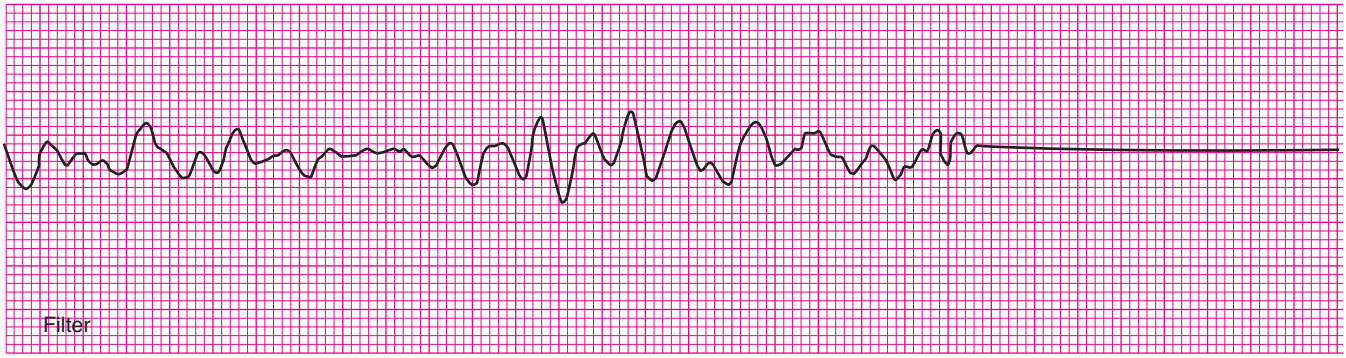

Fig. 12-16 Ventricular fibrillation degenerating into asystole.

observing V-fib or asystole, only to feel foolish when a lead is reattached to the patient and normal rhythm is restored. These dysrhythmias are always accompanied by loss of consciousness and pulse; therefore, a clinician should assess the patient before taking action. Similarly, during activity or exercise, movement artifact may easily be mistaken for V-tach. By assessing the patient and asking him or her to hold still, the issue may be quickly resolved.

Conduction Blocks

Conduction blocks are another type of ECG abnormality with which physical therapists should be familiar. The propagation of a cardiac impulse may be inhibited or terminated along the conduction pathway. Blockage can occur at the sinus node, between the atria and ventricles, or within the ventricular conduction system. Sinus block occurs if the impulse cannot propagate beyond the sinus node. In this case, the AV junction usually takes over as the pacemaker, and a junctional rhythm is seen with the absence of P waves.

More common are the AV blocks (Figure 12-17). They are ranked as first-, second-, or third-degree, depending on the extent of delay or obstruction of the cardiac impulse between the atria and ventricles. First-degree AV block is characterized by a prolongation of the P-R interval beyond its normal 0.2 second (Figure 12-17, *A*). Remember that the P-R interval is measured from the *beginning* of the P wave to the *beginning* of the QRS complex. Each impulse is delayed between the atria and ventricles, but each eventually reaches the ventricular conduction system, resulting in a normal QRS complex. Thus for each P wave, there is a QRS complex; therefore the conduction ratio is 1 : 1.

Second-degree AV block takes two forms, although in each form there are some sinus impulses that are not conducted to the ventricles. In second-degree block Mobitz type 1, also known as Wenckebach periodicity or block, the P-R interval lengthens progressively until a P wave fails to conduct to the ventricles (Figure 12-17, *B1*). Notice how the first three P-R intervals lengthen until, after the fourth P wave, a QRS complex fails to appear. The cycle then repeats itself. Second-degree block Mobitz type 2 (Figure 12-17, *B2*) is characterized by a fixed P-R interval with a "dropped" QRS following every second, third, or fourth P wave. The conduction ratio in Figure 12-17, *B2* is 3 : 1, or three P waves for each QRS complex. Both first- and second-degree AV blocks are considered to be incomplete heart blocks.

Third-degree AV block, or complete heart block, is also known as AV dissociation. In this rhythm, P waves are present, but there is no relationship between P waves and QRS complexes. Typically, a longer strip of rhythm is required to make this diagnosis. P waves may be superimposed on QRS complexes, but none of the sinus impulses are conducted to the ventricles; the atria and ventricles are contracting independently of each other. In the absence of clinical intervention such as artificial pacing (Figure 12-17, *C*), ventricular depolarization is initiated by a junctional or ventricular pacemaker.

Clinically, AV blocks range in severity from benign, as is usually the case with first-degree AV block, to potentially lethal. Whether hemodynamic compromise occurs depends on the extent of impairment of cardiac output caused by too slow a rate of ventricular contraction.[4] Slow rates of ventricular contraction may cause lightheadedness or syncope. In most cases of third-degree block, treatment now includes the implantation of an artificial pacemaker. In Figure 12-17, C, the needle-like spikes indicate that an artificial pacemaker is depolarizing the ventricles at a rate of 60 beats per minute.

Myocardial Ischemia or Infarction

The ECG provides much more information than that gleaned from dysrhythmia analysis. Because physical therapists often treat patients with coronary heart disease, information regarding myocardial ischemia or infarction (MI) is also of interest. Although physical therapists do not medically diagnose myocardial ischemia or MI, they should have a working knowledge of its electrocardiographic evidence and the consequences of ischemia. During myocardial ischemia, blood flow to a portion of myocardium is compromised, resulting in alteration of myocardial metabolism. In MI, a portion of myocardium has died, but an adjacent zone of ischemic myocardial cells endures. These ischemic cells may remain leaky and partially depolarized. A persistent current flows from the injured regions to the healthy regions (that are fully polarized), resulting in a current of injury, which is seen as a shift in the S-T segment above or below the isoelectric line (Figure 12-18).[3,8] S-T segment shifts have significant diagnostic value. For example, S-T segment elevation (Figure 12-18, *A*) is associated with transmural MI, whereas S-T segment depression (Figure 12-18, *B*) is associated with nontransmural or subendocardial MI. Also, the onset of S-T segment depression during activity is often considered diagnostic of myocardial ischemia.[12,16] Figure 12-18, *B* is an example of exercise-induced S-T segment depression observed in one lead during exercise.

The following is a brief discussion of other abnormalities of the ECG observed in coronary artery disease (CAD). A prominent, pathological Q wave is indicative of a transmural MI.[8,12] Indeed, non-Q is synonymous with nontransmural, in terms of MI. In addition, the presence of a prominent Q wave (Figure 12-19) does not distinguish between an old and an acute event. Figure 12-20 shows an algorithm for the classification of ischemia and MI based on the ECG.[16]

The T wave itself may also undergo changes during myocardial ischemia or MI. During ischemia, for example, the T wave may invert as a result of prolongation of repolarization.[3] Similarly, during MI, changes in the T wave may evolve with the infarct, at first becoming indistinguishable within an elevated S-T segment, then inverting, then perhaps reverting to the original configuration after the passage of time. Although ST segment changes and the presence of a Q wave are compelling indicators for the diagnosis of ischemia or MI, it must be kept in mind that they are neither 100% sensitive nor 100% specific.

Summary

Understanding the significance of a normal ECG and abnormal tracing is fundamental to contemporary physical therapy practice. Changes in cardiac rhythm can occur during activity and exercise, as well as at rest. The physical therapist needs to understand the factors that alter ECG rhythm (pathological, such as ischemia and/or impaired cardiac neural conduction system, and nonpathological, such as stress and coffee) and how the capacity to respond to physical activity and exercise can be altered. Optimal electromechanical coupling within the myocardium helps ensure that cardiac output is appropriate to supply the working muscles and tissues with the oxygen they require. Also, such knowledge informs the physical therapist about monitoring precautions and the level of safety that needs to be observed.

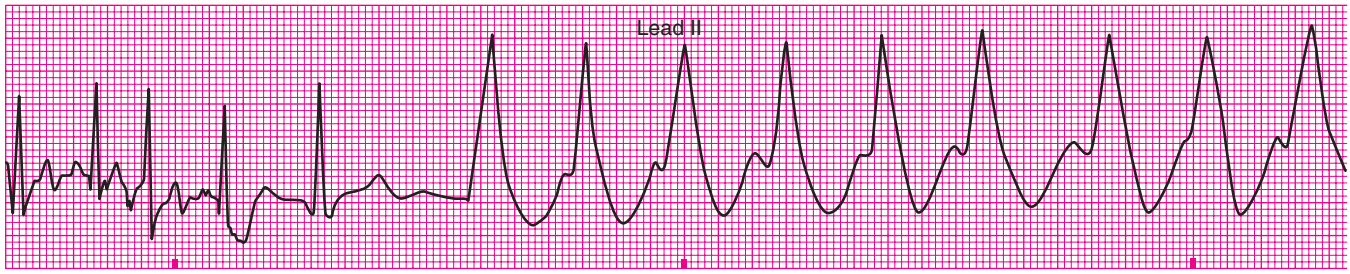

Fig. 12-21 ECG tracing for Case Study 1.

Cases Studies

Case Study 1

An 81-year-old man is referred to physical therapy 2 days after angioplasty for treatment of coronary heart disease and blockages in the left circumflex and diagonal arteries. The patient has had an uncomplicated course and no cardiac arrhythmias since surgery. He is evaluated in the physical therapy gym and given a submaximal predictive treadmill test with electrocardiogram monitoring. The test consists of walking a 5% grade at 3 mph for 5 minutes. His ECG is normal at rest, but at 4 minutes of ambulation he complains of shortness of breath and requests that the test be stopped. The ECG in the last 6 seconds of ambulation is shown below (Figure 12-21). Answer the questions related to these findings. The answers can be found after the Review Questions.

1. Identify this dysrhythmia.
2. What are the hemodynamic and functional consequences of this dysrhythmia?
3. What action should be taken by the evaluating physical therapist?

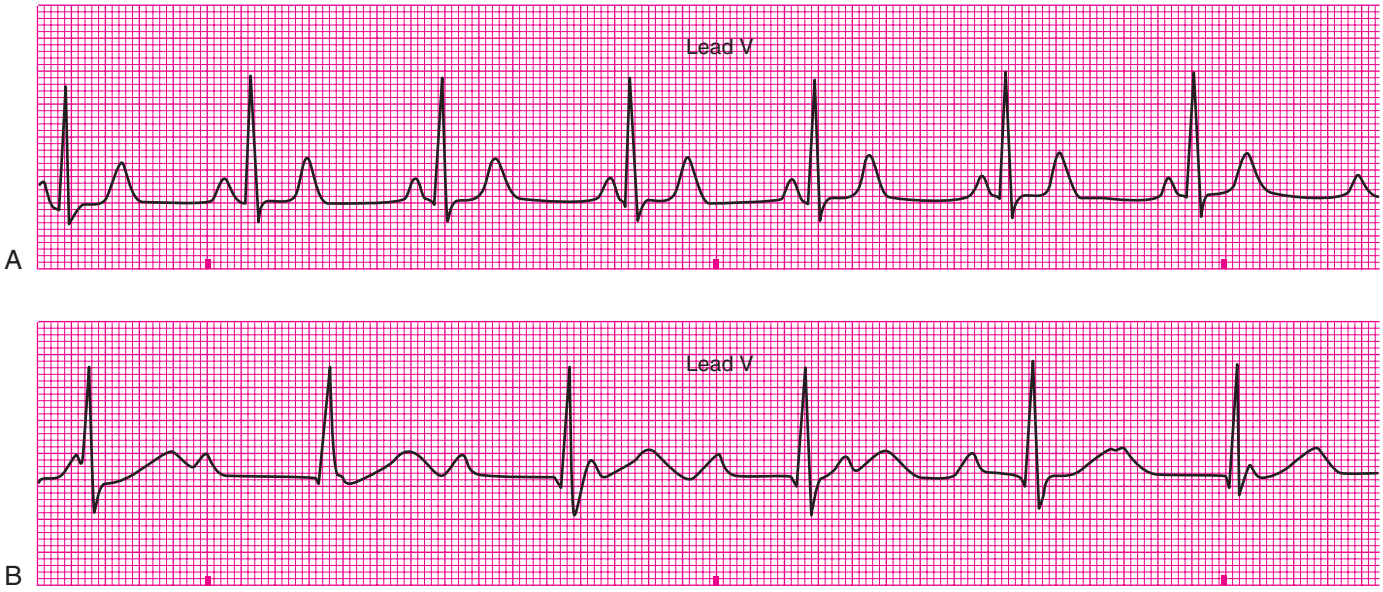

Fig. 12-22 ECG tracing for Case Study 2. **A,** Normal ECG. **B,** Typical dysrhythmia during 24-hour Holter monitoring.

Case Study 2

A 20-year-old basketball player is referred to a sports medicine clinic for a medical examination because of a knee injury. The physical examination shows mild tenderness and edema of the right knee but no other medical problems. During the examination by the physician, the athlete confides that he often experiences dizziness throughout the day. The physician performs a single-lead electrocardiogram and exercise test at that time. The test shows sinus bradycardia at rest and a normal response to exercise (Figure 12-22, *A*). The patient is sent home with a Holter monitor (a device that records an ECG continuously over a 24-hour period). Analysis of the recording reveals that the pattern in Figure 12-22, *B,* is occurring sporadically approximately 25% of the time.

1. Identify this dysrhythmia and determine the patient's heart rate (3-second intervals are marked on the strip).
2. What are the possible hemodynamic consequences when this dysrhythmia occurs, and how could it lead to the patient's complaint of dizziness?

Review Questions

1. How may the following dysrhythmias be perceived by a clinician without the benefit of ECG monitoring? How may they be perceived by a patient?
   Atrial fibrillation
   Supraventricular tachycardia
   Premature ventricular contractions
   Third-degree AV block
   Ventricular fibrillation
2. What determines the clinical significance of a dysrhythmia?
3. What property of the SA node allows it to pace the heart? Under what conditions do other portions of the conduction system act as pacemakers?
4. Does an impulse originating within the ventricular myocardium generate an effective myocardial contraction? If not, why not?
5. Why is ECG monitoring indicated after myocardial infarction?
6. What event is represented by each of the following:
   P wave
   QRS complex
   T wave
   U wave
7. What is the possible clinical significance of S-T segment depression? Of S-T segment elevation? What symptoms might be anticipated in the presence of those conditions?

Answers to Case Study 1:

The ECG shows the beginning of a run of ventricular tachycardia with a rate of approximately 100 beats per minute. The consequences of this dysrhythmia range from asymptomatic to signs and symptoms of angina and acute heart failure to loss of consciousness and death. The physical therapist should help the patient to lie down as quickly, but as safely, as possible in a supine position and continue to observe and monitor him. Depending on the patient's symptoms and whether the V-tach is sustained, the therapist should either notify the physician immediately and discuss the course of action or call a code.

Answers to Case Study 2:

Careful inspection of panel B in Figure 12-22 reveals that there is complete dissociation of the ventricular rhythm from the atrial rhythm, indicating third-degree or complete heart block. The rhythm strip shows that a regular atrial pattern (P waves) is superimposed on a regular ventricular rhythm (QRS complexes), but the QRS complexes do not follow the P waves. The heart rate is the ventricular rate and therefore approximately 40 beats per minute. Third-degree heart block results in asynchrony between the atrial ejection and the ventricular filling. In addition, the ventricular rate is typically very low and the combined effects of decreased filling and low heart rate may cause decreased blood pressure. The resulting hypotension, particularly during changes in position or movement, may lead to dizziness.

Summary 179
Review Questions 180
References 180

The purpose of this chapter is to describe the rationale for multisystem assessment in the patient managed for cardiovascular and pulmonary dysfunction and to discuss some common laboratory tests related to multisystem assessment. The bases of tests that assess the function of the following organ systems are presented: blood, pulmonary, cardiac, peripheral vascular, kidney, endocrine, liver, and immune systems. The normal ranges are given for common laboratory tests and investigations. The information in this chapter is supplemental to the elements of the cardiovascular and pulmonary assessments and related laboratory investigations described in other chapters of Part II.

The oxygen transport system affects and is affected by virtually every organ system in the body. The signs and symptoms of systemic disease can mimic other conditions, including cardiovascular and pulmonary dysfunction, which is treated by physical therapists. Therefore the physical therapist must be able to differentiate among these presentations to determine what treatment, if any, is indicated, and what treatments may be contraindicated. Knowledge of multisystem function helps to confirm a diagnosis, as well as to predict a patient's response to treatment and his or her recovery and prognosis. In addition, this information is crucial in guiding clinical decision making, that is, refining and modifying treatment prescription. These abilities have become increasingly important in this era of professional accountability and with the advent of direct patient access.

Rationale for Multisystem Assessment

The cardiovascular and pulmonary systems support cellular respiration and life. Thus every system and every cell in the body is affected by the adequacy of oxygen transport, which is dependent on cardiovascular and pulmonary function. In addition, these systems are affected by virtually every other system in the body. The cardiovascular and pulmonary physical therapist, therefore, needs thorough knowledge of multisystem function and of the interdependence of the organ systems, as well as the ability to assess multisystem function and to integrate this information into a comprehensive and progressive treatment plan.

The lungs and heart are anatomically and physiologically interdependent, and they function as a unit to transport oxygen via the peripheral circulation so as to perfuse and nourish tissues. Tissue homeostasis is dependent on the adequacy of the anatomy and physiology of the blood. The

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

adequacy of peripheral perfusion determines the adequacy of the function of all organ systems in the body. Therefore knowledge of the failure of the various organ systems can reflect impaired oxygen transport or may identify a threat to oxygen transport.

The elements of laboratory evaluation and testing, as well as the normal values, have been compiled from the following sources: Dean (1999)[1]; Fischbach (2004)[2]; Hall (2010)[3]; Jacobs et al (2001)[4]; Le Fever Kee (2000)[5]; Pagana and Pagana (2002)[6]; and Wallach (2000)[7].

Elements of Multisystem Assessment

Blood

Some common blood tests are listed in Table 13-1, along with their normal values.

The average blood volume consists of 5 L of blood—3 L of plasma and 2 L of cells. Plasma is the medium that suspends and transports blood cells. The complete blood count (CBC) is one of the most commonly ordered laboratory procedures. This basic screening test helps to establish the patient's diagnosis, treatment response, recovery, and prognosis. The CBC includes the red blood cell count (RBC), a variety of red blood cell indices, differential white blood cell count (WBC), hematocrit (Hct), hemoglobin (Hgb), and platelet count.

Tests of coagulation and hemostasis reflect bleeding pathology, which often involves injury of blood vessels and cells. Damage to the blood vessel wall leads to constriction, a primary mechanism of hemostasis. Circulating platelets adhere to exposed subendothelial tissues, which can predispose thrombus formation.

The fluidity of the blood is regulated by the facilitation and the inhibition of thrombin formation. When these two processes are in balance, the blood has an optimal consistency; it is neither too thick nor too thin. This allows blood to flow optimally through the circulation without unduly affecting the work of the heart. Blood vessel injury can disrupt this balance and can promote coagulation.

Disseminated intravascular coagulation (DIC) results from an imbalance between the formation and deposition of fibrin, which leads to the formation of thrombi. The continuous production of thrombin causes depletion of the coagulation factors, and bleeding results. Tests used to assess bleeding capacity include thrombin time and fibrin clotting time (partial thromboplastin time [PTT]).

Proteins (amino acids) serve as regulators of metabolism. Examining and measuring proteins provides much useful clinical information because proteins regulate many important physiological functions in the body. Plasma proteins serve as a source of nutrition for the body tissues and function as buffers when combined with hemoglobin.

Albumin, a protein formed in the liver, maintains normal water distribution in the body (colloid osmotic pressure). It transports blood constituents such as ions, pigments, bilirubin, hormones, fatty acids, enzymes, and certain drugs. Approximately 55% of total protein is albumin. The remainder is globulin, which functions in antibody formation, and other plasma proteins (fibrinogen and prothrombin) involved with coagulation.

Two other blood proteins are noteworthy. Hemoglobin A1c or glycated hemoglobin provides a measure of plasma glucose concentration over time, and values over 6% has become a marker for type 2 diabetes mellitus. High values of hemoglobin A1c are associated with complications of diabetes. The C reactive protein is a marker of inflammation. In acute infection it rises markedly. However, perhaps more importantly, this protein is elevated in people with risk factors of or manifestations of chronic lifestyle-related conditions such as ischemic heart disease. The western lifestyle has been described as pro-inflammatory in that lifestyle behaviors such as smoking, high fat diet, inactivity, and stress common in high-income countries such as western countries, contribute to a systemic low-grade inflammatory state. Measures of these proteins are important to the physical therapist to evaluate outcomes of health education and exercise.

Lactic acid, a product of carbohydrate metabolism, is produced when cells receive inadequate oxygen in relation to oxygen demand (anaerobic metabolism). When the production of lactic acid exceeds its removal from the blood by the liver, lactic acid accumulates in the blood.

Cholesterol is used in the production of steroid hormones, bile acids, and cell membranes. Cholesterol is found in muscles, red blood cells, and cell membranes. Low-density and high-density lipoproteins (LDLs and HDLs) transport cholesterol in the blood. High levels of LDLs and low levels of HDLs are associated with atherosclerosis and increased risk for coronary artery disease (CAD).

Electrolyte assessment is based on the electrolyte constituents of a blood or urine sample. Although present in minute quantities, electrolytes are essential in maintaining normal cellular function and homeostasis. The electrolytes that are routinely studied are sodium, potassium, chloride, calcium, phosphorus, and magnesium.

Pulmonary Function

See Chapters 9 and 15 for a detailed description of the assessment of the pulmonary system and its function.

Cardiac Function

A detailed description of the assessment of the cardiac system and its function appears in Chapters 11, 12, and 15.

Peripheral Vascular Function

Assessment of the peripheral vascular circulation is essential to provide information regarding central and peripheral hemodynamic status as well as peripheral tissue perfusion. This assessment is crucial in establishing the integrity of the patient's hemodynamic status at rest and during the physical and exercise stress that is associated with most physical therapy treatments. Laboratory tests include segmental blood pressure studies, skin temperature studies, pulse wave analysis, Doppler ultrasound studies, and arteriography. The physical examination corroborates the results of the laboratory investigations and includes the patient's history; inspection of the integrity of the peripheral circulation, particularly to the extremities; palpation to assess peripheral pulses; and auscultation, which can be helpful in detecting bruits or areas of turbulent blood flow associated with arterial stenoses.

Table 13-1 Common Tests of Multisystem Function and Their Normal Values: Blood Tests

Test	US Unit	SI Unit
Red blood cell count (RBC)		
Men	4.4-6.2 million/μL	4.5-6.2 × 10^{12}/L
Women	4.0-5.5 million/μL	4.0-5.5 × 10^{12}/L
Hemoglobin (Hgb)		
Men	13.6-18 g/dL	8.44-11.17 mmol/L
Women	12-16 g/dL	7.45-9.9 mmol/L
Hemoglobin A1c	<6%	
Hematocrit (Hct)		
Men	39%-51%	0.39-0.59
Women	35%-47%	0.35-0.47
Platelet count	150,000-400,000/mm^3	150-400 × 10^9/L
Prothrombin time (PT)	10-15 seconds	10-15 seconds
Partial thromboplastin time (PTT)	<70 seconds	<70 seconds
White blood cell count (WBCC)*		
Men	4500-11,000/μL	4.5 × 11.0 × 10^9/L
Women	4500-11,000/μL	4.5 × 11.0 × 10^9/L
Erythrocyte sedimentation rate (ESR)		
Men	15-20 mm/hr	
Women	20-30 mm/hr	
Proteins		
Albumin	3.5-5.0 g/dL	35-50 g/L
$Alpha_1$ globulin	0.1-0.4 g/dL	1.0-4.0 g/L
$Alpha_2$ globulin	5.0-10 g/dL	0.5-1.0 g/L
Beta globulin	7.0-12 g/dL	0.7-1-2 g/L
Gamma globulin	8.0-16 g/dL	0.8-1.6 g/L
Fibrinogen	200-400 mg/dL	2.2-4.0 g/L
Lactate		
Venous	0.5-2.2 mEq/L	0.5-2.2 mmol/L
Arterial	0.5-1.6 mEq/L	0.5-1.6 mmol/L
Electrolytes (blood)		
Sodium (Na^+)	136-145 mEq/L	136-145 mmol/L
Potassium (K^+)	3.5-5.3 mEq/L	3.5-5.0 mmol/L
Calcium (Ca^{2+})†		
Total	8.2-10.7 mg/dL	2.10-2.70 mmol/L
Ionized	4.45-5.30 mg /dL	1.10-1.30 mmol/L
Chloride (Cl^-)	95-108 mEq/L	95-108 mmol/L
Cholesterol total		
Men ≤40 years	124-270 mg/dL	3.21-699 mmol/L
Men >40 years	151-277 mg/dL	3.91-7.17 mmol/L
Women ≤40 years	122-242 mg/dL	3.16-6.27 mmol/L
Women >40 years	147-303 mg/dL	3.81-7.85 mmol/L
Creatine kinase (total)		
Men	20-200 international units/L	20-200 international units/L
Women	20-180 international units/L	20-180 international units/L
C reactive protein	Normal: <0.8 mg/L Low risk: <1.00 mg/L Average risk: 1.00-3.00 mg/L High risk: >3.00 mg/L	

*Differential WBCC includes counts of neutrophils, eosinophils, basophils, lymphocytes, and monocytes.

†Norm 46%-56% of total serum.

Normal values may vary depending on the laboratory performing the measurement. Within-subject variation occurs as a result of age and variations in the pretest standardization procedures.

Some common tests of peripheral vascular function are listed in Table 13-2, along with their normal values.

Kidney Function

Urine consists of the end products of cellular metabolism and is produced by the large volumes of blood (approximately 25% of the cardiac output [CO]) that flow through the kidneys. When the kidneys are compromised, death can ensue within a few days. Although fluid is lost through several routes, the kidneys are primarily responsible for processing and regulating fluid balance in the body.

Urea, the major nonprotein nitrogenous end product of protein catabolism, is measured in the blood as blood urea nitrogen (BUN). The urea is then carried to the kidneys by the blood to be excreted in the urine.

Creatinine is a byproduct in the breakdown of muscle creatine phosphate resulting from energy metabolism. The production of creatinine is constant as long as muscle mass is constant. Kidney dysfunction reduces the excretion of creatinine, resulting in increased levels of blood creatinine. Analysis of urine for creatinine provides an index of kidney function.

Increased osmolality stimulates the secretion of antidiuretic hormone (ADH) that acts on renal tubules. This results in the reabsorption of water, more concentrated urine, and less concentrated serum.

Some common tests of kidney function are listed in Table 13-3, along with their normal values.

Table 13-2 Common Tests of Multisystem Function and Their Normal Values: Tests of Peripheral Vascular Function

Test	Normal Values
Skin temperature	Ranges from ambient temperature to 30° C (86° F)
Ankle systolic pressures	97% of brachial pressure
Peripheral pulses	Apex heart rate
Capillary filling after quick pressure over the nail bed	Instantaneous filling

Table 13-3 Common Tests of Multisystem Function and Their Normal Values: Tests of Kidney Function

Test	US Unit	SI Unit
Blood urea nitrogen (BUN)	5-20 mg/dL	1.8-7.1 mmol/L
Creatinine (urine)		
Men	<40 mg/24 hr	0-307 µmol/day
Women	<80 mg/24 hr	0-615 µmol/day

Normal values may vary depending on the laboratory performing the measurement. Within-subject variation occurs because of age and variations in the pretest standardization procedures.

Endocrine Function

Endocrine glands are responsible for producing the substances and neuromediators responsible for maintaining homeostasis and enabling the body to adapt when physically and psychologically challenged or perturbed from a resting state. The key endocrine glands are the pancreas, the thyroid gland, and the adrenal glands. Endocrine glands regulate metabolism and are responsible for increasing blood flow and pressure and for reducing vascular resistance when metabolic demands increase.

Some common tests of endocrine function are listed in Table 13-4, along with their normal values.

Pancreatic Function and Insulin Production

Insulin, a hormone produced in the pancreas by the beta cells of the islets of Langerhans, regulates the metabolism of carbohydrates (as do the liver, adipose tissues, muscles, and other target cells) and is responsible for maintaining a constant level of blood glucose. The rate of insulin secretion is determined primarily by the level of blood glucose perfusing the pancreas and also by hormonal status, the autonomic nervous system, nutritional status, smoking, restricted mobility, physical stress such as traumatic insult to the body during illness and injury, and pharmacological agents.

Table 13-4 Common Tests of Multisystem Functions and Their Normal Values: Tests of Endocrine Function

Test	US Unit	SI Unit
PANCREATIC FUNCTION		
Glucose tolerance test		
Fasting glucose	<110 mg/dL	<6.1 mmol/L
At 2 hr glucose	<140 mg/dL	<7.8 mmol/L
Insulin		
12 hr fasting	<17 international units/mL or 110 mg/L	117 pmol/L
Amylase		
Blood level	30-110 units/L	30-110 units/L
THYROID FUNCTION		
Total thyroxine (T_4)	4.5-12.0 mcg/dL	58.5-155 nmol/L
Total triiodothyronine (T_3)	80-230 mcg/dL	1.2-3.5 nmol/L
ADRENAL FUNCTION		
Epinephrine	0-140 pg/mL	0-762 pmol/L
Norepinephrine	200-1700 pg/mL	1088-9256 pmol/L
Cortisol		
Morning	5-28 mcg/dL	138-773 nmol/L
Evening	2-14 mcg/dL	55-386 nmol/L

Normal values may vary depending on the laboratory performing the measurement. Within-subject variation is dependent on age and variations in the pretest standardization procedures.

Amylase is an enzyme produced in the salivary glands, pancreas, and liver; it converts starch to sugar. Inflammation of the pancreas or salivary glands results in more of the enzyme entering the blood. The amylase test is used to diagnose and monitor the treatment of acute pancreatitis.

Thyroid

The function of the thyroid gland is to take iodine from the circulating blood, combine it with amino acid tyrosine, and convert it into the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). Thyroid hormones have a profound effect on metabolic rate. Increased metabolism causes more rapid use of oxygen than normal and causes greater quantities of metabolic end products to be released from the tissues. These effects cause vasodilation in most of the body tissues, thus increasing blood flow. An increase in the thyroid hormones increases cardiac output, heart rate, force of cardiac contraction, blood volume, arterial blood pressure, oxygen consumption, and carbon dioxide (CO_2) production; hence there is an increase in the rate and depth of breathing and increased appetite, food intake, and gastrointestinal motility. The thyroid gland also stores T_3 and T_4 until they are released into the blood stream under the influence of thyroid-stimulating hormone (TSH) from the pituitary gland.

Adrenal Function

Catecholamines, epinephrine, and norepinephrine are produced by the adrenal medulla of the adrenal glands. Urine samples are used to test for these important vasoactive neurotransmitters in the investigation of various disorders. In addition to their vasoactive properties, the catecholamines are essential in stimulating the sympathetic response in the fight-or-flight mechanism.

Cortisol is produced by the adrenal cortex of the adrenal glands and is involved with metabolism of carbohydrate, protein, and fat. In addition, it inhibits the action of insulin and thus the uptake of glucose by the cells. The normal secretion of cortisol varies diurnally (i.e., it is high in the morning and low in the evening). In addition, cortisol is a stress hormone.

Liver Function

Liver function is especially important in that dysfunction of this organ can be life-threatening. The liver has a primary role in carbohydrate and protein metabolism; it produces bile and is responsible for detoxification of the blood. Its function is assessed by tests of liver enzymes such as amylase and alkaline phosphatase.

Some common tests of liver function are listed in Table 13-5, along with their normal values.

Table 13-5 Common Tests of Multisystem Function and Their Normal Values: Tests of Liver Function

Test	US Units	SI Units
Alkaline phosphatase	44-147 units/L	44-147 units/L
Bilirubin		
Direct	0.0-0.3 mg/dL	1.7-5.1 μmol/L
Indirect	0.1-1-0 mg/dL	1.7-17.1 μmol/L

Normal values may vary depending on the laboratory performing the measurement. Within-subject variation occurs as a result of age and variations in the pretest standardization procedures.

Table 13-6 Common Tests of Multisystem Function and Their Normal Values: Tests of Immunological Function

	Differential White Blood Cell Count	
	Absolute Value (cells/μL)	Relative Value (by %)
Neutrophils	2500-8000	55-70
Lymphocytes	1000-4000	20-40
Monocytes	100-700	2-8
Eosinophils	50-500	1-4
Basophils	25-100	0.5-1

Normal values may vary depending on the laboratory performing the measurement. Within-subject variation occurs from age and variations in the pretest standardization procedures.

Immunological Function

Immunological function is dependent on the adequacy of the function of several tissues and organs—namely, bone marrow, the thymus gland, the lymph nodes, and the vessels of the lymphatic system, spleen, tonsils, and intestinal lymphoid tissue. Immunological function can break down if insufficient protective immune factors are produced, or if the system is overwhelmed by an invading organism for which the body has inappropriate or insufficient resistance.

Some common tests of immunological function are listed in Table 13-6, along with their normal values. Specific detailed accounts of immmunodiagnostic studies and tests for autoimmune deficiencies are beyond the scope of this chapter but can be reviewed in Fischbach (2004)[2] and Le Fever Kee (2000)[5].

Summary

This chapter describes the rationale for multisystem assessment in the patient being managed for cardiovascular and pulmonary dysfunction and discusses some common tests of multisystem function. The cardiovascular and pulmonary systems affect, and are affected by, virtually every other organ system in the body. Thus primary cardiovascular and pulmonary dysfunction can lead to complications in many organ systems and vice versa; dysfunction of other organ systems can have cardiovascular and pulmonary manifestations. In addition, the signs and symptoms of systemic conditions can mimic other conditions treated by physical therapists. Therefore the physical therapist must be able to differentiate among these presentations in order to determine whether a pathology will respond to management by physical therapy, what treatments are not indicated, and what treatments may be contraindicated. Multisystem monitoring provides the fundamental

information needed to guide clinical decision making, that is, to refine and progress the treatment prescription. These abilities are essential in contemporary physical therapy practice.

Review Questions

For each of the following types of tests assessing organ system function, (a) describe the test(s) and (b) explain the clinical implications of high or low values for the physical therapist.

1. Describe blood composition tests.
2. Describe pulmonary function tests.
3. Describe tests of heart function.
4. Describe tests of peripheral vascular function.
5. Describe tests of kidney function.
6. Describe tests of endocrine function.
7. Describe tests of liver function.
8. Describe tests of immune function.

The medical workup of a patient with cardiac or pulmonary disease uses many tools. The patient interview, physical examination, chest x-ray, and electrocardiogram (ECG) can provide adequate information to make a diagnosis. However, when the diagnosis remains unclear, special tests that use more complex technology are required. These special tests may be invasive or noninvasive. Current clinical practice guidelines recommend that noninvasive tests be performed before invasive tests such as angiography.[1] Nuclear medicine offers a variety of noninvasive tests for evaluation of cardiac and pulmonary function. Echocardiography, which is particularly useful in children, is another noninvasive method that provides information about the cardiovascular system, including valve function, ventricular performance, and estimation of filling pressures. In comparison with cardiovascular tests, special tests of the respiratory system are less commonly required in the initial diagnosis and treatment of disease. The generally high-quality information obtained from standard x-ray examination in combination with the patient's respiratory symptoms, pulmonary function tests, and the results of the physical examination is usually sufficient, making special tests unnecessary.[2-4]

However, in some cases, an invasive test is still the best choice. Pulmonary and cardiac angiography is not without risk; however, for evaluating blood flow in the heart and lungs, as well as determining cardiac anatomy and direct volume and pressure measures, it is without equal. Another invasive test that is often warranted is transesophageal echocardiography.

Following the initial assessment of the problem, these same special tests may be used to assist in the determination of appropriate therapy and to evaluate prognosis and response to treatment. The noninvasive tests, in particular, are important in determining ongoing surgical, interventional, or medical therapy. Physical therapists must have a strong understanding of all special tests (invasive and noninvasive) and

how they are used in making a differential diagnosis and determining treatment.

Various factors are involved in the decision of which special tests may be beneficial for a patient. These tests afford different benefits to patients in terms of diagnostic and prognostic accuracy (Table 14-1). Radiation exposure is an additional factor in selection of tests. These tests have helped to clarify our understanding of the physiology and pathophysiology of the cardiovascular and pulmonary system. Therapists need to understand the pathophysiological basis for a patient's movement dysfunctions to select the most appropriate treatment strategies. Many special tests can and are being used in research to evaluate treatment interventions. For example, radiolabeled aerosols are used to evaluate mucociliary clearance, providing a method to evaluate the effectiveness of pulmonary hygiene techniques.[5] Clinically, physical therapists need to use information from the tests to develop a framework for predicting how the patient may respond to a physical therapy intervention. For example, nuclear imaging can provide information about left ventricular ejection fraction. This information helps the therapist determine whether the patient should be stratified into high-risk or low-risk categories. Monitoring of an exercise session may depend on the risk level, and the therapist's interpretation of the patient's response to treatment may be affected by this information.

This chapter will review some of the special technology used to examine the cardiac and pulmonary systems. First, the general method used to acquire data will be described. Next, the type of data available from the technology will be defined, and finally, specific application to the cardiac or pulmonary system will be discussed.

Nuclear Imaging Systems

Physics of Nuclear Imaging

A general view of how nuclear imaging systems work should help the physical therapist understand some of the differences between the wide variety of tests used today. This area of medicine continues to experience rapid growth and change as technology changes the equipment used to perform the test, the radiopharmaceuticals available, and the speed at which data can be acquired and analyzed.

Radionuclide imaging allows for the noninvasive acquisition of images from a variety of body tissues. An imaging system requires three basic parts. The first requirement is a radiopharmaceutical that emits gamma radiation and is taken up by the body tissue of interest. Next, a radiation detector or camera is needed. Finally, computers are required to collect and analyze the data. Thus an image is formed based on the brightness of the tissue, which is proportional to the radiation the tissue has absorbed.[6]

Radionuclides are elements that are unstable; they gain stability by emitting particles or photons. This is called radioactive decay, and gamma radiation is released. Radionuclides are either cyclotron- or generator-produced. The cyclotron accelerates alpha-particles, deuterons, and protons to energies suitable for the production of the required radionuclide.[7] A radionuclide generator is a system of a long-lived parent radionuclide which decays to produce a daughter radionuclide. The system is constructed so that the daughter can be removed (called "milking" the generator) for patient use.[8] A generator system produces short-lived radionuclides.[7]

These elements are often attached to other substrates for transport in the body to the particular tissue of interest. The radionuclide is administered via an intravenous infusion. The elements have differing characteristics, such as energy output and half-life. Because of their varied distribution in the body tissues, they provide different information.

Detection of the radioactive energy emitted by a specific radiopharmaceutical requires a camera. When certain materials are struck by ionizing radiation, light is emitted. A scintillation detector detects this light (Figure 14-1). A gamma camera (a scintillation detector) is able to detect photons exiting the body. It uses a large, collimated crystal monitored by an array of photomultiplier tubes.[9] A collimator is a device that allows only those photons traveling in an appropriate direction to reach the crystal. There are several types of collimators: parallel-hole collimators (most common), pinhole collimators, and converging and diverging collimators. The photomultiplier tube records the amount of light from the

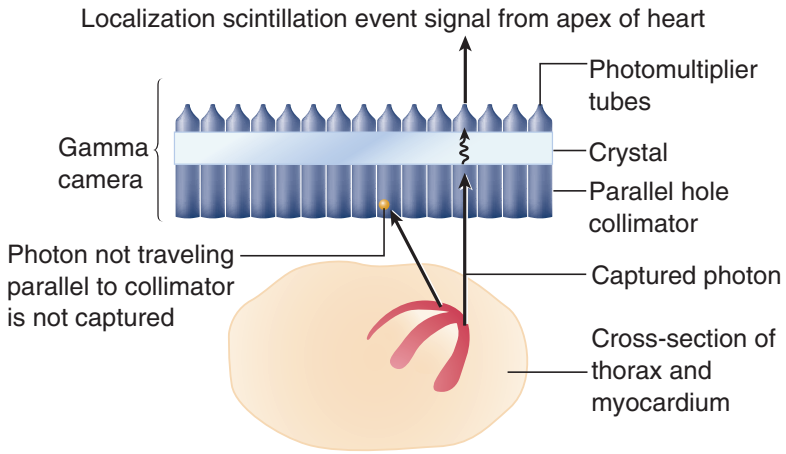

Fig. 14-1 Diagrammatic illustration of a multi-hole collimator where gamma rays admitted in line with the collimator holes are transmitted to the crystal, whereas gamma rays emitted obliquely are absorbed by the collimator septa. *(From Hendee WR, Ritenour R, editors:* Medical imaging physics, *ed 3. St. Louis, 1992, CV Mosby.)*

crystal and converts it into a voltage that is proportional to the intensity of the light.[9] The camera system is connected to a computer that stores the light images. The computer is able to derive two-dimensional images from the data. The newer software algorithms that construct the images have improved, allowing for better spatial resolution, contrast, and overall image quality.[10]

Planar Imaging

A single crystal camera produces a two dimensional or planar image. Multicrystal cameras also produce planar images but are also able to perform fast, dynamic imaging used in first pass and gated studies. Planar images are unable to reflect the depth of an image.[6] Planar imaging may be the only option available for obese patients who do not "fit" the single-photon emission computed tomography (SPECT) camera or for those who cannot remain immobile.[11]

Single-Photon Emission Computed Tomography Imaging

The most common nuclear study of myocardial perfusion is SPECT imaging.[12] Planar images or tomographs are collected by rotating the scintillation detectors (single-, dual-, or triple-head scintillation cameras) around the patient, taking images at 3-degree increments.[10] SPECT images allow for quantification of radioactivity.[6] However, attenuation artifacts (absorption of the radioactive energy by other body tissues, preventing the camera from detecting it) are greater than with planar images, particularly those images involving the inferior wall of the heart in men and the anterior wall in women, and may produce false-positive scans.[13] Quality of the images is dependent on the use of stringent quality control measures and experience of the staff. The most commonly used radionuclides are thallium-201, technetium-99m-sestamibi, and technetium-99m-tetrofosmin.[14] Image quality is also patient-dependent. Patients must be able to lie perfectly still for 15 to 20 minutes, with their hands over their heads, while data are collected. Newer systems allow for a 50% reduction in duration of the scan as well as reduced processing time.[10] Currently available systems also allow for seated positioning.[10]

Therapists should identify patients who would have difficulty with arm movements or with remaining still. For these patients, other imaging modalities such as echocardiography may be appropriate.

Positron Emission Tomography

Positron emission tomography (PET) uses positron-emitting radionuclides. The images obtained by PET can provide information regarding cellular processes in living tissue. Both cardiac and lung tissue can be quantitatively examined to obtain information on metabolism, blood perfusion, tissue viability, autonomic regulation, and other processes.[15,16] PET is valuable in delineating myocardial areas with reversible and irreversible injury, thus assessing the feasibility of revascularization, in patients with CAD or left ventricular dysfunction.[17] PET studies use short scanning times (5-35 minutes) and because of the short half-life of PET tracers, multiple scans can be repeated in a relatively short period of time.[18] Although PET scans offer superior imaging, in part due to greater correction for attenuation artifact,[18] PET's technological complexity, short-lived radio tracers, and specialized equipment have resulted in high costs and more limited clinical application.[15] However, because of increased PET use in oncology imaging, opportunities for imaging of the cardiorespiratory system are now increasing.[15,19] Current FDA-approved PET nuclides are rubidium-82 (82-Rb), 13N-ammonia (13-NH3), and fluorine-18-fluorodeoxyglucose (18F-FDG).[15]

Nuclear Tests of the Cardiovascular System

First-Pass and Gated Equilibrium Scans

In a first-pass study, data are collected on a radiolabeled bolus of blood as it passes through the cardiac chambers, which is one method of radionuclide angiography. A first-pass scan allows for clear identification of the four cardiac chambers. During first-pass studies, data are collected over several cardiac cycles. Gated equilibrium studies or multiple-uptake gated acquisition (MUGA) scans average several hundred cardiac

cycles. Each R wave of the ECG triggers the acquisition of data; thus the average cycle observed is the compilation of many cycles.[20] The quality of the image is best when the patient has a stable sinus rhythm. Patients with irregular heart rates, such as atrial fibrillation, have images of poorer quality.

Exercise Stress Studies

Many of the tests performed using radionuclides are coupled with an exercise test. A treadmill exercise test is performed, and at the peak of exercise, a tracer is injected. Shortly afterward, depending on the tracer, images are acquired. Exercise imaging enhances the identification of ischemic areas. These tests are then often compared with rest studies. Rest/stress or stress/rest protocols can be used.[14]

Pharmacological Stress Studies

Some patients are unable to exercise to an intensity sufficient to produce stress on the cardiovascular system. When patients are unable to exercise, pharmacological agents can be administered instead. For example, dipyridamole (Persantine) can be used to dilate the patient's coronary arteries; or to increase the metabolic demand of the heart, beta-agonists such as adenosine and dobutamine are most commonly used. The newest approved agent is regadenoson, a selective A2A adenosine receptor agonist. Pharmacological stress tests can be coupled with SPECT and PET nuclear imaging techniques or with echocardiography to determine regions of ischemic myocardium suggesting functionally significant blockage in the coronary artery supplying that area.

Nuclear-Derived Measurements

Data derived from radionuclide images provide information about perfusion, function, and viability. Radionuclides taken up by the myocardium provide a picture of the heart that includes wall thickness and an outline of the chamber. In radionuclide angiography, which includes first-pass and gated studies, the blood is highlighted as it passes through the chambers. Qualitative and quantitative measurements can be taken.

The most important of these measurements, the ejection fraction (right and left ventricle) is a measure of myocardial function. It is derived from quantitative counts of the ventricular area during diastole and systole:[20]

$$([\text{end-diastolic counts} - \text{end-systolic counts}] \times 100) / \text{end-diastolic counts}$$

Left ventricular ejection fraction (LVEF) has been shown to be predictive of mortality. LVEF normally ranges from 50% to 85%, whereas LVEF below 40% indicates moderate-severe congestive heart failure.[21,22] LVEF is linearly related to mortality up to 45% EF[23] and inversely related to moderate- to large-sized infarcts.[24] Right ventricular ejection fraction (RVEF) has been found to have a wide range of normal values (35% to 75%)[25] but is not as predictive of function without data about wall motion abnormalities. The strongest radionuclide predictor of outcome is the exercise LVEF. In terms of predicting outcome, multivariate analysis of clinical data, catheterization data, and radionuclide measurements have shown that the radionuclide results (exercise LVEF, resting end-diastolic volume, and change in heart rate [HR]) have the same prognostic power as the catheterization data.[26]

Another important measurement is wall motion. Quantitative and qualitative evaluation of the movement of the myocardium can be made. Wall thickness and wall movement are compared during systole and diastole. Assessments are made about akinesia (absence of wall motion), global or regional hypokinesia (reduction of wall motion), and dyskinesia (outward bulging of the wall during systole).[27] Global left ventricular function is a strong predictor of survival. It can help clinicians differentiate a weak heart from one that is stiff, thus allowing the appropriate treatment. Regional wall function, when correlated with knowledge of coronary artery anatomy, allows for the identification of potential blockages or areas of infarct. Assessing wall thickness can provide information about hypertrophy or aneurysm but is done more reliably by echocardiography.

Infarct size is an important measurement because it predicts short-term mortality. It is also important as a clinical endpoint in determining the effectiveness of reperfusion strategies and pharmacological interventions, which should result in a decrease of infarct size.[28] The size of a myocardial infarct can be estimated by using the measurements previously described (i.e., ejection fraction, end-systolic volume, and global or regional wall motion).[28] Perfusion defects of the myocardium can be measured acutely, after intervention, or during recovery.

Anatomical measurements of chamber size can be made. From these data, chamber volume can be calculated, as well as stroke volume and cardiac output (Table 14-2).

Myocardial Perfusion Imaging

Perfusion of the myocardium is a vital factor in the viability and function of the heart. Information about myocardial perfusion is used for diagnostic decisions, treatment decisions, and prognosis. Perfusion of the myocardium under rest and exercise conditions is important in the diagnosis of CAD. For those patients with left ventricular dysfunction, identifying tissue that is viable but still at risk is critical for improving long-term outcomes. The efficacy of reperfusion strategies, such as angioplasty and thrombolytic therapy, must be evaluated. Information gained from combined perfusion and metabolic studies has helped to increase the understanding of ischemic myocardium. Two types of contractile dysfunction have been delineated. Hibernating myocardium is the result of prolonged ischemia. In this case, the contractility of the muscle fiber is affected so that there may appear to be regional wall motion abnormalities. The tissue is alive but not contracting. It is theorized that this is a measure to reduce energy expenditure and ensure myocyte survival. The second condition, myocardial stunning, occurs under conditions of acute ischemia. In this case, contractile dysfunction that initially occurs during the acute ischemic episode persists for some time after perfusion has returned to normal. Both conditions are reversible. Patients demonstrating hibernating myocardium may benefit from revascularization procedures. Patients with stunned myocardium may only require supportive care until contractile function returns.[29] The type of imaging performed and the specific radiopharmaceutical used provides similar but not necessarily interchangeable imaging results and measurements.[14]

Table 14-2 **Summary of Special Tests of the Cardiopulmonary System**

	Cardiac Tests	
	Specific Tests	**Clinical Findings**
Nuclear imaging	**Planar, SPECT, MUGA, First pass** Common isotopes: 201-Thallium, 99m-Technitium sestamibi, 99 Technitium-tetrofosmin **PET Scans** Common isotopes: 82-rubidium 13-N-ammonia,15-O labeled water, and 18-fluorine-fluorodeoxyglucose (18F-FDG)	Evaluates myocardial perfusion, used in exercise stress studies and to assess reversibility of defects. Quantitatively can be used to determine: ejection fraction (EF), stroke volume (SV), cardiac output (CO), regional function, ventricular volumes, intracardiac shunt, valvular regurgitation. Quantitatively assesses cell activity of living tissue. Has ability to assess glucose (18F-FDG) and oxidative metabolism, perfusion and potential for revascularization.
Echocardiography	**M-mode; 2-D; transesophageal (TEE); Doppler; myocardial contrast echo (MCE)**	Evaluates myocardial structure. 2-D used in exercise stress studies. 2-D Quantitatively measures: chamber size, wall thickness, valve structure TEE and function, pressure and flow through valve, valve area, EF.
Computed tomography (CT)	Electron-based CT (EBCT)	Identifies calcium concentration in tissues, which is related to the amount of atherosclerotic plaque.
Magnetic resonance imaging (MRI)	MRI with contrast (Gandolium-DTPA)	Identifies ventricular volumes, EF, CO. Contrast imaging can be used to identify perfusion defects, flow, areas of infarction.
Angiography		Quantitative measures of pressure, resistance, flow, oxygen consumption, arteriovenous oxygen difference EF, CO
	Pulmonary Tests	
	Specific Tests	**Clinical Findings**
Pulmonary scans	**Perfusion scan** Common isotopes: MAB **Ventilation scan** Common isotopes: 99m-Tc -DTPA **Gallium scan** **PET Scans** Common isotopes: 18F-FDG	Identifies regions of decreased pulmonary perfusion, used to identify pulmonary embolism. Identifies regions of decreased ventilation. Used in conjunction with 133-Xe perfusion scan to identify patients with pulmonary embolism. Identification of neoplastic or inflammatory pulmonary lesions Aids in differential diagnosis of solitary pulmonary nodules, inflammation and malignant lesions.
Computed tomography	High-resolution CT; spiral CT	HRCT used in the diagnosis of bronchiectasis; spiral CT can be used to diagnose PE.
Magnetic resonance imaging	Dynamic MRI Gd-DTPA contrast	MRI with contrast used for MR angiography; dynamic MRI used in workup of lung transplant to examine ventilation, pulmonary mechanics
Angiography		For diagnosis of PE

Thallium-201

Thallium-201 (201-TL) is the oldest radioactive isotope used in myocardial perfusion studies.[14] It is a cyclotron-produced isotope that emits low-energy radiation (68 to 80 kiloelectron volts [keV]). Thallium concentrations in the myocardium depend on 201-TL properties, uptake, and redistribution. Administered intravenously, its distribution throughout the body depends on blood flow, and within 5 minutes, myocardial uptake represents myocardial blood flow.[30] The first-pass myocardial uptake coefficient is 85%.[14] Extraction from the blood and transport across the cell membrane depend on active and passive transport mechanisms. Thallium is transported across the cell membrane through the sodium-potassium ATPase pump and facilitative diffusion.[30] Normally perfused and functioning myocardium will take up the thallium tracer, while damaged cells will demonstrate weaker uptake. Within 15 minutes thallium begins washout (also called redistribution) in normal myocardium. Images taken 4-24 hours later show clearance of the 201-Tl, again as a result of normal blood flow, while abnormal cells have more tracer as it has not been washed out.[30]

Thallium-201 images can be qualitatively and quantitatively evaluated. Normally perfused myocardium demonstrates uniform uptake of the tracer. Uniform uptake can occur as long as blockages are less than 50% of the artery. Ischemic but viable myocardium initially appears as areas of decreased uptake; these areas fill in over time, a function of redistribution. Because blood flow is decreased, clearance of thallium-201 from the defect region is slower.[30] In infarcted areas, these defects remain unchanged over time. Thus perfusion and tissue viability can be assessed with 201-TL. Qualitative evaluation requires visual inspection of the images. Quantitative evaluation is performed by specialized software individual to the imaging system used. The computer analyzes the amount of radioactivity taken up in a particular region of interest (ROI). It then quantifies this count so that regions can be compared with each other and with normalized data. In

this way, unperfused or hypoperfused areas can be identified (Figure 14-2).

Thallium-201 is used to acquire planar and SPECT images for rest studies, exercise stress studies, and pharmacological stress studies. The traditional thallium-201 stress study calls for injection of the tracer at the peak of exercise with collection of the stress data within 10 to 15 minutes. The redistribution study is completed at a minimum of 4 hours later. Alternative study protocols include reinjection of thallium before the 4-hour redistribution study and use in dual-isotope studies.[30] Reinjection of thallium and repeat imaging 24 hours after initial study can help identify severely ischemic (greater than 90% blockage) areas, which may take much longer to demonstrate redistribution.

Technetium-99m-Sestamibi or Technetium-99m-Tetrofosmin

The technetium (Tc)-99m–based radionuclides were developed because of a number of advantages they have over thallium imaging. Sestamibi and tetrofosmin provide improved SPECT image quality as a result of higher count rates and higher energy, in the 140 keV range. Tc-99m is generator-produced. These isotopes have a 6-hour half-life and are excreted via the hepatobiliary system.[14] Because of the short half-life, higher doses can be injected, and although the percentage of extraction is lower (65% for sestamibi and 54% for tetrofosmin), uptake in relation to flow is similar to that of thallium.[14] These factors result in higher count rates, which thus allow the use of gated images and first-pass acquisition studies. Higher count rates are preferred when evaluating obese patients. One of the greatest limitations of Tc-99m is that it does not readily redistribute; therefore reversibility of defects cannot be ascertained as well as with thallium. This

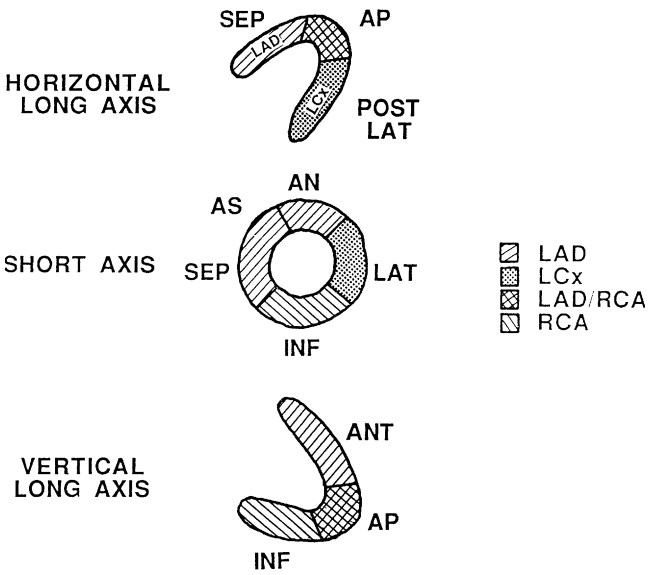

Fig. 14-2 Illustration of the SPECT series. In Guiberteau MJ, editor:* Nuclear cardiovascular imaging, *New York, 1990, Churchill Livingstone.)*

factor is one reason thallium is much more popular. Two-day protocols or dual isotope protocols can be used to overcome this limitation.[31] Lack of redistribution has been exploited in evaluating the impact of thrombolytic therapy in acute situations. A patient with an acute myocardial infarction (MI) can be injected with tracer, given thrombolytics, stabilized, and scanned 4 hours later. The scan results show myocardial perfusion at the time of injection when the myocardium was ischemic. Later scans demonstrate the new perfusion situation.

Protocols using this isotope are designed to take advantage of the rapid uptake and washout. When used with pharmacological stress studies, a rest-stress study can be completed within minutes.[32] This may have future application in studying reperfusion following balloon angioplasty or reperfusion therapy with thrombolytic agents.[32]

Positron Emission Tomography Tracers

PET tracers are also used to evaluate perfusion. The most commonly used tracers are 13N-ammonia, rubidium-82, and 15-O-labeled water.[33,34] The benefit of using PET tracers is that it is possible to quantify myocardial blood flow in mL/g/min.

13N-Ammonia

13N-Ammonia (13-NH3) provides high-quality images of myocardial perfusion because of its high first-pass extraction fraction (80%).[34] The tracer diffuses into myocardial cells and becomes trapped.[15]

Rubidium-82

One of the oldest approved tracers, rubidium-82 (82-Rb) is taken up by the myocardium via the Na/K-ATPase mechanism. Imaging myocardial blood flow is not optimal, because first-pass extraction is only 60% and uptake becomes nonlinear with increased blood flow.[34] However, it is easily produced via generator. The very short half-life of 82-Rb is useful in the clinical setting. It is most often used with pharmacological stress studies.[34]

15-O-Labeled Water

The PET tracer 15-O-labeled water (H2-15O) can be delivered by a variety of methods. It can be administered by bolus injection (the same method used for 82Rb and 13-NH3), but it can also be inhaled or given as an infusion. Myocardial uptake is uniform over a wide range of flow rates and is modeled as an inert freely diffusible tracer, which easily crosses capillary and sarcolemmal membranes.[33] However, the short half-life and reduced count density of H2-15O result in less-than-optimal image quality, making visual analyses problematic.[34] H2-15O is not currently an FDA-approved tracer.

Myocardial Metabolism

Fluorine-18-Fluorodeoxyglucose

Fluorine-18-fluorodeoxyglucose (18F-FDG) is a glucose analogue that crosses the capillary and sarcolemmal membrane at a rate proportional to that of glucose. 18F-FDG becomes trapped in the myocardium, because it is not a useful substrate

in metabolic pathways. The distribution of 18F-FDG is relative to uptake of unlabeled glucose.[35] Glucose utilization is therefore used as a marker of tissue viability.

Identification of areas with normal metabolism, altered metabolism, or no metabolism is based on the use of glucose as an energy substrate. Normally perfused myocardial cells use a combination of fatty acids and carbohydrates for adenosine triphosphate (ATP) production when in a fasting state and use glucose as the primary energy source in the postprandial state. Ischemic myocardium uses glucose in the fasting state and the postprandial state. Infarcted or scarred areas show no metabolic activity. Therefore increased uptake of 18F-FDG in the postprandial state occurs in both hibernating and normal myocardium, but in the fasting state, it occurs only in the hibernating myocardium. Clinical studies in patients with infarct showed that areas with persistent thallium-201 perfusion defects have evidence of remaining metabolic activity in 47% of regions when studied with a PET scan, indicating overestimation of irreversible injury. Use of reinjection and late redistribution imaging has significantly lowered this number.[36] The implication derived from this finding is that in areas with perfusion defects, if glucose activity remains, the region is viable (mismatch pattern); conversely, if such activity is absent, the area is likely to be infarcted or necrotic (match pattern).[37] Viewed in functional terms, mismatch simply implies the potential for improvement; match implies no potential for improvement in contractility after successful revascularization.[38]

11C-Acetate

Another way to evaluate myocardial viability is to use an isotope that is incorporated into the metabolic pathways related to myocardial oxygen consumption. 11C-acetate in its activated form, acetyl-CoA, represents the entry point for all metabolic pathways into the tricarboxylic acid cycle, which is tightly coupled to oxidative metabolism. Its advantage over 18F-FDG is that it does not rely on substrate use (i.e., glucose versus fat metabolism). 11C-acetate accurately reflects oxidative metabolism and can distinguish viable from nonviable myocardium in both acute and chronic ischemic conditions.[39]

Nuclear Tests of the Pulmonary System

Ventilation-Perfusion Lung Scan

The ventilation-perfusion (VQ) lung scan is a combination of two separate imaging procedures. It is primarily used in the diagnosis of pulmonary embolism (PE), with limited use for other clinical problems.[40] The perfusion portion requires the injection of radioactive tracer. Technetium-99m- macroaggregated albumin is accepted (almost universally) as the perfusion tracer of choice.[41] The ventilation scan requires the inhalation of radioactive gas, usually 133-XE gas or Tc-99m-diethylenetriamine pentaacetic acid (DTPA) aerosol. Other isotopes can be used for ventilation scanning (e.g., Kr-81M, Xenon-127), but they are more difficult to obtain (Figure 14-3).

A normal perfusion scan essentially rules out recent pulmonary embolus. If the perfusion scan is abnormal, it is compared with the ventilation scan for match or mismatch of defects. An interpretation scheme is used, such as Pioped, which classifies the probability of PE as present (high probability), absent (normal or very low probability), and nondiagnostic (low probability or indeterminate).[5,41] Patients with high-probability scans should begin anticoagulation therapy.[41] The D-dimer test and pretest probability of a PE also help to determine if the patient is high probability and thus requires anticoagulation.

Since the PIOPED II conclusion that computed tomography pulmonary angiogram (CTPA) has superior diagnostic accuracy for pulmonary emboli, the VQ scan is used less frequently.[41-44] However, VQ scans remain valuable for patients concerned with radiation exposure, intolerance to intravenous contrast agents or during pregnancy.[45]

Miller and O'Doherty[5] note other applications of ventilation/perfusion scanning, including monitoring of response to radiotherapy and assessment of resectability of bullae. The scan is used to predict whether someone can tolerate a pneumonectomy based on percent flow to the opposite lung and extent of disease present.

Positron Emission Tomography

PET scans using 18F-FDG isotopes are being used to identify metabolically active tissue (glucose metabolism) in the lungs. It has found application in the differential diagnosis of pulmonary nodules, inflammation, and potential malignant lesions.[46] PET with 18F-FDG is used as a diagnostic tool for pulmonary nodules and mass lesions.[46] Solitary pulmonary nodules (SPN) are often found during screening tests. They are of significant concern because of the risk for malignancy. Gould and colleagues[46] performed a meta-analysis and concluded that sensitivity is 96.8% and specificity is 77.8% for detecting malignancy in SPNs. PET 18F-FDG is not recommended for nodules less than 1 cm in size.[47] In addition to difficulty accessing PET scanners, cost may be a limiting factor—based on Medicare reimbursement figures, PET scans using 18F-FDG can cost six times more than conventional CT scans of the chest.[47]

Gallium Scintigraphy

PET or SPECT imaging has largely replaced gallium scanning for lung disease.[48] However, this isotope is still used in some centers and in specific clinical situations. Gallium-67-citrate binds with transferrin. This complex binds with transferrin-receptors in neoplastic cells while in areas of inflammation and infection gallium binds to lactoferrin and siderophores.[48] The radioisotope is injected intravenously, but it takes 48 to 72 hours before imaging can be performed; this delay is one reason it is out of favor.

Gallium is used in the evaluation of patients with inflammation and infection. Non-infectious inflammatory processes include: sarcoidosis, amiodarone toxicity, following cytotoxic therapy with bleomycin, and interstitial pulmonary fibrosis, as well as many other entities.[48] Gallium scanning is used to monitor response to treatment in lymphoma and where PET scans are not available can be useful in the diagnosis of lung cancer.[48] Gallium continues to be useful in infections (e.g., TB) as it helps discriminate active infection from fibrosis. Similarly, discriminating active disease from scarring is useful in

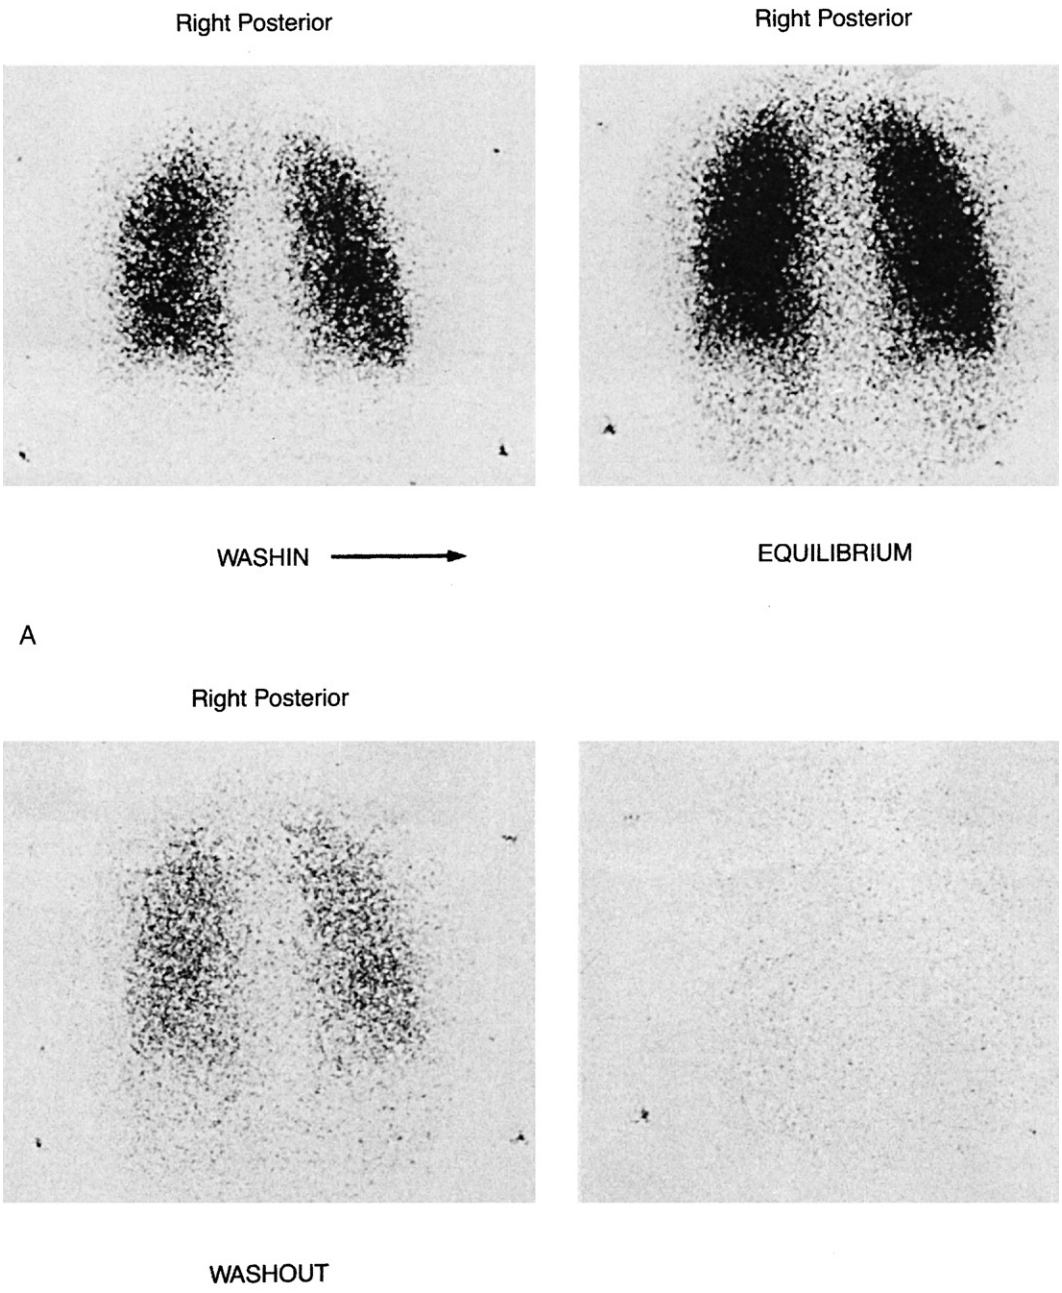

Fig. 14-3 The value of ventilation/perfusion lung scans in the diagnosis of thromboembolism. A xenon inhalation lung scan **(A)** discloses normal ventilation parameters during the washin, equilibrium, and washout phases.

evaluating AIDS patients with *Pneumocystis carinii* pneumonia (PCP).[48] The sensitivity of gallium scanning for *PCP in patients with AIDS* approaches 94% to 96%.[43]

Angiography

Angiography is the radiographic examination of the arterial system using an opaque contrast dye injected into the arterial segment to characterize flow. Angiography provides information about the detailed structural anatomy of the vascular system under study. Angiography requires an x-ray generator tube and image intensifier/cine camera.[49] The radiopaque dye is injected into the vascular supply of the region of interest. Radiographic images can then monitor the contrast material as it moves through the circulation. The development of coronary angiography via cardiac catheterization techniques allowed for the development of many of the catheter-based interventions now used today.[50]

Cardiac Imaging

The gold standard with which many of the cardiac noninvasive tests are compared is that of cardiac catheterization. It is an invasive test, with a small but serious risk to the patient.

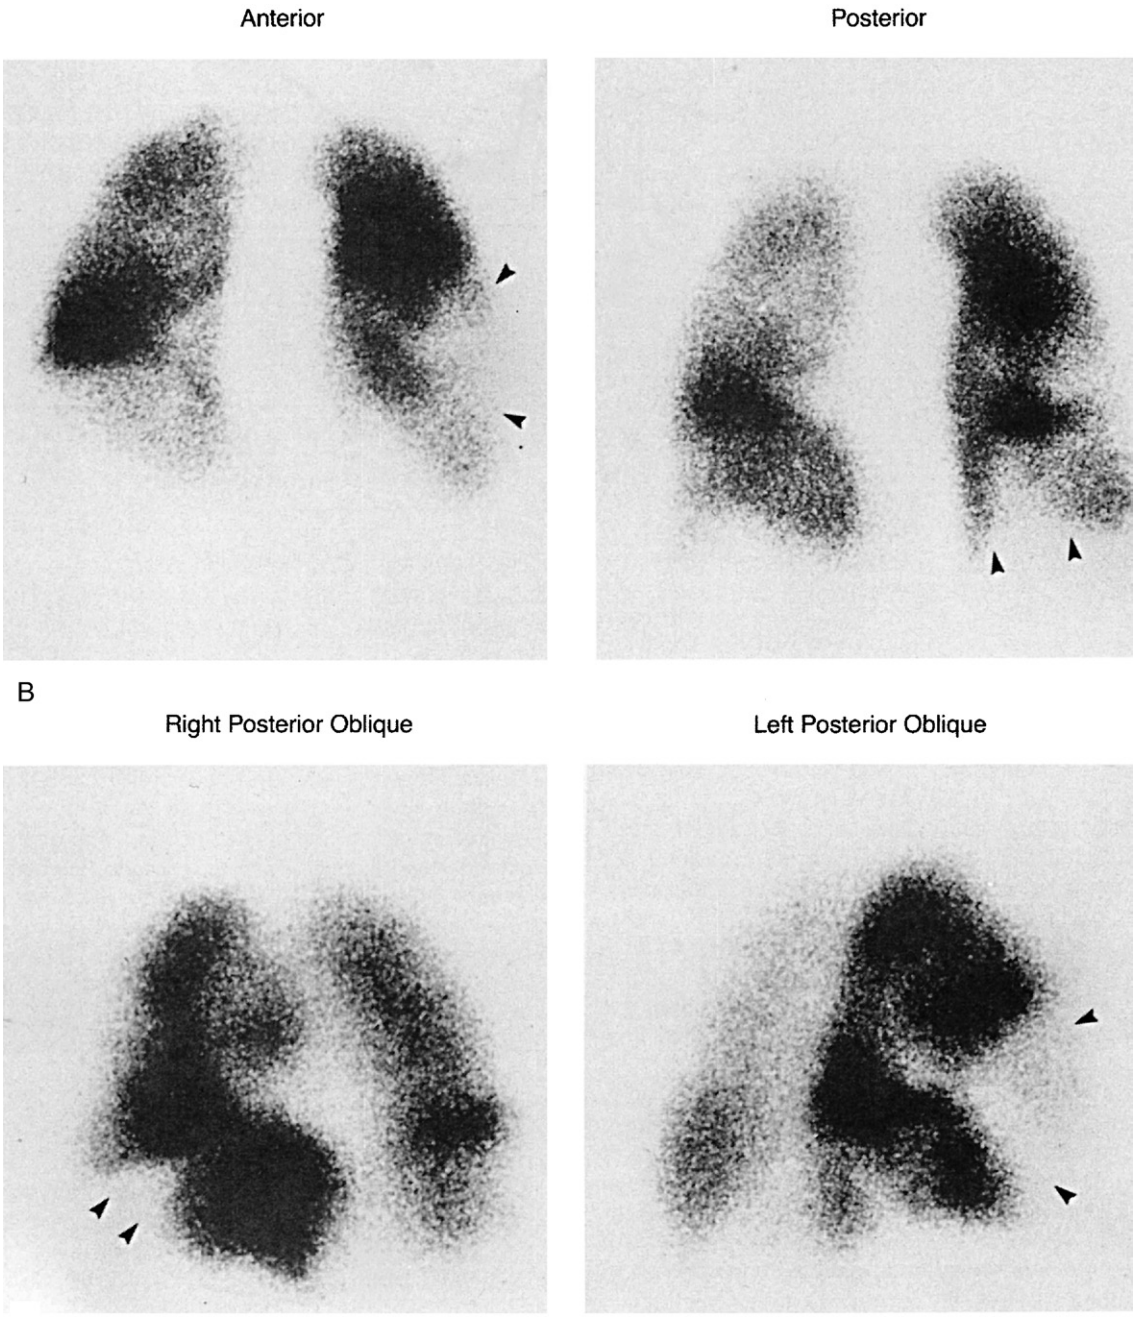

Fig. 14-3, cont'd Corresponding technetium-99m–labeled macroaggregated albumin perfusion lung scans **(B)** in anterior, posterior, and right and left posterior oblique projections identify multiple segmental filling defects throughout both lungs (*arrowheads*). These findings, in concert with the ventilation study are virtually diagnostic (high probability) of pulmonary thromboembolism. The patient was a 65-year-old man with acute dyspnea. *(From Fraser RS, Paré PD, Coman N, et al:* Diagnosis of diseases of the chest, *ed 4, Philadelphia, 1999, WB Saunders.)*

Complications include death, stroke, MI, bleeding, arterial trauma or thrombus, renal dysfunction, and arrhythmias.[49] The test is indicated in patients presenting with ST elevated MI (STEMI) who are candidates for reperfusion as well as those presenting with chest pain and non-STEMI who are at risk for further cardiac events.[51] There is some debate as to whether the NSTEMI population should undergo a coronary angiogram with potential for revascularization within 24 hours or should wait. Current guidelines recommend the early procedure.[52] Patients who have CAD with angina that is unresponsive to medical therapy may also need catheterization.

The procedure for cardiac catheterization of the left side of the heart requires the threading of a catheter, guided by fluoroscopy, through the femoral artery or brachial artery to the

aorta. Direct measurements of chamber pressures, blood flow, and oxygen saturation can be obtained. When selective coronary arteriography is performed, radiopaque contrast material is injected from the catheter into the left main or right coronary artery. Cine recordings are made after the injection, and injections are repeated until the entire coronary tree is visualized. The location of an arterial obstruction can be identified, as well as the percentage of blockage (stenosis) (Figure 14-4).

More recently, additional physiological measures can be obtained that provide flow and pressure data at the site of the lesion within the coronary artery.[53] These measures have become particularly important for monitoring outcomes after the administration of reperfusion therapy (e.g. thrombolytics, angioplasty, stenting).[54,55] Coronary artery flow grades—for example, thrombolysis in myocardial infarction (TIMI) grades 0-3—are based on the visual analysis of the rate of opacification of the artery of interest, typically 90 minutes after intervention.[54] TIMI myocardial perfusion grades (TMPG 0-3), or myocardial blush, grade the reperfusion of the myocardium by the contrast medium.[55] Higher TIMI and TMPG grades have been associated with reduced mortality over 2 years.[55]

Cardiac ventriculography is a procedure in which dye is injected into the ventricle and the entire chamber becomes outlined. Several cardiac cycles are recorded on cine. This provides valuable information about global and segmental wall motion, valve motion, and the presence of abnormal anatomy.

Pulmonary Imaging

Pulmonary angiography is used primarily for the diagnosis of PE. It is the gold standard with which ventilation/perfusion scans are compared.[41] Contrast dye is injected into the pulmonary circulation through the pulmonary artery. Additional techniques such as balloon occlusion, segmental injections, or increased magnification improve the sensitivity of the test.[40] Interobserver reliability studies performed on the interpretation of pulmonary angiograms are 83% to 86%.[41]

Echocardiography

Another noninvasive method of evaluating the heart uses the physical properties of sound. Echocardiography (sometimes simply called "echo") provides information about blood flow, structure, and function of the heart. Motion mode (M-mode) and two-dimensional (2-D) images are highly reliable methods of evaluation. Recent developments of technique and technology include color flow Doppler echo, transesophageal echo, and intravascular echo. These techniques, when used in combination, can provide much of the information previously available only by cardiac catheterization.[56,57] Echocardiography is an important tool in the assessment and management of patients with thoracic trauma.[58]

Physics of Echocardiography

Imaging systems that use ultrasound require a source for generation of the sound wave, a transducer, and a receiver to pick up the reflected sound waves. Sound is absorbed or reflected differentially by specific tissues. Therefore the sound wave reflected from muscle differs from that reflected from vascular space, or valvular structures. Returning signals are converted into electrical signals that generate an image. This is the basis for M-mode and 2-D echo. In M-mode echocardiography, the transducer transmits a single sound wave through the chest wall (transthoracic echocardiography, or TTE). A thin slice of the heart, an "ice pick" view, directly under the sound wave, reflects the wave back to the transducer. M-mode, though useful when a high-resolution image is required, is rarely used.[59] The primary diagnostic mode is 2-D. In 2-D echocardiography, the transducer is able to pick up a wedge section of the heart. In 2-D mode, the transducer acts as the transmitter and receiver. A "real time" two-dimensional picture of the heart is recorded on videotape. The heart can be viewed in motion, and wall motion can be evaluated (Figure 14-5).

Doppler Echocardiography

Doppler echocardiography relies on the Doppler effect to determine velocity. When a sound wave is aimed at moving objects, such as red blood cells, the known transmitted frequency from the soundhead and the reflected frequency differ, a phenomenon known as a frequency shift. The greater the frequency shift, the greater the speed of the targeted object.[57] *Velocity of flow* is the term used to express Doppler frequency shifts. Both continuous-wave and pulsed-wave Doppler modes are used.

Color flow Doppler echocardiography was introduced in the mid-1980s. It is usually superimposed on a two-dimensional image in real time but can be used with M-mode. It is a method that displays anatomical and spatial blood flow velocity estimates with indication of flow direction in real time.[60] Color is matched based on the direction of flow, and shading is indicative of intensity based on the mean velocity flow estimates.[60] It is primarily used to assess the extent of regurgitant jets across "leaky valves," as well as to indicate areas of abnormal shunts such as atrial septal defects. Turbulence created by narrowed valves creates wide color shading.

Measurements Derived from Echocardiography

Echocardiographic results can be viewed qualitatively and quantitatively. An experienced viewer can analyze the anatomical relationships and structure of the heart, wall motion, valve movement and configuration, and chamber size.

Quantitative measures are calculated from the Doppler frequency shifts. Velocity measures can be used in other equations to estimate pressure and valve area. The modified Bernoulli equation is used to calculate pressure changes around the valve:

$$\Delta P\ (\text{mm Hg}) = 4 \times V_{max}{}^{2}\ (\text{m/sec})$$

where P is the pressure gradient across the valve and V is the velocity of blood flow through the valve.

These measurements allow calculation of stenotic valve gradients and right-sided filling pressures, valve regurgitation, and shunt volumes.[57] Valve regurgitation and shunt calculations are more complicated than the Bernoulli equation alone.

Another important quantitative measure is the estimated area of the valve. The continuity equation is used to estimate valve area. It is based on the principle of conservation of mass;

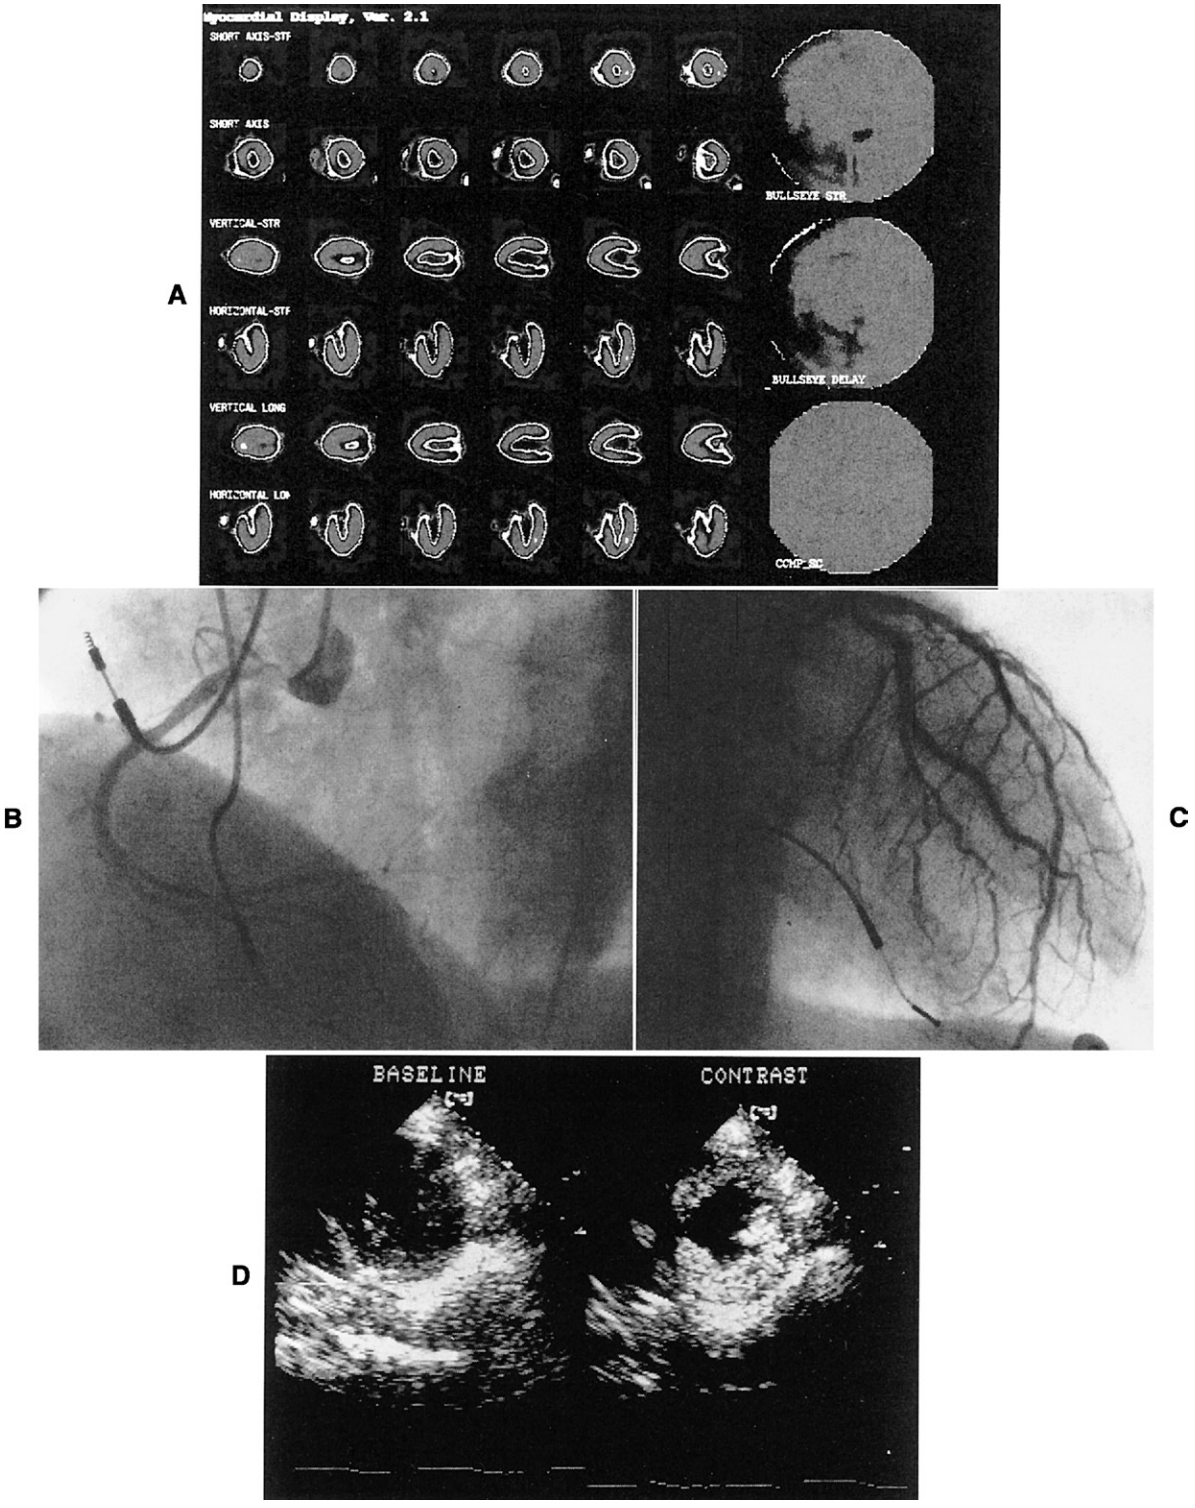

Fig. 14-4 Stress single-photon emission computed tomography reoriented and polar plot images. **A,** Right coronary artery arteriogram; **B,** left anterior descending coronary artery arteriogram; **C,** circumflex coronary arteriogram; and the short-axis two-dimensional echocardiographic images **(D)** at baseline (*left*) and after contrast injection down the LAD coronary artery (*right*). Although this patient had a normal dobutamine thallium-201 SPECT with no discernible perfusion defect after comparison to the normal databank (COMPSC) **(A),** the right coronary artery is noted to have a subtotal ostial stenosis **(B)**. No collaterals are observed to the right coronary artery after left main contrast injection **(C)**. However, on echocardiography **(D),** intense contrast enhancement is noted in the inferior wall after injection of sonicated microbubbles down the LAD, verifying the presence of coronary collaterals to the right coronary artery. Despite a severe right coronary artery stenosis, this patient did not develop a stress perfusion defect because of the well-developed collateral circulation, which was apparent on echocardiography but not arteriography. *(From Malunarian JJ: State of the art for CAD detection: Thallium 201. In Zarit BL, Beller GA, editors:* Nuclear cardiology, *ed 2, St. Louis, 1999, CV Mosby.)*

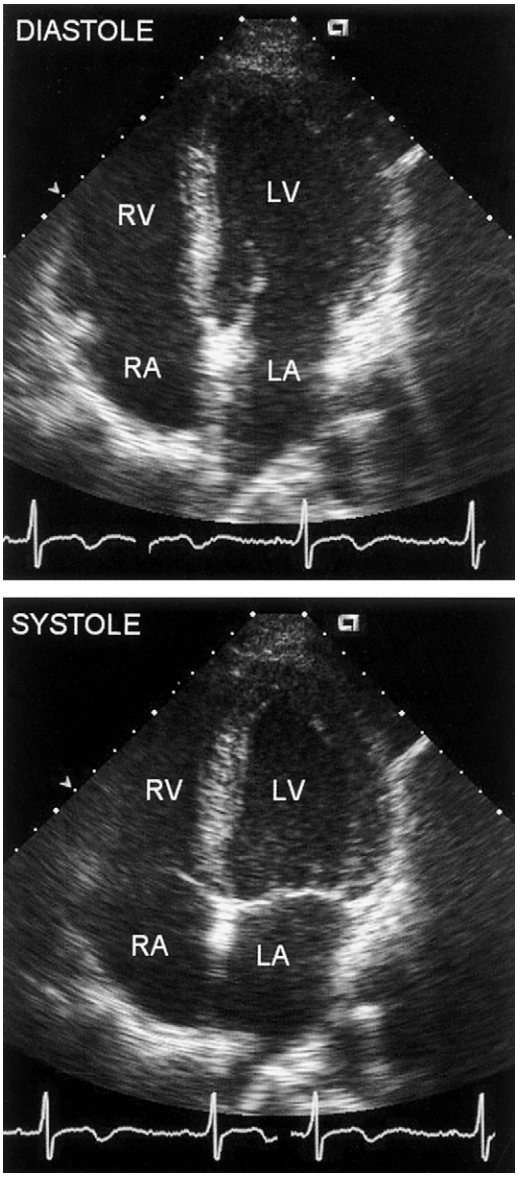

Fig. 14-5 Normal 2-D echo images at end-diastole (*above*) and end-systole (*below*). *(From Otto CM:* Textbook of clinical echocardiography, *ed 2, Philadelphia, 2000. WB Saunders.)*

that is, in a normal heart, the volume of blood that enters the right atrium should be conserved as it passes through the other chambers (stroke volume$_1$ = stroke volume$_2$). Since the volume before the valve must be equal to the volume after the valve, it is possible to measure flow velocity before and after the valve and then solve for the area of the valve:

$$A_1 \times V_1 = A_2 \times V_2, \text{ therefore } A_2 = (A_1 \times V_1)/V_2$$

where V_1 is the velocity of flow at one side of the valve, V_2 is the flow velocity at the other side of the valve, and A is the cross-sectional area.[57]

Exercise Studies

Exercise echocardiography can be done immediately following physiological stress (treadmill or bicycle exercise) or pharmacological stress (dipyridamole, adenosine, or dobutamine). Pharmacological stress offers the advantage of the patient being in a stable position throughout the test. If monitoring during physiological stress conditions is desired, the bicycle test, in the semirecumbent or supine position, is preferred because imaging cannot be performed during a treadmill test.[61]

Transesophageal Echocardiography

Because of consistent technical difficulties with TTE, the technique of transesophageal echocardiography (TEE) was developed to improve spatial resolution. TEE can obtain M-mode, 2-D, 3-D, and color flow Doppler images by using a small probe mounted on the tip of a modified gastroscope. TEE is considered minimally invasive. The probe is advanced into the esophagus, similar to placement of a gastric tube by nasal or oral route, and positioned so that multiple views of the heart are available.[62] For cardiac output measures, it is advanced to the midthoracic level.[63] The technique can be performed on anesthetized patients during surgery and monitored postoperatively; on mildly sedated patients (e.g., those on mechanical ventilation or trauma patients in the intensive care unit); and on those suspected of having aortic dissection or aortic injury.[58] TEE is frequently used for diagnosis of congenital heart disease, evaluation of valve function, and determination of thromboembolic risk. It has become an important monitoring tool during cardiac catheterization procedures and surgery.[64]

TEE is used to assess cardiac valve function as well as to monitor treatment. Image quality of TEE is better than that of TTE. This is especially true when visualizing the mitral valve, because of the proximity to the transducer (valves positioned farther from the transducer afford lower-quality images).[65] It is used to monitor prosthetic valve function, as well as to diagnose and monitor infective endocarditis, particularly the status of valve vegetation. TEE provides superior visualization (compared with TTE) of the left atrium and left atrial appendage, which are often the source of thrombi causing transient ischemic attack (TIA) or stroke. TEE Doppler studies can examine left atrial flow velocities, which also indicate increased stroke risk. TEE Doppler has been successfully used to decrease morbidity and length of stay when hemodynamic management of the patient is critical.[63] TEE has now progressed to 3-D real-time imaging, which allows for improved imaging and quantification of LV function, including preload, afterload, and contractility.[65]

Myocardial Contrast Echocardiography

The ability of echocardiography to evaluate myocardial perfusion was historically based on observation of wall motion abnormalities. The development of a contrast agent that can be used with echocardiography has ushered in noninvasive techniques that do not rely on radioactive agents (see Figure 14-3). In myocardial contrast echocardiography (MCE), microbubbles of air encapsulated in a thin shell are introduced by IV infusion or bolus injection into the venous system as the contrast agent.[66] These small bubbles (<6-10 μm) oscillate when exposed to ultrasound energy and produce harmonic signals (a multiple of the ultrasound frequency) that are then used to produce the images.[67] Although numerous studies have shown the potential benefit of MCE for bedside and

stress perfusion imaging, the FDA has not approved it for this use.[68]

Computed Tomography

Computed tomography (CT) was first developed in the 1970s, allowing the visualization of cross-sectional views of body organs, as opposed to the planar views possible with standard radiographs.[69] Further technological developments in CT have made possible such rapid scan times that CT of the respiratory system can be completed in a single breath-hold, resulting in scans of improved spatial resolution and diagnostic utility.[70] Electron beam CT has found application in the examination of the cardiac system and is currently used as part of risk stratification for asymptomatic patients.[71]

Physics of Computed Tomography

A computed tomographic scan (CT scan) acquires images of a fixed thickness (a cross-sectional slice), which allows examination of a specific part of the body. CT scanners use an x-ray source, collimators, x-ray detectors, and computers to reconstruct the cross-sectional images from the acquired data.[69] The x-ray source rotates around the patient, the speed of rotation dictating how long it takes to acquire a single slice (about 1 second). Slice thickness and the space between slices determine the quality of the spatial resolution of the images. The spatial resolution required depends on the type of tissue being examined and the suspected diagnosis. Imaging can be done with a single-detector or newer multiple-detector row scanners (4, 8, or 16 rows).[72] Multidetector CT (MDCT) scanners allow for faster acquisition of images. Spiral CT scanners simultaneously rotate the source and move the table and patient for continuous data acquisition and improved resolution.[73] The most rapid scanning times are achieved by electron beam computed tomography (EBCT), also called ultrafast CT. EBCT uses an electron gun to generate x-rays to a fixed tungsten "target."[71] The electron beam is electronically moved, rather than mechanically rotated, resulting in images that can be made in milliseconds. The cost and the limited number of available EBCT scanners are factors that limit their routine use.[72]

Cardiac Imaging

Electron-beam tomography is currently used to identify calcium in atherosclerotic plaques within the coronary arteries.[71] A scoring system developed to quantify the amount of calcium in the coronary arteries is used to identify future risk of cardiac events.[71] Scores are based on Housenfeld units (HU), which are based on the tissue attenuation factor. Calcified areas are identified in the coronary tree and given scores based on HU > 130. Scores are summed across all identified lesions (Agatston method) to provide a total coronary calcium score.[74] In general, the greater the amount of calcium detected, the greater the amount of atherosclerotic plaque in the coronary arteries. A limitation of EBCT is that it cannot localize the plaque anatomically. Sensitivity and specificity for EBCT for CAD is 91% and 49%, respectively.[71] Research is currently being done to determine whether EBCT tests adds valuable data to cardiac risk assessment.[75] In a sample of nearly 9000 asymptomatic low- to intermediate-risk middle-aged adults, the relative risk for a cardiac event significantly increased at higher quartiles of calcium scores.[75] However, it is not recommended for screening in asymptomatic patients or for patients at high pretest probability for CAD.[76,77] Cardiac CT has been deemed appropriate for symptomatic individuals with low to intermediate pretest probability of significant coronary stenosis or pre-operative evaluation in low-risk patients.[77] A particular strength of CT is its ability to image cardiac structure and ventricular function.[77]

Pulmonary Imaging

Compared with standard radiography, CT is not commonly used in the initial diagnosis of pulmonary disease. However, the CT scan has been found to be a useful first-line diagnostic tool in the evaluation of mediastinal disease, including mediastinal masses, staging of mediastinal cancers, and identification of cysts.[40]

High-resolution computed tomography (HRCT) has improved the documentation of morphological changes associated with chronic airflow obstruction. Webb's 1994 review[78] of the application of this new technology identified the utility of this test in a variety of obstructive diseases. HRCT is sensitive in the diagnosis of early emphysema, although it is rarely used clinically. In cystic disease, such as histiocytosis X and lymphangiomyomatosis, HRCT is able to demonstrate cysts less than 10 mm in diameter and can also visualize wall thickness.

In the diagnosis of bronchiectasis, HRCT demonstrates a high specificity (Figure 14-6) and is the procedure of choice after standard chest radiography. It can discriminate among the three different types of abnormal bronchi seen in bronchiectasis (cylindrical, varicose, and cystic); however, there is little clinical significance in this distinction.[78] HRCT can be used to differentiate lymphangitic spread of cancer versus heart failure when that distinction is clinically unclear. It also can be used to evaluate clearing of persistent pneumonias. Overall, HRCT has helped clarify disease morphology, but its clinical significance for diagnosis and for patient pulmonary function is less clear.

Spiral CT, with and without a contrast agent, has become the test of choice in the diagnosis of acute pulmonary embolism.[79] Multidetector scans (>4 detectors) provide sensitivity and specificity >83% and 89% respectively.[79] The combination of CT and V/Q scans provide examination of lung function (V/Q) and structure (CT) which may surpass CT alone for diagnosis of PE.[80] Hybrid cameras that can perform both V/Q SPECT and CT will increase utilization of these scans. Future applications may be seen in planning radiation therapy of the lung and lung volume reduction surgery.[81]

Magnetic Resonance Imaging

Technically, MRI, which was adopted clinically in the 1970s, uses nuclear magnetic resonance to build tissue images—that is, nuclei are made to resonate in a magnetic field.[82] However, since MRI is a technique that does not use radiopharmaceuticals or ionizing radiation, it was thought to be less confusing to leave "nuclear" out of the name. Thus MRI is a noninvasive, test that involves no exposure to radiation and is able to

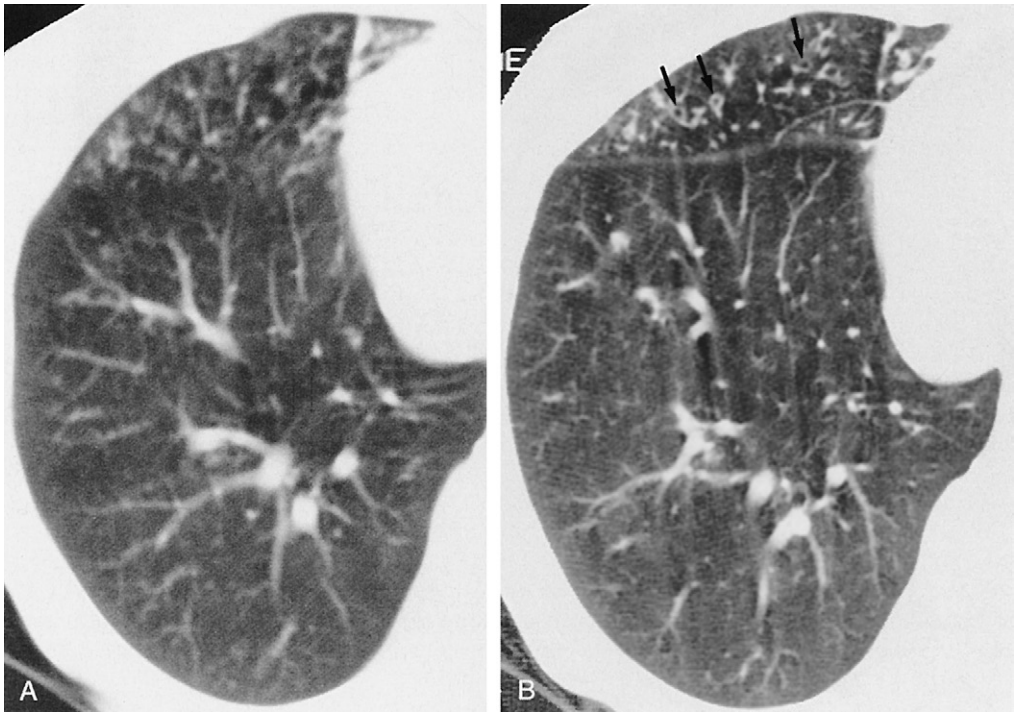

Fig. 14-6 HRCT versus conventional CT for bronchiectasis. A conventional 10-mm-collimation CT scan **(A)** in a 65-year-old woman demonstrates small focal areas of ground-glass attenuation and consolidation in the right middle lobe. An HRCT scan (1.5-mm collimation) **(B)** performed immediately after the conventional CT scan demonstrates right middle lobe bronchiectasis (*arrows*). *(From Fraser RS, Paré PD, Coman N, et al:* Diagnosis of diseases of the chest, *ed 4, Philadelphia, 1999, WB Saunders.)*

provide high quality imaging without the use of contrast dyes. Furthermore, with the development of ultrafast imaging, MRI has found utility for the examination of the cardiovascular and pulmonary systems.

Physics of Magnetic Resonance Imaging

MRI relies on the creation of a stable, powerful magnetic field that causes hydrogen (also carbon-13, fluorine-19, and sodium-23) nuclei to align with the field. A radiofrequency pulse specific to the hydrogen (or other) nuclei causes the nuclei to resonate.[82,83] Additional magnets that apply magnetic fields of different gradients are used to locate the image. When the radiofrequency is turned off, the nuclei release the stored energy. This energy is analyzed via Fourier transformation, which results in the image. The images are highly dependent on the timing and magnitude of the radiofrequency.[84] Data acquisition can take 20 to 90 minutes, during which the patient must remain immobile. Application of MRI to the cardiac and pulmonary system was initially limited by the continuous movement of the heart and lungs, but the development of ultrafast imaging has overcome some of these problems.[85] Contrast materials such as gadolinium diethylenetriamine pentaacetate (Gd-DTPA) can be used to enhance signal intensity.

Cardiac Imaging

MRI is a useful technique in evaluating cardiac structures. It can identify cardiac masses and is the modality of choice for evaluating the pericardium. MRI is still secondary to CT in evaluating the mediastinum and detecting CAD.[84,86] Coronary artery imaging is still problematic due to cardiac motion.[87] Cardiac images from MRI do allow the measurement of right and left ventricular volumes, ejection fraction, and cardiac output.[82, 87] MRI is able to detect tissue composition such as myocardial fat infiltration and identification of myocardial edema caused by inflammation or ischemia.[87] Data collection of the heart requires the use of different testing sequences and specialized equipment to capture the beating heart.[87]

Tests to Evaluate Myocardial Perfusion

Contrast agents such as Gd-DPTA can be used in stress MRI studies to examine perfusion defects in the myocardium.[72] Cardiac MRI is able to characterize blood flow, as well as uptake and washout of the contrast agent. Unlike other modalities, cardiac MRI can distinguish tissue layers, enabling identification of areas of subendocardial or transmural defects.[72] MRI can also identify areas of myocardial edema, which is the result of ischemia. This allows identification of at risk areas which will benefit from reperfusion interventions. [87]

Tests to Evaluate Myocardial Viability

The viability of cardiac tissue can be examined with MRI, using delayed contrast enhancement Gd-DPTA as the contrast agent.[82] Images are taken 10 minutes after the intravenous administration of the agent. An inversion time pulse sequence allows the normal myocardial tissue to fade and the infarcted or scar tissue to be enhanced.

Pulmonary Imaging

Evaluation of the lung parenchyma presents unique problems because of respiratory movement, low proton density, and the air-tissue interface.[85] The development of ultrafast imaging pulse sequences, called dynamic MRI, has improved the utility of this noninvasive test for evaluation of the pulmonary system. Contrast agents such as Gd-DTPA are used to perform MR angiography to diagnose pulmonary embolism.[88] The use of MRI to provide noninvasive evaluation of PE has application in special cases, where typical tests are inconclusive.[88] Without contrast, dynamic MRI is being used to study biomechanical function of the diaphragm and chest wall in patients with and without pulmonary disease. These studies are important for patients undergoing lung volume reduction surgery.[89]

The use of gaseous contrast agents such as hyperpolarized helium-3 (HHe-3), with dynamic MRI and lung motion correction, is a promising new development that allows examination of gas distribution in the lungs.[85, 90] These studies have shown that dynamic MRI with contrast HHe-3 contrast can discriminate healthy lung grafts from native diseased lung in transplant patients[85] and identify ventilation defects that correlate with decreased FEV_1 in patients with asthma.[90]

Bronchoscopy

Bronchoscopy is often used as both a diagnostic and a therapeutic treatment modality.[91] It allows direct visualization of the trachea and its major subdivisions. Fiberoptic bronchoscopy has virtually replaced bronchography.[40] In fiberoptic bronchoscopy, a flexible tube is inserted into the trachea of mildly sedated patients. This tube is able to enter small bronchial subdivisions. Secretions can be removed for evaluation or as a treatment. It is also possible to obtain biopsy samples using tiny forceps or cell brushings. Bronchoscopy is particularly important in the diagnosis of bronchogenic carcinoma.[92]

Summary

Many tests are available to identify cardiopulmonary dysfunction. The attending physician determines which tests are appropriate for the patient's particular medical condition. When the tests are completed, results are given, and an evaluation of the results is documented. Physical therapists need to understand the results of the tests and how they will apply to patient function and response to exercise. This understanding applies to the selection of exercise and work loads the therapist prescribes for the patient. Until a physical therapist reaches a certain maturity level (in terms of experience), as well as a level of understanding and application of the test results to patient treatment, it is highly encouraged that the therapist discuss the tests and the results with the patient's physician. These discussions are excellent learning opportunities, both for the physical therapist and for the physician, who may gain a better understanding of what physical therapy has to offer the patient with cardiopulmonary dysfunction.

Review Questions

1. Why is the ejection fraction an important measure of myocardial function?
2. What is the difference between stunned myocardium and hibernating myocardium?
3. How does EBCT identify CAD risk?
4. Which tests can be used to evaluate myocardial viability?
5. Which test provides the best anatomical information?

Review Questions 212

References 213

The Guide to Physical Therapist Practice provides a thorough patient management model.[1] It identifies the key components necessary for a thorough examination and evaluation of the patient, tests and measures, identification of impairments, and interventions and outcomes that help the therapist in providing a multisystem examination and evaluation that will lead to appropriate treatment and achievement of optimal function and goals (see Figure 17-2).

This chapter will follow and focus on the flow of the examination, which includes patient and family history, systems review, tests and measures overview, evaluation leading to interventions, and identifying and reaching appropriate

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

outcomes. This flow may continue in a forward, circular manner, or it may go back and forth as a patient's condition either improves or declines. It is an active process, which may lead to achieving expected outcomes, discharge, or discontinuation of therapy based on many factors. A given patient may have more than one impairment, so all conditions or a multisystem examination should be done to identify all impairments. In addition, prevention and risk factor assessment must be done. For example, if an orthopedic patient is referred for treatment following a total knee replacement (TKR), the therapist may find that he is also prehypertensive with elevated BP and HR, has a family history of heart disease, and is a smoker. Thus, in addition to treating for the primary referral diagnosis of TKR, the therapist may also use the 6A Prevention Pattern to try to decrease the patient's risk factors for cardiovascular and pulmonary (CVP) disease and to promote wellness.

It is important to remember that although patients may be referred to the physical therapist for a primary cardiovascular and/or pulmonary impairment, they may also have a secondary cardiovascular and/or pulmonary impairment that may or may not have been diagnosed or identified. Another example would be a patient referred to physical therapy after having a cardiovascular accident (CVA). This patient may have right-sided weakness, be slumped to the right side, and have decreasing ventilation on the right lung. Weak pharyngeal muscles may be increasing the patient's risk for aspiration. In addition, a decreased vital capacity and weakened abdominal muscles may reduce the patient's ability to keep the airway clear, and poor breath support may make it difficult for the patient to speak clearly, if at all. If the therapist only considers the primary diagnosis of CVA, the potentially life-threatening secondary cardiovascular and pulmonary impairments would be missed, which would limit optimal outcomes.

Screening for risk factors for cardiovascular and pulmonary issues is essential in all patients, including a thorough family history and assessment of other risk factors. A patient may come to the physical therapist after having a "simple" orthopedic procedure such as an ACL repair, but after discussing family history it is discovered that the 30-year-old patient's father died at age 32 after a massive heart attack. If the therapist checks the patient's BP on screening, finds that it is 180/100, and discovers that the patient hasn't been to a doctor in years, the therapist can identify risk factors and help to provide secondary prevention, as well as the primary treatment.

The examination and evaluation provide the therapist with a baseline, against which future visits or sessions will be compared. Depending on the site of practice (e.g., acute care versus long-term care or outpatient, school, or home care), this may occur each time the therapist sees the patient or once a week; regardless, the baseline data are essential as a place to start.

History: Review and Interview

Medical Chart Review

The first component in the examination is obtaining a history. Initially, this can be a review of the medical chart, paying close attention to the notes of the physician, the nurse, and the physician assistant and looking through lab values, tests that were ordered and their results, vital signs, and summary notes. Each practice setting has a variety of available information; as a rule, the more acute the patient's condition is, the more notes, tests, and results there are to review. It is helpful to learn to screen the chart quickly but also thoroughly in order not to miss information. After the chart review, the therapist should discuss the patient's case with the nurse, physician, physician's assistant, and/or other members of the interprofessional team to help develop an understanding of the patient's condition before beginning the examination.

Patient/Family Interview

If a direct patient interview is possible, asking specific open-ended questions is most valuable. It is optimal to interview the patient directly, and even if the person has some limitations, the initial questions should be directed to the patient. If the patient is very ill or cognitively impaired and unable to provide information, the family and significant others in his or her life may be able to give important information not found directly on the medical chart. It is important for the physical therapist to take the time to listen carefully to what is expressed and relate it to what was found in the chart before performing the examination and evaluation.

In outpatient settings, rehabilitation facilities, or schools, very little information may be available other than a physician's referral and/or notes. In these cases, the therapist needs to be effective at drawing out important information from the patient during the interview. It is important to be thorough and yet be aware of appropriate time management and efficiency. Interviewing is a skill that improves with practice as the therapist gains more knowledge of diagnoses and patient presentations and becomes better able to obtain information in an organized efficient manner.

A sequencing strategy is helpful in reviewing charts. With experience most therapists develop a specific system that works well for them. Here is just one example of a strategy for reviewing charts:

1. Read the history and the physical and admission medical notes (i.e., the preadmission symptoms, past medical history)—this includes the physician's notes and the nurse's notes.
2. Read the most recent medical notes.
3. Scan the remainder of the chart.
4. Read any reports from medical specialists and consultants, such as pulmonologists, neurologists, or oncologists.
5. Review any pertinent lab tests, such as chest radiograph, arterial blood gases (ABGs), complete blood count (CBC), cardiac tests, CAT scans, and MRIs.
6. Review medications—in particular, pulmonary and cardiac drugs.
7. Review any procedures performed (e.g., surgery, intubation, chest tubes, NG tubes).
8. Review the psychosocial information (e.g., family, support systems, education, financial concerns, psychological issues, architectural barriers).

In acute care, discharge planning begins with the first time a therapist sees a patient. Patients are often in the hospital only a brief time, and the physical therapist will be asked to make recommendations for discharge. Any detail of a patient's background that would affect discharge planning is crucial to

know, even on the first day of treatment. Additional information that may be helpful to review (and falls into the category of "as time allows") includes any documentation recorded by other health professionals, such as nurses, occupational therapists, or speech pathologists. Finally, when the initial chart review is finished, a mental picture of the patient should exist, even before the physical therapist steps into the patient's hospital room.

Details regarding the patient interview have been covered in Chapter 7. However, there are questions that should be posed to any patient, even if his or her primary condition is not cardiovascular and/or pulmonary. The patient whose primary referring impairment is musculoskeletal or neurological needs to have a screening of the cardiovascular and pulmonary system. The therapist should consider the following questions: What is the patient's smoking history? Does the patient have a family history of premature coronary artery disease (i.e., a parent or sibling who had a myocardial infarction)? Can the symptoms presented also be signs of a cardiovascular or pulmonary illness? Does the patient have an active or a sedentary lifestyle? What activities precipitate the patient's symptoms? Do these symptoms include breathlessness? Are there problems with airway clearance, congestion, etc.?

Every patient should be seen as a human being with multiple organ systems. The patient's problem, whether orthopedic or cardiovascular and pulmonary, should not be viewed in isolation. Another example is the outpatient with a physical therapy diagnosis of low back pain. When questioned about limiting symptoms, the patient might describe cramping leg pain, which is suggestive of peripheral vascular disease (PVD). This should be considered a "red flag" that would lead the therapist to look further into cardiovascular and pulmonary issues or impairments. If this is not taken into consideration and the patient is treated only for low back pain, optimal outcomes and function cannot occur.

System Review and Tests and Measures

Physical Examination of the Chest

After the general physical therapy examination of muscle strength, ROM, activity, and function, the physical examination of the chest comes next. The therapist begins by obtaining vital signs (BP, HR, T, etc.) and then progresses to the examination of the chest wall and auscultation of the heart and lungs. When the information provided by each of these techniques is integrated with the patient's history, interview, and chart review, the physical therapist can then do the assessment and identify the impairment, prognosis, and appropriate interventions that will lead to optimal outcomes for the patient. It is important to include all of these assessments in an appropriate sequence. For instance, auscultating breath sounds without evaluating the patient's posture or asymmetry of the chest wall would fail to provide needed clues to the total patient picture and would not facilitate the development of an appropriate plan of care for the patient. All components of the examination must be considered before deciding which interventions should be implemented and which goals and/or outcomes can be developed.

Before we discuss the individual aspects of the chest assessment, a review of the pertinent anatomic landmarks and topographic lines is warranted. Knowledge of the superficial anatomy and its relationship to the underlying heart and lungs aids the therapist in making crucial decisions. The topographical lines allow for more accurate descriptions of the physical findings.

Topographic Anatomic Landmarks

Key anatomic structures include the following:

- Sternum
- Clavicles
- Suprasternal notch
- Sternomanubrial angle (angle of Louis for identification of the second rib)
- Costal angle
- Vertebra prominens

See Box 15-1 and Figure 15-1 for specific definitions and anterior and lateral views of the thorax. Imaginary topographic lines are used to more clearly describe any physical findings (e.g., location of surgical incisions, abnormal breath sounds, etc.; Figure 15-2).

The anterior view of the thorax has three vertical lines:

- Midsternal line (MSL)—a vertical line bisecting the sternum
- 2 Midclavicular lines (MCLs)—parallel to the MSL, bisecting each clavicle; the borders of the lower lung cross the sixth ribs at the MCLs

Laterally, there are also three vertical lines, originating in their respective axillary folds:

- Anterior axillary line (AAL)
- Midaxillary line (MAL)
- Posterior axillary line (PAL)—like the MCLs, these lines are bilateral

The posterior chest has the following three lines:

- Vertebral or midspinal line—runs through the spinous processes of the vertebrae
- 2 Midscapular lines (MSLs)—parallel to the midspinal line, bisecting the inferior angles of the scapulae

Box 15-1 Anatomic Structures

- Suprasternal notch: A depression palpable at the top of the sternum
- Sternomanubrial angle: A bony bump where the manubrium meets the body of the sternum; about 5 cm distal to suprasternal notch; also known as the angle of Louis; palpating lateral to this junction, the second ribs are found; they are reference points for identifying intercostal spaces and successive ribs; also, a superficial marking for where the underlying trachea divides into right and left main stem bronchi
- Costal angle: The angle formed by the joining of the costal margins with the sternum; normally, no greater than 90 degrees
- Vertebra prominens: The spinous process of the seventh cervical vertebra (C7); allows numbering of thoracic vertebra

Visual Inspection

Inspection is the foremost element of a systematic review of the chest. The physical therapist should not only observe the features of the patient, but also consider the equipment and any aspect of the patient's surroundings that would contribute to delineating the true picture of that patient. The therapist should already have a preliminary idea of the patient based on review of the chart and discussion with the physician, nurse, or physician assistant. Interacting with the patient is necessary to determine whether the initial assessment was realistic. Other clinical signs and symptoms the patient exhibits will also be taken into account during the first interaction. Examination and evaluation should continue during any subsequent interventions and patient visits.

General Appearance

The examination should begin as soon as the therapist walks into the patient's room. Many questions about the appearance of the patient, as well as his or her surroundings, must be considered in order to help determine the patient's status. The following are some examples of questions typical for the acute care setting:

Does the patient appear comfortable? Is there any facial grimacing? Is the patient awake and alert or somnolent or disoriented? Is there any nasal flaring, wheezing, or pursed-lip breathing? (These are signs of respiratory distress. Nasal flaring can be defined as the outward movement of the nares with inspiration.[2]) Are the accessory muscles of respiration (i.e., sternocleidomastoid and trapezius) hypertrophied? How is the patient positioned? Is the patient resting comfortably or leaning forward over the bedside table and struggling for breath? What is the patient's build—stocky, thin, or cachectic? Is the patient's mobility limited? Can the patient sit unsupported? Should the assessment be performed in stages, allowing the patient to be supine and then to lie on each side? Is there any extra equipment in the patient's surroundings? Is the patient using supplemental oxygen? Is the oxygen delivered through a nasal cannula or other device? What is the fraction of inspired oxygen (FiO_2)? Are there any monitoring lines, and where are they located? For instance, if an arterial line is present, is it placed in the radial or the femoral artery? Are there electrocardiogram (ECG) leads? Is it a hard line (directly connected to a monitor) or a telemetry line (communicating through radio transmitter)? Are there intravenous (IV) sites? Are they peripheral (antecubital) or central (subclavian or jugular)? Is there a urinary catheter? Are there chest tubes?

These are just a few examples. In other settings, different questions will apply (such as posture and breathing considerations related to functional activities). However, many of these same questions will apply, regardless of the setting. Remember that a visual inspection of general appearance does not apply only to the patient but also to the immediate surroundings, including any equipment or devices that may be attached to the patient. It is extremely important to know what equipment is being used, to understand the purpose of each medical devices, and to be aware of how movement may affect these devices. All tubes and lines attached to the patient must be identified and thought must be given to what may happen to each of these before any physical therapy activity or intervention is performed. In certain cases, a line or tube being dislodged or detached could be a life-threatening occurrence (such as with an arterial line). In other cases, a dislodging or disturbance of lines may only cause inconvenience (such as with an IV) or discomfort (in the case of a urinary catheter). Regardless of the potential consequences, extreme care and planning must precede any movement of or by patients.

Skin

Does the skin have a pink, healthy color or a pallor? Is cyanosis present? Cyanosis is a bluish tinge that can be seen centrally or peripherally. Central cyanosis is a result of insufficient gas exchange within the lungs and is not usually seen unless oxygen saturation is less than 80%. A bluish tint may be seen at the mucous membranes (e.g., tongue and lips). Peripheral cyanosis, on the other hand, occurs when oxygen extraction at the periphery is excessive. This type is more closely associated with states of low cardiac output. Areas to observe for peripheral cyanosis include fingertips, toes, nose, and nail beds. A differentiating feature between central and peripheral cyanosis is that peripheral cyanosis normally occurs in the cooler body parts, such as the nail beds, and usually vanishes when the part is warmed. In contrast, central cyanosis does not disappear when the area is warmed.

Are any scars, bruises, or ecchymoses observed? Are there reddened areas suggestive of prolonged pressure? Do the bony landmarks appear more prominent than usual? Are there any signs of trauma to the thorax or any other body parts? Does the skin appear edematous? Does this edema appear to limit joint motion? Are there any surgical incisions, new or old? Do these incisions appear to be healed or seem reddened and swollen? Is there evidence of clubbing of the digits? Digital clubbing can be defined as the loss of angle between the nail bed and the distal interphalangeal joint (Figure 15-3). The cause of clubbing is explained by a variety of theories, including increased perfusion secondary to hypoxemia with arterial desaturation, but this is not an exclusive phenomenon; clubbing has also been observed in nonpulmonary diseases such as hepatic fibrosis and Crohn's disease.[2-4]

Neck

Are the accessory muscles of respiration being recruited for a resting breathing pattern? Do the sternocleidomastoid or trapezius muscles appear prominent? This is an early sign of obstructive lung disease.[2]

Jugular Venous Distention

The jugular veins empty into the superior vena cava and reflect right-sided heart function. Right atrial pressure (RAP) is evident based on the extent to which the jugular venous pulse (JVP) can be visualized. The more superficial external jugular veins may be seen superior to the clavicles; the internal jugular veins, though larger, lie deep beneath the sternocleidomastoids and are less visible. Jugular venous distention (JVD) can be best seen when the patient lies with the head and neck at an angle of 45 degrees (Figure 15-4). The presence or absence of symmetry of JVD should be noted. The veins are distended bilaterally if there is a cardiac cause such as

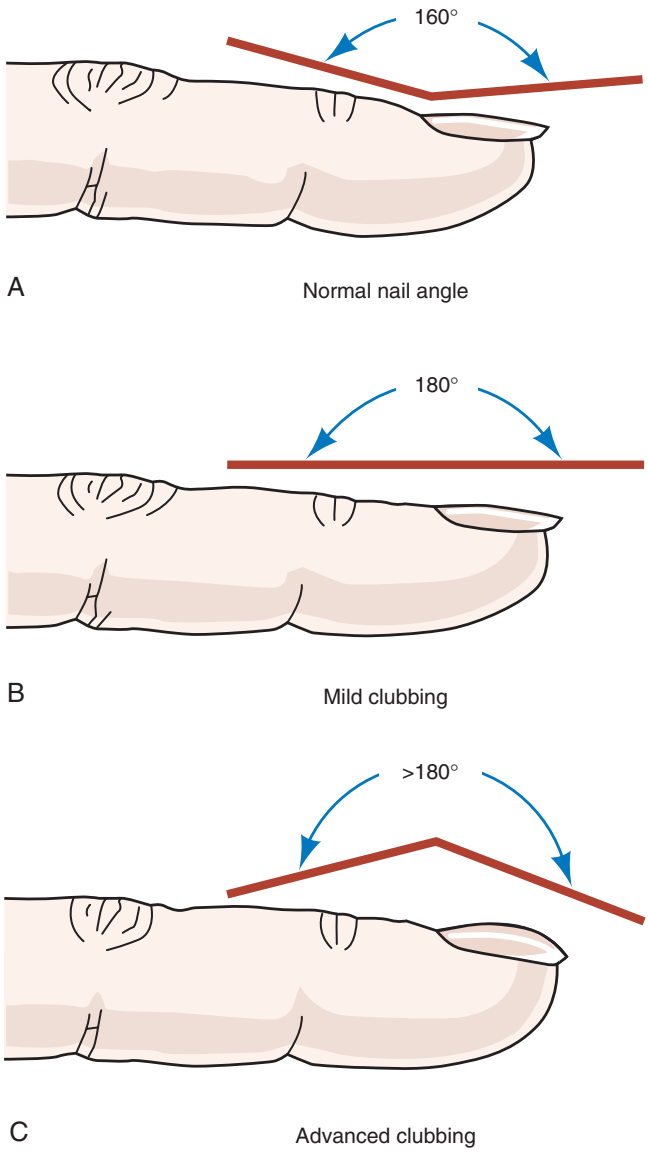

Fig. 15-3 A, Clubbing of the fingers is best assessed by determining the ratio of the diameter at the base of the nail, **B** and **C,** to the diameter at the distal interphalangeal joint. This ratio is normally less than 1. *(From George RB:* Chest medicine, *ed 2, Baltimore, 1990, Williams and Wilkins.)*

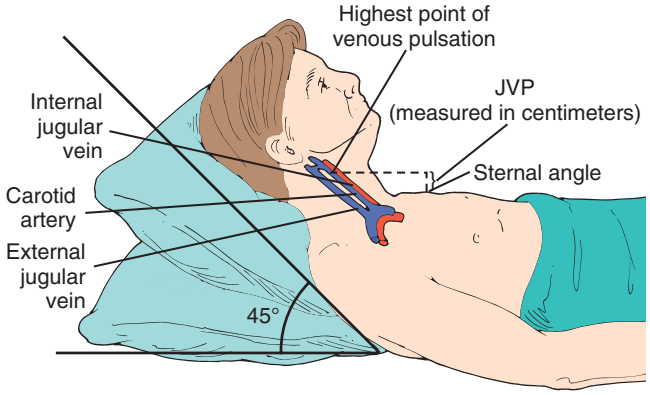

Fig. 15-4 Proper positioning to observe jugular venous distention. *(From Seidel HM:* Mosby's guide to physical examination, *ed 5, Philadelphia, 2003, Mosby.)*

congestive heart failure (CHF). A unilateral distention is an indication of a localized problem.[4]

Chest Wall Configuration

The normal thoracic cage is elliptically shaped when free of disease. The anteroposterior (AP)-to-lateral diameter is 1:2 or 5:7. The angle of the ribs is less than 90 degrees. The ribs articulate with the vertebra posteriorly, at a 45-degree angle. The thorax should be observed anteriorly, laterally, and posteriorly. In patients with COPD, the ribs become more horizontal and the AP diameter increases; thus the term *barrel chest* is used. In infants, the chest is round, with the anteroposterior and transverse or lateral diameters of about equal dimensions. As a child grows to adulthood, the chest becomes more elliptical. With the aging process, the chest returns to a more rounded appearance. The increased anteroposterior diameter in this population is a result of the multiple factors of decreasing lung compliance, decreased strength of the thoracic and diaphragmatic muscles, and skeletal changes in the thoracic spine. The symmetry or absence thereof of the thoracic cage should also be noted. Asymmetry can be the result of structural defects or an underlying intrathoracic pathology or neurological weakness. Various impairments will be seen in different views, as mentioned above, anteriorly, laterally or posteriorly.

Structural defects of the anterior chest may include the following: pectus excavatum, or funnel chest—a depressed lower sternum that usually causes restriction only when it is severe; pectus carinatum, or pigeon chest—a prominent upper sternum that does not restrict chest wall movement; and flail chest—an inward movement of the chest wall with inspiration, such as with multiple rib fractures.

Other structural defects are spinal deformities. These are best viewed posteriorly. Kyphoscoliosis is one example of how a posterior and lateral spinal deviation can limit chest wall and lung expansion. Another example is a patient with COPD, who usually has a forwardly tilted head and thoracic kyphosis (Figure 15-5).

Breathing Patterns

Respiratory rates normally range between 14 and 20 breaths per minute in adults (ages 15 and older). In children, the following ranges are normal: newborn, 30 to 60 breaths per minute; early childhood, 20 to 40 breaths per minute; late childhood, 15 to 25 breaths per minute.[5]

Eupnea is a normal breathing cycle. Apnea is a temporary halt in breathing. Tachypnea is a rapid, shallow breathing pattern; this is an indicator of respiratory distress. Bradypnea exists when respiration is slowed to less than 12 breaths per minute. Causes could be neurologic or metabolic. Kussmaul breathing is an increased rate and depth of respirations and is associated with metabolic acidosis.

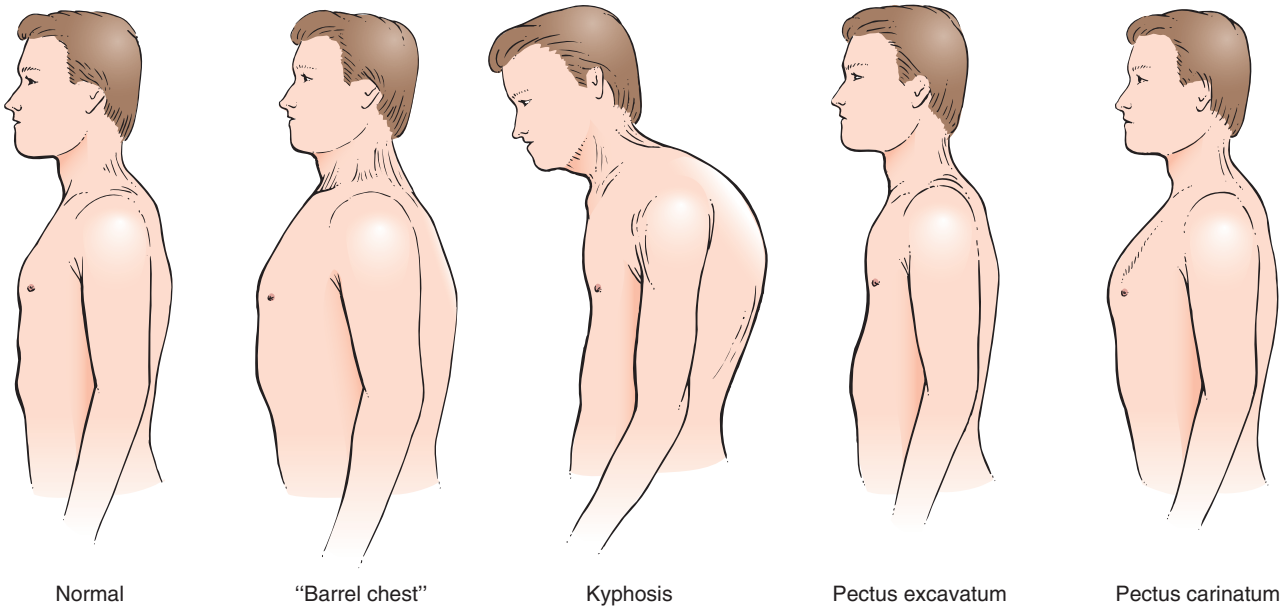

Fig. 15-5 Chest wall configurations. *(From Schwartz MH:* Textbook of physical diagnosis: History and examination*, ed 6, St Louis, 2010, Saunders.)*

Dyspnea is the patient's subjective feeling of shortness of breath. Dyspnea worsens as the severity of the disease increases. An easy method for documenting the level of dyspnea is to count the numbers of words that the patient is able to speak per breath. For instance, six-word dyspnea is not as significant as one-word dyspnea. The type of activities that elicit shortness of breath should also be ascertained. For example, is breathlessness precipitated by stair climbing, taking a shower, and so forth? The normal ratio of inspiratory time to expiratory time is 1:2. As the respiratory rate increases, the inspiration-to-expiration (I:E) ratio decreases to 1:1. This is seen in respiratory distress; as the patient struggles to breathe in, the expiratory phase is shortened, and a vicious circle continues. With pursed-lip breathing, the idea is to prolong the expiratory phase and slow the breathing pattern.

Other objective ways of measuring dyspnea (e.g., the Borg scale, the ventilator response index [VRI], the American Thoracic Society Dyspnea Scale, the Bog Scale of Perceived Exertion) are discussed in Chapter 8. Choosing a scale that the patient understands and can easily use will work best for identifying activities and interventions that cause more or less dyspnea. Later, patients can use the scale to self-monitor their dyspnea in relation to their activities and know when to increase or decrease activity secondary to dyspnea.

Auscultation

Auscultation is the art of listening to sounds produced by the body. Lung and heart sounds are the focus of this chapter. Skill in auscultation is dependent on the following four factors.

1. A functional stethoscope
2. Proper technique
3. Knowledge of the different categories of lung sounds: normal, abnormal, adventitious breath sounds, and voice sounds
4. Knowledge of the various categories of heart sounds and murmurs

Stethoscope

A stethoscope need not be sophisticated to be effective. A physical therapist skilled in auscultation can use any basic stethoscope and be able to identify lung sounds. The stethoscope functions more as a filter to the extraneous noises than as an amplifier. A basic stethoscope consists of earpieces, tubing, and a chest piece. The bell portion of the chest piece assesses low-pitched sounds (i.e., heart sounds). The diaphragm portion discerns high-pitched sounds (Figure 15-6). The tubing should not be so long that sound transmission is dampened. An appropriate length is between 30 cm (12 inches) and 55 cm (21 to 22 inches). The earpieces should fit the physical therapist's ears comfortably and allow the tuning out of external sounds. Another consideration is to position the earpieces anteriorly, or forward toward the ear canals. Warming the diaphragm before placing it on the patient's skin is appreciated by the patient.

A study by Gurunga and colleagues evaluated the use of computer lung sound analysis as a diagnostic aid for auscultation. Their conclusion was that the interlistener automated variability was limited by the acuity of the individual listeners and that the use of the automated identification of lungs sounds may improve the overall sensitivity to more accurately pick up wheezes and crackles. The computerized lung sound analysis was 80% more specific and 85% more sensitive to wheezes and crackles. The authors concluded that their data are limited but may prove clinically promising in the future.[6]

Technique

Environment is another element in the correct performance of auscultation. The room or cubicle should be as quiet as possible. Television and radio should be turned off, and any

extraneous noises should be minimized or eliminated. This is especially important when auscultation is a new technique for the therapist. Clothing should be removed or draped so that it does not interfere in the assessment of the breath sounds. The patient should be in a sitting position, if possible, for lung sounds. The anterior, lateral, and posterior aspects of the chest should be auscultated both craniocaudally (apices to bases) and side to side (Figure 15-7). The physical therapist places the diaphragm on the patient's skin so that it lies flat. The patient is instructed to breathe in and out through the mouth. A slightly deeper breath than tidal breathing is suggested. A minimum of one breath per bronchopulmonary segment allows for a comparison of the intensity, pitch, and quality of the breath sounds. Moving the diaphragm from one side to the other side while simultaneously moving it craniocaudally enables the therapist to compare the right side of the chest with the left side of the chest.

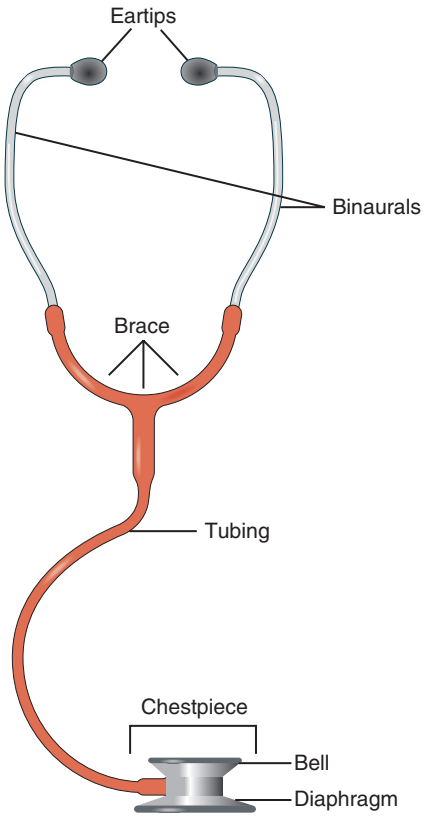

Fig. 15-6 Stethoscope and its various parts. *(From Cameron MH, Monroe L: Physical rehabilitation: Evidence-based examination, evaluation, and intervention, Philadelphia, 2007, WB Saunders.)*

Chest Sounds

Chest sounds may be divided into the following categories.

1. Breath sounds—normal, abnormal, adventitious
2. Extrapulmonary sounds—pleural or friction rubs
3. Voice sounds—egophony, bronchophony, whispered pectoriloquy
4. Heart sounds

Breath Sounds

The terminology of breath sounds provided in this chapter is a compilation of multiple resources and clinical experience. Recognition of normal breath sounds is the key to the identification of abnormal and adventitious sounds because it offers the listener a point of reference. Normal breath sounds can be broken down into bronchial, bronchovesicular, and vesicular. The American Thoracic Society (ATS) and the American College of Chest Physicians (ACCP) have attempted to provide standardization of the nomenclature and continue to conduct surveys of health care professionals for use of this terminology in clinical practice.

Bronchial sounds can be described as high-pitched and are heard in both the inspiratory and the expiratory phase. A distinguishing feature is the pause that exists between the inspiratory and expiratory phases (Figure 15-8). These sounds are also described as tracheal because their normal location is over the trachea. Bronchovesicular sounds are similar in that they are also high-pitched and have equal inspiratory and expiratory cycles. However, a differentiating feature is the lack of a pause (see Figure 15-8). Bronchovesicular sounds are heard best wherever the bronchi, or central lung tissue, are close to the surface. These areas are supraclavicular and suprascapular (the apices), as well as parasternal and interscapular (the bronchi). The ATS and ACCP, in their 1977 recommendations for pulmonary nomenclature, used the term *bronchial* to include both bronchial and bronchovesicular sounds. The difference is minor (the pause between the inspiratory and expiratory phases). This recommendation is meant to provide uniformity to lung-sound terminology. Vesicular breath sounds are heard over the remaining peripheral lung fields. These sounds have primarily an inspiratory component, with only the initial one-third of the expiratory phase audible. Their intensity is also softer because of the dampening effect of the spongy lung tissue and the cumulative effect of the air entry from numerous terminal bronchioles. The idea that

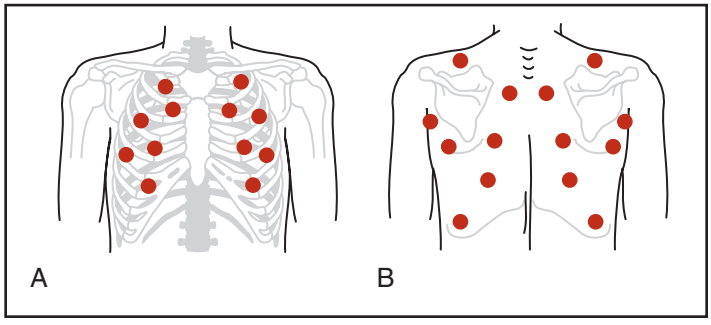

Fig. 15-7 One method of auscultating the chest. **A,** The chest. **B,** The back. *(Redrawn from Buckingham EB:* A primer of clinical diagnosis, *ed 2, New York, 1979, Harper & Row. In Hillegass E: Essentials in cardiopulmonary physical therapy, ed 3, St Louis, 2011, Saunders.)*

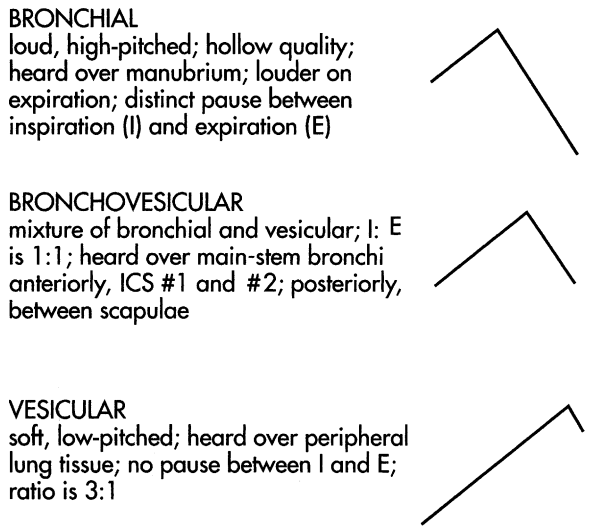

Fig. 15-8 Normal breath sounds.

vesicular sounds reflect air entry in the alveoli has been disproved. Thus, as the therapist auscultates from top to bottom, the breath sounds are quieter at the bases than at the apices. Infants and small children have louder, harsher breath sounds. This is as result of the thinness of the chest wall and the airways' being closer to the surface.

ABNORMAL BREATH SOUNDS

Abnormal breath sounds can be described as changes in the sound transmission as a result of an underlying pathologic process. Sound is filtered by the lung tissues because these organs are air-filled; thus sound transmission is dampened over the bases more than over the apices. On the other hand, sound transmission is enhanced when a liquid or solid is the medium. Certain lung pathologies produce abnormal lung sounds. Abnormal sounds can be divided into three types: bronchial, decreased, and absent. Bronchial sounds occur in peripheral lung tissue when it becomes airless—either partially or completely. In a consolidating type of pneumonia, the lung tissue is "airless" because of the complete obstruction of segmental or lobar bronchi by secretions. Sound from the adjacent bronchi is enhanced and becomes higher pitched, and the expiratory component is louder and more pronounced. Compression of lung tissue from an extrapulmonary source also produces bronchial sounds. Examples include compression secondary to increased pleural fluid (pleural effusion) or tumor. *Tubular breath sounds* is a term used synonymously to mean abnormal bronchial breath sounds.

Decreased or absent breath sounds occur when sound transmission is diminished or abolished. Decreased breath sounds occur when the normal vesicular sounds are further diminished. The term *absent sounds* means that no sounds are audible. Decreased or absent sounds can be caused by an internal pulmonary pathology or can be secondary to an initially nonpulmonary condition. Hyperinflation caused by emphysema causes decreased sound transmission as a result of the destruction of the acinar units and causes increased air as a result of the loss of normal lung structure. The loss of lung compliance resulting from pulmonary fibrosis also may produce decreased or absent breath sounds. Extrapulmonary causes include tumors, neuromuscular weakness (i.e., muscular dystrophy), and musculoskeletal deformities (i.e., kyphoscoliosis). Pain is a common cause for decreased or absent breath sounds. When the patient attempts to take a deep breath, the volume is limited because of the onset of pain. The causes of the pain can be varied—from incisional (e.g., midsternotomy) to traumatic (e.g., fractured ribs). If no underlying pathologies are present, decreased breath sounds may be a reflection of the depth of respiration or the thickness of the chest wall (e.g., in obesity or with the presence of bandages). The skill of auscultation lies in the differentiation between normal and abnormal breath sounds.

ADVENTITIOUS BREATH SOUNDS

Adventitious breath sounds are the extraneous noises produced over the bronchopulmonary tree and are an indication of an abnormal process or condition. These sounds may be more easily identifiable than abnormal sounds. Adventitious sounds are classified as crackles (rales), rhonchi, and wheezes. Crackles (rales) are described as discontinuous, low-pitched sounds. They occur predominantly during inspiration. The sound of rubbing hair between the fingers or of Velcro popping simulates crackles. Crackles usually indicate a peripheral airway process. Rhonchi are low-pitched but continuous sounds. These occur in both inspiration and expiration. *Snoring* is a term used to describe its quality. Rhonchi are attributed to an obstructive process in the larger, more central airways. Wheezes are continuous but high-pitched. A hissing or whistling quality is present. Wheezes that occur predominantly during inspiration are an indication of bronchospasm; wheezes during exhalation are an indication of airway secretions. The airways get larger on inspiration and smaller on exhalation. Consequently, when the patient has bronchospasm, a high-pitched wheeze is heard on inspiration. During exhalation, the airways become more narrow, consequently when air goes past secretions in a narrowed airway, an expiratory wheeze is heard on auscultation. Being able to identify the difference between inspiratory and expiratory wheezing is very important because this will help to determine what treatment is indicated. Inspiratory wheezing indicates that a bronchodilator is needed, whereas expiratory wheezing suggests the need for airway clearance techniques.

EXTRAPULMONARY SOUNDS

An adventitious sound that is nonpulmonary is the friction rub. It can be described as a rubbing or leathery sound, and it occurs during both inspiration and expiration. The sound is produced when the visceral (inner) pleural lining rubs against the parietal (outer) pleura and is a sign of a primary pleural process, such as inflammation or neoplasm. Pain is usually associated with a friction rub.

VOICE SOUNDS

Voice sounds are vibrations heard through a stethoscope and produced by the speaking voice as it travels down the tracheobronchial tree and through the lung parenchyma. These sounds, over the normal lung, are low-pitched and have a muffled or mumbled quality. The transmission of these vocal vibrations can be increased or decreased in the presence of an

underlying pulmonary pathologic process. Bronchophony describes the phenomenon of increased vocal transmission. Words or letters are louder and clearer. It is caused by conditions in which there is increased lung density, as in consolidation due to pneumonia. To assess for bronchophony, the patient is usually asked to repeat "blue moon" or "one, two, three." Egophony may also be present when there is increased transmission of the vocal vibrations. In this case, the patient is asked to say "eeee." The underlying process distorts the e sound so that an "aaa" sound is heard over the peripheral area by the examiner. Egophony coexists with bronchophony.

Whispered voice sounds also produce low-pitched vibrations over the chest that are muffled by normal lung parenchyma. In whispered pectoriloquy, these whispered voice sounds become distinct and clear; "one, two, three" or "ninety-nine" are used to evaluate this sound. Whispered pectoriloquy can be present when bronchophony and egophony are absent. This sign is helpful in identifying smaller or patchy areas of lung consolidation.

Voice sounds are a method of confirming abnormal breath sounds. If a patient with significant atelectasis secondary to compression of lung tissue presents with bronchial breath sounds, then egophony and bronchophony are also audible.

Websites are available that allow the beginner in auscultation to hear actual lung sounds. The two websites included in this chapter's references have links to these auditory sites. Other sites may be found by doing an online search (using Google or another search engine) with key words such as "auscultation of breath sounds."

Heart Sounds

As with lung sounds, superficial topographic landmarks assist the therapist in auscultation of heart sounds and murmurs. The left ventricular apex is normally located at the midclavicular line (MCL) in the fifth intercostal space (ICS). The cardiac apex is also known as the point of maximum impulse (PMI), where the pulse is most strongly heard. There are four reference areas for cardiac auscultation; they do not correspond directly to the underlying cardiac anatomy. On the other hand, these areas do relate to the events arising at the individual cardiac valves. These four areas are defined as the following.

- Aortic: second ICS, at right sternal border (RSB)
- Pulmonic: second ICS, at left sternal border (LSB)
- Tricuspid: fourth and fifth ICS, LSB
- Mitral: cardiac apex, fifth ICS, MCL

Technique

An environment that is as quiet as possible is recommended. Positions used for cardiac auscultation include the following: supine—used for all areas; left lateral decubitus (side-lying)—listening to cardiac apex or mitral area, bell usually used; and sitting—used for all areas. Clinically, there are times when positions may be limited. In those cases, the therapist must listen with the patient in the best position available. However, if possible, the left side-lying position is most valuable because the pathological S_3 and S_4 sounds are heard most clearly. If the patient is in a sitting position, a leaning-forward position may also be used for better auscultation.

Normal Heart Sounds

The first heart sound (S_1) signifies the closing of the atrioventricular valves. Its duration is 0.10 seconds; it is heard the loudest at the cardiac apex. The two components of S_1 are tricuspid and mitral. Both the diaphragm and the bell of the stethoscope can be used to hear S_1. Its loudness is enhanced by any condition in which the heart is closer to the chest wall (i.e., thin chest wall) or in which there is an increased force to the ventricular contraction (e.g., tachycardia resulting from exercise; Figure 15-9).

The second heart sound (S_2) represents the closing of the semilunar valves and the end of ventricular systole. Its components are aortic and pulmonic. During expiration, these two components are not distinct because the time difference in the closure of the valves is less than 30 milliseconds. However, during inspiration, a splitting of S_2 is audible. This physiologic split results from the increased venous return to the right heart secondary to the decreased intrathoracic pressure that occurs during inspiration. The pulmonic valve closure is delayed as the right ventricular systolic time is lengthened. A split S_2 is heard commonly in children and young adults. The diaphragm of the stethoscope should be used to hear the split. The pulmonic component is the softer sound and is best heard at the LSB, in the second to fourth ICS. The two components may be heard best in the aortic and pulmonic areas, respectively. When the split is heard in both phases of respiration, an underlying cardiac abnormality is suspected. Causes may include right bundle branch block and pulmonary hypertension.[2,7]

Gallops

The third heart sound (S_3) is a faint, low-frequency sound and reflects the early (diastolic) ventricular filling that occurs after the atrioventricular valves open. S_3 is normal in children and young adults; however, it is usually abnormal in individuals

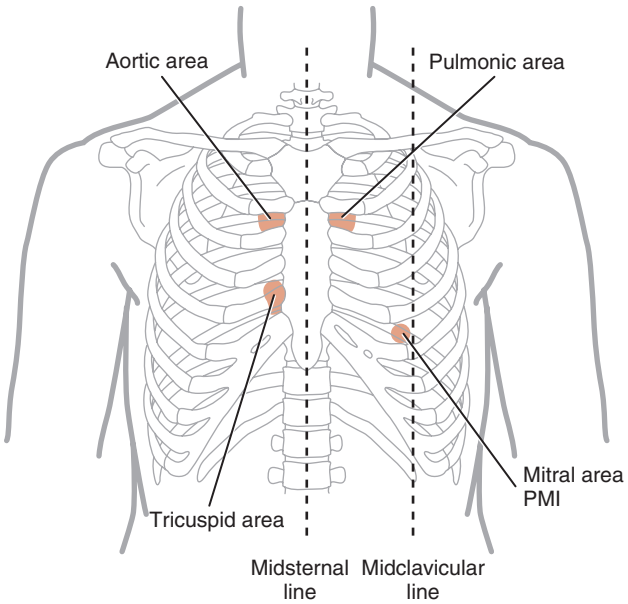

Fig. 15-9 Cardiac auscultation. *(From http://www.kumc.edu/kumcpeds/cardiology/tofmsllecture/auscultaitonareas.gif.)*

over age 40. An extra effort must be made to auscultate S_3; the bell of the stethoscope should be used. The ideal position to hear S_3 is left side-lying; the bell should be placed over the cardiac apex. Causes of a pathological S_3 may include ventricular failure, tachycardia, or mitral regurgitation. "Ken-TUCK-y" is one sound that has been used to approximate the sound sequencing of S_3 in the cardiac cycle (S_1, S_2, S_3).

The fourth heart sound (S_4) signifies the rapid ventricular filling that occurs after atrial contraction. When present, it is heard before S_1. S_4 may be heard in the "normal" individual with left ventricular hypertrophy. The location of S_4 is similar to that of S_3. Its sound can be described as dull because of the sudden motion of stiff ventricles in response to increased atrial contraction. Pathologies eliciting an S_4 may include systemic hypertension, cardiomyopathies, and coarctation of the aorta. "TENN-es-see" is a sound that approximates the sound sequencing when S_4 is present (S_4, S_1, S_2).

Murmurs

Cardiac murmurs are the vibrations resulting from turbulent blood flow. They may be described based on position in cardiac cycle (systole, diastole), duration, and loudness. Systolic murmurs occur between S_1 and S_2; diastolic murmurs occur between S_2 and S_1. A continuous murmur starts in S_1 and lasts through S_2 for a portion or all of diastole. The loudness of a murmur is a factor of the velocity of blood flow and the turbulence created as it flows through a specific opening such as a valve. Grades I to VI are described in Table 15-1.

Murmurs that are grade III or higher are usually associated with cardiovascular pathology.

Mediate Percussion

Mediate, or indirect, percussion allows the therapist to assess the density of the underlying organs. Striking the chest wall produces vibrations in the underlying structures that, in turn, give rise to sound waves or percussion tones. The quality of tone depends on the density of the tissue or organ (i.e., it becomes louder over air-filled structures). These tones are described by the following terms:

- Resonant: loud or high amplitude, low pitch, longer duration; heard over air-filled organs such as the lungs
- Dull: low amplitude, medium to high pitch, short duration; heard over solid organs such as the liver
- Flat: high pitch, short duration; heard over muscle mass such as the thigh
- Tympanic: high pitch, medium duration; heard over hollow structures such as the stomach
- Hyperresonant: very low pitch, prolonged duration; heard over tissue with decreased density (increased air-to-tissue ratio); abnormal in adults; heard over lungs with emphysema

Table 15-1 **Grading of Heart Murmurs**

Grade	Loudness	Comments
I	Faint	Requires concentrated effort to hear
II	Faint	Audible immediately
III	Louder than II	Intermediate intensity
IV	Loud	Intermediate intensity; associated with palpable vibration (thrill)
V	Very loud	Thrill present
VI	Audible without stethoscope	

Technique

The middle finger of the nondominant hand is placed firmly on the chest wall in an intercostal space and parallel to the ribs. The top of the middle finger of the dominant hand strikes the distal phalanx of the stationary hand with a quick, sharp motion. The impetus of the blow comes from the wrist rather than the elbow and has been likened to that of a paddle ball player (Figure 15-10).[2] As with auscultation, the therapist must follow the sequence of apices to bases and side to side so that comparisons can be made. This technique is not usually used in infants because percussion is too easily transmitted by a small chest.

Diaphragmatic Excursion

Assessment of diaphragmatic movement can be made with mediate percussion. The patient is asked to breathe deeply and hold that breath. The lowest level of the diaphragm on maximal inspiration coincides with the lowest point where a resonant tone is heard. The patient is then asked to exhale, and mediate percussion is repeated. The lowest area of resonance now moves higher, as the diaphragm ascends with relaxation. The distance between these two points is described as the diaphragmatic excursion; the normal range is 3 to 5 cm (Figure 15-11). Diaphragmatic movement is decreased in patients with COPD.

Palpation

Physical therapists use palpation in all areas of practice. Touch is an integral part of physical therapy. As part of the chest examination, palpation is used to assess areas of tenderness, abnormalities, chest wall excursion, edema, tactile fremitus,

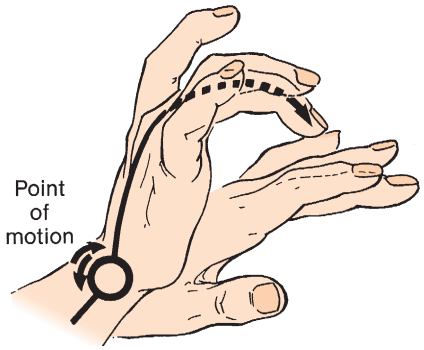

Fig. 15-10 Mediate percussion technique. *(Adapted from Buckingham EB:* A primer of clinical diagnosis, *ed 2, New York, 1979, Harper & Row. In Cameron MH, Monroe LG: Physical rehabilitation: Evidence-based examination, evaluation, and intervention, St Louis, 2007, Saunders.)*

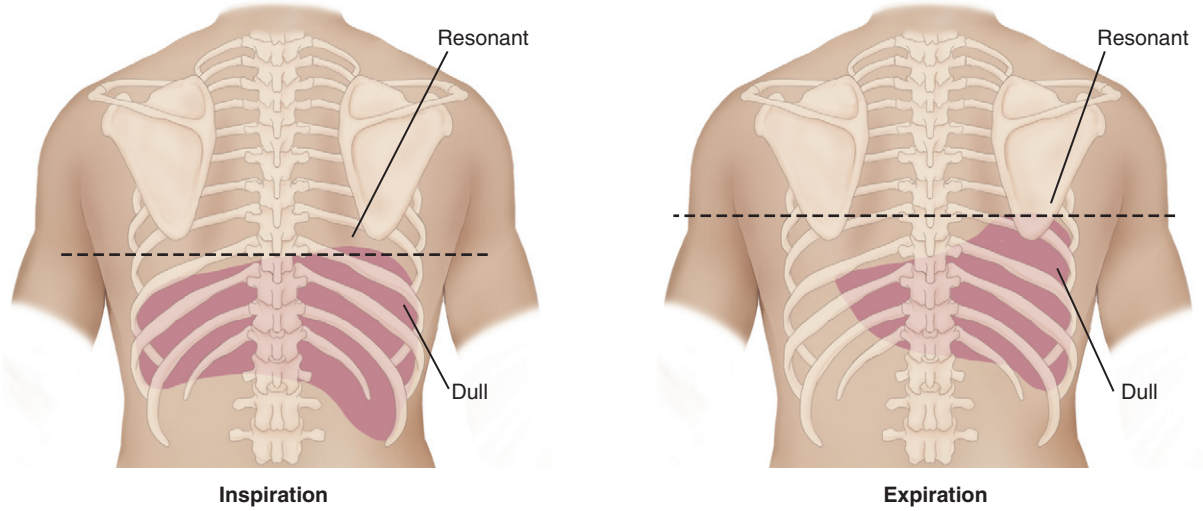

Fig. 15-11 Diaphragmatic excursion. *(From Schwartz MH:* Textbook of physical diagnosis: History and examination, *ed 6, St Louis, 2010, Saunders.)*

and tracheal deviation. It can help to differentiate between musculoskeletal impairments and pulmonary impairments.

Tenderness

Specific superficial or deep landmarks are identified by means of palpation. Determination of gross spinal alignment can be performed by tracing the spinous processes in a cephalocaudal direction. Certain structures can be identified, such as the T4 vertebra or the sternal angle; this augments the physical therapist's evaluation. Areas of tenderness can be assessed for degree of discomfort and reproducibility. Differentiation of chest wall discomfort of an organic nature, such as in angina, from that of a musculoskeletal condition may be made through palpation. In a patient complaining of chest pain, angina may be ruled out if the physical therapist can reproduce or increase the discomfort by increasing tactile pressure. However, one must also determine that corroborating symptoms (e.g., diaphoresis, tachycardia) are not present. Angina or chest pain secondary to myocardial ischemia usually results from exertion and may be relieved by rest. Crepitus is a crunchy sound often associated with articular structures. However, when bubbles of air occur within subcutaneous tissue, a crackling sensation can be palpated. An air leak from a chest-tube site is one circumstance in which crepitus is palpated over the chest wall. Crepitus can also be secondary to a pleural or friction rub.

Edema

Palpation allows the physical therapist to assess peripheral edema. Dependency of body parts such as lower extremities or sacrum can cause swelling related to cardiac and noncardiac conditions. Assessment of edema is performed by pressing two fingers into the particular areas for 2 to 3 seconds. If an impression is left once the fingers are removed, then pitting or dependent edema is present. The degree of edema is based on the length of time that the indentation lasts. 1+ is the least degree; 4+ is the worst.

Chest Wall Excursion

Evaluation of thoracic expansion allows the therapist to observe a baseline level by which to measure progress or decline in a patient's condition. Chest wall movement can be restricted unilaterally as a result of lobar pneumonia, scoliosis, muscle weakness, paralysis or a surgical incision. A symmetrical decrease in chest wall motion occurs in the patient with COPD.

The hyperinflation associated with COPD produces an increase in the anteroposterior diameter with a progressive loss of diaphragmatic excursion. Normal chest wall excursion is about 3.25 inches (8.5 cm) in a young adult between 20 and 30 years of age. One method is to use a tape measure at the level of the axilla and xiphoid. In a study of 120 normal subjects, ages ranging from 20 years to 70+ years, Kinney LaPier[8] performed tape measure readings of subjects in a sitting or standing position at rest and at maximal inspiration (vital capacity) breaths. They found that subjects 20 to 29 years of age had 5.1 ± 6.2 CM excursion. In subjects 70 years and older, the excursion was only 2.5 ± 2.9 cm. The study found a definite decrease in chest wall excursion with age and recommends not utilizing chest wall excursion by tape measure in patients over 65.[8]

The most common method involves direct hand contact. This technique is performed in all planes and from top to bottom. Symmetry and extent of movement are noted. The procedures for this method are found in Table 15-2.

Tactile Fremitus

Spoken words produce vibration over the chest wall. Voice sounds have been previously discussed under auscultation. When the physical therapist's hands are placed on the chest wall, the vibrations of spoken words can be felt; these are described as tactile fremitus. The presence or absence of tactile fremitus provides information about the density of the underlying lungs and thoracic cavity.[2]

Table 15-2 Methods for Evaluating Thoracic Expansion

Method	Steps
Apical or upper lobe motion (Figure 15-12, *A*)	1. The physical therapist faces the patient. The area to be examined is exposed and draped as needed. 2. The physical therapist's hands are placed over the anterior chest. The heel of the hand is at about the level of the fourth rib and the fingertips reach toward the upper trapezii. 3. The thumbs lie horizontal at about the level of the sternal angle and meet at the midline, slightly stretching the skin. 4. The patient is asked to inhale. 5. The hands should be relaxed to allow for movement beneath. 6. The symmetry and extent of movement are assessed.
Anterolateral or middle lobe/lingula motion (Figure 15-12, *B*)	1. See step 1 of Apical, above. 2. The physical therapist's hands are placed with the palms distal to the nipple line and the thumbs meeting in the midline. The fingers lie in the posterior axillary fold. 3. See steps 4 to 6 of Apical, above.
Posterior excursion/lower lobe motion (Figure 15-12, *C*)	1. The physical therapist stands behind the patient. 2. The area to be examined is exposed with draping used as appropriate. 3. The physical therapist's hands are placed flat on the posterior chest wall at the level of the tenth rib. The thumbs meet at the midline; fingers reaching toward the anterior axillary fold. 4. See steps 4 to 6 of Apical, above.

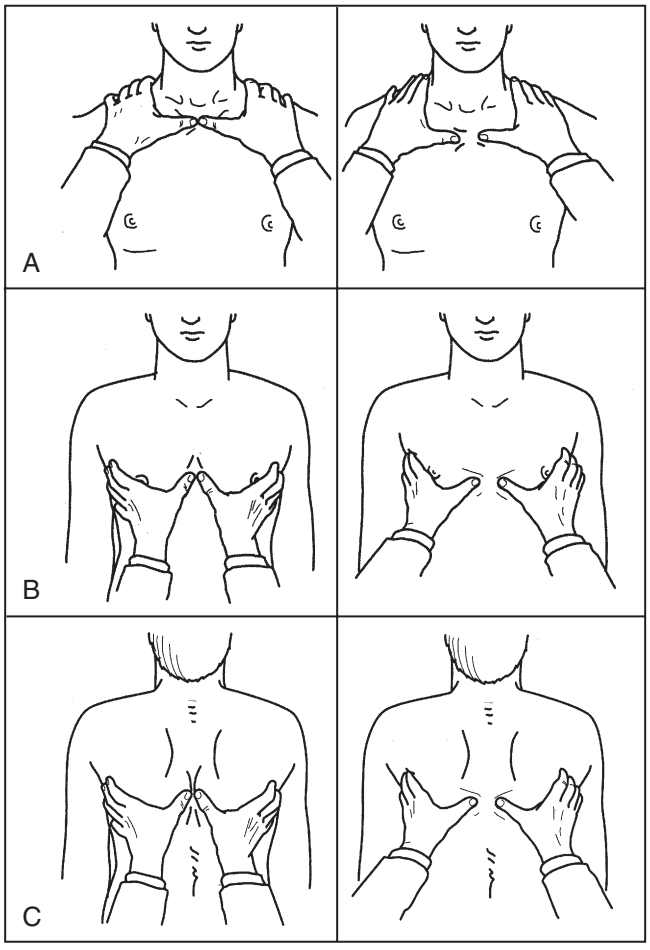

Fig. 15-12 Palpation of upper lobe motion (**A**), right middle and left lingula lobe motion (**B**), and lower lobe motion (**C**). *(Redrawn from Cherniack RM, Cherniack L:* Respiration in health and disease, *ed 2, Philadelphia, WB Saunders, 1972.)*

Technique

Two methods can be used to evaluate for tactile fremitus (Figure 15-13). In the first technique, the therapist uses the palmar surface of one or both hands. The second method involves the use of the ulnar border of one hand. With both techniques, the sequence is, again, cephalocaudal and side to side. In either method, the next step is to ask that the patient speak a predetermined phrase. The two most commonly used phrases are "ninety-nine" and "one, two, three." A light but firm touch is recommended.

Tracheal Deviation

The trachea's midline position can be examined anteriorly (Figure 15-14). The physical therapist places an index finger in the medial aspect of the suprasternal notch. This is repeated on the opposite side. An equal distance between the clavicle and the trachea should exist bilaterally. Tracheal deviation may be caused by a pneumothorax, atelectasis, or a tumor. Whether the deviation is ipsilateral or contralateral depends on the underlying cause. A right pneumothorax or pleural effusion deviates the trachea away from the affected side (i.e., the left); a left lower lobe atelectasis, however, deviates the trachea toward the affected side (i.e., the left).

Case Studies

Case Study 15-1

A 30-year-old man with cystic fibrosis presents with a 1-week history of increased sputum production, loss of appetite, fatigue, and a 3-pound (6.6-kg) weight loss. With a system review of the chest (visual inspection) and the tests and measures of auscultation, mediate percussion, and palpation, the following findings are shown:

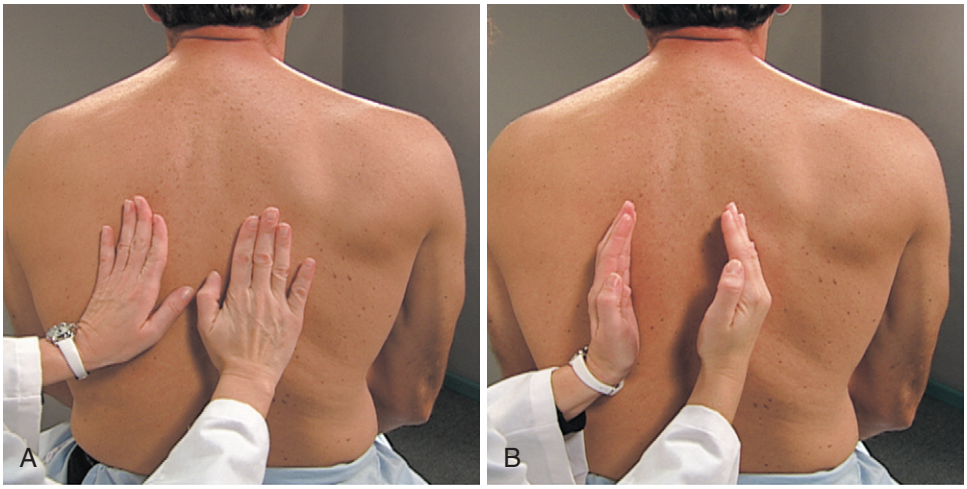

Fig. 15-13 Technique for evaluating fremitus. **A,** Method one. **B,** Method two. *(**B** from Schwartz MH. Textbook of Physical Diagnosis: History and Examination, ed 6. St. Louis, 2010, Saunders.)*

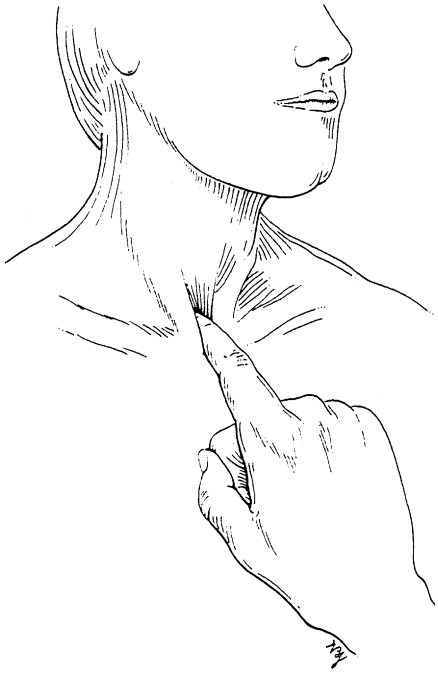

Fig. 15-14 Technique for determining the position of the trachea. *(From Schwartz MH.* Textbook of physical diagnosis: History and examination, *ed 6, St Louis, 2010, Saunders.)*

- Visual inspection: Forward head and neck, protracted shoulders, kyphotic posture, and increased anteroposterior diameter are present; the patient appears thin and fatigued; respiratory rate 24, use of accessory muscles observed; the patient has an effective and wet cough producing green thick mucus
- Auscultation: Decreased breath sounds with scattered crackles throughout all lung fields, especially over right posterior upper lobe and right middle lobe
- Palpation: Limited chest wall excursion (CWE), especially laterally on right
- Mediate percussion: Dull over right middle and lower chest, especially laterally

The evaluation component utilizes the above findings to identify the appropriate outcomes and treatment interventions. Based on the acuity of the examination, acute exacerbation of cystic fibrosis may be the diagnosis. The focus may be on secretion clearance and identification of the most appropriate airway clearance techniques. Would the high-frequency chest oscillations (ThAIRapy Vest) or manual techniques of chest percussion, vibration/shaking, and specific postural drainage positions be the choice for this patient? Scheduling airway clearance techniques and coordination treatments with respiratory therapy and inhaled medications is indicated as well. Ongoing daily reexamination will determine whether the treatment interventions need to be modified or continued as is. The patient's home exercise and airway clearance program should be reevaluated to prevent recurrence. The use of a daytime device such as Acapella or Flutter or other easy-to-use equipment may be helpful to enhance the patient's airway clearance program (see Chapter 21).

For more information about musculoskeletal issues in people with cystic fibrosis, see the article by Massery (2005).[9]

Case Study 15-2

An 8-year-old female admitted to the pediatric inpatient unit presents on chart review (history) with a 4-day history of recurrent fevers, shortness of breath, and lethargy. A chest radiogram shows a right middle lobe infiltrate, based on the following findings:

- Visual inspection: Tachypnea; RR 44; I:E ratio 1:1; weak, shallow cough
- Auscultation: Bronchial over right midanterior chest; egophony also present
- Mediate percussion: Dull over affected area
- Palpation: Trachea midline, markedly decreased CWE on right side

Anticipated outcomes may include the following.

1. The patient will demonstrate an effective cough.
2. The patient will demonstrate decreased work of breathing.

Treatment interventions may include manual chest percussion, vibration/shaking, postural drainage to right middle lobe

Table 15-3 **Differentiation of Common Pulmonary Conditions**

Condition	Inspection	Palpation	Percussion	Auscultation
Emphysema	Increased anteroposterior diameter; use of accessory muscles; thin individual	Decreased tactile fremitus	Increased resonance; decreased excursion of diaphragm	Decreased lung sounds; decreased vocal fremitus
Chronic bronchitis	Possible cyanosis; short, stocky individual	Often normal	Often normal	Early crackles
Pneumonia	Possible cyanosis	Increased tactile fremitus; splinting on affected side	Dull	Late crackles; bronchial breath sounds
Pulmonary embolism	Sudden onset of dyspnea; chest pain	Usually normal	Usually normal	Usually normal
Pneumothorax	Rapid onset	Absent fremitus; trachea may be shifted to other side; may have decreased chest wall excursion on affected side	Hyperresonant	Absent breath sounds
Pleural effusion	May be no outward clinical sign	Decreased fremitus; trachea shifted to other side; decreased chest wall excursion on affected side	Dullness	Absent breath sounds
Atelectasis	Often no outward clinical sign	Decreased fremitus; trachea shifted to same side; decreased chest wall excursion on affected side	Dullness	Absent breath sounds

Modified with permission from Swartz MH: *Textbook of physical diagnoses—History and examination,* ed 2, Philadelphia, 1994, WB Saunders.

area and instruction in huff coughing. Games that may be incorporated to facilitate the huffing and also increase the I:E ratio include blowing bubbles, windmills, kazoos. Handheld airway clearance devices, such as the Flutter, TheraPEP, or Acapella, may also be used.

Case Study 3

A 72-year-old woman presents with symptoms of persistent fevers, left chest wall discomfort, and history of a fall 1 week ago. A CT scan shows a loculated pleural effusion on the left. A left chest tube has been inserted for drainage. The working medical diagnosis is empyema. The patient is a nonsmoker. The following information is learned during the examination component of the patient management model:

- Visual inspection: RR 30; I:E ratio 1:2; epidural catheter for pain control; effective dry cough
- Auscultation: Absent breath sounds halfway up left lower lateral chest wall
- Mediate percussion: Flat over left lower lateral chest wall
- Palpation: Trachea deviated to right; decreased CWE on left; range of motion of left shoulder joint limited in flexion and abduction at about 90 degrees maximum; no preadmission shoulder limitations

Outcomes and treatment interventions must expand beyond the pulmonary diagnosis of empyema because the surgical insertion of a chest tube and the fall itself have impacted the musculoskeletal system as well.

An anticipated outcome would be for the patient to demonstrate no abnormal lung sounds as a result of increased lung volumes. Interventions would include breathing strategies (i.e., left lateral costal and diaphragmatic breathing). Ventilatory strategies could be incorporated into range-of-motion exercises for the shoulder. Incentive spirometry may also facilitate increased lung volumes. Finally, as the patient's condition becomes less acute, further evaluation may determine whether a balance impairment was the cause of the initial fall.

Table 15-3 presents differentiation of diagnoses by the elements of a chest physical examination.

Summary

As demonstrated in the case studies, each of the examination skills discussed contributes to the physical therapist's evaluation of the individual patient. This initial examination component of the patient management model makes it possible to perform the remaining components of evaluation, diagnosis, and prognosis.

Review Questions

1. Describe the sequence used to auscultate lung sounds.
2. Name two causes for decreased breath sounds.
3. What do bronchial breath sounds indicate if found where normal vesicular breath sound should be heard?
4. Name two causes for a pathologic S_3.
5. Why is it more appropriate to have the patient in a left side-lying position to evaluate heart sounds?
6. Formulate a plan for the evaluation of a patient with an acute right lower lobe pneumonia.
7. Which components of the chest physical examination might a physical therapist include in the initial assessment of an older adult patient with a recent left total hip replacement and a history of COPD and CHF?

The primary goal of the intensive care unit (ICU) team is to achieve hemodynamic stability and optimal oxygen transport for each patient who is critically ill, keeping a view toward the patient's eventual return to maximal functional participation in life and activity. This chapter introduces monitoring systems used in the evaluation of cardiovascular and pulmonary status in patients in the ICU and describes some related elements of cardiovascular and pulmonary regulation and control that are relevant to the assessment of risk and oxygen transport status, and to physical therapy intervention.

ICUs are highly specialized. Medical advances now preserve lives that would have been lost in the past. Patients admitted to the ICU require intense and often invasive yet life-preserving medical management. ICUs can be categorized as either general or specific. In major hospital centers, units are often designed and staffed for the exclusive management of specific types of conditions such as medical, surgical, trauma, burns, coronary care, and neonatal care. Although monitoring priorities may differ among specialized ICUs, the principles are similar and relate either directly or indirectly to the foremost goal of preserving life by maximizing oxygen transport and minimizing threat to it and by preventing the risks associated with recumbency and restricted mobility. In recent years, attention has focused on long-term outcomes of people who have had ICU stays—that is, the emphasis is on patients thriving after, rather than simply surviving, a course of ICU care.

The cardiovascular and pulmonary status of the patient in the ICU is often jeopardized by fluid and electrolyte disturbances and acid-base imbalance. This chapter describes the regulation of these systems and the clinical implications of imbalance relevant to the physical therapist. The principal monitoring systems used in assessing cardiovascular and pulmonary sufficiency in the ICU are highlighted. These include the electrocardiogram (ECG), arterial and venous lines, intracardiac monitoring, and the intracranial pressure (ICP) monitor. Although not monitoring systems per se, ventricular-assist devices (e.g., the intraaortic counterpulsation technique) are used to augment myocardial efficiency. These

Fig. 16-1 General view of an intensive care unit.

warrant special attention by the physical therapist with respect to determining the patient's readiness for treatment, establishing treatment parameters, and assessing safety.

Familiarity with the extensive monitoring facilities in the ICU relieves some of the apprehensions the physical therapist may have about practicing in this setting. Such monitoring is central to the standard of physical therapy care in the ICU to guide progressive mobilization and management overall.[1] On introduction to the unit, the physical therapist is immediately struck by the high-tech environment. Quality care in this setting depends on harnessing the potential of high-tech monitoring equipment to optimize assessment, evaluate treatment parameters, and establish anticipated and actual effectiveness of intervention, as well as to reduce untoward risk for the patient.

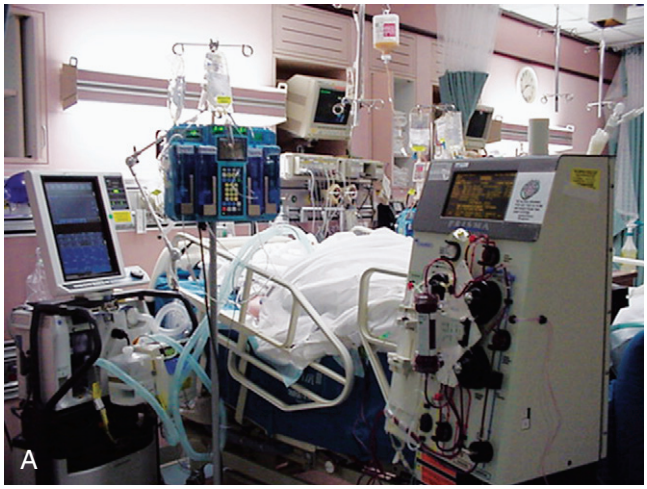

Figure 16-1 illustrates a general view of a typical ICU. A view of a patient's bedside area in the ICU shows life-support equipment and the various lines and catheters that are in place (Figure 16-2). A closer view of the patient demonstrates precisely where the various lines and catheters are positioned and identifies where caution must be observed. Treatments are modified according to the types and positions of the lines and catheters for each patient (Figure 16-3).

Intravenous Lines

Intravenous (IV) lines are routinely established in the superficial veins, such as those on the back of the hand, often before admission to the ICU if the patient is admitted through the emergency department or transferred from the ward. These lines provide an immediate route for fluids, electrolytes, nutrition, and medications. The choice of specific lines to use depends on the patient's needs based on the history, laboratory tests, clinical and physical examinations, and ongoing evaluation.

Fluid and Electrolyte Balance

When the normal regulation of fluid intake, utilization, and excretion are disrupted, fluid, electrolytes, and acid-base imbalances result. Essentially, all medical and surgical

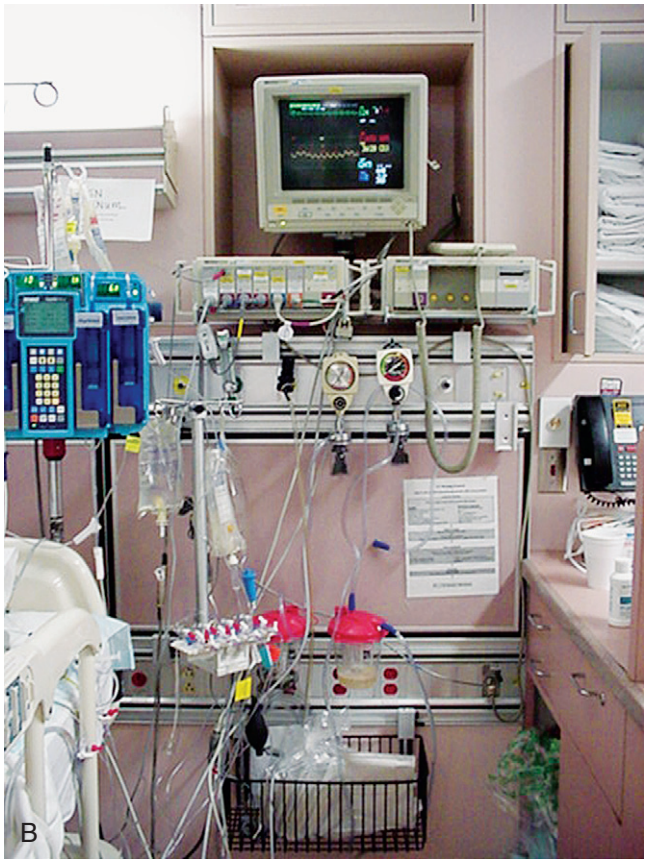

Fig. 16-2 A, Closer bedside view of a patient in the intensive care unit. Note that with all the equipment, the patient is almost lost. **B,** Bedside monitoring equipment.

conditions threaten these life-dependent mechanisms to some degree. Minor imbalances may be corrected with modification of the patient's nutrition and fluid intake. Major imbalances can be life-threatening, necessitating immediate, highly invasive medical intervention.

Imbalances are reflected as excesses, deficits, or as an abnormal distribution of fluids within the body.[2] Excesses result from increased intake and decreased loss of fluid and electrolytes. Deficits result from abnormal shifts of fluid and electrolytes among the intravascular and extravascular fluid

Fig. 16-3 **A,** Note the Swan-Ganz catheter on the right jugular vein. **B,** The patient is on a ventilator with a nasoendotracheal tube in place. **C,** Tracheostomy and left subclavian central venous catheter.

compartments of the body. Excesses can occur with kidney dysfunction, promoting fluid retention, and with respiratory dysfunction, which promotes carbon dioxide retention. Deficits are commonly associated with reduced intake of fluids and nutrition. Diaphoresis and wounds can also contribute to major fluid loss. Diarrhea and vomiting drain the gastrointestinal tract of fluid. Hemorrhage always results in fluid and electrolyte loss. Deficits may be secondary to fluid entrapment and localized edema within the body (third-spacing), making this source of fluid unavailable for regulation of homeostasis.

Moderate to severe fluid imbalance can be reflected in the systemic blood pressure and central (jugular) venous pressure (CVP). Elevated blood pressure can be indicative of fluid overload, but an intravascular fluid deficit of 15% to 25% must develop before blood pressure drops significantly. The jugular vein becomes distended with fluid overload. Normally, the jugular pulse is not visible 2 cm above the sternal angle when the individual rests at a 45-degree angle. If the jugular pulse is noted, this can be a sign of fluid overload.

Fluid replacement is based on a detailed assessment of the patient's needs. Whole blood is preferred for replacing blood loss. Plasma, albumin, and plasma volume expanders such as Dextran can be used to substitute for blood loss and to help reestablish blood volume. Albumin and substances such as dextran increase plasma volume by increasing the osmotic pressure of the blood, hence the reabsorption of fluid from the interstitial space. Low-molecular-weight dextran has the added advantage of augmenting capillary blood flow by decreasing blood viscosity and is therefore particularly useful in treating shock.

Excesses and deficits of fluids and electrolytes can be determined on the basis of laboratory determinations of serum levels of the specific electrolytes. Electrolyte levels and hematocrit are decreased with fluid excess (hemodilution) and are increased with fluid loss (hemoconcentration).

Excess fluid can be managed by controlled fluid intake, normal diuresis, and diuretic medications. Replacement of fluid and electrolyte losses can be achieved by oral intake, tube feeding, IV infusion, and parenteral hyperalimentation.

Assessment of fluid and electrolyte balance is based on both subjective and objective findings (Table 16-1). At the bedside, the physical therapist must be alert to complaints of headache, thirst, and nausea, as well as changes in dyspnea, skin turgor, and muscle strength. More objective assessment is based on fluid intake, output, and body weight. Fluid balance is so critical to physical well-being and cardiovascular and pulmonary sufficiency that fluid input and output records are routinely maintained at bedside. These records also include fluid volume lost in urine and feces, wound drainage, and fluids aspirated from any body cavity (e.g., abdomen and pleural space).

A patient's weight may increase by several kilograms before edema is apparent. The dependent areas of the body manifest the first signs of fluid excess. Patients on bed rest show sacral swelling; patients who can sit on the edge of the bed or in a chair for prolonged periods tend to show swelling of the feet and hands.

Decreased skin turgor can indicate fluid deficit. Tenting of the skin over the anterior chest in response to pinching may suggest fluid depletion. Wrinkled, toneless skin is more common in younger patients.

In contemporary ICU care, supplemental nutrition is a priority to maintain fluid and electrolyte balance, minimize weight loss, preserve strength and stamina, and support healing and recovery. Prescribing nutritional supplements for the patient in the ICU is a specialty in the field of nutrition and can take various forms depending on the patient's needs.

Table 16-1 Assessment of Fluid and Electrolyte Imbalance

Area	Fluid Excess/ Electrolyte Imbalance	Fluid Loss/ Electrolyte Imbalance
Head and neck	Distended neck veins, facial edema	Thirst, dry mucous membranes
Extremities	Dependent edema "pitting," discomfort from weight of bed covers	Muscle weakness, tingling, tetany
Skin	Warm, moist, taut, cool feeling when edematous	Dry, decreased turgor
Respiration	Dyspnea, orthopnea, productive cough, moist breath sounds	Changes in rate and depth of breathing
Circulation	Hypertension, jugular pulse visible at 45-degree sitting angle, atrial dysrhythmias	Pulse rate irregularities, dysrhythmia, postural hypotension, sinus tachycardia
Abdomen	Increased girth, fluid wave	Abdominal cramps

Modified from Phipps WJ, Long BC, Woods NF, editors: *Medical-surgical nursing: Concepts and clinical practice,* ed 6, Philadelphia, 1999, Elsevier.

The cardiovascular and pulmonary assessments can reveal changes in fluid balance. Lung sounds are valuable in identifying fluid overload. Vesicular sounds may become more bronchovesicular. Crackles may increase in coarseness. In the presence of fluid retention involving the pleurae, breath sounds diminish to the bases. Dyspnea and orthopnea may also be symptomatic of fluid excess.

An early sign of congestive heart failure (CHF) with underlying fluid overload is an S_3 gallop (Ken-TUCK-y) caused by rapid ventricular filling.

Vigilance by the physical therapist with respect to fluid and electrolyte balance is essential in all areas of practice, not only in the ICU. Fluid imbalance is common in older people and in young children, so it needs to be watched for on the ward, in the home, and in the community.

Chest Tube Drainage and Fluid Collection Systems

Chest tubes are large catheters placed in the pleural cavity to evacuate fluid and air and to drain into a graduated collection reservoir at bedside.[2] A typical chest tube drainage and collection system is shown in Figure 16-4, *A*. The removal of thick fluids such as blood and organized exudates by chest tubes is often indicated to prevent entrapment and loculation. Chest tubes are commonly inserted in the sixth intercostal space in the mid- or posterior axillary line. Chest tubes inserted into the pleural space are used to evacuate air or exudate. Chest tubes can also be inserted into the mediastinum to evacuate blood such as after open heart surgery (Figure 16-4, *B*).

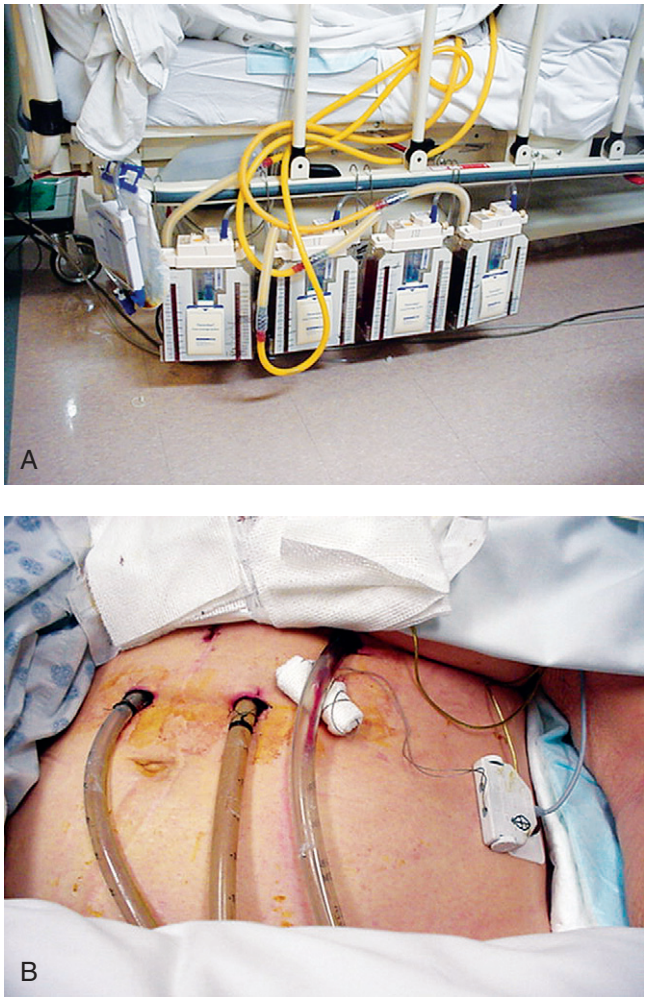

Fig. 16-4 A, Chest tube drainage. **B,** Anterior view; mediastinal drains.

Any collection system is designed to seal the drainage site from the atmosphere and offer minimal resistance to the drainage of fluid and gas. This is accomplished by immersing the end of the collection tube in water. This is referred to as an underwater seal system. Additional reservoirs are included to decrease the resistance to fluid leaving the chest. This resistance is greater in a single-reservoir system in which the reservoir serves as both the collection receptacle and the underwater seal. A third reservoir can be added to the system; it is attached to the suction and serves as a pressure regulator. The more elaborate drainage systems are used for precise measurement of fluid loss in patients after thoracic and cardiovascular surgery.

The amount of exudate collected in the reservoir is measured every several hours or more often if the patient is losing considerable amounts of fluid or less than the amount predicted. This information is incorporated into the overall fluid-balance assessment. In addition, changes in the quantity and quality of exudates should be noted by the physical therapist before, during, and after changes in position and therapeutic interventions. Chest drainage systems should always be upright and below level of tube insertion. Keeping the container lower than chest level facilitates fluid drainage. It also prevents fluids from flowing back into the chest cavity. Continuous bubbling in water-seal bottle/chamber indicates an air

leak. Physical therapists mobilizing patients with chest tubes should be alert to sudden severe respiratory distress and/or pain, which can indicate a tension pneumothorax. If a chest tube is accidently dislodged during physical therapy, the site needs to be immediately compressed, and the nurse must be called.

Acid-Base Balance

Control of acid-base balance in the body is achieved by regulation of the hydrogen ion concentration in the body fluids.[3,4] The pH of the body is normally maintained within a narrow range of 7.35 to 7.45 or slightly alkaline. When pH of the blood drops below 7.35, a state of acidosis exists; above 7.45, a state of alkalosis exists. Regulation of pH is vital because even slight deviations from the normal range cause marked changes in the rate of cellular chemical reactions. A pH below 6.8 or above 8 is incompatible with life.

Acid-base balance is controlled by several regulatory buffer systems, primarily the carbonic acid-bicarbonate, phosphate, and protein buffer systems. These systems act very quickly to prevent moment-to-moment changes in pH. In compensation, pH is returned to normal by altering the component not primarily affected. If the primary cause is respiratory, the compensating mechanism is metabolic. If the primary cause is metabolic, the compensating mechanism is respiratory. The lungs compensate for metabolic problems over hours, whereas the kidneys compensate for respiratory problems over days (see Chapter 10).

A guide to the clinical presentation of acid-base imbalances is shown in Table 16-2. Along with the major distinguishing characteristics of acid-base imbalance described in this chapter and elsewhere in this volume, potassium excess (hyperkalemia) is associated with both respiratory and metabolic acidosis, and neuromuscular hyperexcitability is associated with both respiratory and metabolic alkalosis.

Table 16-2 Signs and Symptoms of Common Acid-Base Disturbances

	Respiratory Disturbances	Metabolic Disturbances
Acidosis	Hypercapnia Hypoventilation Headache Visual disturbances Confusion Drowsiness Coma Hyperkalemia Ventricular fibrillation (secondary to hyperkalemia) Depressed tendon reflexes	Bicarbonate deficit Hyperventilation Headache Mental dullness Deep respirations Stupor Coma Hyperkalemia Cardiac dysrhythmias (secondary to hyperkalemia)
Alkalosis	Hypocapnia Lightheadedness Numbness/tingling of digits Tetany Convulsions Hypokalemia Cardiac dysrhythmias (secondary to hypokalemia)	Bicarbonate excess Depressed respirations Mental confusion Dizziness Numbness/tingling of digits Muscle twitching Tetany Convulsions Hypokalemia Cardiac dysrhythmias (secondary to hypokalemia)

Blood Gases

Analysis of the composition of arterial and mixed venous blood provides vital information about respiratory, cardiac, and metabolic function (see Chapter 10).[5,6] For this reason, blood gases are usually analyzed in the ICU. In cases in which the patient's condition is changing for better or worse over a short period of time or when a specific treatment response is of interest, blood gases may be analyzed several times daily. With an arterial line in place, frequent blood gas analysis is feasible and not traumatic for the patient. Should the patient be anemic, however, blood loss associated with repeated arterial blood sampling may mean that it is contraindicated. Thus requests for arterial blood gas analysis need to be particularly stringent in patients who are anemic.

Arterial saturation (Sa_{O_2}), the proportion of hemoglobin combined with oxygen, can be readily monitored noninvasively by a pulse oximeter (Sp_{O_2}). The earlobe or a finger is warmed by rubbing before the oximeter sensor is attached. Within seconds, the Sp_{O_2} can be read directly from the monitor. Pulse oximetry is a useful adjunct for routine evaluation of the effectiveness of mechanical ventilation, the effect of anesthesia, and the treatment response. Continuous estimation of Sa_{O_2} is particularly useful before, during, and after mobilization and exercise, position changes, and other therapeutic interventions. The Sa_{O_2} may appear to be reduced in patients who are anemic or jaundiced or those who have reduced cardiac output. The Sp_{O_2} reading may be inaccurate in patients with poor peripheral perfusion, who have cold extremities, or who have pigmented skin. The oxygenation of patients in the ICU varies considerably over time and even moment-to-moment, irrespective of sedation, high post end-expiratory pressure, or inverse ventilation.[7]

Mixed venous oxygen saturation ($S\bar{v}_{O_2}$) provides a useful index of oxygen delivery and utilization at the tissue level.[8] $S\bar{v}_{O_2}$ is highly correlated to tissue oxygen extraction, and thus is a good index of the adequacy of oxygen delivery. The $S\bar{v}_{O_2}$ is particularly useful as a significant warning sign, a guide to myocardial function, and a tool to titrate positive end-expiratory pressure support. The normal value of $S\bar{v}_{O_2}$ is 75%. Concern is raised by $S\bar{v}_{O_2}$ values of less than 60% or a drop of 10% for several minutes. Excessive $S\bar{v}_{O_2}$ values above 80% are also cause for concern. High $S\bar{v}_{O_2}$ values may occur in patients with left-to-right shunts in the heart, hyperoxia, hypothermia, cyanide toxicity, sepsis, anesthesia, and drug-induced paralysis. Despite its general clinical usefulness, $S\bar{v}_{O_2}$ is a nonspecific indicator of the adequacy of oxygen transport (i.e., of the balance between oxygen supply and demand). Abnormal $S\bar{v}_{O_2}$ values do not indicate precisely where the problem lies; so other hemodynamic variables need to be considered. Further, $S\bar{v}_{O_2}$ has been reported to fluctuate as much as ±6% in patients in the ICU in response to routine activity and treatment.[9] Maintaining normal $S\bar{v}_{O_2}$ in patients with multiple trauma improves survival rates over those in whom

oxygen transport values are maintained at above normal levels.[10] Enhancing cardiac output and hemoglobin as well as $S\bar{v}O_2$ is essential to increase oxygen delivery (DO_2) above its critical level and avoid tissue oxygen debt.[11] Impaired extraction at the tissue level has been attributed to heterogeneity of oxygen delivery.[12]

Hypoxemia

In health, age and body position are factors that reduce arterial oxygen tension.[13] Arterial oxygen levels diminish with age as a result of reduced alveolar surface area, pulmonary capillary blood volume, and diffusing capacity. Normal PaO_2 levels expressed in mm Hg in older people should exceed the value of 110-0.5 (age). In a young adult, PaO_2 ranges from 90 to 100 mm Hg in the upright seated position. In the supine position, this range is reduced to 85 to 95 mm Hg; in sleeping, to 70 to 85 mm Hg. These values are clinically significant because in older people, smokers, and people with pathology, these positional effects are accentuated. Despite sedation in patients who are critically ill, spontaneous variability of PaO_2 is considerable, and factors unduly influencing it must be controlled when using PaO_2 as an outcome.[7]

Hypoxemia refers to reduced oxygen tension in the blood. Some common signs and symptoms of various degrees of hypoxemia in adults appear in Table 16-3. Although the brain is protected by autoregulatory mechanisms, an arterial oxygen tension of 60 mm Hg produces signs of marked depression of the central nervous system, reflecting the extreme sensitivity of cerebral tissue to hypoxia.

Hypoxemia is compensated primarily by increased cardiac output, improved perfusion of vital organs, and in the long term, polycythemia. Secondary mechanisms of compensation include improved unloading of oxygen at the tissue level as a result of tissue acidosis and anaerobic metabolism, which is achieved through a rightward shift of the oxyhemoglobin dissociation curve.

The progressive physiological deterioration observed at decreasing arterial oxygen levels will occur at higher oxygen levels if any one of the major compensating mechanisms for hypoxemia is defective. Even a mild drop in PaO_2, for example, is poorly tolerated by a patient with reduced hemoglobin and impaired cardiac output. Alternatively, the signs and symptoms of hypoxemia may appear at lower arterial oxygen levels (e.g., in patients with chronic airflow limitation who have adapted to reduced PaO_2 levels).

Monitoring oxygen kinetics is essential to understanding oxygen transport status in patients who are critically ill and thus ensuring early intervention.[12,14] DO_2 and $\dot{V}O_2$ and their constituents can be measured directly or indirectly with calorimetry. Patients who survive heart failure have distinct oxygen kinetic profiles.[15] In response to improved cardiac index and DO_2 in survivors, $\dot{V}O_2$ did not change, whereas the oxygen extraction ratio (OER) decreased. In nonsurvivors, $\dot{V}O_2$ increased and the OER did not change. Such profiles can assist in establishing baseline information, detecting changes early, and modifying physical therapy interventions.

Table 16-3 Signs and Symptoms of Hypoxemia

Pao_2	Signs and Symptoms
80-100 mm Hg	Normal
60-80 mm Hg	Moderate tachycardia, possible onset of respiratory distress
50-60 mm Hg	Malaise Lightheadedness Nausea Vertigo Impaired judgment Incoordination Restless Increased minute ventilation
35-50 mm Hg	Marked confusion Cardiac dysrhythmias Labored respiration
25-35 mm Hg	Cardiac arrest Decreased renal blood flow Decreased urine output Lactic acidosis Poor oxygenation Lethargy Maximal minute ventilation Loss of consciousness
<25 mm Hg	Decreased minute ventilation (secondary to depression of respiratory center)

Hyperoxia

Mean tissue oxygen tensions rise less than 10 mm Hg when pure oxygen is administered to a healthy person under normal conditions. Therefore the function of nonpulmonary tissues is little altered. In the lung, high concentrations of oxygen replace nitrogen in poorly ventilated regions. This results in collapse of areas with reduced ventilation-perfusion matching (de-nitrogen atelectasis). Lung compliance is diminished.

High concentrations of oxygen (inspired oxygen fractions greater than 50%) can directly injure bronchial and parenchymal lung tissue. The toxic effect of oxygen is both time- and concentration-dependent. Very high concentrations of oxygen may be tolerated for up to 48 hours. However, high concentrations of oxygen in combination with positive pressure breathing can predispose the patient to oxygen toxicity and lung parenchymal injury. At concentrations of inspired oxygen less than 50%, clinically detectable oxygen toxicity is unusual regardless of the duration of oxygen therapy.

Hypocapnia

Acute reductions in arterial carbon dioxide levels (hypocapnia) result in alkalosis and diminished cerebral blood flow secondary to cerebral vasoconstriction. The major consequences of abrupt lowering of $PaCO_2$ are altered peripheral and central nerve function. Mechanical ventilation may initially cause an abrupt decrease in arterial PCO_2 and lead to a life-threatening situation. In addition to blood gas analysis, end tidal CO_2 measurement is useful in that it provides an index of $PaCO_2$.

Hypercapnia

CO_2, the principal end product of metabolism, is a relatively benign gas. CO_2 has a key role in ventilation and in regulating changes in cerebral blood flow, pH, and sympathetic tone.

Acute increases in CO_2 (hypercapnia) depress the level of consciousness secondary to the effect of acidosis on the nervous system. Similar but slowly developing increases in CO_2, however, are relatively well tolerated. A high $PaCO_2$ is suggestive of alveolar hypoventilation, which causes a reduction in alveolar and arterial PO_2. Some patients with severe chronic airflow obstruction have been reported to be able to lead relatively normal lives with $PaCO_2$ in excess of 90 mm Hg if hypoxemia is countered with supplemental oxygen. Acute administration of oxygen to patients with chronic obstructive lung disease, however, may be hazardous, because it interferes with their hypoxic drive to breathe, on which they are reliant.

Acute hypercapnia enhances sympathetic stimulation, causing an increase in cardiac output and in peripheral vascular resistance. These effects offset the effect of excess hydrogen ions on the cardiovascular system, allowing better tolerance of low pH than with metabolic acidosis of a similar degree. At extreme levels of hypercapnia, muscle twitching and seizures may be observed. Trends in $PaCO_2$ can be monitored indirectly using end tidal CO_2 measures.

ECG Monitoring

A single-channel ECG monitor with an oscilloscope, strip recorder, and digital heart rate display is typically located above the patient at bedside in the ICU (Figure 16-5). Often, the ECG can be observed at bedside and at a central monitoring console, where the ECGs of all patients in the ICU can be observed simultaneously.

The ECG monitor allows for continuous surveillance of heart rate and rhythm regardless of activity. Low and high heart rates are determined; rates below and above those rates will trigger an alarm. For routine monitoring in the coronary care unit, a modified chest lead is often used. Depending on the lead configuration desired, as few as three electrodes can be positioned on the chest to provide optimal information regarding changes in heart rate and rhythm, and thereby ensure close patient monitoring. The positive electrode is positioned at the fourth intercostal space at the right sternal border. The negative electrode is positioned at the first intercostal space in the left midclavicular line. The ground electrode, used to dissipate electrical interference, is often positioned at the first intercostal space in the right midclavicular line, although the ground electrode may be positioned wherever convenient. Other electrode placements may be required, for example, in patients with pacemakers or chest burns.

Fig. 16-5 ECG monitor.

Problems with the ECG monitor usually result from faulty technique, electrical interference, or movement artifact. A thickened baseline can be caused by 60-cycle electrical interference. An erratic signal often results from coughing and movement. The cause of any irregularity must be explained and abnormal electrical activity of the myocardium ruled out. It is a dangerous practice for the physical therapist to turn off the ECG alarm system during treatment.

Cardiac dysrhythmias can be broadly categorized into tachydysrhythmias and bradydysrhythmias. Tachydysrhythmias are subdivided into supraventricular and subjunctional tachycardias. Bradydysrhythmias are subdivided into sinus bradycardia and those related to heart block and conduction abnormalities. The subjunctional tachycardias and ventricular dysrhythmias are particularly life-threatening. Ventricular tachycardia and ventricular fibrillation are medical emergencies requiring immediate recognition and treatment.

The characteristic features of common dysrhythmias are illustrated in Chapter 12. Physical therapists specializing in ICU management should be thoroughly familiar with ECG interpretation and the implications of the various dysrhythmias on patient management. For further elaboration of ECG application and interpretation, refer to Kinney and Packa[16] and Dubin.[17]

The clinical picture associated with cardiac dysrhythmias depends on the nature of the dysrhythmia, the age and condition of the patient, the medications, and specifically, the absence or presence of underlying heart disease. The distinguishing clinical features of common atrial and ventricular dysrhythmias are outlined in Table 16-4.

The subjunctional or ventricular dysrhythmias are typically associated with severe illness. Cyanosis and duskiness of the mucosal linings and periphery may be apparent. The patient is unresponsive, the pulse is ineffective, and spontaneous respirations are likely to be absent. In this case, defibrillation is initiated by the nursing and medical staff to restore an effective, more normal rhythm. The high incidence of myocardial conduction irregularities warrants a defibrillator being present in the ICU for rapid implementation of this common cardioversion procedure by the medical and nursing staff. Ventricular dysrhythmias may be better tolerated if ventricular rate is low, thereby improving cardiac output. Even in this circumstance, however, these dysrhythmias present an emergency.

The ECG of a patient with a pacemaker reflects either an imposed fixed or intermittent rhythm and rate, depending on whether a fixed rate or a demand pacemaker has been inserted. The electrical impulse from the pacemaker has a unique ECG wave form.

Hemodynamic Monitoring

Hemodynamic status reflects the adequacy of blood volume and electromechanical coupling of the myocardium to effect adequate cardiac output and peripheral perfusion

Table 16-4 **Clinical Picture of Common Dysrhythmias**

Dysrhythmia	No Underlying Cardiovascular Disease	Underlying Cardiovascular Disease
TACHYCARDIAS		
A. Supraventricular tachycardia	No symptoms Abrupt-onset palpitations, lightheadedness, nausea, fatigue	May precipitate congestive heart failure, acute coronary insufficiency, myocardial infarction, pulmonary edema
1. Sinus tachycardia	Awareness of the heart on exertion or with anxiety	Secondary to some precipitating factor, such as fever, electrolyte imbalance, anemia, blood and fluid loss, infection, persistent hypoxemia in COPD, acute MI, congestive heart failure, thyrotoxicosis
2. Paroxysmal atrial tachycardia (PAT)	Prevalent, sudden onset, precipitated by coffee, smoking, and exhaustion	Common supraventricular tachycardia Spontaneous onset of regular palpitations that can last for several hours May be obscured by myocardial insufficiency and CHF in older patients Increased anxiety and report of fatigue
3. Atrial flutter	Rare May be difficult to distinguish from PAT May be precipitated by alcohol, smoking, physical and emotional strain	Rapid regular-irregular rate Suggests block at AV node Atrial flutter waves in jugular venous pulse
4. Atrial fibrillation	Rare, occasionally with alcohol excess in the young	Usually secondary to a variety of cardiac disorders
5. Paroxysmal atrial tachycardia with block	Rare	Common arrhythmia seen with digitalis toxicity
B. Subjunctional	Rare	Usually related to MI, pulmonary embolus, severe CHF Often unconscious, cyanotic; ineffective pulse, blood pressure, and respiration
1. Ventricular tachycardia	Rare	Predisposed to ventricular fibrillation
2. Ventricular fibrillation	Rare	Ineffective cardiac output, unconscious, dusky; cardiac arrest threat
BRADYCARDIAS		
A. Sinus bradycardia	Physiological in very fit young adults	In older patients, may suggest sinus node and conduction system pathology; can produce syncope or CHF
B. Heart block	Rare	Hypotension, dizziness, lightheadedness, syncope In chronic block with sustained bradycardia, CHF may be more frequent Most common dysrhythmia iatrogenically produced with digitalis excess Associated with numerous cardiac conditions; commonly in age-related degenerative disease in conducting system, inferior and occasionally anterior MIs

commensurate with changing metabolic demand. In individuals who are not critically ill, monitoring fluid input and output, heart rate, and blood pressure may suffice in providing a profile. To monitor a patient's hemodynamics more closely in the ICU, however, the insertion of various invasive lines may be indicated in addition to the lines and leads needed to monitor basic fluid and electrolyte balance and ECG. These require invasive arterial and venous lines.

Intraarterial Lines

An arterial line is established by direct arterial puncture. It is usually in the radial artery; however, it can be seen in the femoral, axillary, or brachial artery (Figure 16-6, *A, B*). Blood pressure can be measured directly from this line. A digital monitor displays systolic and diastolic blood pressures above the patient at bedside. High and low blood pressure levels are set, above and below which the alarm will sound. Blood gas analysis can be performed routinely with an intraarterial line in place without repeating the puncture of a blood vessel.

Pulmonary Artery Balloon Flotation Catheter

The pulmonary artery balloon flotation (Swan-Ganz) catheter is designed to provide an accurate and convenient means of hemodynamic assessment in the ICU by monitoring intracardiac pressures and, in combination with other measures, assessing cardiac reserve, an important determinant of outcome following critical illness.[18] The catheter is usually inserted into the internal jugular vein, the subclavian vein, or

Fig. 16-6 A, Radial arterial line. Also note the pulse oximeter sensor on the finger. **B,** Femoral arterial line.

a large peripheral arm vein and is directed by the flow of blood into the right ventricle and pulmonary artery (see Figure 16-3, *A*). The catheter is carefully secured to prevent dislodging. Some of the complications that have been associated with pulmonary artery catheterization, however, include infection, venous thrombosis, myocardial irritation, air embolism, and pulmonary ischemia or infarct to segmental lung tissue.[19]

Complex catheters are available for monitoring a variety of parameters. In a two-lumen catheter, the first lumen is used to measure pulmonary artery pressure (PAP) and obtain mixed venous blood samples. The second lumen terminates in a balloon with a volume of less than 1 mL, which is inflated and deflated to obtain pulmonary artery occlusion or wedge pressure (PAOP or PAWP, respectively). The normal range of the systolic PAP is 20 to 30 mm Hg, and it normally reflects right ventricular pressure (RVP). The diastolic PAP ranges from 7 to 12 mm Hg and reflects left ventricular pressure in the absence of pulmonary disease. The average range of PAWP is 8 to 12 mm Hg and gives an estimation of mean left atrial pressure (LAP) and the pressure in the left ventricle (LVP). Figure 16-7 shows the normal cardiac pressures in each heart chamber. More elaborate catheters have pacing wires, thermistors for cardiac output determination, and sensors for arterial saturation.

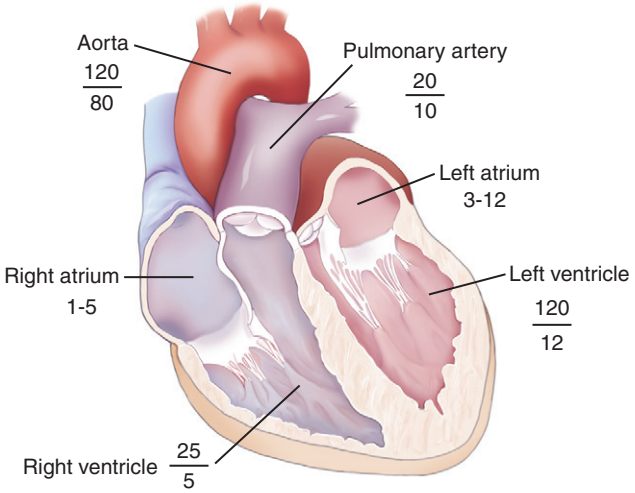

Fig. 16-7 Normal cardiac pressures in each heart chamber.

The PAP increases as a result of elevated pulmonary blood flow, increased pulmonary arteriolar resistance secondary to primary pulmonary hypertension or mitral stenosis, and left ventricular failure. Measurement of PAP and PAWP, in particular, allows for more prudent management of heart failure and cardiogenic shock.

The PAP, PAWP, and end-diastolic LVP are directly related. Impaired left ventricular contractility that compromises normal emptying (e.g., left ventricular failure, mitral stenosis, or mitral insufficiency) results in an elevated end-diastolic LVP, which in turn, elevates PAWP and PAP. An end-diastolic PAP greater than 20 mm Hg or a PAWP greater than 12 mm Hg is considered abnormal.

The PAP and PAWP are low during hypotension secondary to hypovolemia. Infusion of normal saline, whole blood, or low-molecular-weight dextran elevates the blood volume and blood pressure. Restoration of blood volume returns end-diastolic PAP and PAWP to normal.

Elevation of the end-diastolic PAP secondary to heart failure with pulmonary edema can typically be reduced with appropriate medication. The effectiveness of a drug and its prescription parameters can be assessed by the observed changes in the end-diastolic PAP.

Deterioration of cardiovascular status and worsening of the clinical signs and symptoms of heart failure elevate end-diastolic PAP and PAWP, decrease cardiac output, decrease arterial and right atrial oxygen tension, and increase the oxygen difference between arterial and venous blood. As the heart pump continues to fail, arterial oxygen tension decreases, suggesting abnormal lung function and probably elevated LAP. Pulmonary dysfunction at this stage includes diffusion abnormalities, redistribution of pulmonary blood flow into the less well-ventilated upper lobes, and right-to-left shunting, which causes deoxygenated blood to bypass well-ventilated regions of the lungs. All patients with acute infarction or shock have reduced arterial oxygen tension. When the failing heart is unable to effectively eject blood through the aorta to the systemic circulation, fluid may back up into the lungs. Pulmonary congestion must be cleared before the patient can appropriately respond to oxygen administration.

Despite the enormous benefits of direct invasive hemodynamic monitoring to patient assessment and management, the

benefits of basic hemodynamic assessment are a fundamental part of the cardiovascular and pulmonary assessment, regardless of whether the patient has an invasive line inserted.[20] Basic hemodynamic monitoring includes heart rate, ECG, blood pressure, and peripheral tissue perfusion. These are fundamental to the physical therapy assessment of all patients across settings. Even though ECG may not necessarily be monitored by the physical therapist directly in non-ICU settings, knowledge of its status is imperative in order to establish whether an individual is safe to treat and, if so, how treatment should be modified and what precautions should be taken.

Central Venous Pressure Monitoring

CVP is monitored by means of a venous line or catheter inserted into the subclavian, basilic, jugular, or femoral vein (see Figure 16-3, *C*). The catheter is advanced to the right atrium by way of the inferior or superior vena cava, depending on the site of insertion. Minimal risk for phlebitis or infection is associated with this procedure.

CVP is the blood pressure measured in the vena cavae or right atrium. Normal CVP ranges from 0 to 5 cm H_2O or from 5 to 10 cm H_2O if measured at the sternal notch or midaxillary line, respectively. Essentially, the CVP provides information about the adequacy of right heart function, including effective circulating blood volume, effectiveness of the heart as a pump, vascular tone, and venous return. Measurement of CVP is particularly useful in assessing fluid volume and fluid replacement. If the patient has chronic airflow limitation, ventricular ischemia, or infarction, the CVP will reflect changes in pathology rather than fluid volume.

Specifically, CVP provides an index of right atrial pressure (RAP). The relationship between RAP and end-diastolic LVP is unreliable; therefore end-diastolic PAP and PAWP are used as the principal indicators of cardiovascular and pulmonary sufficiency in patients in failure and shock.

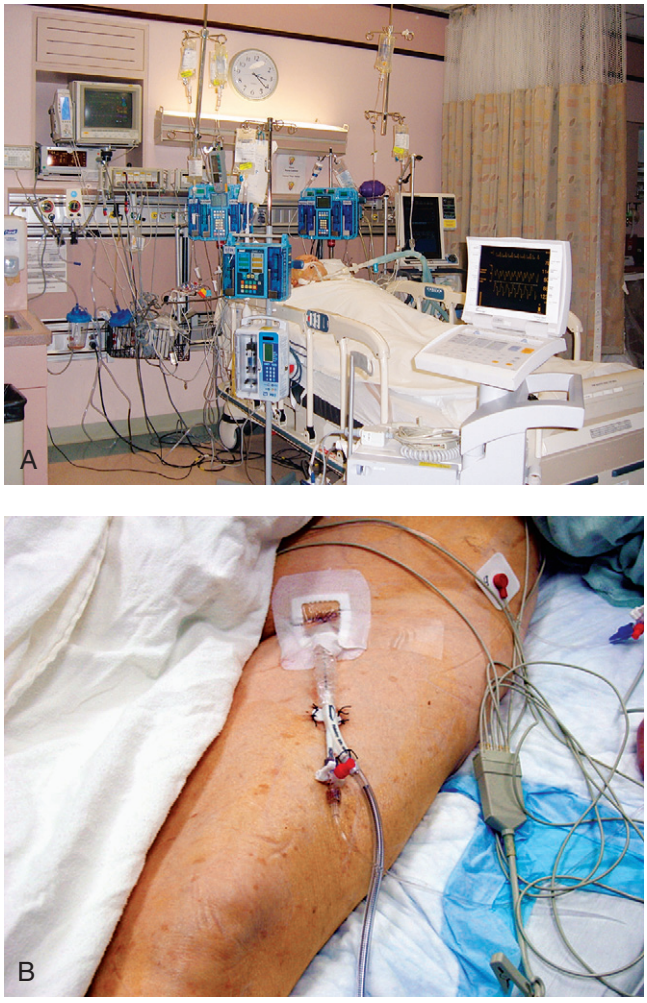

Fig. 16-8 A, Patient on an intraaortic balloon pump (IABP) support. **B,** Close-up of the IABP insertion on the femoral artery.

Intraaortic Balloon Counterpulsation Device

Intraaortic balloon counterpulsation (Figure 16-8, *A*) provides mechanical circulatory assistance by using an intraaortic balloon. The balloon is inserted into the femoral artery (see Figure 16-8, *B*). To maintain proper placement and good circulation, the patient's leg must be extended. The presence of an intraaortic balloon must be taken into consideration whenever the patient is being treated and positioned. Inflation and deflation of the balloon with helium is correlated with the ECG. The intraaortic balloon is deflated during ventricular systole and assists the emptying of the aorta. Stroke volume is potentiated, afterload is reduced (hence reducing ventricular pressure), and myocardial oxygen delivery enhanced. The balloon is inflated during diastole, thereby restoring arterial pressure and coronary perfusion. Counterpulsation improves cardiac output, reduces evidence of myocardial ischemia, and reduces ST-segment elevation. Intraaortic balloon counterpulsation is commonly used after open-heart surgery and for CHF, medically refractory myocardial ischemia, ventricular septal defects, and left main coronary stenosis in patients who are in shock. The intraaortic balloon pump provides protection for the myocardium in many instances until surgery can be performed. Limb ischemia, the most common complication, occurs in 10% to 15% of patients.

Left ventricular assist devices are used when patients develop cardiogenic shock and are unresponsive to conventional management. These devices take over the pumping action of the left ventricle and decrease myocardial workload and oxygen consumption. These types of assistive devices may have considerable potential in the management of refractory heart failure.

Intracranial Pressure Monitoring

Increased ICP results from neurological insults such as head injury, hypoxic brain damage, aneurysm, hemorrhage, and cerebral tumor. If severe and unrelenting, the pressure may need to be decompressed with surgery; otherwise, brain tissue may be irreversibly damaged, leading to permanent neurological deficits. In the adult, the cranial vault is rigid and noncompliant. Increases in the volume of the cranial contents from tissue edema result in an elevated ICP and decreased cerebral perfusion pressure.

Changes in consciousness are the earliest and most sensitive indicators of increased ICP.[21] Altered consciousness reflects herniation of the brainstem and compression of the midbrain. Compression of the oculomotor nerve and the pupilloconstrictor fibers results in abnormal pupillary reactions that are associated with brain damage.

The effects of ICP on blood pressure and pulse are variable. Blood pressure may be elevated secondary to elevated ICP and hypoxia of the vasomotor center. A reflex decrease in pulse occurs as blood pressure rises.

Compression of upper motor neuron pathways interrupts the transmission of impulses to lower motor neurons; progressive muscle weakness results. A contralateral weakened hand grasp, for example, may progress to hemiparesis or hemiplegia. The Babinski sign, hyperreflexia, and rigidity are additional motor signs that provide evidence of decreasing motor function as a result of upper motor neuron involvement.

Herniation can produce incoordinate respirations that are correlated with the level of brainstem compression. Cerebrate rigidity results from tentorial herniation of the upper brainstem. This results in the blocking of the motor inhibitory fibers and the familiar extended body posture. Seizures may be present. These neuromuscular changes may further compound existing cardiovascular and pulmonary complications in the patient in the ICU.

Clinically, increased ICP is best detected by altered consciousness, blood pressure, pulse, pupillary responses, movement, temperature, and respiration. The ICP monitor provides direct measurement of ICP. A hollow screw is positioned through the skull into the subarachnoid space. The screw is attached to a Luer-Lok, which is connected to a transducer and oscilloscope for continuous monitoring.

The prevention of further increase in ICP and a corresponding reduction in cerebral perfusion pressure is a treatment priority. High ICP and low cerebral perfusion pressure are highly correlated with brain injury. Measures to reduce venous volume are maintained until ICP has stabilized within normal range. Prudent body positioning is used to enhance venous drainage by elevating the bed 15 to 30 degrees and maintaining the head above heart level. Neck flexion is avoided by the placement of a neck support or sand bags. Fluid intake and output are carefully regulated and monitored; the patient may need to be fluid restricted. Stimulation of the Valsalva maneuver is avoided because intrathoracic pressure and ICP may increase correspondingly.

The normal range of the ICP is 0 to 10 mm Hg for adults and 0 to 5 mm Hg for patients under 6 years of age. The ICP may reach 50 mm Hg in the normal brain; typically, however, this pressure returns to baseline levels instantaneously. In patients with high levels of ICP and low cerebral compliance, extra care must be exercised during routine management and therapy. An ICP up to 30 mm Hg that is elicited by turning or suctioning may be acceptable, provided the pressure drops immediately following removal of the pressure-potentiating stimulus. Patients may be mechanically hyperventilated to keep arterial P_{CO_2} at low levels, because hypercapnia dilates cerebral vessels and hypocapnia constricts them.

To establish whether a patient will tolerate a treatment that requires movement or body positioning, an indication of cerebral compliance is needed. This can be obtained by observing changes in ICP during routine nursing procedures or by titrating small degrees of movement or position change and observing the rate at which the ICP returns to baseline following the challenge. Rapid return to baseline minimizes the risk for reduced cerebral perfusion pressure secondary to the increased ICP. A slow return to baseline or sustained elevation of ICP is consistent with poor cerebral compliance and indicates that treatment should be modified or possibly not performed at all, depending on the absolute level of the ICP. Physical therapy assessment only may be indicated until compliance improves.

Assessment of Arousal and Brain Activity

Patients in the ICU tend to have low arousal directly or indirectly related to underlying pathology, as well as from induced sedation and antianxiety medications.[22] Although medication is often indicated to reduce arousal, a balance must be maintained by the medical staff to avoid under- or oversedating the patient. To benefit maximally from physical therapy and actively participate in treatment, patients need to be as consciously aware as possible. Tools such as the Richmond Agitation-Sedation Scale[23] have been developed to quantify arousal state, which can be helpful in directing the course of treatment.

The Glasgow Coma Scale is a common tool for the clinical assessment and evaluation of the adequacy of basic brain function; it includes review of motor, sensory, pain, arousal, and cognitive status. An electroencephalogram (EEG), provides useful information about gross cerebral functioning and changes in level of consciousness. A single-channel EEG monitor can be readily used in the ICU to reveal evidence of posttraumatic epilepsy when the clinical signs may be inhibited by muscle relaxants. An EEG assessment may be of benefit in assessing arousal, prognosis, the response to treatment of cerebral function, and the planning and prescribing of treatment.

Neuromuscular Assessment

The neuromuscular assessment is a fundamental component of the assessment of the patient in the ICU. The patient may have been admitted for a primary neuromuscular condition with risk for respiratory failure. In addition, all patients in the ICU are at risk for ICU-acquired weakness. ICU-acquired weakness is defined as weakness developing in a patient who is critically ill with no identifiable cause other than nonspecific inflammation.[24] It has been associated with the administration of steroids, neuromuscular blockade, hyperglycemia, sepsis, multiple organ failure, bedrest (recumbency), and restricted mobility. The terms critical illness polyneuropathy (CIP) and critical illness myopathy (CIM) are commonly used in the ICU. The neuromuscular manifestations of CIP and CIM are difficult to assess in a valid manner. Despite this, their early identification is essential in order to avoid significant weakness, irreversible deterioration, delayed recovery, and prolonged dependence on mechanical ventilation.[25] Other causes need to be ruled out. Prognosis is good if ICU-acquired weakness is detected early and rehabilitation is instituted.

Because many patients in the ICU are administered sedatives and muscle relaxants, placing them at increased risk for ICU-acquired weakness, the physical therapist needs to monitor level of arousal and sedation. The use of agitation and sedation scales can be useful in monitoring arousal and the patient's capacity to cooperate with treatment.[23,26] The physical therapist has an important role in minimizing the need for pharmacological sedation by optimizing pain control, relaxation, comfort, and the individual's perception of control.

Peripheral-nerve electrical stimulation (e.g., of the median nerve) is used to monitor potential neuropathies in a patient in a coma or under neuromuscular blockade. Such stimulation is sufficient to activate the pathways of the ascending reticular activating system associated with consciousness and to hasten awaking from coma.[27] In addition, patients score better on repeated assessment with the Glasgow Coma Scale initially and at 1 month after injury, and they have shorter ICU stays.

There is no specific treatment for ICU-acquired weakness. It is prudent to consider reducing patients' exposure to the risk factors. Recent studies have demonstrated that the most promising management of ICU-acquired weakness is physical therapy, even while the patient is receiving life-and-organ support interventions.[28,29]

Cognitive Assessment

The ICU experience can contribute to cognitive impairment or worsen it in patients who are already impaired.[30,31] These effects can extend for several months beyond the ICU stay.[32] Risk factors include functional dependence and low body mass, as well as previous cognitive impairment.[33] Preexisting cognitive impairment must be identified and changes in cognition should be monitored so they can be detected early. Strategies can be implemented to avoid cognitive impairment, including frequent orientation of the patient to time and place, surrounding the individual with familiar objects and family and friends, using familiar tape recordings (voices or music), taking time to talk to the patient, and being reassuring. Further, strategies to reduce anxiety, stress, restlessness, and negative mood states can reduce the duration of hospitalization in patients in the ICU.[34]

Acute distress disorder comparable to traumatic stress syndrome has been described recently in individuals after accidental injuries. In addition to the nature of the accident itself and the associated threat to life, factors contributing to an individual's overall stress include hospitalization, length of the ICU stay, the ICU experience, and pain management.[35,36] Thus optimizing the patient's perception of care is important in preventing and offsetting symptoms of acute distress.

With improvement in the management of acute respiratory distress syndrome (ARDS), long-term studies have examined the relationship between cognitive performance, employability, and return to work in survivors. These patients may exhibit long-term cognitive deficits and impaired health status, which contribute to disability and marked reduction in health-related quality of life.[37] An understanding of these potential consequences will help their prevention and the comprehensive management of ARDS.

Pain Assessment

Pain has been described as one of the vital signs. Assessing pain in the ICU is particularly challenging, given that patients cannot readily communicate their discomfort and pain. Physical therapists need to monitor discomfort and pain as part of the ongoing assessment to ensure not only that the patient is comfortable but also that therapeutic interventions do not contribute to compromised oxygen transport by increasing distress and that they do not interfere with sleep and recovery. Further, noninvasive interventions should be used as much as possible to reduce the necessity of pharmacological agents that can compromise the patient's capacity to cooperate with treatment. Optimal management can be achieved only with accurate assessment and ongoing evaluation as the basis for progressing treatment. Pain assessment tools include the McGill Pain Questionnaire, a pain analog scale, the Wong-Baker FACES pain scale, and others.[38] The therapist should choose the format to which the patient can most readily respond.

Long-Term Outcomes Related to ICU Care

The study of outcomes of patients who have experienced ICU stays has become a focus of research. In previous decades, if a patient survived the ICU stay, this was viewed as the primary outcome. These days, most patients survive the ICU; however, outcomes related to their return to a full and active life may be less favorable.[39] Focusing on long-term outcomes can be integrated into the physical therapy care in the ICU. This includes assessment and evaluation of some aspects of functional status, as well as a premorbid evaluation based on the patient's self-report, if possible, or that of family members. In addition, the practice of physical therapy needs to extend from the ICU to the ward and then to the home, with judicious follow up after the patient has returned to the community. Depending on the age of the patient, the reason for ICU admission, and comorbidity, return to a maximal level of functioning could take a year or more.

Summary

The capacity of patients in the ICU to participate in life and perform the requisite activities is severely compromised because of life-threatening illness or injury (i.e., involving the oxygen transport system). The immediate goal of the ICU is to provide intense life-preserving, specialized care with the view of ultimately returning the individual to a healthy and productive life. Monitoring cardiovascular and pulmonary functions and oxygen transport is an essential component of management. Regulation of homeostasis is disrupted in disease or following highly invasive medical and surgical interventions. Physical therapists practicing in the ICU need to have a thorough understanding of homeostatic regulation and the monitoring of fluid and electrolyte balance, acid-base balance, and blood gases. Physical therapy has an essential role in restoring homeostasis in patients requiring intensive care by using conservative, noninvasive approaches, in addition to averting the musculoskeletal, neuromuscular, and

multisystem complications associated with recumbency and restricted mobility. The selection of treatment and the assessment of treatment response are based on quantitative evaluation of the parameters affecting oxygen transport and cardiovascular and pulmonary functions, as well as the patient's subjective sense of well-being. Detailed monitoring is necessary to provide well reasoned and informed management of the patient in the ICU, as well as to prevent deterioration and detect complications early. In the ICU, where a patient's status may change from moment to moment, the information gathered from monitoring is essential to maximize physical therapy effectiveness and minimize deleterious effects. This information is critical in establishing the indications for physical therapy, prescribing treatment parameters, and determining when to progress, withhold, or discontinue treatment. The windows of opportunity for intervention are often narrow, so the physical therapist must be able to identify these expeditiously on the basis of frequent serial assessment and to intervene appropriately.

Further, psychosocial assessment is fundamental to eliciting the most favorable outcomes. Other anticipated outcomes include reduced requirement for invasive care (i.e., drugs and surgery) and shorter length of stay in the ICU and in hospital afterwards. Physical therapists have a major role in employing noninvasive, ethical interventions in the ICU and in helping to minimize the costs of this expensive, high-tech, labor-intense area of care. Databases and longitudinal studies of the profiles and long-term outcomes of patients following various critical illnesses after return to the community are needed. Such prognostic information would help to refine the assessment of patients by physical therapists, as well as the short- and long-term management of patients in the ICU. Finally, the physical therapist has a primary role in ensuring that the patient has returned as fully as possible to life in the community in the following months after discharge. ICU outcomes have now extended from merely surviving an ICU stay to thriving afterwards—even if this outcome takes a year or more to achieve.

Review Questions

1. Explain how the International Classification of Functioning, Disability and Health (see Chapters 1, 7 and 17) relates to physical therapy goals for patients in the ICU and how this classification can be applied in this setting with special reference to the role of monitoring.
2. Explain the determinants of fluid and electrolyte balance and factors that contribute to fluid excesses and deficits.
3. Describe the basis of acid-base balance.
4. Describe the physiological effects of hypoxia and hypercapnia.
5. Explain the physiological basis of ECG monitoring and common supraventricular and ventricular dysrhythmias.
6. Explain (a) the physiological basis of the pulmonary artery balloon flotation catheter, and (b) what is represented by altered CVP, RAP (systolic and diastolic), PAP (systolic and diastolic), and PAWP.
7. Describe the basis of the intraaortic balloon counterpulsation device with respect to improving myocardial function.
8. Describe intracranial pressure monitoring, its physiological basis, and the clinical implications of such monitoring.
9. What is ICU-acquired weakness? What is its clinical significance in the ICU? What are the implications for the physical therapist?
10. Provide the rationale for cognitive assessment in the ICU.
11. What is the physical therapist's role in pain assessment in the ICU environment?
12. As primarily a noninvasive practitioner, the physical therapist plays what role in patient management in the high-tech ICU environment?

Review Questions 242

References 242

As direct access to patients becomes globally accepted, the capacity of the physical therapist to diagnose problems that are amenable to, as well as not amenable to, physical therapy is crucial for effective, safe, and responsible care. After formulating the diagnoses in partnership, as much as possible, with the patient and consistent with the health care team overall, the physical therapist prioritizes the diagnoses to address those most critical to the patient. These diagnoses may not necessarily be the reason the individual initially sought care from, or was referred to, a physical therapist. This is the essence of evidence-informed practice in the context of epidemiological indicators as distinct from evidence-based practice that supports the effectiveness of specific interventions (see Chapter 1).

This chapter provides a basis for clinical decision making and intervention prescription in physical therapy for patients ranging from the individual who is medically unstable and critically ill to the individual who is medically stable with cardiovascular and pulmonary dysfunction or at risk and living in the community. In addition, physical therapists have an active role in wellness and its promotion in the form of structured programs as well as one-on-one care. Thus the individuals they counsel include those with cardiovascular and pulmonary pathologies secondary to impairments or threats of other organ systems as well as those with primary impairments or threats of the cardiovascular and pulmonary systems (see Chapter 6).

Clinical reasoning is the process of critically analyzing the patient's status (participation in life and activities, as well as anatomic structures or physiological function) with respect to the individual's psychosocial, cultural, and environmental contexts (see Chapters 1 and 17). What is the individual able to do (and not able to do)? What is the status of the organ systems? How do these two interrelate? The answers to these questions serve as the basis of the detailed diagnostic work-up by the physical therapist. This process results in the diagnoses or problems that are then prioritized to ensure that the patient's needs are addressed appropriately—that is, "the right interventions targeted at the right problems at the right time." Initial priorities include life-preserving interventions (including addressing threats) and the minimizing of physical and

psychological distress. Facilitators and barriers to the patient's adhering to the intervention recommendations, including health literacy and lifestyle education, are clearly identified, and education and interventions are adapted to meet the needs of the individual. With this database, the physical therapist prescribes interventions so that their outcomes are maximized in the short term and the long term.

International Classification of Functioning, Disability and Health

Participation

For most individuals, the highest priority is the capacity to live a life consistent with their needs and wants according to their sociocultural norms. The World Health Organization (WHO) acknowledges this in its International Classification of Functioning, Disability and Health, which emphasizes the interrelationship among structure and function, activity, and participation in life. Health has been defined by WHO as emotional, spiritual, intellectual, and physical well-being—not merely the absence of pathology.[1] Participation refers to the capacity of individuals to fulfill these needs in a social context and thereby fulfill the multiple roles in their lives—as parent, child, sibling, employee, employer, student, or homemaker, as well as in avocational pursuits (Figure 17-1). Participation in life is assessed by open-ended questions asked during the history and interview. In addition, an increasing number of questionnaire tools and scales are available for clinical use. Table 17-1 outlines some common generic and condition-specific tools that can be used to assess quality of life, life satisfaction, sickness impact, and subjective sense of well-being. These can be useful outcome measures (technically, these scales provide scores that are indexes rather than actual measures of the constructs) for the physical therapist and the patient. Many of these scales have been shown to be reliable as well as valid. Validating these scales is conceptually and methodologically challenging; hence their limitations must be recognized.

Activity

Participation in life and fulfilling one's roles and obligations require the ability to perform a range of certain activities to some level of proficiency (see Figure 17-1). The role of a parent, for example, requires being able to identify the needs of children, as well as to plan and coordinate activities involved with their care (e.g., picking them up, bathing and dressing them, performing physical activities and playing with them, and taking them to school). With respect to occupational roles, for example, to fulfill the needs of being a truck driver, the individual needs to be able to get to work, climb into the truck, check the engine, crawl under the truck, load and unload the truck, read a map, and operate a standard

transmission. To be an elementary school teacher requires being able to move around the classroom, help children with physical tasks, and anticipate their needs, stay alert to danger, and respond quickly. The physical therapist's assessment must identify the composite activities that are limited and that affect an individual's capacity to participate in fulfilling his or her roles.

Structure and Function

Limitations of anatomic structure and physiological function often interfere with the performance of specific activities that are involved in fulfilling roles and obligations in life (i.e., participating in life) (see Figure 17-1). Some limitations may be specific to a particular role, and some may interfere across roles. The physical therapy assessment identifies the limitations of structure and function and the degree to which they interfere with given activities and roles in life. Some limitations of structure and function related to oxygen transport do not necessarily limit activity or participation; yet they can be the most clinically important, life-threatening problems (e.g., high blood pressure, cardiac dysrhythmias, abnormal clotting factors, high blood glucose, and aerobic deconditioning). Given the prevalence of lifestyle-related conditions and their risk factors, each individual needs to be assessed for risk for heart disease, smoking-related conditions, hypertension and stroke, diabetes, and cancers (see Chapter 1). Assessment of a patient's bone health and risk for osteoporosis and arthritis is also prudent, especially now that individuals are generally living longer and often have lifestyles that predispose them to osteopenia and osteoporosis. Physical therapists have a primary role in assessing these risks for several reasons:

First, these problems can be the most important clinically in terms of health and threat to life (chronic morbidity and premature death) for the patient, either directly or indirectly.

Second, identifying these problems enables the physical therapist to work collaboratively with the health care team in addressing and following the patient in a coordinated, integrated manner. If a patient was not referred and new problems are detected, the physician needs to be alerted. With direct-access practice, this is a primary responsibility of the contemporary physical therapist. If risk factors have been identified or have manifested clinically, the patient may be taking medication or may be a candidate for surgery. The physical therapist has a primary role in avoiding or minimizing the need for invasive care (specifically, drugs and surgery)—this is a particularly important and often underestimated goal of the physical therapist, who is committed to using and promoting noninvasive care. The physical therapist must closely monitor a patient's responses to invasive care (i.e., drugs and surgery) in relation to problems of direct relevance to them, with the intention of reducing such intervention.

Third, the physical therapist needs to institute relevant and targeted health education for lifelong behavior change (i.e., assess the patient's needs, including health literacy, knowledge deficits about health and health status, learning readiness, and learning style; tailor the education materials to the learner; and assess the outcome of the educational intervention comparable to other physical therapy interventions) (see Chapters 1 and 27).

Fourth, the presence of risk factors may require a higher level of patient monitoring, including the results of invasive testing (e.g., blood work for cholesterol, triglycerides, and blood glucose) and other tests such as imaging results and ECGs.

Fifth, physical therapy interventions and their prescriptive parameters may need to be modified based on an individual's risk factors for lifestyle-related conditions.

Sixth, special attention to medications may be indicated, and these may need to be coordinated with physical therapy management.

Seventh, the presence of risk factors for lifestyle-related conditions requires long-term management and follow-up.

Psychosocial and cultural factors are assessed to identify beliefs, attitudes, lifestyle behaviors, and expectations of care (see Chapter 1). A learning assessment (see Chapter 28) is conducted to identify health literacy and knowledge deficits, the learning style of the patient, and readiness to participate in intervention. Identifying facilitators and barriers that will impact the outcome of the therapeutic relationship is central to ensuring maximal therapeutic outcomes, including an individual's subjective sense of well-being and empowerment.

Clinical decision making and intervention prescription are based on the answers to several questions related to oxygen transport status, which underpins an individual's capacity for activity and participation, as well as threats to health. With respect to a given patient, the following must be considered:

- What are the problems with respect to participation, activity, and structure and function (impairments)? What are the interrelationships among these problems? (Remember: The interrelationships will be specific to the individual).
- What is the prognosis—with and without intervention?
- What is the relationship between the prognosis for each problem and the objectives of intervention and prescription?
- What are the intervention priorities, and why?
- What are the interventions of choice, and why?
- What are the prescriptive parameters for each, and why? How should they be sequenced, and why?
- What is the course of intervention, and why? What are the requirements for follow-up in the short and long term, and why?
- What are the boundaries of knowledge that would guide a physical therapist to refer a patient to another health care professional (e.g., counselor, nutritionist, personal trainer, physician, psychologist)?

Considering that a patient can have oxygen transport limitations in the absence of participation and activity limitations—and the fact that, based on epidemiological evidence, this is true for many people—oxygen transport limitations and risks need to be evaluated in every patient. Underlying risk, without overt manifestation clinically or in daily life, can constitute significant risk to the patient and the potential for significant impact on participation and activity. Furthermore, physical therapy, by definition, emphasizes the physiological aspects of the patient, so awareness of the possibility of such underlying threats is essential to ensure that the appropriate monitoring is instituted to maximize safety and that interventions are modified to maximize therapeutic outcome in the short and long term.

The principles involved in relating cardiovascular and pulmonary physical therapy interventions to the patient's needs depend on an analysis of those needs with respect to the patient's level of participation in life and ability to perform the identified composite activities. The degree to which limitations of anatomic structure and physiological function (with a focus on impairments of the steps in the oxygen transport pathway; Chapter 2) affect activity and participation is assessed. The relationship of impairment to an individual's ability and participation cannot be assumed. Verification can be extracted from the history and overall assessment, including measures and indexes of the individual's capacity to perform activities and participate in life. These aspects of the assessment can be obtained through the use of standardized questionnaire tools that reveal the impact of health-related quality of life and sickness; these tools can be used as outcome measures in conjunction with measures of anatomic structure and physiological function (see Table 17-1). Changes in structure and function with intervention may or may not have a corresponding effect on health-related quality of life or sickness. For example, high blood pressure is most often asymptomatic, but the patient may be prescribed a stringent exercise program and education program. Such knowledge may help to identify those individuals whose quality of life is most likely to improve, as well as where intervention should be targeted.[20]

The physical therapist formulates a physiologically based intervention hierarchy based on the premise that physiological function, including oxygen transport, is optimal when humans are upright and moving (see Chapters 18, 19, and 20). Applying a systematic physiological approach to diagnosis and the analysis of the patient's problems, with respect to limitations in the oxygen transport pathway, leads directly to identifying effective interventions. Such an approach provides a rational basis for modifying or discontinuing intervention based on the use of appropriate outcome measures.

What Is the Problem?

Consistent with the International Classification of Functioning, Disability and Health, there are three primary levels of analysis:[21]

Structure and function (impairment)
Ability (disability)
Participation in life (handicap)

These components are affected by facilitating factors and barriers (see Figure 17-1).[21] Structure and function refer to the underlying anatomic and physiological limitations that may or may not contribute to the patient's symptoms but are clinically important and warrant remediation or being addressed in management. Limitation of activities contributes to a compromised capacity to fulfill one's roles in life, such as those of occupation, profession, parent, and member of various groups that make up an individual's identity. Usually, a patient presents clinically with complaints of being unable to complete tasks or fulfill roles because of pathophysiological, psychological, or environmental and physical barriers and limitations.

Measures and tools are standardized (concerning validity and reliability, see Chapter 7) for the assessment of each of these levels. With an increased focus on the quality of participation in life, numerous scales have emerged to quantify the subjective sense of well-being and health-related quality of life (see Table 17-1 for some examples).

Oxygen transport is determined by a multitude of factors that affect the steps in the oxygen transport pathway, thereby affecting participation in life and related activities (see Figure 17-1; see Chapter 2).[22-24] For intervention to be directed specifically to the underlying problems, the physical therapist needs to consider several levels of analysis of the deficits contributing to impaired or threatened oxygen transport. To be proficient in such analysis, the physical therapist must have a thorough knowledge of the multiple factors that contribute to normal gas exchange and those that contribute to abnormal gas exchange. This knowledge base includes a thorough understanding of the relevant anatomy and physiology; the multisystem and integrative pathophysiology; the impact of medical, surgical, and nursing procedures; the effects of various laboratory tests and procedures; and the impact of pharmacological agents on cardiovascular and pulmonary function (Box 17-1). Assessment of oxygen transport reserve and reserve capacity is fundamental to the management of all patients[25] and their risk factors,[26] regardless of disease acuity. Routine procedures contribute to fluctuations in oxygen demands.[27] Maximizing the ratio of oxygen delivery to consumption improves clinical outcomes in patients who range from being medically stable to being unstable.[28,29,30]

For a given patient, the cardiovascular and pulmonary physical therapist prescribes intervention by extracting the relevant information from the history, the laboratory tests and investigative procedures, and the assessment (Box 17-2; see Part II). Although physical therapists are primarily noninvasive practitioners, they use and request the results of invasive

Box 17-1 Fundamental Knowledge and Expertise to Diagnose Limitations in Oxygen Transport and Risk Factors

- Oxygen transport deficits and how they affect or threaten participation and activity
- Normal cardiopulmonary and cardiovascular anatomy and physiology
- Knowledge about how the above are affected by normal conditions such as aging and lifestyle habits (e.g., smoking, stress, and the physical environment)
- Physiological adaptation to hypoxia and cardiopulmonary impairment
- Cardiopulmonary and cardiovascular pathophysiology and disease processes; how they affect normal cardiopulmonary and cardiovascular function
- Multisystem and integrative pathophysiology that can have a secondary effect on cardiopulmonary function and oxygen transport
- Effects of medical, surgical, and nursing procedures on oxygen transport and gas exchange
- Investigative laboratory procedures and tests and their effects on cardiopulmonary function
- Pharmacological effects on cardiopulmonary function of any medication

Box 17-2 Steps in Diagnosing Limitations in Oxygen Transport

1. Determine what factors are specifically contributing to impaired oxygen transport and which steps in the pathway are affected.
2. Determine those factors that threaten oxygen transport and the steps in the pathway that are involved.
3. Determine the relative magnitude of the effect of each factor that is either impairing or threatening oxygen transport; prioritize the importance of each.
4. Distinguish those factors that are amenable to, and those that are not amenable to, physical therapy. In the case of the latter, intervention may have to be modified and the type and level of monitoring may have to be reevaluated.
5. Based on the answers to 1 through 4, select, prioritize, and apply specific interventions prescriptively, addressing each factor that contributes to cardiopulmonary dysfunction and is amenable to physical therapy.

From World Health Organization: Definition of health. 2011. http://www.who.int/suggestions/faq/en/.

tests and investigations in their assessments and evaluations. Problems are prioritized on the basis of the relative magnitude of each problem's threat or effect on oxygen transport limitation, along with the evidence supporting the effectiveness of various noninvasive interventions in addressing each diagnosis or problem. Once the mechanisms of the cardiovascular and pulmonary dysfunction have been identified, specific interventions are selected and prioritized and the prescriptive parameters of each intervention are then defined. With respect to education, a learning assessment is an essential component of the overall assessment; it identifies health status knowledge deficits and prescribes learning interventions consistent with the patient's needs (see Chapter 28).

The Diagnoses or Problems

The diagnostic work-up is designed to relate oxygen transport limitations and threats to an individual's participation in life and its composite activities. The components of the analysis of oxygen transport limitations (impairment diagnoses) follow. Physical therapists have a particular interest and focus of care related to the interrelationships among limitations (impairments) of structure and function and an individual's activity and his or her participation in life (i.e., limitation or improvement at one level and its association with limitation or improvement in the other levels).

Impaired Oxygen Transport

Two levels of problems must be identified: functional and physiological limitations. Functional limitations are those that affect the patient's ability to perform activities of daily living (ADLs), such as reduced activity or exercise tolerance as a result of reduced peripheral oxygenation; reduced mobility related to deconditioning resulting from resting in bed; extremity or internal injury; anticoagulant therapy; drug-induced paralysis; impaired physical mobility related to muscle weakness and partial paralysis; paralysis; depressed consciousness; or anemia.

Anatomic and physiological limitations are the individual's overall deficits in oxygen transport and those that specifically arise at the individual steps in the pathway. Examples of the limitations at each step in the pathway appear in Tables 17-2 and 17-3.

Threatened Oxygen Transport

Although the complications of restricted mobility and static body positions are well understood, the precise prescription parameters for mobilization and body positioning to avoid these complications have not been defined in detail (see Chapters 18, 19, and 20). With respect to cardiovascular and pulmonary complications, a 1- or 2-hourly turning regimen is commonly accepted. For the patient who is flaccid or comatose, range-of-motion (ROM) exercises every several hours facilitates blood flow through dependent areas and enhances alveolar ventilation, as well as mobilizing joints and muscles. Antiembolic stockings and pneumatic compression devices are routinely used to minimize circulatory stasis in the legs and thereby the potential for thrombi formation.

The physical therapist has a major role in preventing infection of all types but particularly cardiovascular and pulmonary infections. Cardiovascular and pulmonary assessment and intervention involve handling and close contact with patients. Thus the risk for nosocomial infection is high in patients who are hospitalized. Some standard means of preventing infection include meticulous handwashing before and after visiting each patient, avoiding contact with open wounds and body fluids, and using clean technique in proximity to invasive lines and catheters. The physical therapist moves and repositions patients often, so it is essential that the positions of lines, leads, and catheters be continuously monitored to avoid displacement. The physical therapist must consider when it is appropriate to gown, mask, and use gloves so as to protect and be protected from the patient adequately.

Factors That Contribute to or Threaten Oxygen Transport

The factors that can impair oxygen transport directly or can threaten it fall into four primary categories (Table 17-4): the underlying cardiovascular and pulmonary pathophysiology, restricted mobility (loss of physical exercise stress), recumbency (loss of vertical gravitational stress), extrinsic factors (i.e., factors related to the patient's care), and intrinsic factors (i.e., factors related to the patient).

Restricted Mobility and Recumbency

Although bed rest can be considered an extrinsic factor (i.e., a therapeutic intervention that contributes to cardiovascular and pulmonary dysfunction), the negative consequences of this intervention are often not appreciated fully because of the widespread use of rest in bed. To emphasize the importance of considering the effects of this intervention with each patient, the effects of restricted mobility and recumbency are analyzed separately (see Chapters 18, 19, and 20).

Table 17-2 Examples of Limitations and Threats to the Steps in the Oxygen Transport Pathway

Area of Limitation	Specific Threats
Central control of breathing	Altered central nervous system (CNS) afferent input and control of breathing Impaired efferent pathways Pharmacological depression Substance-abuse depression
Airways	Aspiration related to lack of gastrointestinal (GI) motility Aspiration secondary to esophageal reflux Obstruction secondary to airway edema, bronchospasm, or mucus Inhaled foreign bodies
Lungs	Altered breathing pattern secondary to decreased lung compliance Ineffective breathing pattern related to decreased diaphragmatic function and increased lung volumes, respiratory muscle weakness, respiratory muscle fatigue, CNS dysfunction, guarding, reflex, fatigue, and respiratory inflammatory process Ineffective airway clearance related to restricted mobility, immobility, sedation, and pulmonary dysfunction secondary to long smoking history, impaired mucociliary transport, absent cilia, or dyskinesia of cilia, retained secretions, ineffective cough and mucociliary mechanisms, infection, inability to cough efficiently, artificial airway/intubation and endotracheal tube, drug-induced paralysis, and sedation Large airway obstruction secondary to compliant oropharyngeal structures Chest wall rigidity and decreased compliance Loss of normal chest wall excursion movements (pump- and bucket-handle motions) and capacity to move appropriately in all three planes of motion Chest wall and spinal deformity Impaired lung fluid balance and acute lung injury
Blood	Bleeding abnormalities, altered body temperature (hypothermia, hyperthermia), fever, inflammation, hypermetabolism secondary to mediator systems Altered body temperature related to integumentary disruption Low hematocrit secondary to GI bleed (more prone to hypoxia) Anemia Thrombocytopenia Disseminated intravascular coagulation Abnormal clotting factors (i.e., balance between clotting and not clotting, sludging of blood) Thromboemboli Bleeding disorders with liver disease; abnormal clotting factors
Gas exchange	Alveolar collapse, atelectasis, intrapulmonary shunting or pulmonary edema, shallow breathing and tenacious mucus, body position, consolidation and alveolar collapse, ventilation/perfusion mismatch, airway constriction, fluid volume excess, pleural effusions, breathing at low lung volumes, abdominal distension and guarding, ineffective airway clearance, pulmonary microvascular thrombi and altered capillary permeability secondary to circulating mediators, closure of small airways secondary to dynamic airway compression, decreased functional residual capacity, and intrapulmonary shunting, increased lung surface tension Diffusion defects
Respiratory muscles	Upper abdominal surgery, weakness, fatigue, neuromuscular disease, ileus related to gastric distension, mechanical dysfunction
Myocardial perfusion	Coronary artery occlusion Tachycardia Potential for cardiac dysrhythmia related to reperfusion Cardiac dysrhythmia related to myocardial hypoxia Compression by edema or space-occupying lesions
Heart	Decreased venous return and cardiac output secondary to volume deficit, ascites, myocardial ischemia, hemorrhage, and coagulopathies Conduction defects Mechanical defects Defects in electromechanical coupling Abnormal distension characteristics and myocardial wall compliance Abnormal afterload

Table 17-2 Examples of Limitations and Threats to the Steps in the Oxygen Transport Pathway—cont'd

Area of Limitation	Specific Threats
Systemic hemodynamic	Blood pressure Volume deficit (related to volume losses during surgery and inadequate oral intake, blood loss, internal injuries (e.g., hematoma and third-spacing phenomenon); hormonal imbalance; increased intestinal motility; vomiting; diarrhea; fluid sequestration in tissues; nasogastric [NG] suction and diarrhea; hypovolemia; sepsis and shock; surface capillary leak and fluid loss as in burns and excoriated wounds; fluid shifts, and secondary to recumbency and restricted mobility; or some combination) Alteration in peripheral tissue perfusion related to acute myocardial infarction, myocardial depression, maldistribution of blood volume, and altered cellular metabolism Volume excess (related to excessive intravenous administration, impaired excretion, renal failure, water intoxication, therapeutic volume expansion, acute myocardial infarction (MI) and acute renal failure related to renal retention of sodium and water and increased levels of aldosterone, renin, angiotensin II, and catecholamines; or some combination)
Tissue perfusion	Impaired cardiac output Impaired due to disseminated microvascular thrombi Atherosclerosis and thromboembolic events, decreased circulating blood volume, decreased vascular integrity, and inflammatory process Decreased cardiac output related to reduced venous return, impaired right ventricular function, dysrhythmias, increased afterload, and bradycardia Low oxygen content in the blood Thromboembolism, vasoconstriction secondary to toxins, sepsis, etc., blood flow alterations and hypermetabolism secondary to mediator systems
Tissue oxygenation	Multisystem organ failure with altered peripheral tissue perfusion and gas exchange at the cellular level

Table 17-3 Factors That Can Contribute Indirectly to Oxygen Transport Limitations or Impairments

Type of Factors	Specific Limitations or Impairments
Factors related to infection	Pulmonary and nonpulmonary infections increase the demands on the oxygen transport system
Cognitive factors	Impaired neurological status and central cardiopulmonary control Alteration in mental status secondary to inadequate cerebral perfusion with hypotension and cardiogenic shock Sleep pattern disturbance; altered blood gases, and fatigue Anxiety and agitation related to powerlessness and lack of knowledge, breathlessness, pharmacological paralysis, impaired verbal community secondary to intubation, paralysis
Psychosocial factors	Anxiety related to the condition, shortness of breath, hospitalization Social isolation secondary to impaired communication Fear and hopelessness Pain response
Nutritional factors	Altered nutritional needs secondary to greater need than resting state (i.e., increased caloric need and nutrients associated with illness, inability to ingest food, inability to absorb food) Restricted ingestion of food and water High caloric needs secondary to infectious process and protein catabolism

Table 17-4 Factors That Can Limit or Impair Oxygen Transport

Factors	Type of Limitation or Impairment
Cardiopulmonary pathophysiology (see Chapter 5)	Primary (acute, chronic, acute on chronic) Secondary (chronic, acute on chronic)
Noncardiopulmonary pathophysiology (abnormalities in other systems that can impair oxygen transport [see Chapter 6])	Central nervous system Musculoskeletal Gastrointestinal Endocrine (diabetes) Renal Liver abnormalities Nutritional deficits and obesity
Restricted mobility	Loss of physical-exercise stress (see Chapter 18) Recumbency Loss of vertical-gravitational stress (see Chapter 19)
Extrinsic factors	Those related to the patient's care (see Chapter 2)
Intrinsic factors	Those related to the patient (see Chapter 2)

Intervention Goals

Once the deficits and threats to oxygen transport have been determined by the physical therapist, the goals of intervention fall into three categories: short-term, long-term, and preventive (Table 17-5). In addition to improving the outcomes of primary physical therapy interventions, physical therapists seek to eliminate, reduce, or delay the need for invasive care (i.e., drugs and surgery) as much as possible. These are core contemporary physical therapy goals.

Practice Patterns

The American Physical Therapy Association's (APTA's) Guide to Physical Therapist Practice (2003)[31] has evolved over the past couple of decades, and it currently reflects a broad scope of practice. The Guide describes examination (history, systems review, and tests and measures), evaluation, diagnosis, prognosis (including plan of care), and intervention (with anticipated goals and expected outcomes). Each physical therapy area of practice has multiple associated practice patterns. Each practice pattern addresses reexamination, global outcomes, and criteria for termination of physical therapy services. Given the APTA's adoption of the International Classification of Functioning, Disability and Health,[21] the evaluation consists of a review of health rather than strictly a primary focus on illness. The iterative cycle of clinical decision making based on outcomes and the modification of interventions is designed to achieve the expected outcomes within a prescribed time frame (Figure 17-2). Based on the consensus of several hundred clinicians in the United States, several primary practice patterns have been defined for each specialty. Once patients are evaluated, their profiles may be described by one or more practice patterns, within one or more specialty areas of practice. There are eight practice patterns in the cardiovascular and pulmonary area (Box 17-3). These patterns and the Guide (2003)[31] provide an overall frame of reference for practice rather than serving as a basis for practice. Patients are increasingly complex, given increasing life expectancy and concomitant comorbidities, coupled with lifestyle-related factors and their impact on the patient's presenting complaint or underlying risk factors. Therefore categorizing a patient in one or more practice patterns may be insufficient to address the patient's complaints. These patterns serve as guides only.

Box 17-3 Cardiovascular and Pulmonary Preferred Practice Patterns Based on Oxygen Transport Limitations and Risks

- Pattern A: Primary Prevention/Risk Reduction for Cardiovascular/Pulmonary Disorders
- Pattern B: Impaired Aerobic Capacity/Endurance Associated with Deconditioning
- Pattern C: Impaired Ventilation, Respiration/Gas Exchange, and Aerobic Capacity/Endurance Associated with Airway Clearance Dysfunction
- Pattern D: Impaired Aerobic Capacity/Endurance Associated with Cardiovascular Pump Dysfunction or Failure
- Pattern E: Impaired Ventilation and Respiration/Gas Exchange Associated with Ventilatory Pump Dysfunction or Failure
- Pattern F: Impaired Ventilation and Respiration/Gas Exchange Associated with Respiratory Failure
- Pattern G: Impaired Ventilation, Respiration/Gas Exchange, and Aerobic Capacity/Endurance Associated with Respiratory Failure in the Neonate
- Pattern H: Impaired Circulation and Anthropometric Dimensions Associated with Lymphatic Systems Disorders

Data from American Physical Therapy Association: Guide to physical therapist practice, ed 2, Washington, DC, 2003, APTA.

Table 17-5 Short-Term, Long-Term, and Preventive Intervention Goals for Patients With Oxygen Transport Deficit or Its Risk

Short-Term Goals	Long-Term Goals	Preventive Goals
Empower the patient to manage symptoms and learn strategies to reduce health risk through effective education for life-long health.	Empower the patient through health education that promotes life-long health and well-being and minimizes the likelihood of the recurrence of problems.	Promote life-long health (full participation in life and its activities) and subjective well-being through patient empowerment and self-responsibility—health and participation for all; in so doing, increase the threshold for chronic conditions and their rates of progression, thereby increasing the threshold for morbidity and premature mortality.
Correct or reverse cardiovascular and pulmonary dysfunction that underlies the threat to or limitations on participation in life and its composite activities.	Enhance the efficiency of the steps in the oxygen transport pathway overall.	Maximize oxygen transport and aerobic conditioning to prevent cardiovascular and pulmonary dysfunction.
Reduce the rate of deterioration.	Enhance the efficiency of those specific steps in the oxygen transport pathway that compensate for impaired steps that may or may not be reversibly affected.	Prevent multisystem organ complications and all-cause infection that will lead to restricted movement, recumbency, and potential deterioration.
Avoid worsening the patient's condition.	Maximize oxygen transport capacity to sustain and optimize healing and allow for maximal functional activity.	Provide supportive palliative care for patients at the end of life.
Avoid, reduce, or postpone the need for drugs (including supplemental oxygen) and surgery.	Avoid, reduce, or postpone the need for drugs (including supplemental oxygen) and surgery.	Reduce the impact and burden of lifestyle-related conditions on individuals, their families, their communities, society as a whole, and the health of the population as a whole.
	Minimize the need for doctor- and hospital-based care.	
	Reduce the cost of invasive doctor- and hospital-based care and related health care costs.	

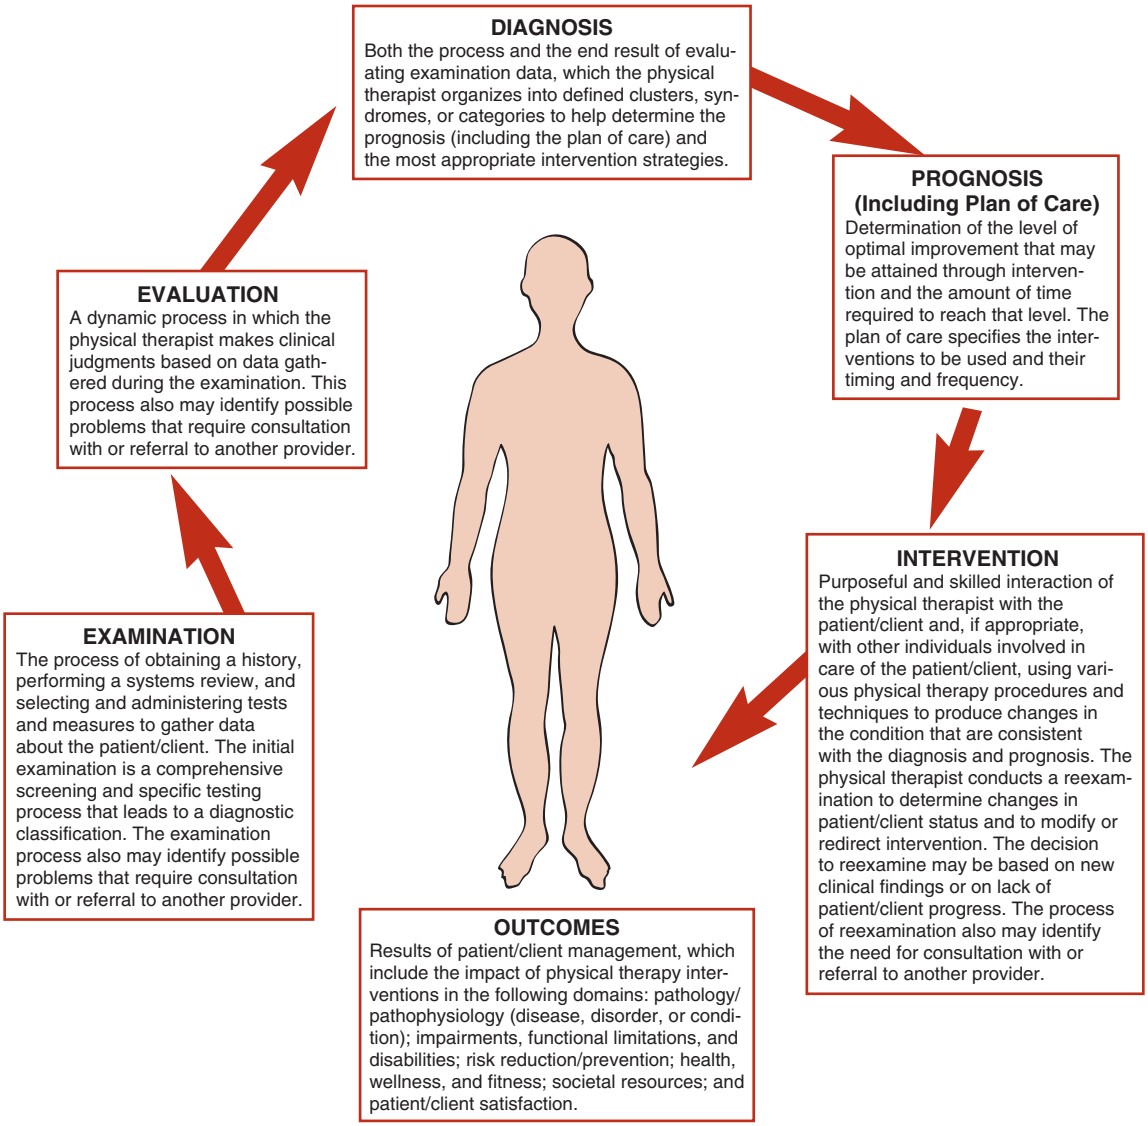

Fig. 17-2 Iterative process of clinical reasoning and decision making. *(From American Physical Therapy Association:* Guide to physical therapist practice*, ed 2, Alexandria, VA, 2003, APTA.)*

They are not diagnoses, nor do they replace sound clinical reasoning and judgment.

What is the Intervention, and Why?

Clinical Decision Making

The basis for clinical decision making in the management of the patient with cardiovascular and pulmonary dysfunction or its risk is to pair the most effective interventions with impaired or threatened steps in the oxygen transport pathway. Considerable time may pass between interventions, so a maximal therapeutic effect is dependent on the effectiveness of between-intervention interventions (i.e., teaching the patient to carry out prescriptive intervention whenever possible, motivating the patient to adhere to and follow the intervention plan, and eliciting the assistance of the patient's family or nursing staff in supporting the patient in doing so).

When confined to hospital, patients may spend excessive time recumbent and in restricted body positions; they tend to turn and move less frequently and are not upright or moving much of time. Depending on the particular oxygen transport deficits of a patient, the body positions the patient assumes can have a positive, negative, or neutral effect on oxygen transport. Thus the patient's position and his or her reduced activity level must be monitored and adverse effects anticipated, countered or, preferably, prevented.

Examples of some common intervention goals in managing the patient with cardiovascular and pulmonary dysfunction are shown in Box 17-4. Specific interventions are identified to address these goals and for each deficit or threat to oxygen transport. Intervention goals and specific interventions are prioritized according to the relative significance of the impact of each on oxygen transport.

A physiologically based intervention hierarchy is shown in Table 17-6. The intervention hierarchy is based on the premise that physiological function, including oxygen transport, is optimal when a person is upright and moving. Thus the purpose of the hierarchy is to implement the interventions that are most physical first: active movement and exercise in

Box 17-4 Common Intervention Goals in the Management of a Patient with Cardiovascular and Pulmonary Dysfunction or Its Risk

Overall Goals

Direct intervention at maximizing or preserving participation and activity by addressing structural and functional deficits in oxygen transport and gas exchange

- Direct intervention at specific steps involved
- Increase efficiency of all steps in the pathway
- Augment medical management
- Use medical management to augment physical therapy outcomes
- Use physical therapy to augment medical management
- Coordinate with nursing management (e.g., in critical care)

Specific Goals

Direct intervention at specific steps in the oxygen transport pathway

- Increase air entry and alveolar ventilation (minimize airflow resistance)
- Increase air distribution (optimize lung compliance and chest wall compliance and reduce airway resistance)
- Increase ventilation and perfusion matching
- Increase diffusion
- Increase oxyhemoglobin saturation
- Decrease work of breathing (from increased resistance, reduced or excessive compliance)
- Decrease work of the heart (from increased preload, contraction, increased afterload)
- Increase efficiency of heart mechanics
- Minimize ECG irregularities (identify factors that contribute to irregularities; anticipate problems)
- Optimize blood flow distribution
- Optimize oxygen extraction ratio
- Decrease excessive or unnecessary energy expenditure
- Optimize CO_2 removal
- Optimize blood volume and distribution to maintain hemodynamic status
- Support nutrition and hydration initiatives where possible

the upright position. The hierarchy ranges from these to the interventions that are the least physical: conventional chest physical therapy techniques such as ROM, postural drainage and percussion, and suctioning. The latter may simulate some of the physiological effects of being upright and moving, but their effects are more limited and less scientifically substantiated, and they facilitate fewer steps in the oxygen transport pathway. They do not substitute for the more active physical interventions that are higher in the intervention hierarchy. Each of the interventions in the hierarchy has a role in the management of cardiovascular and pulmonary dysfunction or its risks, but they are implemented in descending order to ensure that the most effective interventions are used first.

Intervention Plan

The intervention plan consists of interventions that will most expediently and efficiently remediate the problems that have been identified. These interventions are prioritized according to the greatest effect they are predicted to have on remediating the oxygen transport deficit or minimizing any threat to oxygen transport and on maximizing their benefit-to-risk ratio given the specific patient's presentation. Depending on the specific intervention goals and the adequacy of balance between oxygen supply and demand, the coordination of physical therapy interventions with other care (e.g., nursing care and certain tests and procedures) is commonly indicated.

Intervention Prescription

Once the specific pathophysiological problems underlying deficits or threats to oxygen transport have been identified, they are differentiated into (1) those that can be addressed by physical therapy (i.e., noninvasive physical interventions); (2) those that are not amenable to physical therapy but need to be considered during intervention to determine whether intervention is contraindicated or needs to be modified and whether specific outcome and intervention-response measures are indicated; and (3) those that are best managed invasively, which may necessitate referral to a physician.

Problems amenable to physical therapy are prioritized. Optimal interventions are identified for each problem, and their parameters are prescribed. The intervention goals are identified: to reverse pathophysiological mechanisms contributing to impaired oxygen transport: to compensate for irreversible pathophysiological deficits (improve the efficiency of other steps in the oxygen transport pathway); to decelerate deterioration; to avoid making the patient worse; to provide palliative care, support, and comfort; and to prevent the occurrence of problems in the future (see Intervention Goals, earlier in this chapter). Based on the goals of intervention, the parameters of the intervention are defined. Intervention parameters in the management of a patient with cardiovascular and pulmonary problems are shown in Box 17-5. To achieve these goals, a range of modalities and aids may be needed in the short term and in the long term (Box 17-6).

What Is the Course of Intervention?

Once an intervention has been prescribed, the prescription must be reviewed at each intervention session and modified accordingly (i.e., the prescription parameters change as the patient's condition changes). In addition, the parameters may be modified within an intervention on the basis of the patient's response. The physical therapist also decides when to discontinue a given intervention, as well as which cardiovascular and

Table 17-6 **Physiological Intervention Hierarchy for Management of Limited Oxygen Transport to Optimize Participation and Activity**

Order of Interventions	Goal	Specific Type of Interventions or Effects
I. Mobilization and exercise	Elicit an exercise stimulus that addresses one of the three effects on the various steps in the oxygen transport pathway, or some combination thereof	Acute effects Long-term effect Preventive effects
II. Body positioning	Elicit a gravitational stimulus that simulates being upright and moving as much as possible: active, active-assisted, or passive	Hemodynamic effects related to fluid shifts Cardiopulmonary effects on ventilation and its distribution, perfusion, ventilation, and perfusion matching and gas exchange
III. Breathing control maneuvers	Augment alveolar ventilation, facilitate mucociliary transport, and stimulate coughing	Coordinated breathing with activity and exercise Spontaneous eucapnic hyperventilation Maximal tidal breaths and movement in three dimensions Sustained maximal inspiration Pursed-lip breathing to end-tidal expiration Incentive spirometry
IV. Coughing maneuvers	Facilitate mucociliary clearance with the least effect on dynamic airway compression and the fewest adverse cardiovascular effects	Active and spontaneous cough with closed glottis Active-assisted (self-supported or supported by other) Modified coughing interventions with open glottis (e.g., forced expiratory technique, huff)
V. Relaxation and energy-conservation interventions	Minimize the work of breathing and of the heart and minimize undue oxygen demand	Relaxation procedures at rest and during activity Energy conservation, (i.e., balance of activity and rest, performing activities in an energy-efficient manner, improved movement economy during activity) Pain-control interventions
VI. ROM exercises (cardiopulmonary indications)	Stimulate alveolar ventilation and alter its distribution	Active Assisted-active Passive
VII. Postural drainage positioning	Facilitate airway clearance using gravitational effects	Bronchopulmonary segmental drainage positions
VIII. Manual techniques	Facilitate airway clearance in conjunction with specific body positioning	Autogenic drainage Manual percussion Shaking and vibration Deep breathing and coughing
IX. Suctioning	Facilitate the removal of airway secretions collected centrally	Open suction system Closed suction system Tracheal tickle Instillation with saline Use of manual hyperinflation bag (bagging)

pulmonary physical therapy interventions to employ; again, these decisions are based on the patient's responses to the intervention and on the outcome. Some change in intervention should be effected with one or two intervention sessions, confirming that improvement is being maximized. If no improvement is noted, an explanation is found and the intervention is changed to elicit improvement. When no improvement is demonstrated, particularly in patients who are seriously ill, physical therapy may still have a role in preventing deterioration, so it should not necessarily be withdrawn. However, a rationale should always be proposed for continued intervention in the event of no demonstrable change. Continued intervention may be indicated, for example, in a patient in an induced coma. Hemodynamic and oxygen transport status must be maintained in anticipation of the induced coma being reversed. In most other situations, however, some improvement toward the eventual goal of maximizing activity and participation status should be expected from every intervention.

Measures to assess response and outcome to interventions are selected so that they reflect (1) activity and participation status, (2) the status of oxygen transport overall, and (3) the integrity of the step or steps in the oxygen transport pathway that were identified as being the primary problems contributing to cardiovascular and/or pulmonary dysfunction in the original assessment (Table 17-7; see Part II). Cardiovascular and pulmonary dysfunction is determined on the basis of the history, assessment, and laboratory investigations such as pulmonary function testing, breathing pattern, cardiac function testing, fluid balance and renal function, arterial blood gases, arterial saturation, vital signs, and hemodynamic variables, including heart rate and ECG, blood pressure, and rate pressure product. Subjective reports are also clinically relevant, such as subjective ratings of perceived exertion, breathlessness,

Box 17-5 Parameters of the Intervention Prescription in the Management of a Patient with Cardiovascular and Pulmonary Dysfunction or Its Risk

- Determine whether to intervene or not to intervene at this time
- Define measures and outcomes on which intervention progression and determination of whether goals have been met are based
- Define parameters of intervention based on history, laboratory investigations, tests, and assessment
- Intervention types
- Intensity of each intervention (if applicable)
- Duration of each intervention
- Frequency of each intervention
- Instruct patient in the between-intervention intervention and, if applicable, also instruct the nurse, a family member, or both
- Reassess every intervention
- Modify as necessary within each intervention
- Modify and progress interventions as indicated
- Determine when intervention is to be discontinued
- Request additional supportive information, tests, and investigations as indicated throughout the course of intervention
- Predict time course for optimal effects and course of intervention to determine intervention efficacy; modify as necessary
- Schedule and coordinate interventions in conjunction with other interventions: medical, surgical, nursing; respiratory therapy (weaning); oxygen supplementation; sympathomimetic drugs; ADLs; balance with sleep and rest periods; food intake and feeds; peak energy times; peak of drug potency and effects (e.g., pain, reduced sedation, reduced neuromuscular blockade)

Box 17-6 Use of Modalities and Aids

Goal: To incorporate the use of the modalities and aids that enhance the prescribed interventions over the short and the long term

Modalities	Pharmacological Agents
Treadmill, ergometer, rowing machine	Oxygen
Weights	Bronchodilators
Pulleys	Vasodilators
Nebulizers and aerosols	Antihypertensives
Flutter valve	Antiinflammatories
BIPAP* and CPAP†	Mucolytics
Incentive spirometer	Surfactant
Orthoses, braces, and supports	Analgesics

**Bilevel positive airway pressure.*
†Continuous positive airway pressure.

musculoskeletal or wound pain, angina, and fatigue. These same measures are used as outcome measures to detect improved oxygen transport and gas exchange.

Considering that clinical decision making is based largely on the results of tests and measures, it is essential that these measures have certain characteristics. Measurements must be objective and their procedures standardized to maximize test validity and reliability. Although physical therapists specialize in noninvasive assessment procedures as well as interventions, noninvasive measures are prone to imprecision, thereby leading to measurement error and unreliability. It is therefore essential that assessment measurements be performed in a systematic manner and according to measurement guidelines in order to maximize their quality and usefulness in guiding and directing intervention (Chapter 7). Invasive interventions, including blood work, scans, and radiographs, are also fundamental to the physical therapist's assessment and ongoing evaluation. Assessment measurements always precede intervention to ensure that the intervention and its prescriptive parameters are appropriate. Measurements during intervention provide information about the patient's responses, both beneficial and detrimental. This feedback determines the parameters of intervention and whether the intervention should be modified in some way or possibly discontinued. The overall intervention response is established by further monitoring and assessment at the termination of intervention and often at periodic intervals post-intervention so that delayed effects can be monitored. Frequent and periodic measurements over time are referred to as serial measurements and provide useful trend data. The pre- and post-intervention responses and any noteworthy responses during intervention are charted, along with sufficient information about the procedures that were used (i.e., assessment, as well as intervention procedures).

Physical therapists often require the results of invasive tests such as blood work or invasive hemodynamic monitoring to establish intervention response and outcome; thus these may need to be requested.

Assessment and reevaluation data provide feedback to the physical therapist about her or his clinical decision making and the therapeutic outcomes, as well as about the effectiveness of the prescribed interventions in the management of a given patient. Patient satisfaction with the physical therapist and with management, elicited by means of a formal evaluation by the patient, is also critical for evaluating service and the overall outcome of physical therapy for each individual.

Summary

This chapter provides a framework for clinical reasoning and decision making based on oxygen transport characteristics that underlie a limitation in activity and participation in life as defined by the model of ability advocated by the World Health Organization.[21] Carried out in partnership with the patient, as much as possible, the process includes diagnoses and intervention prescriptions in the management of patients with cardiovascular and pulmonary dysfunction, who range from the individual who is medically unstable and critically ill to the individual who is medically stable with cardiovascular and pulmonary dysfunction, or its risk, and living in the community. The purpose of a systematic approach to clinical decision making is to maximize intervention outcome and cost effectiveness. This is done by focusing on physiological and evidence-based practice within the context of evidence-informed practice (i.e., informed by epidemiology) and monitoring to gauge improvement after every intervention so as to

Table 17-7 Measures and Outcomes to Assess Limitations in the Steps in the Oxygen Transport Pathway

Status or Function	Measures or Outcomes
Central control of breathing	Central drive to breathe test Arterial blood gases Cerebral perfusion and pressure
Ambient air	Partial pressures of O_2, N_2 and CO_2 Air pollution and quality Humidity
Airways	Clinical assessment including auscultation Pulmonary function tests Arterial blood gases Chest radiograph Histamine challenge exercise tests
Lungs	Clinical assessment, including inspection, percussion, palpation, and auscultation Pulmonary function tests Ventilation and perfusion scans Diffusion capacity test Arterial blood gases Chest radiograph Immunological status Respiratory muscle assessment Assessment of the structure and integrity of chest wall Lung water studies
Blood	Circulating blood volume and cardiac output Arterial oxygen content Venous oxygen content Plasma volume Red and white blood cell counts Protein constituents Platelets Hemoglobin Coagulability Viscosity Stasis Hydration Immunological status
Pulmonary circulation	Perfusion scan Pulmonary artery balloon floatation catheter to assess central venous pressure, pulmonary artery pressures, wedge pressure
Heart	Clinical assessment, including percussion, palpation, and auscultation Inspection and clinical observation tests, including jugular venous distension test Heart rate, systolic and diastolic blood pressures, and rate pressure product ECG Hemodynamic studies to assess cardiac output, stroke volume, cardiac distensibility, and ejection fraction Ultrasound procedures to examine mechanical integrity Scans Coordination of electromechanical behavior of heart Coronary artery perfusion studies Stress test Hemodynamic monitoring including central venous pressure, pulmonary artery pressures, and wedge pressure Angiography Chest radiograph
Peripheral circulation	Clinical assessment findings Segmental blood pressures of the extremities Ultrasound studies Arterial and venous lab studies and investigations Adequacy and efficiency of lymphatic drainage system of the heart and lungs, and peripheral circulation Stress test
Tissue	Enzyme studies Tissue biopsies Vascularization of tissue Adequacy and efficiency of arterial and venous tissue Blood flow Tissue fluid balance; hydrostatic pressure, oncotic pressure, and lymphatic pressure Blood work including serum lactates and $S\dot{V}O_2$ Tissue oxygenation and pH Nutritional and hydration status

ensure that the patient is progressing and time is not wasted. The clinical decision-making process involves diagnosis (i.e., specific analysis of the patient's problems—limitations in activity and participation) in relation to the physiology and underling pathophysiology, the contribution of restricted mobility and recumbency, and extrinsic (related to the patient's care) and intrinsic (related to the patient's characteristics) factors. Based on this analysis, interventions and their parameters are prescribed so that they have the greatest physiological and scientific justification for being likely to return an individual to health and participation in life. Interventions and their prescription parameters should have clear and justifiable rationales. Specific monitoring of the impaired steps in the oxygen transport pathway is essential to establishing and confirming the diagnoses, determining the potentially most effective interventions, evaluating the intervention response, refining and progressing the intervention, and determining when to discontinue intervention and physical therapy overall or to discharge the patient from care. The specific components of the intervention prescription include the intervention, its intensity (if applicable), duration, and frequency, as well as its course and progression. A problem-solving approach to patient care has become essential across health care professions, given the prohibitive cost of such care and the need for health care to be physiological, evidence-based, cost-effective, and ethically justifiable. As noninvasive practitioners, physical therapists need to evaluate their effectiveness in avoiding, reducing, or postponing the need for invasive care (i.e., drugs and surgery). Although these outcomes are exceptionally important, they all too often are underestimated in practice.

Review Questions

1. Describe the three levels of assessment, based on the World Health Organization's model of ability and participation.[21]
2. Describe the use of the oxygen transport pathway as a conceptual model of cardiovascular and pulmonary practice and as the basis for defining problems related to cardiovascular and pulmonary dysfunction and risk (structure and function level).
3. Distinguish among the short-term goals, long-term goals, and preventive goals of cardiovascular and pulmonary physical therapy management. Relate to participation, activity, and structure and function.
4. Discuss the significance of the reduction of invasive care (avoidance, reduction, and postponement of drugs and surgery) as a primary outcome for patients under the care of physical therapists who specialize largely in noninvasive management.
5. Distinguish the four categories of factors that contribute to cardiovascular and pulmonary dysfunction or threat (i.e., pathophysiology, restricted mobility and recumbency, extrinsic factors, and intrinsic factors).
6. Describe the factors that need to be considered in intervention prescription.
7. Describe the factors that need to be considered in determining the course of intervention.
8. Describe the process of modifying, progressing, or discontinuing intervention with respect to the iterative process of evaluation and modifying intervention prescription.
9. What is the role of prognosis in intervention planning in the short term and long term?
10. Describe why physical therapists prescribe interventions rather than administer interventions with standard protocols for given limitations of oxygen transport and address restrictions in activity and participation.

Summary 268
Review Questions 268
References 268

Physical therapists use mobilization and exercise as the basis for patient assessment, evaluation, and intervention; the two concepts in conjunction are a therapist's primary tools. These tools are used to prevent, remediate, or delay limitations in participation and activity. They can also be used to assess and evaluate limitations in structure and function or in exercise capacity. This chapter will begin with an overview of the terminology, then move into the basic physiology of mobilization and exercise. The bulk of the chapter will use those introductory concepts to look at the physiology as a basis for assessment, evaluation, and training.

The routine application of mobilization and exercise should be distinguished from the prescriptive application of mobilization and exercise; the three objectives of prescribing mobilization and exercise for the purpose of maximizing oxygen transport are differentiated in this chapter. The detrimental multisystem effects of prolonged sedentary activity and restricted activity (bed rest) in the general population are outlined, and techniques to counter those effects are described. The acute and chronic responses to exercise described in this chapter are typical for individuals without pathology. Chapter 19 outlines testing and training prescription principles and practical details for exercise testing and prescription. Special considerations in common patient populations with respect to exercise testing and training prescription are described in Chapters 24 and 25.

Terminology in Mobilization and Exercise

Before moving into the physiology of mobilization and exercise, a few definitions are necessary to clarify the discussion. Strict definitions are important when discussing the following concepts:

- Mobilization
- Exercise versus physical activity
- Training
- Oxygen consumption

Mobilization

Mobilization is the therapeutic and prescriptive application of low work load activity in the management of cardiovascular and pulmonary dysfunction. Primarily, the goal of mobilization is to exploit the acute effects of exercise in order to optimize oxygen transport. Although this activity is considered low work load, it can elicit high patient-specific relative metabolic demand. Even a relatively low dose of a mobilization stimulus can impose considerable metabolic demand on a patient with cardiovascular or pulmonary compromise, which is why it is prescribed for patients who are acutely ill. Mobilization is also used because of its beneficial effects on other organ systems such as the musculoskeletal, neurological, integumentary, gastrointestinal, and renal systems. Whenever possible, mobilization is performed in the upright position, which is the physiological position (Chapter 20), to optimize gravitational stress on fluid shifts and central and peripheral hemodynamics. Mobilization is thus prescribed as both a gravitational stimulus and an exercise stimulus.

Exercise Versus Physical Activity

Physical activity is defined as bodily movement produced by muscle contraction that increases metabolic demand substantially over the resting state. Exercise, then, is defined as a form of physical activity that is structured and repetitive. Exercise typically requires at least moderate physical exertion, such that respiratory rate and heart rate are noticeably accelerated, especially when performed to develop or maintain fitness. Exercise is prescribed by physical therapists in the management of subacute and chronic cardiovascular or pulmonary dysfunction. The ultimate goal of exercise is the maximization of function in all steps of the oxygen transport pathway down to supporting structures (i.e., muscles and other tissues). A short-term goal of exercise is the exploitation of its cumulative physiological effects to adapt to long-term exercise.

Training

Although specific principles of training have been designed for athletes involved in performance-based activities, these principles also apply to any patient that physical therapists encounter. Training in both cases, is defined as the systematic application of progressive exercise stimuli to elicit a specific physiological, functional, or skill-based goal (or goals). Typically, to achieve specific patient-based goals, the application of multiple exercise modes and training guidelines is required. This type of training often involves both aerobic and anaerobic exercise using cyclic and resistance-based exercises. Application of training principles to exercise testing and prescription is discussed further in Chapter 19.

Oxygen Consumption

The amount of oxygen taken in during a given activity is measured as oxygen consumption ($\dot{V}O_2$). Oxygen consumption is dictated by fluctuating metabolic requirements: demand is at its lowest point when the body is rest but increases to intermediate levels during submaximal activity and reaches a peak at the maximal level of exercise an individual can volitionally tolerate. Metabolic cost increases with illness or injury as a result of healing and repair. Two abbreviations frequently appear in the exercise physiology literature to denote oxygen consumption: $\dot{V}O_{2max}$ and $\dot{V}O_{2peak}$. Although often used interchangeably, these terms are technically distinct.

$\dot{V}O_{2max}$ Versus $\dot{V}O_{2peak}$

A true "maximal" value would reflect the oxygen consumption of *all* muscles working maximally: the value would be the product of cardiac output (CO) × arteriovenous oxygen content difference (a–v O_2 content difference) (see Figure 2-2). This is documented as $\dot{V}O_{2max}$.

The problem with using $\dot{V}O_{2max}$, however, is that most exercise activities, including exercise tests, are selective in their focus and tend to work just the legs or the arms, or work the legs in different ways (i.e., cycling a lower-extremity ergometer versus walking on a treadmill). $\dot{V}O_{2peak}$, then, measures oxygen consumption in the context of the exercise: where $\dot{V}O_{2max}$ is then a theoretical value, $\dot{V}O_{2peak}$ is a practical one.

Maximal effort resulting from leg work generates a greater $\dot{V}O_{2peak}$ than maximal effort resulting from arm work; further, maximal effort resulting from treadmill walking or running generates a greater $\dot{V}O_{2peak}$ than maximal leg work on a cycle ergometer (about 10% more). This greater $\dot{V}O_{2peak}$ may be explained by the larger muscle mass of the legs than the arms in the first situation, and the arm work and requirement for increased postural stabilization in the second situation. The more a patient's muscle groups work simultaneously, the closer $\dot{V}O_{2peak}$ approximates true $\dot{V}O_{2max}$.

Whether $\dot{V}O_{2max}$ can be achieved is an academic question. Maximal effort exerted during Nordic (cross-country) skiing approximates theoretical $\dot{V}O_{2max}$ most closely in that the activity requires strenuous arm and leg work coupled with marked postural stabilization. In the laboratory, $\dot{V}O_{2max}$ is obtained based on a maximal exercise test in which metabolic evaluation is performed. Such evaluation indicates when the individual's maximal level of physiological capacity is reached, including the attainment of age-predicted maximal heart rate. The evaluation may also include a plateau of or decrement in $\dot{V}O_2$ with increasing work rate.

In the update of the literature in this and other chapters, the term used is the same term used by the cited investigators in describing their work. Literature published in recent years tends to adopt the more precise terminology, $\dot{V}O_{2peak}$, when describing the $\dot{V}O_2$ achieved by an individual when performing a maximal effort during a specified exercise testing condition.

Aerobic Capacity

An additional problematic term typically used in exercise physiology literature is *aerobic capacity*. $\dot{V}O_{2max}$ represents the maximal rate of aerobic glycolysis (or maximal aerobic power). Though aerobic capacity is often used to describe $\dot{V}O_{2max}$, aerobic capacity actually refers to the total amount of energy produced aerobically and better reflects aerobic endurance than $\dot{V}O_{2max}$. The term *maximal aerobic power* is more appropriate to describe $\dot{V}O_{2max}$.

Basic Principles of Mobilization and Exercise

Exercise as an Assessment and Evaluation Tool

Exercise has been the basis for physical therapy for more than 100 years, but exercise science has only emerged as a discipline within the past 60 years. Over this time, typical responses of various organ systems to both short- and long-term exercise stress have been detailed by researchers. The main question being addressed pertains to what physiological changes can be expected when an individual initiates exercise (particularly in a test with a standardized protocol). Changes in breathing, heart rate, blood pressure arterial saturation, $\dot{V}O_2$, and $\dot{V}O_{2max}$, as well as subjective responses of exertion and fatigue, are all aspects of this study. An understanding of these responses has enabled physical therapists to use exercise as a tool in the assessment, evaluation, and training of patients.

Physiological response can vary in deconditioned people where a given work rate is perceived as highly strenuous, yet the absolute work rate is relatively low. These responses can be markedly altered in people with a range of pathologies (depending on their types and severities) and these differences need to be anticipated and considered (see Chapters 24 and 25) in the assessment of a patient.

For evaluation, exercise tests can serve as standardized outcome measures. As evaluation tools, tests are repeated periodically (e.g., every few weeks) in order to progress the exercise or training prescription until the target conditioning goal is achieved. Special attention is paid in these cases to pre-exercise conditions and the standardization of both exercise procedures and measurement procedures (Chapter 19).

Clinically, physical therapists select which test outcomes are relevant based on the patient's needs and goals. In some patients, objective responses such as HR or SpO_2 may be primarily of interest, whereas subjective responses such as breathlessness, fatigue, or pain may be of particular interest. Some pathologies can limit the level of conditioning that is achievable with training; thus a comprehensive multisystem assessment is needed to establish realistic goals for the training, along with parameters to maximize its benefits and limit potential adverse effects.

Often for people with chronic conditions, many of whom may be older, submaximal tests can be used to compare responses from one time to another for given work rates. In other cases, the physical therapist may wish to estimate $\dot{V}O_{2max}$ by conducting a $\dot{V}O_{2peak}$ test, which can be done directly or indirectly. Direct measurement of $\dot{V}O_2$ requires metabolic measurement with a cart and capacity for expired gas analysis for O_2 and CO_2 (Figure 18-1). Such carts require pretest gas calibration in addition to calibration of the exercise modality (treadmill or ergometer). The patient needs to be familiarized and habituated to the tester(s) and testing situation, and practice beforehand, to ensure the results are valid. Indirect assessment of $\dot{V}O_{2max}$ is imprecise but can provide an index of general conditioning if methods are tightly standardized; this is particularly important when test results are used as outcome measures. Practices related to exercise testing and training prescription are detailed in Chapter 19.

Oxygen Transport and Metabolic Demand of Patients

In health, when individuals have a typical reserve capacity, the acute and long-term responses to an exercise stimulus can be largely predicted. Specifically, minute ventilation (VE), cardiac output (CO), and each of their components (hence, DO_2) increase commensurate with work rate and oxygen demand.

In patients whose oxygen transport capacity is reduced or threatened, mobilization and exercise constitute a metabolic load that is superimposed on other factors that increase metabolic cost (Table 18-1). Hospitalized patients may be hypermetabolic. In addition to their basal metabolic demands, their energy demands are increased secondarily to factors such as pain, anxiety, increased body temperature, healing and repair processes, increased work of breathing, and increased work of the heart, as well as in response to interventions and

Table 18-1 Factors That Contribute to Increased Metabolic Demand and Oxygen Consumption in Patient Populations

Type of Factors	Specific Factors
Pathophysiological Factors	Fever (secondary to an infectious agent or inflammation, surgery, multiple trauma, severe illness) Thermoregulatory challenges (too hot or too cold, altered ambient temperature and humidity) Healing and repairing (secondary to illness, trauma, surgery) Combating infection
Intervention-Related Factors	Alerting, noxious, and painful responses to routine nursing, medical, and physical therapy interventions, including injections, insertion of lines, procedures, and neurological checks Feeding, enterally or parenterally Being handled physically (by health care workers) Body position Changing body position (passive, active assist, or active changes) Range of motion exercises (passive, active assist, or active) Mobilization and exercise Pharmacological agents
Psychosocial Factors	Social contact (with health care workers, family) Anxiety Discomfort Pain
Miscellaneous	Noise Disrupted circadian rhythms when ill, hospitalized, or away from daylight

procedures such as physical therapy. The goal, therefore, in prescribing mobilization and exercise is to ensure a safety margin wherein the patient's demand for oxygen does not exceed the available normal supply or delivery. This can be indicated clinically if the patient's oxygen transport levels worsen by either objective or subjective measurement.

Several interventions can increase $\dot{V}O_2$ and overall metabolic demand;[1,2] therefore the capacity of the oxygen transport system to meet the patient's metabolic demands needs to be established in the assessment. These interventions include:

- Mobilization
- Exercise
- Body positioning
- Arousal
- Breathing control maneuvers
- Coughing
- Postural drainage
- Manual techniques
- Bagging
- Suctioning
- Range-of-motion (ROM) exercises

Questions to ask include the following: Can the oxygen transport system support the patient's metabolic demands? If so, what reserve capacity is available to support a mobilization or exercise stimulus? The exercise stimulus is designed to exploit the potential of the reserve capacity. Estimating reserve capacity is essential so that the effectiveness of the therapeutic exercise stimulus (i.e., neither subthreshold or suprathreshold) can be maximized.

Metabolic demand and $\dot{V}O_2$ are determined by many factors. In patients, the effect of arousal, anxiety, pain, and noxious stimulation, in addition to the hypermetabolic demands of recovery, contribute to energy cost and demand on the oxygen transport system. Thus relaxing and calming patients are central components of physical therapy because these interventions reduce oxygen demand, as do physical therapy interventions for pain management. Although relaxation, often coupled with sedation or analgesia, is central to physical therapy management in other settings, relaxation procedures should be applied in the management of patients with cardiovascular and pulmonary dysfunction in situations in which agitation, anxiety, and pain contribute to increased oxygen demand. This is especially true in intensive care, where oxygen transport is compromised or threatened in most patients (see Chapters 34 and 35).

The typical method for prescribing exercise to achieve desired acute and long-term adaptations is longer duration, whole-body aerobic exercise at a moderate-vigorous intensity. This type of stimulus appropriately optimizes both central (cardiac, blood volume, oxygen delivery) and peripheral (oxygen extraction, glycolytic/mitochondrial enzyme function, capillarization) components for increasing $\dot{V}O_{2max}$. This type of training, however, also requires an adequate central response of the cardiovascular and/or respiratory systems to produce a high level of cardiac output during exercise. In patients with compromised cardiovascular or respiratory function, this type of exercise is extremely difficult and can often lead to undue fatigue. The stimulus for increasing metabolic demand with exercise can be achieved in ways that can help minimize $\dot{V}O_2$, thus reducing the impact of reduced cardiovascular and/or respiratory function.[3] For example, in patients with chronic obstructive lung disease, breathing a low-density helium gas mixture relieves some of the respiratory loading, resulting in increases in exercise tolerance[4] and peripheral muscle trainability.[5] Use of such breathing gases is not usually practical in clinical settings, however. Other methods such as single limb training and high-intensity interval training, have been shown to reduce central demand and optimize peripheral load (see Chapter 19).

Cellular Energetics in Response to Acute Mobilization and Exercise

The integrity of the cardiopulmonary unit is fundamental to maximize oxygen transport and cellular respiration. Oxygen is continuously being used by every cell in the body for oxidative phosphorylation and the synthesis of adenosine triphosphate (ATP). The splitting of a phosphate bond from ATP to form adenosine diphosphate yields a considerable amount of energy for metabolism. The energy for this process comes from the reduction of hydrogen in the formation of water and carbon dioxide, which are the end products of the Krebs cycle and the electron transfer chain (i.e., cellular respiration). These metabolic processes, which make up oxidative phosphorylation, take place in the mitochondria of the cells (see Chapter 2).

The balance between oxygen consumption and oxygen delivery is precisely regulated to ensure not only that there is an adequate supply of oxygen but also that, under typical resting conditions, approximately four times as much oxygen is delivered to the tissues as is used. This safety margin permits the immediate availability of oxygen when the system is perturbed by physical, gravitational, or psychological challenges (see Chapter 2).

Anaerobic metabolism is prevalent at the initiation of all movement/activity/exercise and also during intense, short, sprint-type activities (i.e., sports such as hockey, soccer, and volleyball or functional activities such as stair climbing, heavy lifting/carrying, and vigorous walking/running). Physical therapists tend to focus on aerobic rather than anaerobic exercise; however, in situations where tasks to be improved involve high levels of intensity, training programs may be designed to elicit anaerobic adaptations. In conditions for which D_{O_2} is compromised, patients may rely on anaerobic metabolism to sustain ATP production and breakdown to provide energy. Anaerobic capacity and, specifically, the anaerobic threshold can increase with training; however, anaerobic training effects are less than aerobic training effects achieved with aerobic training.

Although the term *anaerobic* implies that the exercise is performed in the absence of oxygen, anaerobic metabolism provides a short-term means of supporting phosphorylation, using substrates other than oxygen to generate and split ATP. If insufficient oxygen is available, the amount of ATP that can be generated anaerobically is limited; thus this process can be sustained for only a short period.

Lactic acid accumulates in the blood during anaerobic metabolism. In healthy, untrained individuals lactic acid increases exponentially at an exercise intensity of about 55% of maximal aerobic power.[6]

Anaerobic metabolism is thought to be triggered by tissue hypoxia, though the term *anaerobic* is somewhat a misnomer: oxygen is still needed to pay the oxygen debt. In healthy patients the need for oxygen is delayed rather than eliminated; in patients with disease, anaerobic metabolism occurs when a patient's oxygen transport system cannot meet the metabolic demand required (i.e., patients with sepsis and multisystem organ dysfunction). Serum lactate levels are elevated in these patients, resulting in metabolic acidosis, which is unfavorable to the maintenance of homeostasis.

During exercise, the cellular P_{O_2} is lower than the surrounding interstitial fluid P_{O_2} and oxygen diffuses rapidly through cell membranes. At the onset of physical exercise, the increased metabolic demand of the muscle and supporting tissues increases the oxygen diffusion gradient. Feedback mechanisms are triggered to increase D_{O_2}, which depends primarily on arterial oxygen content and CO.

The first line of defense is the response to an increase in pericellular pH. The concentration of carbon dioxide is increased, and this, as a result of the decrease in pH, facilitates the dissociation of oxygen from hemoglobin (i.e., it shifts the oxyhemoglobin dissociation curve to the right). CO, the product of stroke volume and heart rate (SV × HR), increases commensurate with metabolic demand. The immediate response to oxygen utilization and lowered tissue oxygen is an increase in CO to increase D_{O_2}. This averts arterial desaturation that is not typically observed in health, even with extreme exertion. With progressive exercise intensity, SV increases disproportionately at lower intensities to increase CO, with HR contributing to a greater extent at moderate and high exercise intensities. However, older individuals exercising at high intensity in upright positions rely more on the Frank-Starling effect than on HR.[7] In health, exercise-induced cardiac fatigue has been proposed as a limiter to prolonged exercise.[8] The mechanisms of the associated reduced left ventricular systolic and diastolic function are unclear.

The increase in systemic CO results in increased venous return and pulmonary CO. The SV plateaus at 40% of $\dot{V}_{O_{2max}}$, and thereafter CO is augmented by increases in HR (Figure 18-2). One exception in health is in elite athletes, whose SV may continue to increase commensurate with exercise intensity.[9] To oxygenate a greater volume of blood in the lungs, an increased volume of air must be inspired. To increase $\dot{V}_E$, tidal volume (V_T) and respiratory rate (RR) increase. At low intensities of exercise, V_T increases disproportionately to RR, whereas at moderate to high intensities, V_T plateaus and further increases in $\dot{V}_E$ are effected by an increase in RR (Figure 18-3).[10] Exercise is associated with a small increase in airway diameter and length of pulmonary structures, hence, a reduction in airway resistance. Zone 2, the zone of greatest alveolar ventilation to perfusion ($\dot{V}_A/Q$) matching in the lungs, is increased as a result of pulmonary capillary dilation and recruitment. Diaphragmatic excursion is enhanced, and the distributions of ventilation and perfusion become more uniform throughout the lungs, which minimizes airway closure and atelectasis. Exercise increases diaphragmatic excursion, which leads to inflation of the lungs in three planes (anteroposterior, transverse, and cephalocaudal, particularly in the upright position).

Rhythmic inflation and deflation of the lungs associated with physical activity has several clinically important effects:

- First, this action increases alveolar ventilation ($\dot{V}_A$) by a primary increase in V_T.
- Second, exercise-induced lung motion facilitates lymphatic flow and drainage. Optimal lymphatic drainage is essential for lung water balance with the increased volume of blood being processed through the pulmonary circulation and lung parenchyma. This action may explain, in part, the beneficial effect of mobilization on the distribution and function of pulmonary immune factors.[11] The increased movement of the lungs during exercise has a primary effect on mucociliary transport and mucus clearance.[12] Physical activity may also minimize bacterial colonization in the airways, hence reducing the risk for pulmonary infection.[13]
- Finally, lung movement stimulates surfactant production and its distribution over parenchymal tissue. Surfactant is essential for reducing surface tension in the alveoli, maintaining alveolar stability, and maintaining lung compliance, thereby minimizing airway closure and areas of lung collapse.

Circulation to the heart and periphery is primed and responds to the increased demands of acute exercise. Hemodynamic adjustments occur immediately with the onset of exercise stress and in fact may precede it due to a typical anticipatory response. To maximize the availability of CO to working muscle (e.g., the legs), blood shifts from the venous capacitance reservoirs, such as the venous compartments of the gut and extremities. At rest, most of the circulation (70%) is contained within the highly compliant venous circulation. The

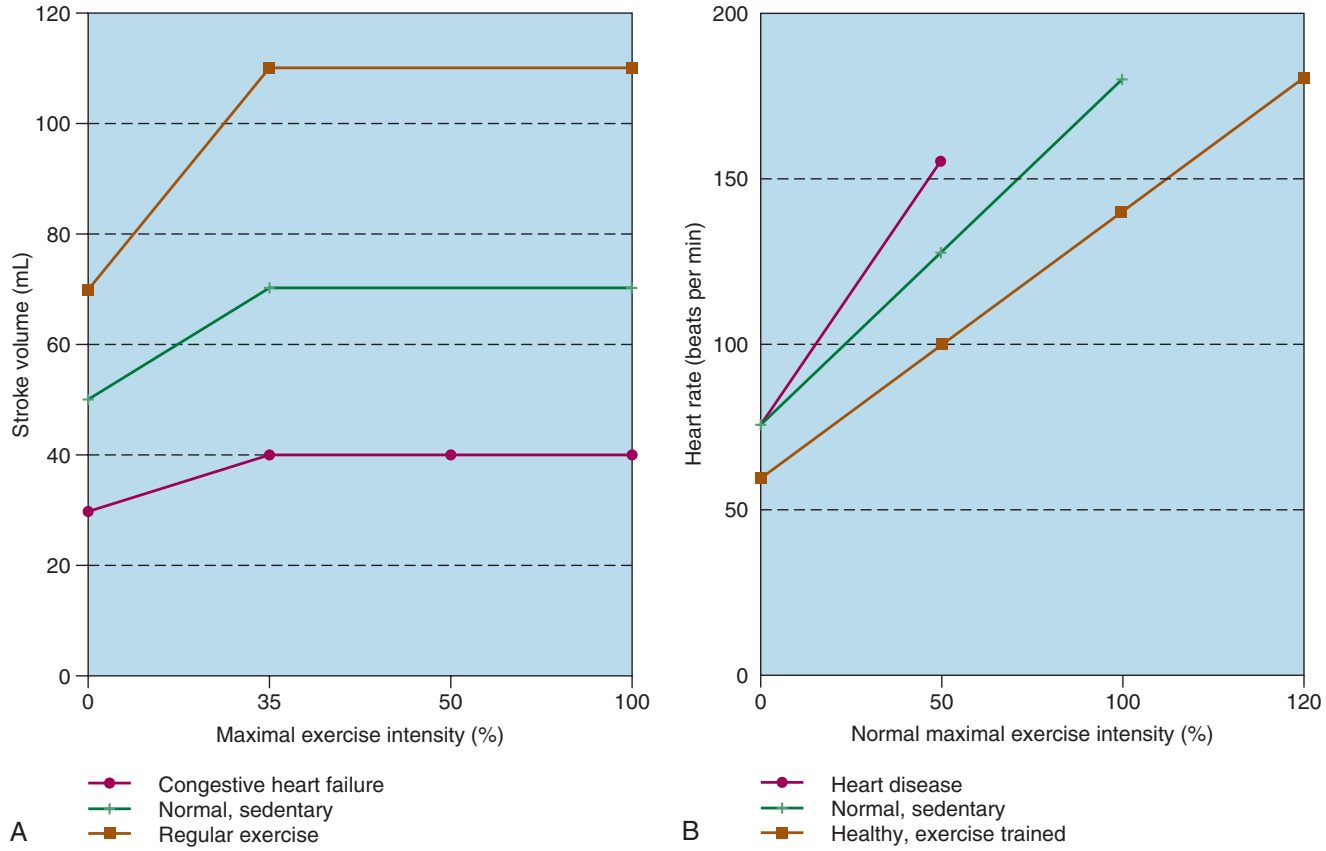

Fig. 18-2 Relationship between stroke volume (SV) and heart rate (HR) with increasing cardiac output (CO) or exercise intensity. Fig. 18-3 Relationship between tidal volume (V_T) and respiratory rate (RR) with increasing minute ventilation (V_E) or exercise intensity. Horizontal axis represents minute ventilation corresponding to exercise intensity; left vertical axis represents V_T (*solid line*); right vertical axis represents RR (*dashed line*).

Starling law of the heart regulates the forward movement of blood commensurate with the volume of blood that is received. The heart chambers are normally distensible; they adjust to changing volumes of blood returning to the heart and pump more forcefully when stretched than at rest, in order to eject blood through the pulmonary and peripheral circulations. Muscle enzymes that extract oxygen at the cellular level are also primed and are synthesized commensurate with chronic metabolic demand.

Effects of Mobilization and Exercise on Oxygen Transport

In health, optimal oxygen transport depends on the integrity of each step in the oxygen transport pathway and the interdependency of these steps. Cardiovascular and pulmonary dysfunction can lead to dysfunction in one or more steps in the oxygen transport pathway. Because of the interdependence of these steps and the ability of functional steps to compensate for dysfunctional steps, gross measures of gas exchange and oxygenation can be normal. The number of steps in the pathway that are affected by pathology and its severity determine the impairment of oxygen transport overall and the degree to which this impairment is reflected in gross measures of oxygen transport.

To maximize the capacity of the steps in the oxygen transport pathway, the oxygen transport system must be exposed to two principal stressors: (1) gravitational stress and (2) exercise stress. These stressors are essential to life in that they enhance the biochemical, physical, and mechanical efficiency of the steps in the oxygen transport pathway and the patient's capacity to respond rapidly to changes in the physical environment.

Conversely, the absence of gravitational stress and exercise stress are the two primary factors contributing to impaired oxygen transport secondary to bed rest deconditioning. Exploiting both gravitational and exercise stress to prevent cardiovascular and pulmonary dysfunction is thus indicated. Further, mobilization and exercise are the two most vital physiological interventions available to the physical therapist for remediating cardiovascular and pulmonary dysfunction. Body position has marked effects on pulmonary and cardiovascular function (Chapter 20) and thus on exercise performance. The more acutely ill a patient is, the more important it is that upright body positioning be coupled with mobilization to increase aerobic capacity and tolerance to exercise stress. The degree to which this is done, however, depends on the patient's status and ongoing monitoring (see Chapters 16, 34, and 35).

The Prescription of Mobilization and Exercise

The prescription of exercise is fundamental to the management of primary and secondary cardiovascular and pulmonary dysfunction. Guidelines have been well developed for prescribing exercise to maximize functional work capacity or aerobic power for healthy people and individuals with chronic heart and lung conditions.[14-21]

As clinical exercise specialists, physical therapists strive to take advantage of the effects of exercise in most patients and adapt the prescription based on the patient's clinical presentation and needs. Exercise training is typically based on a person's responses to a maximum graded exercise test. Although somewhat less precise, exercise training intensity can be prescribed based on a proportion of the individual's age-predicted maximum heart rate provided there is no significant medical history. Submaximal exercise testing is often indicated for patients with severely impaired functional work capacity because of the inherent risks associated with maximal testing and the potential for invalid test results.[22] Submaximal exercise testing has had a greater role in patient assessment and evaluation than as a basis for exercise prescription. Because of the greater utility of submaximal exercise testing in patient populations, guidelines for the latter warrant being better elucidated.

The prescription of mobilization for the patient with acute cardiovascular and pulmonary dysfunction has been a relatively neglected research priority when compared with the number of studies concerning the prescription of exercise. This is surprising, given that early mobilization is generally a key component of cardiovascular and pulmonary physical therapy for patients who are acutely ill. Orlava (1959)[23] was among the first to report the beneficial use of mobilization to manage acute cardiovascular and pulmonary compromise; specifically, bronchopulmonary pneumonia. In addition, the physiological literature has long supported an unequivocal role for therapeutic mobilization to maximize oxygen transport in patients with acute cardiovascular and pulmonary dysfunction.[24] Even for patients who are critically ill, the goal of mobilization is to evaluate the patient's responses with respect to oxygen transport reserve capacity and use this as a basis for estimating the limits of a patient's physiological capacity to be mobilized, with a view to returning the patient to living within the community. The more critically ill the patient, the greater the need to assess the relationship between the patient's $\dot{V}O_2$ and oxygen delivery (DO_2) (see Chapter 2);[25] this ensures that the patient's capacity for oxygen transport is not exceeded.

Unlike exercise testing and prescription for the patient with chronic cardiovascular and pulmonary conditions, the patient with acute dysfunction is not exercise-tested in the conventional manner because of understandable risk and the patient's incapacity to perform such a test. Given the profound and direct effects of mobilization and exercise on cardiovascular and pulmonary function, the physical therapist needs to identify the specific effects of exercise required and define the optimal therapeutic stimulus (i.e., the stimulus that yields the maximal benefit to oxygen transport with the least risk). The parameters for the mobilization prescription are based on factors other than a maximal or peak effort (see Chapters 16, 34, and 35).

Acute and chronic cardiovascular and pulmonary pathology have the additional challenges of compromising functional capacity in two ways. First, in acute illness, the patient tends to be recumbent in bed a great proportion of the time; second, in both acute and chronic illnesses, the patient's physical activity is reduced. Recumbency and restricted mobility have physiologically distinct effects on oxygen transport that contribute jointly to bed rest deconditioning; recumbency, however, has been considered to be the primary determinant of bed rest deconditioning.[26-28] The impact of these factors is exaggerated in smokers, young people, older adults, obese individuals, and patients who are mechanically ventilated.

The goals of mobilization and exercise are directed at correcting impairments and enhancing the patient's capacity for activity and participation (see overview of the WHO International Classification of Function, Disability and Health in Chapters 1 and 17). Outcomes related to improving abilities and participation include self-care, home management, return to work, and resumption of avocational activities. Return to work warrants special mention. Return to work is often related to oxygen transport capacity in terms of aerobic and muscle power. However, there are economic, psychosocial, and environmental factors that need to be considered. These factors, too, should be part of the overall assessment and incorporated when setting overall goals and establishing the appropriate outcomes for a given patient.

Preventive Effects of Exercise

The preventive effects of exercise are evident in prehabilitation. The term *prehabilitation* can be used to refer to patient conditioning before a surgical intervention or hospital admission.[29] Individuals can be prescribed exercise programs commensurate with their age, functional status, and anticipated procedure or surgery. The purpose is to reduce complications,

speed recovery, minimize the time until discharge, and promote a complete return to daily living as soon as possible.

Although it is widely accepted that exercise provides profound preventive benefits for most patients, these benefits have not been adequately researched for the critically ill. Some general practices, however, have become accepted clinically for patients who are acutely ill, including the practice of turning patients. The turning frequency that is widely accepted is every 2 hours, though there is no literature to support evidence of greater preventive effects when a patient is turned every 2 hours rather than hourly or every 4 hours. Sitting up and ambulating are two other practices that are used. The timing of these interventions, however, is often based on convenience, on the patient's other needs, or on a once- or twice-a-day regimen, rather than on a prescriptive basis with consideration of rest or recovery periods between treatments. Patients who sit or walk for preventive reasons may assume suboptimal and even deleterious slumped or asymmetric positions. Patients and their caregivers need to be reminded about the importance of proper body position at all times, and patients should be provided with appropriately supported chairs, firm bolsters, and adjustable beds that maintain optimal body positions. The benefits can be augmented by scheduling such interventions when the patient is rested, or coordinating them with medications, e.g., analgesics or delay of sedating medication.

When prescribing exercise to elicit its optimal preventive effects, the physical therapist needs to consider the same variables as when prescribing exercise for its beneficial acute and long-term effects—that is, the patient's age, capabilities, premorbid functional work capacity, and the type, distribution, and severity of the patient's underlying condition(s). Such preventive mobilization or exercise must be prescribed in such a way as to avoid having any deleterious effects on the patient's overall condition. Even after highly invasive investigative procedures such as heart catheterization, patients can benefit from safe early ambulation.[30]

Prescription of Prehabilitation Exercise

Although much is known about the protective benefits of cardiovascular and pulmonary fitness and conditioning and about the negative effects of bed rest and restricted mobility (discussed later in this section), little has been documented about prescribing exercise to counter orthostatic intolerance in a given patient.[31] The characteristics of deconditioning or detraining in a given individual are determined by age, sex, conditioning status before bed rest, underlying pathophysiology, fluid and electrolyte balance, medications, and the duration of bed rest.[32]

The preventive effects of an exercise stimulus can be defined as that exercise dose that will maintain the patient's conditioning level and prevent deterioration. At present, the prescription of preventive mobilization and exercise is nonspecific. Aerobic exercise and resistance muscle training have differential effects in countering the effects of restricted mobility.[33,34] Although the upright position is the primary means of countering orthostatic changes associated with recumbency, exercise may have a limited role.[35] Even though high-intensity, short-duration, isotonic cycle ergometry training (ITE) and intermittent resistive isokinetic training (IKE) have no effect on orthostatic intolerance associated with recumbency in healthy people, ITE maintains plasma volume, red blood cells, and positive fluid balance, and IKE has no effect on plasma loss but mitigates red blood cell loss.

These differential training effects are of considerable clinical interest; however, they are the result of high-intensity training, and further recumbent exercise should not be considered a substitute for the gravitational stress associated with the upright position. Although patients who are severely ill are not usually capable of performing intense exercise, it is important to note that the responses to upright exercise by healthy people after 5 days of bed rest can be maintained with a daily 30-minute session of intense interval upright exercise training.[36] Further, moderately intense exercise performed against lower body negative pressure to simulate an upright 1-g environment fails to counter orthostatic intolerance after 15 days of bed rest.[37] Also, aerobic pedaling exercise in the supine position during bed rest may be inadequate to maintain hemodynamic function and $\dot{V}O_{2max}$.[38] With respect to the parameters for prescription of mobilization, the intensity of training appears to be singularly important in attenuating the deconditioning effects associated with bed rest. In terms of importance, intensity is followed by frequency.[39]

Resistance training fails to counter the cardiovascular deconditioning associated with bed rest.[40] Some evidence suggests that isometric exercise during bed rest can attenuate the decrement in $\dot{V}O_{2peak}$ and maintain muscle integrity better than isotonic exercise.[41] Markers of lactic dehydrogenase, hence anaerobic threshold, increase with both types of exercise. Over time, however, reduced hydrostatic stress contributes to reduced lactic dehydrogenase in both types of training.

Research is needed to refine exercise prescription for the preventive effects of exercise in recumbent patients whose mobility is restricted. For example, the following questions need to be answered:

- What preventive mobilization/exercise is best for which individuals and under what conditions (i.e., what are the principles of prescription)?
- How do different types of exercise compare with respect to their preventive effects when all else is constant (i.e., patient's age and demographic profile, smoking history, general health, presenting illness and severity, body weight, nutritional status, aerobic condition, stress levels, cognitive status, and medication schedule)?
- Does exercising in some body positions elicit better preventive effects than exercise in other body positions?
- What principles establish the mobilization/exercise intensity, duration, and frequency that are optimal for a given individual whose mobility is restricted?
- What types of exercise are best suited for cross-transfer of their effects between the ipsilateral and contralateral limbs, to limit deconditioning when one limb is immobilized?
- What are the parameters that should guide physical activity during the day to limit prolonged periods of sitting (i.e., maximal duration of periods of inactivity, degree of physical activity needed to offset the deleterious effects of sedentary periods)?
- What constitutes an adequate stimulus to maximize the preventive effects of exercise for a given patient, particularly a patient who is critically ill?

Hazards of Sedentary Activity

Cardiorespiratory conditioning or fitness is related to the volume of regular physical activity; however, its relationship to health measures is less strong.[42] Physical inactivity has been causally implicated in lifestyle-related conditions (Chapter 1), but in general, it is not known whether a precise dose of activity or exercise exists that can provide protection against these conditions. One exception to this occurs with ischemic heart disease, in which a threshold intensity of 6 metabolic equivalents (METs) in conjunction with a minimal volume of regular physical activity is recommended for optimal cardiovascular health.[43] The precise dose for prevention of hypertension and stroke is less clear.[44] Moderate as opposed to heavy exercise has been recommended.[43] The choice of relative or absolute intensity of effort depends on the desired preventive outcomes, as well as the patient's specific characteristics and history.

More and more, life in the developed world tends to be characterized not only by inactivity but by prolonged periods of sedentary behavior. Although an individual may adhere, for example, to a routine exercise program that includes aerobic exercise 3 to 5 days a week at moderate intensity for 20 to 40 minutes, this does not entirely offset the deleterious effects of prolonged periods of inactivity that are characteristic of many people's activity patterns throughout the day, week, year, or their overall lives. The negative effects of inactivity may be particularly injurious for older adults and those with disabilities, who may be less able to perform even the basic activities of daily living. This further contributes to the downward spiral of inactivity, often combined with weight gain, which makes it even more challenging for someone to move and be physically active.

Although a person may exercise an hour a day, the question arises about the remaining 23 hours. Over the past decade, investigators have focused on the health consequences not only of physical inactivity but of prolonged periods of sedentary behavior as well. Research has shown that in addition to regular physical exercise, breaks during periods of sedentary activity (including screen-based activities) are essential to offset the effects of chronic inactivity.[45,46] With the advent of screen-based entertainment, children today are at serious risk for the consequences of hours of sedentary activity; furthermore, sedentary children are more likely to become sedentary adults. Conversely, children who are active and move frequently are more likely to do so as adolescents and adults.[47]

Chronic inactivity increases the risk for chronic lifestyle-related conditions and promotes premature aging. Alternatively, a physically active lifestyle promotes health and well-being, even offsetting lifestyle-related chronic conditions, as people age.[48]

Physiological Effects of Bed Rest

Humans are designed to be upright and moving; indeed "upright and moving" can be described as the normal physiological position. The deconditioning associated with restricted activity in patients is comparable to detraining in athletes,[32,39] yet is distinct from bed rest deconditioning, which is associated with recumbency as well as restricted mobility.

When people are recumbent *and* inactive, gravitational stress (the vertical gravitational gradient) and exercise stress are removed. Bed rest, which requires patients to remain in this recumbent and inactive state, is one of the most commonly used yet seldom questioned therapeutic practices. Despite its widespread acceptance, the body positions it promotes are nonphysiological (Chapter 20). The harmful sequelae of this posture have been well documented;[24,39,49-56] yet the more severely ill the patient is, the more confined that individual is to the bed—thereby the greater the risk for multisystem complications (Table 18-2).

The classic study by Saltin and colleagues (1968)[57] demonstrated marked multisystem deterioration within 3 weeks of bed rest in five healthy young men and the restoration of aerobic capacity with strenuous training afterwards. In a follow-up of the same subjects 30 years later,[58] all were found to have an age-related decrement in aerobic power. When their exercise responses were compared over that time frame, it was revealed that bed rest had had a more profound impact on physical work capacity than 30 years of aging.

Table 18-2 Physiological Consequences of Bed Rest

Bed Rest Consequence	Potential Mechanisms
I. Fluid volume redistribution	Decreased plasma and blood volume Decreased total heart and left ventricular volumes Increased hematocrit Diuresis and natriuresis Venous stasis
II. Muscular inactivity	Increased insulin resistance Decreased muscle mass Decreased muscle strength Decreased muscle endurance
III. Altered distribution of body weight and pressure	Urine stasis, retention, tendency toward calculus formation Hypercalciuria Bone demineralization Local skin changes
IV. Aerobic deconditioning	Increased HR at rest and at all levels of activity Decreased resting and maximum stroke volume Decreased maximum cardiac output Increased risk for venous thrombosis and thromboembolism Decreased orthostatic tolerance Decreased aerobic conditioning Decreased $\dot{V}O_{2max}$ Increased venous compliance
V. Other	Catabolism Anorexia Paralytic ileus Constipation Increased sensitivity to thermal stimuli; increased sweating and hyperemia Increased anxiety, hostility, depression, psychosis Increased auditory threshold Increased focal point, decreased near point of visual acuity Alteration in clearance of some drugs

Adapted from Woods SL: Cardiac nursing, *ed 5, Philadelphia, 2010, JB Lippincott, Williams & Wilkins.*

Of clinical importance is the fact that deterioration of cardiovascular and pulmonary function occurs at a faster rate than musculoskeletal deterioration and that the rate of recovery from the negative effects of bed rest is generally slower than the rate of impairment.[59,60] These effects of bed rest are accentuated in older adults[61] and are likely to further compound the oxygen transport and other deficits of patients with pathology.

Oxidative stress has been implicated in age-related physiological changes.[62] Disuse deconditioning has been implicated as an oxidative stressor contributing to aging, especially when combined with the effects of smoking and a Western-type diet (see Chapter 1). In fact, half of the physical decline associated with aging has been attributed to lack of physical activity.[63] With regular physical activity and prescribed aerobic and strengthening programs, these changes can be substantially offset. As a result, functional capacity is maximized and, in the event of illness, the individual has better physiological reserve to deal with the pathophysiological insult. Regardless of age, however, exercise-induced physiological and health advantages are lost following cessation of exercise.[64] Restricted mobility in older adults has been also associated with clinical depression.[65] Thus the evidence supports the need for sustained physical activity and exercise throughout life to derive their functional and health benefits.

The recumbent, immobile positions associated with bed rest adversely affect most organ systems by means of an apparent down-regulation of the oxygen transport system.[66] This is clinically important because in conventional patient management, there is a direct relationship between how sick the patient is and the amount of time she or he is confined to bed. In addition, the musculoskeletal, neurological, gastrointestinal, and genitourinary systems are adversely affected.

Cardiovascular and Pulmonary Effects

A primary effect of mobilization and exercise on the cardiovascular and pulmonary systems is enhanced mucociliary transport and airway clearance.[12] Frequent changes in body position augment airway clearance and minimize the pooling and stagnation of bronchial secretions, hence reducing airway obstruction and airflow resistance (Chapter 20). The benefits of frequent body position changes to prevent the accumulation of secretions or resolve them can be augmented when combined with mobilization.

The cardiovascular deconditioning resulting from bed rest includes the loss of fluid-volume and pressure regulating mechanisms, the loss of plasma volume, and diuresis.[67-70] In turn, the hematocrit is increased, and the risk for developing deep vein thromboses and thromboemboli is increased. This is exacerbated by increases in blood viscosity, platelet count, platelet stickiness, plasma fibrinogen,[71] and stasis of venous blood flow.

Venous thromboembolic disease is preventable with conservative management, including prophylactic anticoagulation in some instances.[72] In addition to restricted mobility, other risk factors include being older, undergoing venous catheterization, and hormone replacement therapy. Conditions that are associated with risk include previous thromboembolus, myocardial infarction, heart failure, severe lung disease, cancer, obesity, and paralytic conditions such as stroke. After acute stroke, patients are particularly at risk due to paresis, recumbency, restricted mobility, and circulatory stasis.[73] The work of the heart is increased in a patient who is immobile and recumbent, as is the work of breathing. The work of the heart is greater as a result of the increased filling pressures and heart rate associated with chronic recumbency and the increased blood viscosity. The work of breathing is increased because of reduced lung volumes secondary to visceral encroachment on the underside of the diaphragm, increased intrathoracic blood volume, and restricted chest wall motion.

Pulmonary sequelae of recumbency include reduced lung volumes and capacities, particularly functional residual capacity (FRC), residual volumes (RV), and forced expiratory volumes.[74-78] A reduction in FRC in the supine position compared with the sitting position has been attributed to both a decrease in thoracic volume and an increase in thoracic blood volume, thereby increasing pulmonary venous engorgement.[79] Thus alveolar-arterial oxygen difference and arterial oxygen tension are reduced during bed rest.[80-82] Closing volumes are increased, precipitating arterial desaturation in recumbent positions and subsequent complications.

With bed rest, the blood vessels of the muscles and splanchnic circulation dilate. With prolonged bed rest, they may lose their ability to constrict. The ability of these vessels to constrict is essential for preventing the pooling of blood and maintaining circulating blood volume when the patient assumes the upright position. Following bed rest, a patient may feel lightheaded or dizzy and may faint. Individual differences in terms of orthostatic intolerance have been reported and need to be assessed.[67,68,83,84] Individuals with greater venous compliance in the legs recruit mechanisms to compensate, such as activation of the renin-angiotensin-aldosterone system, activation of the sympathetic nervous system, and inhibition of the parasympathetic nervous system, so they tolerate orthostatic challenges better.

Musculoskeletal Effects

With only a few days of bed rest, muscle atrophy is initiated, leading to weakness, discoordination, and balance difficulty.[57,85] With severe weakness, excessive strain may be placed on ligaments and joints. Muscles and their inert structures are differentially affected. In the knee extensors, for example, tendon stiffness is reduced and their hysteresis characteristics become exaggerated, whereas this does not occur in the plantar flexors.[86] Muscle mass and strength may be lost, and muscle and ligament shortening may occur along with joint contractures, skin lesions, and decubitus ulcers.[87,88]

At the cellular level, disuse atrophy begins within 4 hours of bed rest. Compared with type IIa muscle fibers in vastus lateralis, type I fibers have been reported to be more seriously affected by bed rest, and they respond less favorably to muscle-resistance training.[89] Differences in fiber type may explain why muscles in the lower limbs are differentially affected; for example, the plantar flexors are particularly affected.[90] Also, sex differences in muscle strength loss with bed rest have been reported.[91] Muscle imbalance may result from poor postural alignment.

Skeletal muscle protein synthesis is compromised by bed rest, aging, nutritional deficit, uncontrolled diabetes mellitus, and sepsis.[92] Disuse osteoporosis results from reduction of the mechanical stress caused by gravity and from lack of active

muscle contraction across joints. Prevention is a primary goal because recovery of mineral loss in bone is prolonged and its loss is largely irreversible.[93] Bone mass is restored later than muscle mass and function after a period of restricted mobility, which contributes to fracture risk.[94]

The limited positioning alternatives in bed may contribute to poor postural alignment, stiffness, and soreness. Bed rest allocates weight bearing to various body parts not adapted for weight bearing. Skin breakdown most commonly occurs over bony prominences, such as the sacrum, trochanters, elbows, scapulae, and heels. Risk factors for pressure ulcers include age, prolonged hospitalization, restricted mobility and general debility, low body weight, low diastolic BP, and surgical intervention.[95]

Immobile patients are at risk for bone demineralization. An issue of particular importance in older populations, patients with disabilities, postmenopausal women, and patients on steroids is calcium loss. Prevention of disuse osteoporosis is the primary aim because remineralization of bone, even with aggressive exercise, body positioning, electrical stimulation, and possible pharmaceutical agents, is unlikely.[93] In patients who are critically ill, cytokines have been implicated in inactivity-related inflammation and muscle injury and atrophy. Activity has been proposed as a countermeasure.[96]

Renal Effects

Bed rest–induced diuresis increases renal load. Patients with renal insufficiency are particularly seriously affected by this effect, as well as by other sequelae of bed rest.[97] As a result, they may exhibit dysrhythmias, muscle wasting, weakness, neuropathy, glucose intolerance, and reduced bone density.

Central Nervous System Effects

With bed rest and recumbency, orthostatic intolerance in combination with resting tachycardia and reduced exercise capacity occur, reflecting diminished reflex activity of the sympathetic nervous system. Baroreceptor-mediated activity is blunted and appears to involve abnormal processing in the central nervous system at the level of the ventrolateral medulla.[98] CNS changes include slowed electrical activity of the brain, emotional and behavioral changes, slowed reaction times, sleep disturbances, and impaired psychomotor performance.[88,99] Diminished sympathetic activity is the primary factor responsible for orthostatic intolerance along with hypovolemia; the net result is bed rest deconditioning.[100]

Metabolic Effects

Metabolic changes that occur during periods of bed rest and the relative absence of muscle contraction include glucose intolerance and reduced insulin sensitivity;[101] increased calcium excretion due to bone loss; and increased nitrogen excretion secondary to protein loss from atrophying muscle.[102,103] In sedentary people, plasma lipids are elevated and skeletal muscle becomes insulin resistant.[104] Insulin sensitivity and triglyceride levels are highly responsive to changes in diet, activity level, and thermogenic state. Fit people are highly insulin sensitive, whereas unfit sedentary people tend to be insulin insensitive. Reversal and the normalizing of insulin sensitivity are dependent on increasing muscle contraction.

Immunological Effects

Bed rest has been associated with reduced cytokine function and antibody counts, hence, reduced immunity and an increased risk for infection.[105,106] Lymph flow is reduced with bed rest, which may predispose patients to further risk for infection.[107]

Psychological Effects

Bed rest also affects psychological status. Patients may become depressed or sensorily deprived or may develop a psychoneurosis.[108]

Alternatives to the Nonspecific Use of Bed Rest

The evidence supports the following:

1. Bed rest as an effective intervention is lacking.
2. The use of bed rest remains nonspecific and excessive.
3. Bed rest has multisystemic negative effects and thus must be prescribed as specifically and judiciously as medication.
4. Methods other than bed rest to manage very ill patients such as those in the intensive care unit (ICU) must be developed.

Given this evidence, alternatives need to be exploited within and outside physical therapy treatment. Physical therapists, for example, need to become active in designing furniture and devices that are better suited to patients' normal physiological functioning and to the needs of patients' courses of recovery. Such appliances would include the presence in ICUs of a greater number of stretcher chairs that enable easy transfer of patients from bed to chair and upright positioning and a greater availability of patient-lifting devices. Greater attention needs to be given to chair design in settings where patients may be immobile; effective chair design could augment the mobilization process in addition to promoting body position changes.

Kinetic and rotating beds are electromechanical beds that turn the patient through an arc of about 30 degrees to both sides from the supine position over several minutes.[109,110] These beds are used for heavy-care patients who are critically ill and are unable or difficult to turn. Even though studies have shown these beds can enhance oxygenation in severely compromised patients such as those with acute respiratory distress syndrome,[111,112] they need to be used selectively judiciously.[113] Reliance on passive positioning by the bed should not substitute for more active and active-assisted patient positioning. Such interventions constitute the initial stages of mobilization and ambulation.

The use of tilt tables to promote mobilization may be hazardous because the muscle pumping action when the legs are dependent is minimal. Passive standing on a tilt table constitutes a greater hemodynamic stress than does active standing. Upright sitting postures with the legs dependent may elicit greater physiological benefit than passive standing and with less risk because of the resulting increased hemodynamic stress. Leg movement elicited by stepping in place, however, can counter the marked fluid shifts associated with the upright position.

Even in patients who are seriously acutely ill (e.g., those in the ICU), body positioning and mobilization are essential to

offset the deleterious effects of loss of gravitational stimulation from being upright and loss of exercise stimulation from restricted mobility (Chapters 33, 34, 35, and 36).[114]

Indications for Bed Rest

Despite the universal acceptance of bed rest as a medically therapeutic intervention, indications for its therapeutic use have not been well documented, and its effectiveness continues to be questioned.[39] Further, much more is known about the adverse and potentially life-threatening hazards of bed rest than about its benefits. Bed rest should clearly be used as selectively and prescriptively as other medical interventions to ensure that specific benefits are being derived and that the multisystemic negative sequelae are minimized.

Many procedures such as surgery are associated with considerable pain, so being relatively immobile and recumbent in bed is believed to minimize postsurgical discomfort. Minimizing the effects of gravity and the need to bear weight is commonly indicated in patients after orthopedic surgery. Likewise, the bed enables a patient with multiple wounds and fractures to be immobilized and supported in a fixed position that is believed to promote healing.

Conditions that are associated with edema require minimizing the effect of gravity on the affected limbs. Whether edema can be controlled by localized elevation rather than bed rest must be established. Certain conditions may require some activity restriction, particularly in their acute stages in order to reduce the work of the heart, as in cases of myocardial infarction. However, 50 years ago, restriction to a chair was reported to be more beneficial than restriction to bed in patients with heart disease.[115] Despite this finding, many patients continue to recline in beds rather than sit upright in chairs and initiate ambulation. Mobilizing patients and permitting bathroom privileges has also been reported to be less stressful than having to use a bedpan.[116]

Acute Effects of Mobilization and Exercise

Physiology of Acute Exercise

A comprehensive list of the physiological benefits of acute exercise is presented in Table 18-3. The principal benefits include:

- Increased $\dot{V}_E$ secondary to increased V_T, RR, or both
- Improved airflow rates
- Improved mucus transport
- Improved CO secondary to increased SV, HR, or both
- Increased tissue oxygen extraction

The particular benefits of acute mobilization and exercise can be directed at each patient's specific pathophysiological deficits.

After decades of research in exercise science, based in particular on college-aged male students, an increasing number of studies have identified sex differences in exercise responses. Higher $\dot{V}O_2$ peak and muscle strength are found in men compared with women even when adjusted for body weight. These are explained primarily by hormonal differences, specifically estrogen and progesterone in women and testosterone and androgen in men. Differences in autonomic function contribute to the reduced risk by women for heart disease and to their increased longevity.[117] Women have greater

Table 18-3 Acute Physiological Effects of Mobilization and Exercise

Body System	Effects
Pulmonary	Increased regional ventilation Increased regional perfusion Increased regional diffusion Increased zone 2 (i.e., area of ventilation-perfusion matching) Increased tidal volume Altered breathing frequency Increased minute ventilation Increased efficiency of respiratory mechanics Decreased airflow resistance Increased flow rates Increased strength and quality of a cough Increased mucociliary transport and airway clearance Increased distribution and function of pulmonary immune factors
Cardiovascular	Hemodynamic effects Increased venous return Increased stroke volume Increased heart rate Increased myocardial contractility Increased stroke volume, heart rate, and cardiac output Increased coronary perfusion Increased circulating blood volume Increased chest tube drainage Peripheral circulatory effects Decreased peripheral vascular resistance Increased peripheral blood flow Increased peripheral tissue oxygen extraction
Lymphatic	Increased pulmonary lymphatic flow Increased pulmonary lymphatic drainage
Hematological	Increased circulatory transit times Decreased circulatory stasis
Neurological	Increased arousal Increased cerebral electrical activity Increased stimulus to breathe Increased sympathetic stimulation Increased postural reflexes
Neuromuscular	Increased regional blood flow Increased oxygen extraction
Endocrine	Increased release, distribution, and degradation of catecholamines
Genitourinary	Increased glomerular filtration Increased urinary output Decreased renal stasis
Gastrointestinal	Increased gut motility Decreased constipation
Integumentary	Increased cutaneous circulation for thermoregulation
Multisystemic Effects	Decreased effects of anesthesia and sedation Decreased deleterious cardiopulmonary effects of surgery Decreased risk for loss of gravitational stimulus in conjunction with the upright position

parasympathetic control of the heart and less sympathetic activity.

CARDIOVASCULAR AND PULMONARY EFFECTS

Respiratory muscle fitness may affect exercise performance in healthy individuals. Isolated respiratory muscle training increases respiratory muscle endurance and endurance time in response to whole-body exercise.[118-120] Although $\dot{V}O_{2max}$ is unaffected, $\dot{V}_E$ and blood lactate decrease after training. In addition, respiratory muscle training can attenuate breathlessness in healthy people during exercise. However, improved respiratory muscle strength and endurance with specific training have been reported not to transfer to $\dot{V}O_{2max}$ in athletes.[121] Although optimizing respiratory muscle fitness through whole-body functional exercise is the goal in patient care, these findings have some clinical implications.

The increased metabolic demand of acute exercise results in a slight increase in airway diameter and increases in:

- Minute alveolar ventilation
- Alveolar ventilation
- Tidal volume
- Respiratory rate
- Air flow rates
- Cardiac output
- Stroke volume
- Heart rate
- Blood pressure
- Rate pressure product (RPP; the product of heart rate and systolic BP)

In healthy people and those with heart disease, RPP is highly correlated with myocardial $\dot{V}O_2$ and thus with myocardial work[122]), $\dot{V}O_2$, and carbon dioxide production ($\dot{V}CO_2$). Generally, SV increases disproportionately more than HR at low intensities of exercise to effect CO. With increasing intensity, SV contributes proportionately less to HR, which continues to increase until the maximum HR is achieved with incremental exercise. In moderately active young women, however, SV plateaus through moderate to heavy exercise intensity and then undergoes a secondary increase at very heavy work loads.[123] With endurance training, SV is increased, largely reflecting increased diastolic filling and emptying rates and an increase in blood volume. Older people may not increase their maximal CO and SV in response to training, in favor of peripheral adaptation.[124] The area of greatest ventilation-to-perfusion matching in the midzones of the lungs, zone 2, is increased secondary to increased dilation and recruitment of pulmonary capillaries.[125]

The hemodynamic benefits of exercise are maximized in the upright position (as opposed to recumbent positions) because exercise alone fails to counter the loss of volume-regulating mechanisms associated with recumbency.[126] Most important is the role of gravitational stress on maintaining BP control and reducing orthostatic intolerance (see Chapter 19 for the effects of position changes on hemodynamics). During exercise, end-diastolic volume and SV have been reported to be greater in the upright position than the supine position in endurance athletes, which supports greater reliance on the Frank-Starling law.[127] Thus body position determines the relative contributions of HR, myocardial contractility, and the Frank-Starling mechanism to CO during exercise. Patients with impaired venous return and myocardial contractility may benefit from moderate-intensity recumbent cycling in which central circulation and local vasodilation are favored.[128] Plasma volume increases with acute intense exercise, and this has been shown to be position-dependent.[129] Plasma albumen content increases in upright compared with supine positions, and this is thought to be responsible for the increase in plasma volume. By coupling upright positioning with exercise, the physical therapist may directly help to normalize fluid balance and hemodynamics in patients whose fluid homeostasis is threatened.

The effect of acute exercise on blood coagulation and platelet aggregability is of particular interest in individuals with existing risk factors for clotting. The risk for stroke, for example, is of clinical importance in people with atrial fibrillation. Moderate levels of activity are associated with minimal procoagulatory effects compared with high-intensity exercise, which increases platelet activity.[130] Whether this increased platelet activity constitutes a risk factor clinically has yet to be determined.

The role of exercise in preventing deep vein thrombosis is well established. Although controversy has existed regarding its role in managing deep vein thrombosis, aggressive approaches, including walking based on judicious assessment, have been proposed.[131] Recent evidence has shown that leg compression coupled with walking is superior to bed rest in the management of acute deep vein thrombosis in outpatients.[132] Further, a systematic review and metaanalysis have corroborated that mobilization does not increase the rate of pulmonary embolism or complications above that found with bed rest.[133]

ENDOCRINE EFFECTS

Mobilization and exercise stimulate the endocrine system. Catecholamines, released to support the cardiovascular system, sustain a given exercise work rate. Increased sympathetic activity secondary to mobilization can help reduce the patient's need for sympathomimetic pharmacological agents,[134] an important physical therapy outcome. Sympathetic nerve stimulation is increased, resulting in sympathetic neurotransmitters being processed more efficiently (i.e., synthesized and biodegraded). This is a significant effect that can be used as a goal when prescribing mobilization. When exogenous catecholamines are used to augment DO_2 (optimally to 600 mL/min/m^2) in patients in surgical ICUs, the survival rate is improved and there are no increases in cardiac events over those in control patients.[135] Whether this effect, which is probably mediated by improved cardiac reserve, could be achieved by exercise-induced sympathetic stimulation warrants study. An additional benefit of sympathetic arousal in patients who are critically ill may include antiinflammatory effects associated with increased catecholamines.[136]

MUSCULOSKELETAL EFFECTS

Resistance muscle training in patients who are critically ill has been shown to have general and local benefits in terms of acute and long-term effects, as well as its preventive effects. Peripheral and respiratory muscles are important targets of exercise prescription in this patient population, and such training may have implications for avoiding mechanical ventilation or, if mechanical ventilation is indicated, facilitating

weaning.[137] Resistance exercise is an effective countermeasure to muscle atrophy when a patient is recumbent.[33,138]

Resistance muscle training has been a mainstay of physical therapy for motor recovery and conditioning effects in patient populations. There has been an increasing interest in the hemodynamic effects of resistance training and their interactions. Notably, after a resistance training program, healthy older adults show improved aerobic exercise responses. Cardiovascular responses to exertion are reduced, peak responses are delayed, and recovery from maximum exertion is faster.[139] Training effect is determined by a dose-dependent relationship between intensity of resistance training and aerobic exercise responses, in addition to the individual's pretraining status.[140] These effects are of benefit to patients with primary cardiovascular and pulmonary dysfunction; thus modified resistance training has become an integral component of traditional cardiac and pulmonary rehabilitation programs (see Chapter 24). Resistance muscle training, however, is associated with increased arterial wall stiffness, hence reduced compliance and increased pulse pressure.[141] Increased pulse pressure is a risk factor for ischemic heart disease, which suggests the need for caution in prescribing exercise that has a selective effect on pulse pressure.

Caution should be taken with high-resistance exercise, which is defined relative to the individual's strength and endurance status. Sit-ups, for example, require relatively strong abdominal contraction and can elicit a heavy resistance contraction or strong isometric effort in weak individuals. In turn, intrathoracic pressure increases, SV decreases, and vascular injury may be precipitated. There have been reports of catastrophic neurological consequences (stroke and spinal epidural hematoma) in two healthy young men.[142] Thus before abdominal exercise is prescribed, patients should be screened for risk factors. Breathing control should be incorporated to reduce intrathoracic and intraabdominal pressure. The physical therapist needs to be vigilant about detecting neurological signs and symptoms early.

Upper-body and lower-body work have distinct physiological characteristics.[143] These responses may have to be avoided (as in the hemodynamic stress of upper-body work in an individual with myocardial dysfunction) or exploited (as in an individual with lower-body paralysis). Oxygen kinetics differ for the two types of work, as do their hemodynamic responses. $\dot{V}O_2$ kinetics are prolonged in arm cranking compared with leg cycling. This change is consistent with increased type II fiber recruitment. Type II fibers are metabolically inefficient compared with fast, glycolytic, type I fibers.

CENTRAL NERVOUS SYSTEM EFFECTS

CNS responses to mobilization include arousal via activation of the reticular activating system and priming of the various organ systems involved.[144] With respect to autonomic function, parasympathetic inhibition occurs at the start of exercise, followed by sympathetic activation to augment the force and rate of myocardial contraction. Substrate utilization and transfer to working tissue, as well as the capacity for oxygen to be supplied to muscle, are precisely regulated through coordinated control of body temperature, breathing, cardiac function, and vasoactivity, both systemically and locally; at the tissue level, they are regulated by the control of local metabolism and the production of vasoactive and chemoactive substances.

METABOLIC EFFECTS

The metabolic effects of acute exercise, in particular, on glucose metabolism and growth hormone synthesis are of considerable clinical relevance because these functions are fundamental to health and recovery. Restricted physical activity causes hyperinsulinemia and hyperglycemia and reduces growth hormone synthesis.[145] Thus the acute effects of exercise are instrumental in offsetting these changes.

IMMUNOLOGICAL EFFECTS

Acute exercise has profound effects on the immune system. Even a single bout of moderate exercise has a positive effect on immunity.[146] Whether there is a dose-dependent effect is not known. Also unknown is whether there is a cumulative effect of short periods of less intense exercise, such as for the patient who is acutely ill or who has a low functional capacity.

Exercise induces white blood cell production, so it may optimize natural immunity.[147] Generally, moderate levels of regular aerobic exercise are associated with improved immune function.[148] Within the first 10 minutes of intense exercise, leukocytosis increases, as do the thrombocytes responsible for increasing platelet production. These changes are not associated with exercise-related hypovolemia or hyperthermia. Whether leukocytosis and exercise are dependent on dose or whether there is a critical exercise intensity that has to be achieved to stimulate leukocytosis has yet to be established. Prolonged exhaustive exercise has been associated with compromised immunity, which may be avoided with optimal rest and recovery, along with good nutrition and possibly vitamin C supplements.[149] After prolonged heavy exercise in athletes, an "open window" of susceptibility to infection lasting 3 to 72 hours after exercise has been described.[150] The risk for infection may be exacerbated by lack of rest and sleep, inappropriate diet, weight loss, and mental strain, and it may be prevented or reversed by better rest and diet and exercise.[151] Training strategies recommended for athletes to optimize their immunocompetence have relevance for clinical populations. Exercise sessions are monitored for individuals' susceptibility to infection, their general health, and the intensity and duration of the exercise session, as well as recovery, rest, optimal diet, and stress management.[152,153]

PSYCHOLOGICAL EFFECTS

Acute exercise has also been reported to improve psychological well-being and mood.[154] Despite the well-established benefits of exercise on mental health (e.g., reducing anxiety and tension and relieving depression),[155] it is not utilized often enough. To take full advantage of these nonpharmaceutical cost-effective benefits, exercise needs to be a more frequent recommendation.

Prescribing Exercise and Mobilization

The clinical decision-making process involved in defining the optimal mobilization and exercise stimulus for a given patient is multifactorial. The integrity of each step in the oxygen transport pathway and the overall integrity of the system in preserving arterial oxygenation and pH, are determined based on the:

Patient's history
History of the current illness
Assessment
Lab test results
Diagnostic procedure results

Once the necessary specific effects of acute mobilization or exercise are identified and matched to the patient's underlying pathophysiology (Box 18-1), the mobilization or exercise stimulus can be prescribed. Rather than a rigidly structured regimen, the prescription must evolve as the patient progresses in order to maximize its benefits (Table 18-4).

There are two primary components in assessing acute exercise responses:

1. Establishing a stable baseline founded on standardizing the preexercise conditions; and
2. Determining the appropriateness of the quantitative and qualitative changes in the objective and subjective responses during the onset of activity, the steady-state phase of activity, cool-down, and recovery.

Recovery is an important part of the exercise response assessment; postexercise hypotension in a healthy person, for example, is greater and longer after intense exercise.[156] After

Box 18-1 Common Conditions Associated with Acute Cardiovascular and Pulmonary Dysfunction That May Be Helped by the Acute Effects of Mobilization and Exercise

Atelectasis
Pulmonary consolidation
Pulmonary infiltrates
Bronchopulmonary and lobar pneumonias

Cardiopulmonary sequelae of surgery
Cardiopulmonary sequelae of restricted mobility

Table 18-4 Acute Mobilization and Exercise: The Clinical Decision-Making Process Underlying Mobilization Prescription

Step 1	A. Identify all factors contributing to deficits in oxygen transport (Chapter 2): 1. The underlying pathophysiology of the disease or condition 2. Restricted mobility and recumbency 3. Extrinsic factors related to the patient's care 4. Intrinsic factors related to the individual patient B. Identify the parameters that need monitoring before, during, and after each session
Step 2	Determine whether mobilization and exercise are indicated and, if so, which form of either will specifically address the oxygen transport deficits identified in step 1.
Step 3	Match the appropriate mobilization or exercise stimulus to patient's oxygen transport capacity. Examples: activities of daily living, walking unassisted, standing erect with assist and taking a few steps, transferring from bed to chair,* seated dangling position over bed side, moving in bed†
Step 4	Set the intensity within therapeutic and safe limits of the patient's oxygen transport capacity.
Step 5	Combine the various body positions, especially the erect position, with the following maneuvers: 1. Thoracic mobility exercises (flexion, extension, side flexion, and rotation) 2. Active, active assist, or passive range of motion exercises 3. Breathing control exercises, especially when coordinated with body movements 4. Coughing, spontaneous and voluntary, supported by self or others
Step 6	Set the duration of the mobilization sessions according to the patient's responses, such as changes in the measures and indexes of oxygen transport, rather than according to time.
Step 7	Repeat the mobilization sessions as often as possible according to their beneficial effects and their being safely tolerated by the patient.
Step 8	A. Increase the intensity of the mobilization stimulus, the duration of the session, or both, commensurate with the patient's capacity to maintain optimal oxygen transport when confronted with an increased mobilization stressor, and in the absence of distress; monitored variables should remain within the predetermined threshold range. B. Adjust the frequency based on patient response—in general, shorter treatments and increased frequencies (see Table 18-7).
Step 9	Continue progression until: A. The patient's functional status provides a base for resuming activities and full participation in life, with or without further physical therapy, and B. The threat to the oxygen transport system is minimized.

*All sitting positions require upright erect sitting. Propped up, semirecumbent, slouched, or slumped positions, although approximating the upright position, are not physiologically comparable.

†No amount of movement or activity is too small to derive acute or long-term benefits.

the cessation of intense exercise, CO is initially maintained by increased SV; after low-intensity exercise, it is maintained by HR.

Understanding the patient's capacity to respond to maximal or submaximal exercise is fundamental to the physical therapy assessment of most patients:

- $\dot{V}O_{2max}$ reflects the sum of the conductances of an integrated system of oxygen transport from the inspired air to the mitochondria.
- CO is in part passively regulated by the elastic characteristics of the peripheral circulation,[157] so its anatomic and physiological integrity is essential to DO_2.

The diffusive conductance of muscle is a particularly important component of oxygen transport and has become a focus of research related to impaired exercise capacity in patients with chronic heart, lung, and renal disease.[158] This may explain why the correction of central cardiovascular defects in oxygen transport can fail to restore exercise capacity in these patients.

To evaluate an apparently healthy individual who is beginning an exercise program, the Physical Activity Readiness Questionnaire (PAR-Q) is an established screening device (Figure 18-4). The answers help establish whether a progressive exercise program is indicated or whether there are contraindications to the individual's undertaking a progressive exercise program. The person may require a medical workup if cardiovascular and pulmonary risk factors or musculoskeletal limitations exist. Underlying conditions may have to be addressed beforehand or concurrently.

The prescription of mobilization and exercise to stimulate their acute benefits parallels that of the prescription of exercise for its long-term, central, and peripheral aerobic effects. The exercise parameters for achieving long-term adaptations in healthy people have been defined[14] (Table 18-5) and are generally well accepted: the individual engages in aerobic exercise at a heart rate intensity of 40%-85% of heart rate reserve (HRR) for 20 to 40 minutes, 3 to 5 days a week (HRR based on the Karvonen formula: HR_{rest} + 40%-85% [HR_{peak}/HR_{max} – HR_{rest}]). The traditional formula of training exercise (HR 70%-85% of age-predicted maximum or tested maximum, for 20 to 40 minutes, 3 to 5 days a week) may have greater utility in people with mild chronic conditions. Aerobic training effects are usually observed within 2 months.

In severely deconditioned individuals and in some other patient populations, however, such a prescription would not be realistic, ethical, or indicated. Thus exercise is prescribed that is sufficient to elicit progressive oxygen transport adaptation within defined limits of certain objective responses and subjective responses such as perceived exertion, shortness of breath, angina, discomfort/pain, and general fatigue. Considerable research however is needed to refine the prescription of mobilization and exercise for their acute effects in patients with acute cardiovascular and pulmonary dysfunction. Furthermore, specifications for the low-level exercise needed to effect long-term aerobic adaptation have not been elucidated in detail. Nonetheless, based on physiological understanding of acute exercise responses and of cardiovascular and pulmonary pathophysiology, principles for prescribing mobilization to exploit its acute effects related to oxygen transport can be formulated.

Early mobilization has been reported not only to reduce the risk for restricted mobility, but also to initiate the rehabilitation process along its continuum toward return to daily function. After an acute stroke, for example, patients undergo threat to oxygen transport in addition to the risks for restricted mobility during the acute period. A recent review of patients during this period reported low activity levels.[159]

Differences in acute aerobic exercise responses exist between men and women; one example is in those with hypertension.[160] The lower $\dot{V}O_{2max}$ in women has been attributed to both central and peripheral factors. The higher SVO_2 observed in women contributes to their reduced arteriovenous oxygen difference. These findings can be explained by women's smaller muscle mass, capillary density, and oxidative capacity. Older women show depressed cardiac function compared with

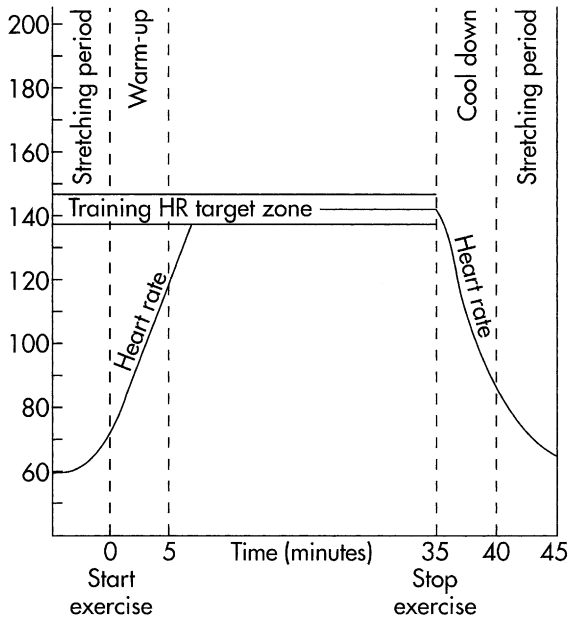

Fig. 18-4 Components of the exercise training session: stretching, warm-up, training zone, cool-down, and stretching. *(From American College of Sports Medicine:* Guidelines for exercise testing and prescription, *ed 6, Philadelphia, 2010, Lippincott, Williams & Wilkins.)*

Table 18-5 Exercise Prescription Parameters to Elicit Long-Term Aerobic Benefits in Generally Healthy People

Parameter	Specification
Exercise type	Rhythmic activity involving the large muscle groups—legs, arms, or both
Intensity	40% to 85% of HRR using predicted HR_{max} or observed HR_{max} (based on Karvonen formula)
Duration	20 to 40 minutes
Frequency	3 to 5 days/week
Course	6 to 8 weeks

HRR, Heart rate reserve, which equals (HR_{max} – HR_{rest}) × desired exercise intensity + HR_{rest}.

Modified from the American College of Sports Medicine: Guidelines for exercise testing and prescription, *ed 8, Philadelphia, 2010, Lippincott, Williams & Wilkins.*

young women; however, this difference is not observed between older and younger men.[161] Specifically, the percentage of increase in ejection fraction and the decrease in vascular resistance are depressed. This may be explained by endothelial dysfunction in postmenopausal women, which impairs peripheral vascular function during exercise.

Acute aerobic exercise responses to resistance muscle training have become more interesting clinically because the aerobic responses may have to be used as a guide to the muscle training prescription, particularly in individuals with cardiovascular risk factors and in those who are severely ill. One study examined the metabolic and cardiorespiratory responses of healthy people to maximal intermittent knee isokinetic exercise at 60 degrees/sec and 180 degrees/sec.[162] In the last 2 minutes of exercise, $\dot{V}O_2$, $\dot{V}_E$, HR, and BP were comparable, consistent with a steady rate. The slope for the increase in $\dot{V}O_2$ was steeper in the 60 degrees/sec protocol than in the 180 degrees/sec, whereas HR was unaffected by angular velocity. Neither systolic nor diastolic BP was related to exercise intensity or angular velocity of exercise. Although the metabolic and cardiorespiratory responses to intermittent isokinetic exercise of the knee mimic dynamic exercise, qualitative differences likely reflect an isometric component associated with postural stabilization. Thus the cardiorespiratory capacity of patients must be screened to ensure that they can safely meet this demand or, conversely, so that the resistance training program can secondarily augment cardiovascular conditioning.

The acute hemodynamic responses to isolated muscle testing and training are seldom considered when such training is prescribed for clinical populations such as people with low back pain. These patients tend to have weak muscle strength and poor physical conditioning.[163] Repetitive McKenzie exercises are commonly used in management; these include forward flexion of the trunk in standing and lying and back extension in standing and lying. The hemodynamic responses to these exercises have been reported to be distinct.[164] The hemodynamic stress (i.e., the effect on HR and BP) is greater in horizontal lying positions (trunk flexion greater than extension) than in the standing position (trunk flexion greater than extension). These differences may reflect the degree of postural stabilization associated with each exercise, thereby explaining the isometric muscle contraction and disproportionate changes in hemodynamic responses compared with aerobic exercise. Thus both the aerobic and isometric hemodynamic consequences of such isolated muscle exercises must be considered, regardless of whether the training is intended for managing back pain or heart disease.

Mobilization Testing for Progression

Evaluating a patient's response to a mobilization stimulus can be assessed in two ways: through challenges or through observation.

If stable, the patient can be exposed to a mobilization challenge test. The patient is monitored before, during, and after mobilization activities comparable to monitoring for a graded exercise test. Box 18-2 outlines levels of mobilization and devices that can be used (by the physical therapist or the patient) to augment the patient's performance; these are factors included in the overall prescription and are likely to be revised frequently from one treatment session to the next, or even within a session. Relatively low-intensity activities, such as bed exercises, moving in bed, changing body position, sitting up, dangling over the bed's side, transferring to a chair, doing chair exercises, and taking short walks with assistance, constitute a sufficient stimulus to elicit the acute effects of exercise, as well as gravitational stimulus. The degree of assistance required to perform the activity should be noted because it demonstrates the patient's individual effort.

If a patient's status is unstable and oxygen transport is jeopardized, monitoring that patient during usual care, such as when turning the patient, performing daily activities, and implementing nursing and medical procedures, can provide an indication of the patient's physiological responses to mobilization and the capacity of the oxygen transport system to meet metabolic demand. Any movement that is sufficient to perturb the oxygen transport system, no matter how minimal, is sufficient to elicit short- and long-term gains. Similarly, responses should be observed during and after the imposed body position change or movement and observed for recovery time to baseline.

Patients who are acutely ill may benefit from recumbent exercise for mobilization testing and training if upright positioning is not tolerated. Body position affects exercise parameters, as well as resting parameters. End-diastolic and end-systolic left ventricular volumes and SVs are larger in the supine position than in a 70-degree upright tilt, at rest, or during exercise.[165] CO was comparable, given an increase in HR in the semirecumbent position. When subjects were tested maximally, the left ventricular ejection fraction was greater in the semirecumbent position than in the supine position. Overall, exercise capacity was greater in the supine and full upright positions than in the semirecumbent position. Thus body position affects exercise responses directly by its effect on hemodynamics and cardiac function. Careful patient monitoring is essential, given that recumbent exercise can be more physiologically stressful than exercise conducted upright.

Box 18-2 Examples of Activities Used to Exploit the Acute Effects of Mobilization

Mobilization Stimuli

Ambulation (independently, with one or more assisting)
Cycle ergometry (lower and upper extremities)
Activities of daily living (independently, with one or more assisting)
Standing (independently, with one or more assisting)
Transferring (independently, with one or more assisting)
Dangling (independently, with one or more assisting)
Cycle ergometry in bed (lower extremity)
Turning in bed
Bed exercises

Mobilization Aids

For the patient:
- Walking aids (crutches, cane, IV pole for support, orthoses)
- Weights
- Pulleys
- Monkey bar
- Grab bars
- Grab rope
- Portable oxygen
- Portable ventilator

For the physical therapist:
- Transfer belts
- Mechanical lifts for patients

It is important to note for the purposes of progressing a patient's mobilization and exercise prescription that differences between sexes exist in response to bed rest. The types of muscle-function changes that occur, for example, differ between men and women. Mechanical efficiency when cycling decreases in both healthy men and women after 20 days of horizontal bed rest,[166] but delta efficiency (i.e., change in work output/change in energy expended) in upright exercise compared with supine exercise is greater for men and goes unchanged in women. This is thought to reflect a selective decrement in slow-twitch muscle fibers associated with a decrease in leg muscle mass in men during bed rest.

MONITORING FOR PROGRESSION

Patients for whom mobilization is prescribed require monitoring. Because of the stress to the oxygen transport system that mobilization elicits, the following variables, in addition to oxygen transport variables, are useful:

HR
Systolic and diastolic BP
RPP
RR
Sa_{O_2}
Arterial blood gases
ECG

The RPP is an index of myocardial $\dot{V}_{O_2}$ during exercise and an indicator of the work of the heart.[167] In individuals with ischemic heart disease, the anginal threshold often can be defined by the RPP. After bed rest, healthy individuals have blunted sympathetic responses to isometric exercise in the antigravity muscles;[168] thus patients who have had periods of recumbency and restricted activity may show similar abnormal responses to exercise. Subjective responses, including discomfort and pain, fatigue, exertion, and breathlessness, can be recorded as needed. Visual analog scales are commonly used, as are modified Borg scales: 0 (nothing at all) to 10 (maximal exertion).[169] Subjective responses are more inherently variable and unreliable, therefore potentially less valid.[170] Nonetheless, intrasubject reliability may be acceptable if measures are conducted in a standardized manner and thus can serve as supplementary outcome measures.

Prescription of a Mobilization Stimulus

Prescribing a mobilization stimulus for its acute effects parallels the prescription of exercise for its long-term effects but with some important differences. In patients with acute disease, a mobilization stimulus often results in a greater response gain than is found with such a stimulus in patients with subacute or chronic illness. In addition to the rapid favorable response an acutely ill patient may have to acute exercise, the patient may exhibit a negative response just as quickly. Thus judicious monitoring of treatment responses in these patients is essential; the prescription is driven by patient response.

Patients for whom mobilization is indicated have had variable periods of recumbency that can alter their hemodynamics and autonomic function, as well as their capacity to respond normally to mobilization.[171] Hemodynamic responses even to static exercise can be blunted, and this may vary from day to day. Further, such responses can vary from hour to hour in acutely ill patients, and day to day in patients with chronic dysfunction. In patients who are severely and acutely ill, passive rather than active exercise may be the only feasible option. Little research has been done to examine the acute and chronic effects of such exercise, although when passive cycling is compared with active cycling (10% of $\dot{V}_{O_{2max}}$) in healthy people, $\dot{V}_{O_2}$, HR, exertion, and electromyographic (EMG) activity are predictably lower.[172] The shortening of the duration of the preejection period and the length of this period in relation to ejection time, however, is similar. Plasma catecholamines remain at resting levels for both types of exercise, but blood lactates increase in both, with higher levels occurring in active cycling. Thus the inotropic response to exercise probably depends on both skeletal muscle mechanoreceptors and the Frank-Starling effect (preload and shortening in the preejection period).

The optimal therapeutic dose of the acute mobilization stimulus, particularly the initial dose, is based on the patient's presentation and history; the specific parameters are determined by the goals of the treatment and the acute effects of exercise that are indicated. The intensity of mobilization necessary for many patients will be the intensity that elicits the reactions outlined in Box 18-3.

Over time, exposure to an acute exercise stimulus of an appropriate intensity, for an appropriate duration and at an appropriate frequency, will stimulate long-term aerobic adaptation to that stimulus. Underprescribing the exercise stimulus results in less potent effects; overprescribing results in excessive, deleterious effects. Although the latter may be tolerated in the short run, the patient's well-being may be jeopardized by suboptimal treatment responses, overtraining signs and symptoms, and risk.

The duration of each mobilization session and the frequency of sessions are response-dependent rather than time-dependent. The optimal mobilization threshold, in which physiological variables increase but not in excess of predetermined acceptable and safe limits, should be maintained for as long as possible within the patient's fatigue and comfort levels and in the absence of adverse responses (determined by ongoing monitoring). The mobilization sessions should be repeated as often as the patient can tolerate them (i.e., as often as the patient exhibits beneficial responses or no deterioration and adequately recovers between treatments). Treatment sessions for acute cardiovascular and pulmonary dysfunction are usually shorter and more frequent than for patients with chronic cardiovascular and pulmonary dysfunction. The patient's condition changes rapidly with respect to both

Box 18-3 Physiological Reactions to Appropriate Mobilization Intensity

Note: All of the reactions above should occur without arterial desaturation, hemodynamic instability, or respiratory distress.

improvement and deterioration. Progression of mobilization for its immediate acute effects is usually rapid. Progression of exercise for its long-term effects may occur every several weeks, whereas progression of mobilization for its acute effects may occur as frequently as every treatment to every few days. Over time, exposure to a progressive mobilization stimulus leads to long-term physiological adaptations throughout the oxygen transport pathway. The goal is to achieve the oxygen transport status that is consistent with being able to discharge the patient from care to home or from one level of care to the next lowest level of care (e.g., from critical care to the ward).

The Mobilization Session

The scheduling of and preparation for a mobilization session is crucial to the response that can be expected. The conditions outlined in Table 18-6 should be adhered to as closely as possible, and their details should be recorded so that any factor that influences the response to treatment can be identified.

Circadian rhythms refer to physiological changes that occur in response to the fluctuating synthesis and secretion of hormones and other endocrine regulators over time (usually over 24 hours). These have a profound effect on physiological function. Circadian rhythms can be exploited in optimizing functional performance. Younger people may want to exercise later in the day, whereas older people might optimize their activity and exercise in the morning.[174] These differences are important to the physical therapist concerned with optimizing performance in patient populations whose response to activity and functional capacities may be dependent on time of day. Growth hormone production is determined by circadian fluctuations, sleep, and exercise.[175] Growth hormone is implicated in metabolism and physical performance throughout life. Thus exercise-induced growth hormone is an important effect of exercise that can optimize levels of growth hormone for general health, well-being, and successful aging. Circadian rhythms can be desynchronized during illness and, in particular, during hospitalization. That is why normal day and night cycles should be maintained, even in critical care units, so as to augment patients' recovery.

The basic components of a mobilization session should approximate the components of an exercise session described by the American College of Sports Medicine for long-term training effects[14] (Figure 18-5). Wherever possible, the session should include warm-up, steady-rate, cool-down, and recovery. These components are less distinct when a patient has minimal functional capacity or is being mobilized to remediate acute cardiovascular and pulmonary dysfunction. The rhythmic movement of large muscle groups is still ideal. Prolonged static maneuvers are usually avoided, particularly if the patient is severely ill, because of their disproportionate hemodynamic response. The movements that are usually

Table 18-6 Preparation for Mobilization

Preparation Recommendation	Specific Considerations
The patient should be physically prepared.	The patient should be rested, should not have eaten heavily in the previous couple of hours, should be as attentive and aroused as possible, and should be experiencing minimal pain, discomfort, or other distress. The patient's clothing should not be restrictive.
The patient's medication schedule should be reviewed.	A review of a patient's medication schedule will ensure that treatments are well timed with respect to analgesia and medications that interfere with an optimal treatment response, such as narcotics.
Any equipment should be noted and positioned appropriately.	Equipment, monitors, or arterial and intravenous lines (including arterial lines, intravenous lines, and catheters) should be positioned to avoid disconnections or mishaps. Mobilizing a patient in intensive care requires the positioning of the mechanical ventilator and other supports before moving the patient. Portable ventilators facilitate mobilizing and ambulating patients.[173]
Move procedures and techniques should be discussed with the team before implementation.	The physical therapist must prepare assistants before moving a patient, particularly if assistance is required. Despite the number of people assisting, the goal is usually to have the patient perform as much of the mobilization activity as possible (within the margins of safety and maximal therapeutic response). To be beneficial, even small degrees of physical movement can provide sufficient stress to the cardiovascular and pulmonary systems.

considered when mobilizing a patient include turning, sitting up, shifting, transferring, standing, and taking some steps. The progression of the levels of mobilization and exercise for medical and surgical patients, based on a consideration of metabolic cost (up to light to moderate activity), is illustrated in Figure 18-6. This schema represents the low end of the incremental staircase of activities based on the MET level shown in Figure 18-7 for a broader range of physical activities (up to very heavy activity).

Patients progress from one level to the next on the basis of their objective and subjective responses. Mobilization can be metabolically demanding for patients with acute cardiovascular and pulmonary dysfunction. Thus pacing the mobilization session allows the patient to rest between stages. The patient is reassured and encouraged to relax and coordinate deep breathing and coughing with the activity. Throughout the session, attention is given to the patient's biomechanical alignment, postural erectness, and stability. Back extension or body positioning minimizes the slumping of the chest wall and compromised ventilation. In this way, chest wall expansion is maximized in three dimensions. The erect position is efficient and requires the least amount of energy to maintain. Less demand is placed on the accessory muscles of respiration in erect sitting, and this effect is enhanced further by leaning forward and supporting the arms.

This chapter emphasizes the principles of mobilization and progression for the patient who is acutely ill but medically stable. Patients who are medically unstable, including those in the ICU, warrant special consideration, which is addressed in Chapters 33, 34, 35, and 36. Regardless of the clinical setting, however, the rate at which progression occurs typically depends on a patient's response rather than a structured protocol.

MONITORING IN THE MOBILIZATION SESSION

The more acute the patient's condition, the more important it is that physiological variables be recorded as outlined previously. The capacity to measure multiple objective measures is available in special care and intensive care units, and often these are continuously monitored. Subjective responses are also vital to refine the adequacy of the mobilization stimulus (not too much and not too little); however, severely ill patients are often unable to respond effectively or may respond unpredictably. Compared with the condition of chronic patients, the condition of acute patients tends to vary more within and between sessions and afterwards, which necessitates greater monitoring.

Monitoring should be performed continuously or at least frequently in patients for whom acute mobilization has been prescribed. First, a baseline of the patient's resting metabolic state must be established. Second, the metabolic responses to stimuli that perturb oxygen transport and the lability of these responses must be established. Obtaining such a profile provides some indication of the upper limit for the target intensity range of mobilization. The target intensity range can be defined in terms of an upper and a lower level of various physiological variables. The variables to be measured depend on the patient (see Chapters 2 and 17). Most commonly, the values described in Box 18-4 are considered basic measures and indexes of exercise response that require no invasive procedures.

Physical Activity Readiness
Questionnaire - PAR-Q
(revised 2002)

PAR-Q & YOU

(A Questionnaire for People Aged 15 to 69)

Regular physical activity is fun and healthy, and increasingly more people are starting to become more active every day. Being more active is very safe for most people. However, some people should check with their doctor before they start becoming much more physically active.

If you are planning to become much more physically active than you are now, start by answering the seven questions in the box below. If you are between the ages of 15 and 69, the PAR-Q will tell you if you should check with your doctor before you start. If you are over 69 year of age, and you are not used to being very active, check with your doctor.

Common sense is your best guide when you answer these questions. Please read the questions carefully and answer each one honestly: check YES or NO.

YES	NO		
☐	☐	1.	**Has your doctor ever said that you have a heart condition and that you should only do physical activity recommended by a doctor?**
☐	☐	2.	**Do you feel pain in your chest when you do physical activity?**
☐	☐	3.	**In the past month, have you had chest pain when you were not doing physical activity?**
☐	☐	4.	**Do you lose your balance because of dizziness or do you ever lose consciousness?**
☐	☐	5.	**Do you have a bone or joint problem (for example, back, knee or hip) that could be made worse by a change in your physical activity?**
☐	☐	6.	**Is your doctor currently prescribing drugs (for example, water pills) for your blood pressure or heart condition?**
☐	☐	7.	**Do you know of any other reason why you should not do physical activity?**

If you answered YES to one or more questions

Talk with your doctor by phone or in person BEFORE you start becoming much more physically active or BEFORE you have a fitness appraisal. Tell your doctor about the PAR-Q and which questions you answered YES.

- You may be able to do any activity you want — as long as you start slowly and build up gradually. Or, you may need to restrict your activities to those which are safe for you. Talk with your doctor about the kinds of activities you wish to participate in and follow his/her advice.
- Find out which community programs are safe and helpful for you.

NO to all questions

If you answered NO honestly to all PAR-Q questions, you can be reasonably sure that you can:

- start becoming much more physically active – begin slowly and build up gradually. This is the safest and easiest way to go.
- take part in a fitness appraisal – this is an excellent way to determine your basic fitness so that you can plan the best way for you to live actively. It is also highly recommended that you have your blood pressure evaluated. If your reading is over 144/94, talk with your doctor before you start becoming much more physically active.

DELAY BECOMING MUCH MORE ACTIVE:

- if you are not feeling well because of a temporary illness such as a cold or a fever – wait until you feel better; or
- if you are or may be pregnant – talk to your doctor before you start becoming more active.

PLEASE NOTE: if your health changes so that you then answer YES to any of the above questions, tell your fitness or health professional. Ask whether you should change your physical activity plan.

Informed Use of the PAR-Q: The Canadian Society for Exercise Physiology, Health Canada, and their agents assume no liability for persons who undertake physical activity, and if in doubt after completing this questionnaire, consult your doctor prior to physical activity.

No changes permitted. You are encouraged to photocopy the PAR-Q but only if you use the entire form.

NOTE: if the PAR-Q is being given to a person before he or she participates in a physical activity program or a fitness appraisal, this section may be used for legal or administrative purposes.

"I have read, understood and completed this questionnaire. Any questions I had were answerd to my full satisfaction."

NAME _____

SIGNATURE _____ DATE _____

SIGNATURE OF PARENT _____ WITNESS _____
or GUARDIAN (for participants under the age of majority)

Note: This physical activity clearance is valid for a miximum of 12 months from the date it is completed and becomes invalid if your condition changes so that you would answer YES to any of the seven questions.

- With cessation of exercise, do the responses revert to baseline? If so, how fast?
- Do the variables return to baseline or remain above baseline?

At the other end of the spectrum is the critically ill patient who has various invasive lines and monitoring equipment, including hemodynamic monitoring and intracranial pressure monitoring. This patient requires more specific and frequent measurement of oxygen transport status. Several measures in high-dependency care areas can be monitored continuously, such as cardiac rhythm, HR, and BP, and arterial saturation. The use of transcutaneous oxygen and carbon dioxide tensions as indexes of gas exchange has been considered limited in exercise testing; yet their use would overcome the need for arterial cannulation.[176] The use of these measures as estimates of gas exchange has been shown to be reliable, provided the electrodes are heated and the workload changes are gradually increased to allow for latency in response time.

Monitoring during nursing procedures and other types of routine care provides an indication of the patient's functional capacity without having to conduct a modified exercise test. Detailed monitoring is conducted during a mobilization or exercise challenge. Qualitative assessments can be made based on the physical therapist's subjective impressions (Box 18-5). The patient's self-reports are also important.

Adaptation to an Acute Mobilization Stimulus

When an individual is exposed to repeated exercise stress of a specific threshold intensity and for a response-dependent duration and frequency, there is a cumulative adaptive response to that repeated stimulation, or a long-term training response. The goal is to adapt the patient to multiple short mobilization sessions per day, as frequently as once per hour as indicated and as tolerated, and progressively increase the intensity of these sessions, reduce the duration, and correspondingly reduce the frequency of sessions. Table 18-7 illustrates the inverse relationship between exercise duration and frequency of the sessions.

Table 18-7 Relationships Among Mobilization and Exercise Prescription Parameters: Examples of Inverse Relationship Between Session Duration and Frequency

Incremental Activity	Session Duration	Session Frequency
Mobilization activities (e.g., self-care, moving in bed, bed exercises, sitting up in bed, sitting on the edge of the bed, standing, transferring to chair, walking)	Short (5 min) Long (20 min)	Once/1 to 2 hours 4 to 6 times/day
Interval continuous aerobic exercise	Short (5 min) Long (20 min)	Once/1 to 2 hours 4 to 6 times/day
Continuous aerobic exercise (light)	Short (5 min) Long (20 min)	Once/1 to 2 hours 4 to 6 times/day
Continuous aerobic exercise (moderate)	Short (10 min) Long (30 min)	2 to 3 times/day Once/1 to 2 days
Continuous aerobic exercise (heavy)	Short (20 min) Long (30 to 45 min)	Daily 3 to 5 days/week

Note: Intensity is set to the needs of the individual (i.e., oxygen transport and aerobic capacity are being stressed sufficiently to meet the treatment goals, with risk being minimized). The duration and frequency of treatments are based on the individual's responses and tolerance, with these being maintained within an optimal margin of safety and of recovery profiles.

Mobilization activities prescribed to enhance oxygen transport can be coupled with resistive muscle work to increase muscle strength and endurance (e.g., weights, use of a monkey bar for moving in bed and sitting up, manual resistive exercise, the use of wrist or ankle weights, ergometry, and walking). Coordinating postural changes, thoracic mobility, and upper-extremity exercises with inspiratory and expiratory efforts can be effective in stimulating increased V_T and improving ventilation-perfusion matching. Chapters 22 and 23 illustrate how such movement and breathing patterns can be combined in order to maximize oxygen transport in patients with neurological conditions. Such coordinated exercise, however, can also be used in patients with acute cardiovascular and pulmonary conditions. Isometric exercises, postures that require increased muscle work for stabilization, and activities that elicit the Valsalva maneuver produce disproportionate hemodynamic responses, which could be detrimental. The capacity of the patient to respond appropriately to these loads must be assessed beforehand to minimize risk.

In deconditioned individuals and in those whose oxygen transport system has been pathologically compromised, the exercise intensity associated with relatively low-intensity mobilizing activities (such as bed exercises, moving in bed, sitting up, dangling over bedside, transferring to chair, chair exercises, and short walks with assistance) constitute sufficient

progressive gravitational and exercise stimuli to initiate adaptation to being upright and moving. However, it is important to stress that optimal adaptation occurs only if these activities are prescribed at the requisite intensity, duration, and frequency, and the exercise prescription progresses commensurate with the individual's adaptation. Mechanical ventilation is not a contraindication to mobilization; new generations of mechanical ventilators are portable and perform comparably to conventional ventilation. They are associated with minimal adverse effects on hemodynamic variables and oxygen transport[173] and can facilitate mobilization and ambulation.

In the management of acute cardiovascular and pulmonary dysfunction, the parameters of mobilization stimuli include a relatively low intensity (although it is often perceived as intense by the patient), short duration, and high frequency of sessions. If the patient is severely compromised, as in end-stage heart or lung disease, interrupted or interval training is indicated. This type of training is characterized by either on-off exercise, which allows for rest in between bouts of exercise, or high-low intensities of activity. The volume of work that can be achieved in an interrupted protocol by a severely compromised patient is greater than that achievable during continuous activity. With physiological adaptation over time, the exercise period can be increased and the rest period decreased and possibly eliminated. When high- and low-intensity exercises are alternated, the workload can be progressed by increasing the respective loads in each phase or by increasing the duration of the higher load period. If the patient has a low functional work capacity but sufficient physiological reserve, adaptation can be rapid, necessitating small, frequent progressions. As the patient's aerobic capacity increases, the response gains are correspondingly smaller. If the patient has both poor functional capacity and poor physiological reserve capacity, progress would be correspondingly slower.

When mobilization is prescribed to remediate acute cardiovascular and pulmonary dysfunction, particularly in patients in the ICU, extensive and often invasive monitoring is required. This permits detailed assessment and ongoing metabolic assessment of the patient's treatment responses and recovery. With these supports, mobilization and exercise can be prescribed effectively for these patients. Judicious monitoring minimizes inherent risks for either under- or overprescribing the intensity of the exercise stimulus (see Part II). Monitoring leads, lines, and catheters may restrict body positions and activities. Such encumbrances, however, do not preclude most activities, including ambulation. Moving relatively immobile patients who are confined to their beds with lines and leads is crucial, because it is these patients who benefit significantly from exercise stress and succumb most severely to its removal.

Long-Term Effects of Mobilization and Exercise

In health, the long-term effects of exercise occur in response to a specific and sufficient exercise stimulus to which the individual is exposed for a finite period. With respect to aerobic training or adaptation, the essential training parameters for generally healthy people are shown in Table 18-5. As central and peripheral adaptation to the exercise stimulus occurs, each step in the oxygen transport system becomes more efficient in facilitating D_{O_2}, $\dot{V}_{O_{2max}}$, and extraction at the cellular level.[6,15,19] The long-term effects of aerobic exercise are summarized in Table 18-8.

CARDIOVASCULAR AND PULMONARY EFFECTS

In addition to an increase in $\dot{V}_{O_{2max}}$, training results in exercise-induced bradycardia and increased SV at rest and in reduction in the physiological demands of submaximal work

Table 18-8 Long-Term Physiological Effects of Mobilization and Exercise

Body System Affected	Specific Effects
Pulmonary	Decreased submaximal minute ventilation Increased respiratory muscle strength and endurance Increased collateral ventilation Increased pulmonary vascularization
Cardiovascular	Increased myocardial muscle mass Increased myocardial efficiency Exercise-induced bradycardia Decreased stroke volume at rest and submaximal work rates Decreased resting heart rate and blood pressure Decreased submaximal heart rate, blood pressure, and rate pressure product Decreased submaximal perceived exertion and breathlessness Increased efficiency of thermoregulation Decreased orthostatic intolerance when performed in the upright position
Hematological	Increased circulating blood volume Increased number of red blood cells Optimize hematocrit Optimize cholesterol Decreased blood lipids
Central Nervous	Increased sense of well-being Increased concentration
Neuromuscular	Enhance neuromotor control Increased efficiency of postural reflexes associated with type of exercise Increased efficiency of reflex control Increased movement efficiency and economy
Musculoskeletal	Increased muscle vascularization Increased myoglobin Increased muscle metabolic enzymes Increased glycogen storage capacity Increased biomechanical efficiency Increased movement economy Muscle hypertrophy Increased muscle strength and endurance Increased ligament tensile strength Maintain bone density
Endocrine	Increased efficiency of hormone production and degradation to support exercise
Immunological	Increased resistance to infection
Integumentary	Increased efficiency of skin as a heat exchanger Increased sweating efficiency Decreased skin abrasions and breakdown Increased healing

rates. Specifically, ventilation and hemodynamic responses to submaximal exercise are decreased. Endurance training increases parasympathetic activity and decreases sympathetic activity at rest.[177] Arterial stiffness is decreased,[178] and microcirculatory function and tissue perfusion are improved.[179] The subjective experience of exercise stress is also reduced. These training effects are commensurate with increases in the efficiency of oxygen transport at each step in the pathway. Unlike the effects in patients with low functional work capacity, however, exercise does not improve ventilatory performance, as is evidenced by the relationship between ventilation and the production of carbon dioxide:[180]

$$\dot{V}_E - \dot{V}_{CO_2} \text{ slope}$$

and

$$\dot{V}_E/\dot{V}_{CO_2}$$

Because of the marked ventilatory reserve in health, it is normally CO, rather than ventilation, that limits exercise. However, there is some evidence that the respiratory system can limit endurance in healthy sedentary people, in athletes (especially women) with a higher fitness level, and in patients with chronic respiratory disease.[181-183]

Although change in $\dot{V}_{O_{2peak}}$ is the gold standard for aerobic conditioning, theoretically, submaximal $\dot{V}_{O_2}$ values for given work rates do not change with training[184] unless improvement in movement efficiency and economy has occurred. With training, an individual reduces the physiological responses to each exercise load on an incremental exercise test and so is able to achieve a higher work load, thus a higher $\dot{V}_{O_{2peak}}$ with training.

The theory that maximum HR (HR_{max}) is genetically determined and does not change with training has been challenged.[185] Factors that down-regulate HR have been implicated in resetting maximum heart rate. Such factors include the baroreceptors, autonomic function, electrophysiology of the sinoatrial node, and a reduction in the number and density of beta-adrenergic receptors.

The rheology of blood plays an important role in cardiovascular disease. Platelet adhesiveness and aggregation are reduced with regular aerobic exercise.[71] Optimal platelet adhesiveness along with blood volume maintain optimal blood viscosity, which is important for blood flow through the heart and blood vessels and for perfusion of peripheral tissue. Increased plasma viscosity and hematocrit have been attributed to exercise-induced hemoconcentration as a result of the shift of fluid from the blood to the interstitium.[186] With long-term endurance training, the plasma volume expands, which may reduce the resistance of blood flow to working muscle.

Exercise is a powerful controller of normal BP and an effective intervention to control high BP in patients with hypertension. The antihypertensive effects of long-term aerobic exercise are mediated through a reduction in total peripheral resistance and altered blood rheology. In addition, exercise may lead to weight loss, which contributes to lower BP. Individuals who are normotensive experience no changes in BP with an aerobic exercise program, even though peripheral resistance is reduced.[187]

Aerobic exercise improves the hemodynamic responses and lipid profiles of individuals with cardiac disease (see Chapter 24). Walking, cycling, and running are common types of aerobic exercise. However, patients from other cultures and those who do not enjoy these types of exercise may prefer tai chi, which also has been shown to have beneficial effects on BP, lipid profiles, and relaxation.[188,189]

Hemoglobin concentration and the number of circulating red blood cells are essential to effecting optimal oxygen transport (see Chapters 2 and 13). A single bout of exercise, as well as long-term exercise, can influence the erythropoietin processes in bone marrow.[190] In the extreme, exercise can interfere with these processes and result in "sports anemia." This condition can reflect postexercise plasma expansion, increased hemolysis with intense exercise, iron deficiency, bleeding into the digestive and urinary systems, and abnormal erythropoiesis.

Changes in cardiac structure and function after prolonged exercise by healthy people have been of interest to researchers in their attempt to understand changes during ill health. Questions such as "Does the heart muscle show signs of fatigue and impaired function with such exercise?" have been posed. One study of highly trained male athletes showed some cardiac damage, along with reduced diastolic filling and contractility of the left ventricle, after completion of a half-ironman triathlon.[191]

CENTRAL NERVOUS SYSTEM EFFECTS

The responses of the CNS to training include autonomic nervous system conditioning that is associated with BP control and thermoregulation.[192] Training is associated with a more sensitive vascular response to stress, which may reflect greater alpha-adrenergic sensitivity.[193] The capacity to sweat is primed in response to exercise, which ensures that the muscle and internal organs remain at a temperature that is metabolically and energetically optimal for a given workload.

As the body adapts to the exercise training stimulus (overload principle), the intensity is increased to elicit further training benefit. This is the basis for the physiological adaptation to a training stimulus. Depending on the goals of the exercise prescription, a decision is made after several weeks about whether the exercise intensity should be raised to further increase aerobic capacity or whether a maintenance program is indicated. The training program is progressed by establishing a new exercise intensity, which usually is based on 40% to 85% of the HRR achieved in a repeat of the initial exercise test.

METABOLIC EFFECTS

The effect of exercise on glucose kinetics is clinically important for several reasons. First, illness creates metabolic stress on glucose metabolism; second, bed rest reduces insulin sensitivity; third, sedentary lifestyle and high-glycemic diets contribute to hyperglycemia and insulin insensitivity; and fourth, physical therapy's primary drug, exercise, places stress on energy substrates, including glucose metabolism, commensurate with the type, intensity, and duration of exercise. The time course of changes in glucose metabolism is important to the physical therapist because the patient must be protected from hypoglycemia and the effects of training on the muscles' sensitivity to insulin must be optimized. Even though these changes are well known to occur with multiple weeks of aerobic training, serial measures over the training period show that after 10 days there are benefits to glucose kinetics.[194]

EFFECTS IN SPECIAL POPULATIONS

Aggressive mobilization/exercise has been reported to have significant functional impact in the management of patients in the ICU. Prolonged intensive physical training, for example, has been reported to result in the regeneration of skeletal muscle after prolonged catabolism and weight loss.[195] Despite studies supporting aggressive mobilization, the physical therapist needs to establish the optimal dose at any given time and to monitor to ensure the best response and the least risk.

Aerobic power declines with age. The capacity to train, however, is not age-limited; training effects have been reported in octogenarians.[196] Often older people show greater gains in response to training because of their reduced levels of baseline conditioning. Oxygen kinetics may be slowed with aging. Training responses reflect an increasing contribution to aerobic training by peripheral as opposed to central adaptations.[197] Furthermore, based on a 30-year follow-up study, age-related decline in aerobic power over the course of 30 years was reversible with aerobic training.[197] Tasks and exercises that involve various physiological systems are differentially affected by aging as well as by training. Training profiles of young and middle-aged adults show an age-related performance decline in cardiorespiratory endurance but not in muscle endurance.[198] This finding has implications for norms of fitness and prognosis for recovery. Finally, lack of exercise has been implicated in the incidence of cognitive impairment in older adults.[199] Physiological changes associated with aging, particularly those related to exercise capacity, are often confounded by deconditioning and related physical deterioration in older adults rather than being an immutable consequence of aging.[200]

Summary

Physical therapists are clinical exercise physiologists whose primary interventions include mobilization and exercise to address limitations in participation and activity irrespective of whether these limitations result from primary or secondary cardiovascular/pulmonary dysfunction. This chapter first distinguishes mobilization, physical activity, and exercise. The role of mobilization and exercise in assessment and evaluation is addressed. Next, the chapter describes three distinct goals associated with the prescription of mobilization and exercise in the management of impaired oxygen transport: to exploit the preventive effects, acute effects, and long-term effects of mobilization and exercise so as to maximize an individual's oxygen transport capacity and his or her capacity for activity and participation in life when that person is limited by impairment of oxygen transport at the structural and functional levels. Special attention is given to prolonged sedentary behavior and to bed rest, focusing on how their injurious effects can be prevented.

The physical therapist needs a comprehensive and detailed understanding of the potent and direct effects of mobilization and exercise on oxygen transport preventively, acutely, and in the long term, as well as their multisystem effects. The specific mobilization or exercise prescription is based on a comprehensive multisystem assessment, an analysis of oxygen transport dysfunction or failure, and the treatment goals for a given patient. Ongoing monitoring is essential for defining the starting point of a mobilization or exercise program, progressing it over time, and evaluating time for discontinuation. Progression is response-dependent rather than protocol-dependent; thus patients will progress at varying rates.

Review Questions

1. Describe how the physical therapy exploitation of the effects of mobilization and exercise is congruent with the levels of the WHO International Classification of Functioning, Disability and Health (i.e., structure and function, activity, and participation).
2. Distinguish among mobilization, physical activity, and exercise.
3. Describe (a) the effect of sedentary activity on health and (b) the implications of prolonged periods of inactivity for people who may exercise regularly according to established guidelines—for example, 40% to 85% of heart rate reserve (based on the Karvonen formula) for 20 to 40 minutes, 3 to 5 days a week.
4. Describe the negative sequelae of restricted mobility and bed rest.
5. Describe the physiological changes that take place as an individual undertakes acute exercise and that must occur to effect a conditioning response.
6. Describe the distinction between "prescriptive" mobilization or exercise and its "routine" clinical use to prevent the sequelae of recumbency and restricted activity.
7. Describe the clinical relevance of physical therapists' prescribing response-dependent versus protocol-dependent mobilization.

Summary 290
Review Questions 290
References 290

This chapter describes the principles and practices for exploiting the preventive, acute, and long-term effects of mobilization, exercise, and training. Mobilization and exercise are prescribed to elicit whichever of these distinct effects is indicated. They are prescribed on the basis of their indications, contraindications, and potential side effects for a given individual. Exercise to exploit each of these effects can be prescribed to address limitations in specific organ systems, as well as augment activity ability and participation. Chapters 24 and 25 expand on these topics, describing special considerations for patient populations with an emphasis on targeting exercise testing and prescription for training based on *people with conditions* rather than for the condition(s) a patient has.

Pre-exercise Test Evaluation

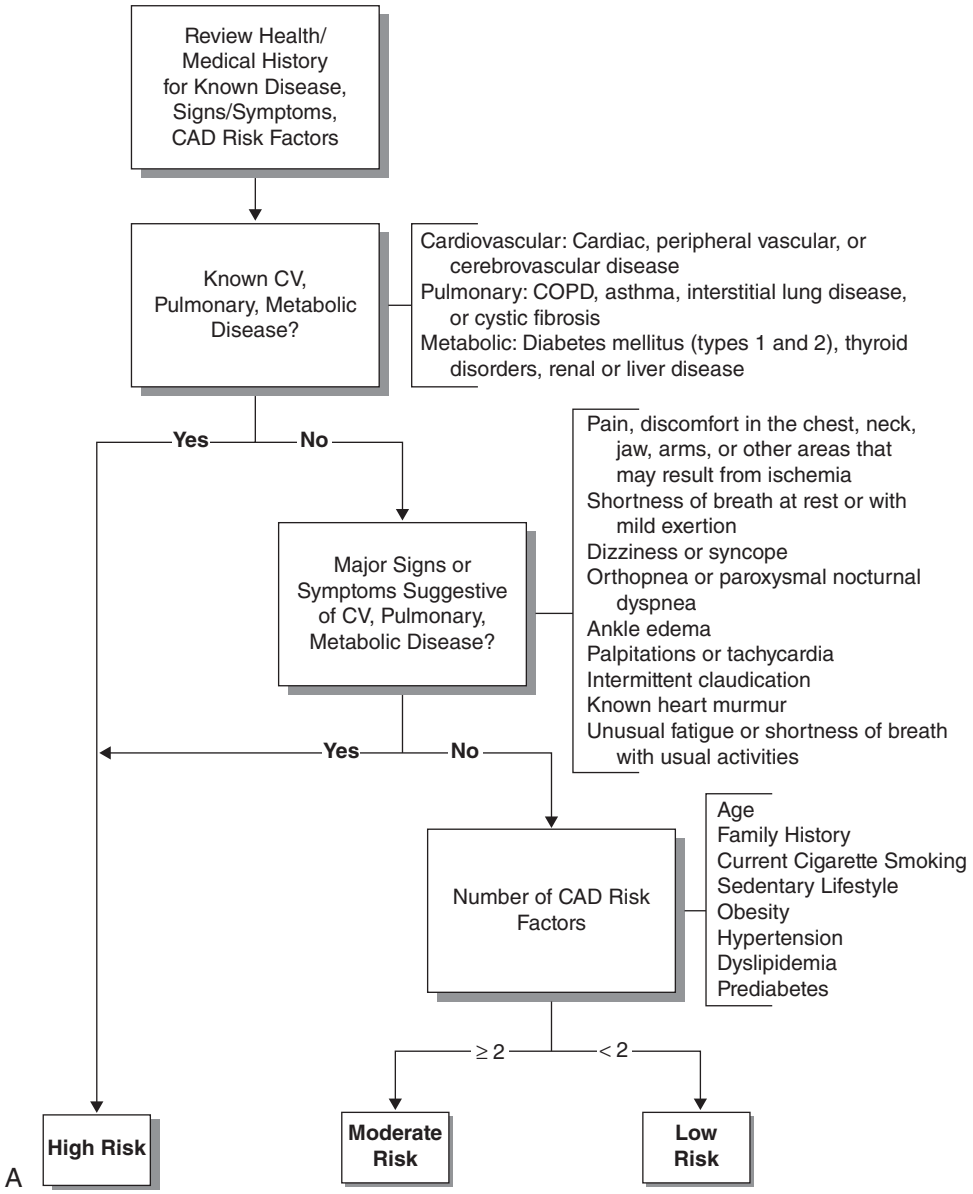
In addition to exercise test indications and contraindications (see next section), a detailed history and examination need to be conducted to determine the appropriateness of test selection, to quantify the relative risk associated with exercise testing, and to determine the level of supervision required. This includes the usual medical and surgical histories to define the types of pathology a patient may have and that may limit his or her exercise capacity. In addition, all medications need to be considered. Which medications impact exercise performance either positively or adversely? Which medications may need to be taken prophylactically? What medications was the patient taking on previous exercise tests? Are these being taken this time? How will this affect the current exercise test results in terms of their comparison? Can medications be withheld? (And should they be?) When is the patient exercising in relation to the timing of medication administration? How might this affect exercise performance? Is this different from a previous test? What about time of day? Does this differ from the time of day when a previous test was performed? Cumulative fatigue and/or discomfort or pain over the course of a day are often reported by patients with certain chronic conditions, thus warranting the establishment of a standard time of day for testing. Other issues must be considered. For instance, how well did the patient sleep last night? How well hydrated is the patient? What and when was the most recent meal? Is the

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

patient a smoker? If so, when was the last cigarette smoked? Additional external factors such as the ambient temperature of the test location and the presence of noise, distraction, and disruption need to be controlled.

Pre-exercise Screening for Minimizing Cardiovascular Risk During Testing

Exercise testing can pose a risk to the patient, so exercise testing must have clear indications, and any contraindications must be ruled out. On the other hand, earlier guidelines for exercise testing in patients, particularly those with cardiac conditions, were too conservative.[1] Patients can be exercised aggressively provided that the indications are based on a comprehensive assessment and a judiciously selected exercise test and protocol and provided that the patient is appropriately monitored throughout testing. The American College of Sports Medicine (ACSM)[2] has developed an algorithm (Figure 19-1, *A*) to determine the risk for cardiovascular events during exercise testing (Table 19-1) as well as guidelines for test selection and level of supervision required based on the risk assessment (Figure 19-1, *B*). As shown in Figure 19-1, *A*, patients with known cardiovascular, metabolic, or pulmonary disease are classified as having a high risk for sustaining a cardiovascular event during exercise. For these individuals, a comprehensive medical examination and physician-supervised exercise testing is recommended before starting a moderate or vigorous intensity exercise program (see Figure 19-1, *B*). For individuals who do not have the conditions listed above, the remainder of the algorithm describes how patient signs and symptoms and coronary artery disease risk factors determine the risk classification and exercise testing and supervision requirements. Physical therapists need to screen patients systematically before exercise testing or prescription.



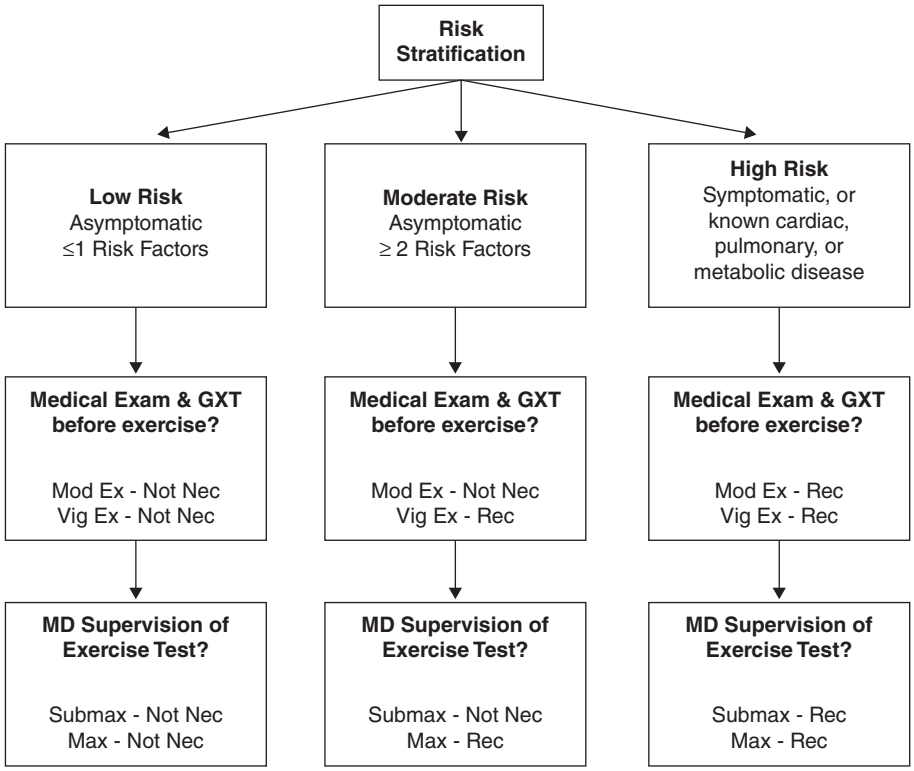


Fig. 19-1 A, Model for risk stratification for cardiovascular disease.

Mod Ex: Moderate intensity exercise; 40-60% of $\dot{V}O_{2max}$; 3-6 METs; "an intensity well within the individual's capacity, one which can be comfortably sustained for a prolonged period of time (~45 minutes)"

Vig Ex: Vigorous intensity exercise; > 60% of $\dot{V}O_{2max}$; 6 METs; "exercise intense enough to represent a substantial cardiorespiratory challenge"

Not Nec: Not necessary; reflects the notion that a medical examination, exercise test, and physician supervision of exercise testing would not be essential in the preparticipation screening, however, they should not be viewed as inappropriate

Rec: Recommended; when MD supervision of exercise testing is "Recommended," the MD should be in close proximity and readily available should there be an emergent need

Exercise Testing

Numerous conditions, including nonprimary cardiovascular and pulmonary conditions, have been shown to benefit from the long-term effects of aerobic exercise (Table 19-2) (see Chapters 24 and 25). Thus for each patient with these conditions, the exercise prescription differs. Comparable with prescribing mobilization in acute conditions, prescribing exercise for long-term adaptations is based on the patient's presentation, history, premorbid status and conditioning level, lab and investigative reports related to physiological reserve capacity, the exercise test, and the goals of the exercise prescription. To promote health, as few as 30 minutes of moderately intense exercise a day on most days of the week is required.[3] However, based on ACSM (2010)[2] guidelines, optimal aerobic exercise adaptation requires an exercise stimulus of 70% to 85% of HR_{max} for 20 to 40 minutes, 3 to 5 times a week for at least 6 to 8 weeks. However, the effect of exercise intensity on $\dot{V}O_{2max}$ and on CO continues to be studied.[4] Improvement in $\dot{V}O_{2max}$ does not appear to be achieved by the same central and peripheral adaptations across a range of exercise intensities. Some individuals have high $\dot{V}O_{2max}$, CO, and SV without a history of training.[5] This may reflect a genetically determined greater blood volume.

The indications for exercise testing are numerous (Box 19-1). They range from quantifying maximum functional, aerobic, or oxygen transport capacities to assessing endurance during low-level activities of daily living (ADLs). The capacity of the oxygen transport system is the most important determinant of maximum oxygen uptake in healthy people. Metabolic studies including $\dot{V}O_2$ provide a link between impairment and functional capacity[6] and can distinguish cardiac versus

Table 19-1 Cardiovascular Risk Factor Threshold for Risk Stratification

	Risk Factors	Defining Criteria
Positive	Age	Men ≥45 years; Women ≥55 years
	Family history	Myocardial infarction, coronary revascularization, or sudden death before 55 years of age in father or other male first-degree relative, or before 65 years of age in mother or other female first-degree relative
	Cigarette smoking	Current cigarette smoker or those who quit within the previous 6 months or exposure to environmental tobacco smoke
	Sedentary lifestyle	Not participating in at least 30 minutes of moderate intensity (40% to 60% $\dot{V}O_2R$) physical activity on at least 3 days of the week for at least 3 months
	Obesity[a]	Body mass index: ≥30 kg × m^2 – or – Waist girth: >102 cm (40 inches) for men >88 cm (35 inches) for women
	Hypertension	Systolic blood pressure ≥140 mm Hg and/or diastolic ≥90 mm Hg, confirmed by measurements on at least two separate occasions, or on antihypertensive medication
	Dyslipidemia	Low-density lipoprotein (LDL-C) cholesterol ≥130 mg × dL-1 (3.37 mmol × L-1) – or – High-density lipoprotein (HDL-C) cholesterol <40 mg × dL-1 (1.04 mmol × L-1) – or – On lipid-lowering medication If total serum cholesterol is all that is available, use ≥200 mg × dL-1 (5.18 mmol × L-1)
	Prediabetes	Impaired fasting glucose (IFG) = fasting plasma glucose ≥100 mg × dL-1 (5.50 mmol × L-1) – or – Impaired glucose tolerance (IGT) = 2-hour values in oral glucose tolerance test (OGTT) ≥140 mg × dL-1 (7.70 mmol × L-1) but <200 mg × dL-1 (11.00 mmol × L-1) confirmed by measurements on at least two separate occasions
Negative	High-serum HDL cholesterol	≥60 mg × dL-1 (1.55 mmol × L-1)

Note: It is common to sum risk factors in making clinical judgments. If HDL is high, subtract one risk factor from the sum of positive risk factors, because high HDL decreases CVD risk.

[a]Professional opinions vary regarding the most appropriate markers and thresholds for obesity; therefore allied health professionals should use clinical judgment when evaluating the risk factor.

Box 19-1 Common Indications for Exercise Testing in Patient Populations

Diagnosis of Limitations of Structure and Function

- Primary cardiovascular and pulmonary dysfunction
- Secondary cardiovascular and pulmonary dysfunction

Diagnosis of Factors Contributing to Limitations of Activity and Participation

- Assessment
  - Maximal functional work capacity
  - Submaximal functional work capacity
  - Endurance
  - Dyspnea
  - Chest pain
  - Ability to work
  - Employment options
  - Cardiopulmonary and cardiovascular conditioning
  - Limitations due to noncardiovascular and pulmonary factors
  - Movement economy
  - Effect of medication (supplemental oxygen, blood pressure medication, antianginal medication, oral hypoglycemic agents and insulin, analgesics, bronchodilators)
  - Adequacy of diabetes management
  - Adequacy of orthotics, walking aids, and prostheses
- Prescription
  - Exercise program
  - Medications (effects and regulation)

pulmonary contribution to exercise intolerance.[7] $\dot{V}O_2$ studies require the use of a nose clip or face mask, which may contribute to perceived exertion in addition to the increased dead space that is created by the inspiratory circuit. In a study comparing the two devices in patients with congestive heart failure, no difference in gas-exchange measurements was observed.[8] Perceived exertion, however, was not reported. This is an important finding given that $\dot{V}O_{2peak}$ is a strong predictor of survival (see Chapter 24).

Contraindications to Exercise Testing

Contraindications to exercise testing and, in particular, maximal testing are classified as relative or absolute (Box 19-2). Absolute contraindications prohibit the safe conduction of an exercise test, whereas the presence of relative contraindications requires that the test, protocol, physiological variables monitored, or end point of the test be modified. Both the indications for the test and any contraindications must be clearly established before performing an exercise test.

The guidelines used to test and train healthy people with no disease are not directly generalizable to patients with chronic illness who are medically stable. Because of functional impairments in these patients (secondary to cardiopulmonary, cardiovascular, neuromuscular, or musculoskeletal dysfunction), exercise testing and training must be modified. Moreover, patients who are physically challenged experience more subjective symptoms in response to exercise than do healthy people, so monitoring the subjective responses to exercise is essential. The Borg scale of rating perceived exertion

Table 19-2 Chronic Conditions That Benefit from the Long-Term Effects of Mobilization and Exercise

Cardiovascular conditions	Congenital heart disease Acquired heart disease Postsurgical heart conditions Angina Hypertension Hyperlipidemia Hypercholesterolemia Chronic heart failure Heart transplantation Peripheral vascular disease
Cardiopulmonary conditions	Chronic obstructive pulmonary disease Chronic ventilatory insufficiency and failure Interstitial lung disease Asthma Cystic fibrosis Postthoracotomy conditions Lung transplantation
Neurological conditions	Stroke Parkinson syndrome Quadriplegia Paraplegia Cerebral palsy Down syndrome Multiple sclerosis Poliomyelitis and post polio syndrome
Endocrine conditions	Thyroid dysfunction Diabetes mellitus
Neoplastic conditions	General conditioning Prevention in some cases
Musculoskeletal conditions	Osteoarthritis Rheumatoid arthritis Ankylosing spondylitis Osteopenia and osteoporosis
Connective tissue conditions	Systemic lupus erythematosus Scleroderma
Nutritional disorders	Insulin resistance associated with physical inactivity Obesity Anorexia
Conditions requiring organ transplantation	Pre- and postsurgical stages
Other systemic conditions	Chronic fatigue syndrome Chronic depression Renal disease Liver disease Alcoholism Nonalcoholic and alcoholic cirrhosis of the liver
Other	Pregnancy

Box 19-2 Relative and Absolute Contraindications to Exercise Testing

Absolute Contraindications	Relative Contraindications
Congestive heart failure	Recent myocardial infarction (less than 4 weeks earlier)
Acute electrocardiogram changes in myocardial ischemia	Aortic valve disease
Unstable angina	Severe cardiomegaly
Ventricular or dissecting aneurysm	Pulmonary hypertension
Ventricular tachycardia	Resting tachycardia
Multifocal ectopic beats	Resting electrocardiogram abnormalities
Repetitive ventricular ectopic activity	Poorly controlled diabetes
Untreated or refractory tachycardia	Severe electrolyte disturbance
Supraventricular dysrhythmia	Severe systemic hypertension
Recent thromboembolic event (pulmonary or other)	Significant conduction disturbance
Uncontrolled asthma	Complete atrioventricular block
Uncontrolled heart failure	Fixed-rate pacemakers
Pulmonary edema	Acute cerebrovascular disease
Uncontrolled hypertension (>250 mm Hg systolic, >120 mm Hg diastolic)	Respiratory failure
Acute infections	Left ventricular failure
	Epilepsy

Adapted from Jones NL, Fletcher J: *Clinical exercise testing,* ed 4, Philadelphia, 1997, WB Saunders.

can be modified for clinical use to score breathlessness, discomfort, pain, and fatigue (Table 19-3).[9,10] If the end points of the scale have been well described and are understood by the patient, the ratings can be used to compare the patient's subjective exercise responses over repeated tests. The patient's subjective reports can be correlated with the exercise response and so can provide a basis for exercise prescription as well as avoiding adverse responses.

The functional impairments and capacities of the patient determine the nature of the exercise test; it can be one of various types, depending on the objective of testing and potential training. If exercise training is an objective of the exercise test, the activity used in the test should be comparable to that to be used in training. Physiological responses and adaptation to exercise are specific to the training stimulus (the specificity-of-exercise principle). Thus if walking is to be the training activity, the test should be a walking test, not a cycling test.

Standardization of Exercise Tests and General Procedures

There are numerous variants of standard exercise tests (Table 19-4). They are categorized as continuous tests or interrupted tests. Continuous tests include maximal and submaximal incremental tests and steady-rate tests; interrupted tests include maximal interval and submaximal interval tests. Interrupted tests are designed for patients with low functional work capacity who cannot sustain prolonged periods of aerobic exercise. These patients can perform more work over time when the workload is intermittent. Specifically, the test allows for alternating fixed periods of work and rest or of high and low intensities of exercise. The proportion of work to rest or high to low exercise intensity is set according to the patient's level of impairment. One patient, for example, may be able to tolerate 3 to 5 minutes of relatively high-intensity work alternated with bouts of 1 to 2 minutes of low-intensity work, whereas another patient may be able to tolerate only 1 minute of low-intensity work alternated with 10 to 20 seconds of rest.

For maximal standardization and the capacity to perform comprehensive monitoring, stationary exercise modalities such as the treadmill, ergometer, or step are recommended.

Table 19-3 Subjective Scales of Exercise Responses

	Perceived Exertion	Breathlessness	Discomfort/Pain	Fatigue
0	Nothing at all	Nothing at all	Nothing at all	Nothing at all
0.5	Very very weak	Very very light	Very very light	Very very light
1	Very weak	Very light	Very weak	Very light
2	Weak	Light	Weak	Light
3	Moderate	Moderate	Moderate	Moderate

10	Very very strong	Very very hard	Very very strong	Very very hard
	Maximal	Maximal	Maximal	Maximal

Based on the Borg rating of perceived exertion scale.

Table 19-4 Exercise Tests Applicable to Patient Populations

Test Type	Indications
CONTINUOUS TESTS	
Maximal	Generally medically stable patient No significant musculoskeletal abnormalities Test maximal functional capacity Basis for aerobic exercise program
Incremental	Incremental work rates, usually 2 to 5 minutes in duration
Steady rate	Endurance test at a given work rate, usually a comfortable walking or cycling speed
Submaximal	For patients in whom maximal testing is contraindicated
Incremental	Approximate maximal exercise testing Test of near-maximal functional capacity or some significant proportion of maximum
Steady rate	Establish baseline of response to steady-rate exercise, usually at 61% to 75% of predicted HR_{max} Establishes an index of endurance, cardiopulmonary conditioning and may give an index of movement economy
INTERRUPTED TESTS	
Maximal or submaximal	Establish level of functional capacity in patients with extremely low functional work capacity On-off protocol or high-low intensity protocol, such as 5 min on to 1 min off, alternate high- and low-intensity exercise in cycles, such as 1 minute high to 15 seconds low

However, there may be indications to perform an exercise test without a modality, such as the 12-minute walk test or some variant like 6 or 3 minutes.[11-13] Standardization of such tests, however, is more challenging. Practice has a significant effect on the results of the 12-minute walk test, so this test must be repeated to achieve a valid test. Also, the instructions for this test are less well standardized clinically than are those for the treadmill or ergometer; this jeopardizes stringent test control and thus must be tightly standardized.[14]

Like other diagnostic and testing procedures, the validity and reliability of the exercise test depend on standardization of the procedures. Test validity and reliability can easily be compromised in the absence of repeated testing and controls.[15,16] Early ergometer training responses at rest along with submaximal heart rates and reduction in EMG activity in the arms and legs can reflect familiarization.[17] Repeated exercise tests reflect the marked effects of practice. Practice reduces energy output, improves practice-related coordination, and reduces muscle activation.[18] However, with good quality control, a test's validity and reliability can be maximized, even in patients with severe disease such as chronic heart failure.[19] The pre-exercise test conditions and the preparation and testing procedures must be standardized (Box 19-3).

The test is terminated as soon as the sign or symptom criteria for terminating the test are reached or when the criteria for prematurely terminating the test are reached (Table 19-5). Recording the test conditions and procedures in detail is essential. An example of an exercise test data sheet that can be modified to any testing protocol that includes an exercise modality is shown in Figure 19-2, *A*. Many patients are unable to be exercise-tested using a modality; these patients can walk on a marked circuit, and the results are recorded on an exercise test data sheet similar to the one shown in Figure 19-2, *B*. Systematic and detailed record keeping will maximize the test's validity and its interpretation and will ensure that the same procedures are used in follow-up tests, thereby maximizing the comparability of the results of repeated tests. It is imperative that retests be comparable in every respect to the

Box 19-3 Pre-exercise Test Conditions

- Establish the indications for an exercise test.
- Determine absolute and relative contraindications to conducting an exercise test.
- Ensure that patient is free of any acute illnesses, including influenza and colds for 48 hours.
- Ensure that patient understands the purpose of the test and provides signed consent.
- Ensure that patient has not eaten heavily, has avoided caffeinated beverages, and has refrained from smoking for at least 3 hours before testing.
- Ensure that patient is rested and has not exercised or been excessively exerted for at least 24 hours before testing.
- Standardize time of day and the influence of circadian rhythm.
- Ensure that patient is appropriately dressed: shorts, nonbinding clothes, short-sleeve shirt, socks, running or walking shoes that have proper support, and secured laces or fastenings.
- Orthoses should be worn unless the test is evaluating changes in functional capacity with and without an orthosis.
- Ensure that patient understands the subjective rating scales and is able to read them when they are held at an appropriate distance.
- Select the type of exercise test, the protocol, and the exercise test termination criteria beforehand.
- Ensure that the patient is familiar with and has practiced performing the test or test activity, preferably before the test day, so as to reduce arousal, improve movement efficiency, and maximize test validity.
- Based on purpose of the test, determine beforehand the premedication status of the patient. If medicated (e.g., bronchodilators or analgesics), ensure that they are at peak effect during test.
- Room temperature (standardized and recorded).

Preparation for an Exercise Test

- Patient changes into exercise clothes and shoes (not new); ensure that laces are secure.
- If the ergometer is used, the seat-to-pedal distance must be established before the test, and the seat should be adjusted to allow for 15 degrees of knee extension when the foot is lowermost in the pedal in the revolution cycle; the knee must not extend fully.
- Patient sits quietly in a supported chair to establish a resting baseline.
- Monitors are attached (e.g., heart rate, electrocardiogram, blood pressure cuff, pulse oximeter), and the subjective rating scales are explained.
- Testing procedures are explained and demonstrated; the patient has an opportunity to ask questions.

General Procedures for an Exercise Test

- Unnecessary conversation and interaction with the patient are kept to a minimum throughout all stages of the test, including postexercise recovery, so as to optimize the validity of the measurements and the test results overall.
- Resting baseline measures are taken over 5 minutes or until they have reached a plateau.
- Patient stands on treadmill or sits erect on cycle ergometer with feet securely strapped into place on the pedals; the metatarsal heads should be positioned comfortably over the pedals.
- Patient uses two fingers for balance on one side, if possible, when walking on the treadmill, rather than a hand grip; if on the ergometer, does not excessively grasp the handlebar.
- Additional baseline measures are recorded in this position for 2 to 3 minutes or until the baseline is stable.
- The test timer is started.
- The warm-up portion of the protocol begins.
- The selected protocol is carried out.
- Patient is monitored objectively and subjectively at least every couple of minutes throughout all stages of the test, including postexercise recovery.
- The test is terminated when the preset exercise test termination criteria or any of the criteria for prematurely terminating an exercise test are reached.
- The cool-down begins.
- When the cool-down portion of the protocol is complete, the patient moves to the supported chair for the postexercise recovery phase, with legs slightly elevated and uncrossed.
- Postexercise recovery continues until resting baseline measures have been reached or are within 5% to 10%.
- Obtain a report from patient about how patient feels.
- Disconnect the monitoring equipment.
- Continue to observe patient for any untoward postexercise signs or symptoms.

original test in terms of the preparation of the patient and the procedures.

Nutrition and preexercise meals as they relate to exercise testing and training of individuals with pathology have been given little attention in the literature compared with the attention given to the nutrition of healthy people and athletes. Nutritional preparation in respect to macro- and micronutrients and the timing of meals with respect to activity and exercise could have a major impact on the functional capacity of an individual with oxygen transport impairments and low functional capacity. The performance by healthy people in a session of moderate- to high-intensity exercise for 35 to 40 minutes is improved if they consume a meal moderately high in carbohydrates and low in fat and protein 3 hours before exercise, rather than 6 hours before.[20] Missing or delaying meals could alter performance on a test or the outcome of training. Because it has been relatively overlooked in patient populations, nutrition as well as hydration should be a focus of the physical therapy assessment and standardized for the pretest and posttest and training sessions.

Exercise testing is considered resource-intense because of the need for highly qualified individuals to perform tests that are safe, valid, and reliable. In addition, pretest conditions must be met, and the patient has to devote a significant amount of time to taking one or more repeated tests. As a means of streamlining such testing, one study, using two different protocols, compared arterial blood gases and respiratory and metabolic measures in patients who reported

Table 19-5 Criteria for Prematurely Terminating an Exercise Test

Miscellaneous	Wish of individual for any reason Failure of monitoring equipment
General signs and symptoms	Fatigue Lightheadedness, confusion, ataxia, pallor, cyanosis, dyspnea, nausea, or peripheral vascular insufficiency Onset of angina
Electrocardiogram signs	Symptomatic supraventricular tachycardia Sinus tachycardia displacement (3 mm) horizontal or downsloping from rest Ventricular tachycardia Exercise-induced left bundle branch block Onset of second- or third-degree atrioventricular block R wave on T wave premature ventricular contractions (one) Frequent multifocal premature ventricular contractions (frequent runs of three or more) Atrial fibrillation when absent at rest Appearance of a Q wave
Other cardiovascular signs	Any fall in blood pressure below the resting level Exercise hypotension (>20 mm Hg drop in systolic blood pressure) Excessive blood pressure increase (systolic ≥220 or diastolic ≥110 mm Hg) Inappropriate bradycardia (drop in heart rate greater than 10 beats/min with increase or no change in work load)

Modified from the American College of Sports Medicine. (2010). Guidelines for exercise testing and prescription, ed 8. Philadelphia: Williams and Wilkins; and Jones, N.L., & Fletcher, J. (1997). Clinical exercise testing, ed 4. Philadelphia: WB Saunders.

shortness of breath.[21] One protocol was an incremental exercise test and the other a constant-work protocol. The data generated by both protocols were comparable; however, Pa_{CO_2} was somewhat higher during the incremental test, as were exercise stress indexes when compared above the anaerobic threshold. No differences were observed below this threshold.

Exercise Tests and Protocols

Common exercise tests and protocols, along with their psychometric properties, are shown in Appendixes C and D for both maximal and submaximal exercise testing. These serve as an easy reference for the clinician regarding the patients for whom they are suited, their protocols and means of standardizing these tests, and how the results can be interpreted.[16] The type of exercise test or tests depends on the patient's needs and the suitability of various tests to achieve the outcomes of interest. Exercise tests can be used for diagnosis, assessment and evaluation, prognosis, and exercise prescription. The purpose is one major consideration in selecting the specific test and its protocol. The exercise test can be a continuous maximal, a submaximal incremental or steady-rate, or an interrupted maximal or submaximal test. Submaximal tests can be used either evaluatively on their own, or they can be used to predict a maximal exercise response. The protocol for the test and the end points to be used in terminating the test are determined beforehand on the basis of the indications for the test and the objectives. Some commonly used protocols are shown in Figure 18-6**,** along with a comparison of the energy expenditure required by the various work stages in their protocols.

Evaluative Submaximal Exercise Tests

Step tests, an example of a fixed-rate exercise test in that the load and rate remain constant, emerged as practical field tests several decades ago. With the emergence of a range of field tests since then, step tests are being used less commonly. Nonetheless, when well standardized and selected appropriately for a given person, step tests can provide valuable information about aerobic fitness because they can elicit vigorous exercise intensities. People who are obese and/or physically deconditioned may require supervision when performing a step test.[22]

The 12-minute walk test and its variants, 6-minute and 3-minute walk tests, were designed to test patients with lung disease.[12] These tests have been favored clinically, because they are functional and do not require exercise equipment. However, these tests are often used for patients who have extremely impaired exercise capacity and are unable to tolerate being tested on an exercise modality. A major disadvantage, therefore, is that the patient cannot be as comprehensively monitored. Thus patients who are to undergo a 12-minute walk test or one of its variants must be selected with care.

When the 6-minute walk test is applied to healthy older adults, it has been shown to be reliable; two familiarization tests are needed to minimize arousal and the learning effect.[23] In the same trial, the subjects walked, on average, at 80% of $\dot{V}O_{2max}$. Based on a comparison with the performance of patients with chronic obstructive pulmonary disease (COPD) to an "encouraged" 6-minute walk test and a standard incremental cycling test, the prognostic value of the walk test was reported to be high.[24] Patients achieved a high steady-rate $\dot{V}O_2$ in the walk test. No differences were reported in $\dot{V}O_2$, HR, and arterial blood gases between the two tests at peak. However, $\dot{V}_E$ and $\dot{V}CO_2$ were lower in the walk test. When performance was "encouraged," the 6-minute walk test was reported to have good prognostic value.

The 6-minute walk test has been favored as an expedient and inexpensive means of evaluating the functional capacity of older adults with multiple comorbidities. A short distance walked by this cohort is associated with having a low level of education; being non-Caucasian; having a reduced capacity to perform activities of daily living; self-reporting poor health; having a history of heart disease, stroke, or diabetes; and showing abnormal levels of C-reactive protein, fibrinogen, and white blood cell count.[25]

The 6-minute walk test can provide a useful measure of the distance an individual can walk. Because it fails to account for body weight, which is a determinant of exercise capacity, the validity of the 6-minute walk test has been questioned.[26] To enhance its usefulness, Carter and colleagues (2003)[27]

proposed the use of the product of the distance of the 6-minute walk and the body weight, to yield the work involved in the 6-minute walk. This measure provides a more valid measure of exercise performance and, in addition, can be converted to provide an index of calorie expenditure, hence serving as a standardized basis of comparison across exercise modalities.

Recently, the 6-minute walk test has been conducted on a treadmill. Although there are advantages of treadmill tests over field tests, the results of the two types of test may differ, at least in people after cardiac surgery.[28]

The shuttle test has been another commonly used exercise test for patients with disabilities. When performance on this test is compared with the 6-minute walk distance in patients with COPD, the two tests appear to assess different pathophysiological processes.[29] The shuttle test is considered a more accurate predictor of maximal exercise capacity than is the 6-minute walk test.

Predictive Submaximal Exercise Testing

One application of exercise testing in patient populations that has been of interest is to predict $\dot{V}O_{2peak}$.[16] Prediction of $\dot{V}O_{2peak}$ involves a large margin of error in healthy populations, and that margin could be expected to be greater in patients who are likely to be more deconditioned, have comorbidities, and are prone to greater variations in their exercise responses. The Astrand-Ryhming Cycle Ergometer Test continues to be one of the most frequently used submaximal tests for exercise prescription as well as for prediction of $\dot{V}O_{2peak}$.[30] Prediction of $\dot{V}O_{2peak}$ is obtained from a nomogram in which the $\dot{V}O_{2peak}$ is estimated from the submaximal HR. To improve its accuracy, an age-correction factor is used to adjust for the age-dependent decrement in HR_{peak}.[31] This ergometer test has the clinical advantage of being applicable to less ambulatory people.

Three equations have been compared to predict $\dot{V}O_{2peak}$ in patients with hypertension and fibromyalgia:[32] one equation is from the ACSM; one equation is from the Fitness and Arthritis in Seniors Trial (FAST); and the third equation was developed by Foster and colleagues (FOSTER). Predicted $\dot{V}O_{2peak}$ for all equations was different from the actual measured values. However, the FAST and FOSTER equations predicted values within 1 MET for both patient groups; the ACSM equation predicted values that were different by more than 2 METs.

The distance walked in the 6-minute walk test can provide valid information regarding the functional capacity of elderly patients with chronic heart failure.[33] The results are highly correlated with $\dot{V}O_{2max}$ and can differentiate between classes III and IV of the New York Hospital Association classification of functional capacity.

The heart rate index has recently been described as a means of predicting energy expenditure with the equation $METs = 6 \times HR_{index} - 5$.[34] This equation was based on secondary analysis of 220 data sets (n = 11,257 of multiple ages, pathophysiology and presence/absence of beta blocker therapy) from 60 published exercise studies. These studies reported resting HR (HR_{rest}), a measured-activity HR ($HR_{absolute}$), and measured oxygen consumption (mL O_2/kg/min) associated with the $HR_{absolute}$. HR_{index} ($HR_{absolute}/HR_{rest}$) was calculated. Regression analysis of oxygen consumption (expressed as METs) was performed against HR_{index} to derive the equation to predict METs. Simple tools are compelling for clinical use and warrant further study.

The oxygen uptake efficiency slope (OUES), which is based on a submaximal test, has been proposed as a valid and reliable index of exercise performance in patients with congestive heart failure.[35] This method was tested on older healthy individuals and on patients on the basis of the rationale that maximal testing is not always valid, feasible, or safe. The OUES involves plotting $\dot{V}O_2$ against the logarithm of total ventilation at submaximal work rates. On repeated tests, the OUES is less variable than endurance or $\dot{V}O_{2peak}$. Thus the OUES is an objective and reproducible measure of cardiorespiratory reserve based on submaximal effort. The measure reflects ventilatory-circulatory-metabolic coupling and is influenced primarily by pulmonary dead-space ventilation and exercise-induced lactic acidosis.

Maximal Exercise Testing

With respect to exercise capacity in patient populations, maximal aerobic performance has been of primary interest for diagnosis, assessment, evaluation, and prognosis. Maximal incremental exercise tests (graded exercise tests, or GXTs) can be highly useful in patient populations as long as consideration for the higher level of motivation required to achieve a maximal response is taken. In addition, because maximal exercise testing inherently involves a higher risk for cardiovascular complications than does submaximal testing, it should be used judiciously.

$\dot{V}O_2$ studies (also called cardiopulmonary exercise tests, or CPETs) have become a primary component of the workup of patients with abnormal exercise tolerance for diagnostic and assessment purposes and for exercise prescription. Metabolic measurement carts are used to conduct these studies. To ensure valid and reliable data, the gases used by the cart must be calibrated and testing procedures tightly standardized before the test as well as during it. A practice session is recommended to reduce learning effects and sympathetic arousal.[36] Before the commencement of the test, a couple of minutes of baseline measures are taken, against which the acute exercise responses and the recovery responses can be compared. The metabolic measurement cart can be programmed to display a variety of exercise variables and graphs of interest. The exercise test results are interpreted according to an evaluation of the resting baseline values, the responses of the exercise variables to changes in the exercise test protocol (qualitatively and quantitatively appropriate), the interrelationship of these changes, and whether they achieve some peak value, such as HR or perceived exertion. Beforehand, a decision is made with respect to whether the test is sign- or symptom-limited. Any unusual responses or events during the test are documented. The full impact of the test may not be manifested for several hours or even the next day; thus the patient is followed so that these changes or effects can be evaluated as well. In some patients, lactate measures that require invasive blood work or, minimally, a finger prick, may be indicated.

From the results of CPETs, there are several important variables that can be used clinically. First, determination of the exercise limitation(s) can be made. As described in Chapter 18, the normal limitation to aerobic exercise performance is usually considered to be cardiac output, more specifically, stroke volume. In this case, subjects will exhibit a near maximal

heart rate (>90% of age predicted maximum), evidence of a high metabolic demand involving anaerobic energy (respiratory exchange ratio – $\dot{V}_{CO_2}/\dot{V}_{O_2}$ – >1.1; or blood lactate levels >8 mmol/L), and near maximal perceptions of effort (rate of perceived exertion >8/10 or >17/20). If these factors are present, a cardiovascular limitation is presumed. In this case, if $\dot{V}_{O_{2max}}$ values are well below the predicted maximal values, the patient may have some degree of underlying cardiovascular pathology or may simply be deconditioned. Examination of the pre-exercise history, the exercise ECG findings, and the levels of O_2 saturation can determine whether the cardiovascular limitation is due to disease or deconditioning. Another common limitation to aerobic exercise observed in clinical exercise testing is due to an inadequate ability to achieve an appropriate level of ventilation. Ventilatory limitations can be detected by the use of pre-exercise spirometry and exercise tidal flow volume loops; or may be detected by comparing the $\dot{V}_E$ achieved at maximal exercise to the predicted or measured maximal voluntary ventilation (MVV). $\dot{V}_E$/MVV >90% is considered to indicate a ventilatory limitation. The interested reader is referred to the ATS/ACCP Statement on Cardiopulmonary exercise testing[37] for more information on these topics.

Second, CPETs provide a range of exercise performance data, including anaerobic threshold, which is often ignored. Recently, however, the anaerobic threshold has been considered an important marker of cardiovascular insufficiency and exercise performance that has importance in evaluating the performance of individuals with low functional work capacity, such as older adults and patients with left ventricular dysfunction, and in prescribing exercise for them.[38,39] In addition, examining the anaerobic threshold may have particular relevance to individuals in these groups, who may be ill-advised to undergo maximal stress tests. From CPET, anaerobic threshold can be determined by the following criteria:

1. $\dot{V}_E/\dot{V}_{CO_2}$ plateau
2. $\dot{V}_E/\dot{V}_{O_2}$ reaching a nadir and increasing incrementally after this point
3. RER approximately 1.0[39]

Third, CPETs can provide valuable information related to the cardiovascular health and fitness of an individual. $\dot{V}_{O_{2max}}$ is considered by many to be the gold standard for determination of fitness. Although this point is debatable, $\dot{V}_{O_{2max}}$ reference values that are specific to age and gender are widely used to determine an individual's level of fitness. In terms of prescribing exercise training, values at peak exercise such as HR_{max} and work rate maximum can be used to help set appropriate levels of intensity.

In the case of a practitioner who wishes to perform maximal testing, but who does not have access to the required equipment and/or expertise to measure respiratory gases (and $\dot{V}_{O_2}$), a maximal GXT may be conducted. A maximal GXT without respiratory monitoring holds the same level of risk associated with CPETs, but it will still provide valid information on maximal work rate attained and also on a subject and modality specific maximal heart rate. In this case, an achieved maximal heart rate or maximal work rate can be used to prescribe exercise training intensity more accurately than using an age-predicted maximal heart rate or a predicted maximal work rate based on submaximal testing. In addition, if all of the monitoring requirements other than $\dot{V}_{O_2}$ are maintained (ECG, Sp_{O_2}, dyspnea, etc.), the safety of using vigorous to high-intensity exercise as a training technique can be ascertained.

General Testing Considerations

Reproducibility of exercise test results is a particular concern in patient populations whose status may change from day to day. When tested weekly for 4 weeks, patients with stable COPD have been reported to have reproducible submaximal physiological exercise responses and ratings of perceived exertion in response to a constant work rate.[40] Exercise performance at a constant work rate is a functional indicator of endurance. On serial exercise testing of patients with chronic heart failure, the mechanical efficiency of walking markedly improves, giving rise to an apparent placebo effect, which has been reported to be independent of motivation and changes in conditioning.[41] This factor can invalidate the findings of a single test. Highly trained individuals show a more marked neuroendocrine (sympathoadrenal and hypothalamopituitary adrenal) response in a second bout than in the first bout of exercise performed on the same day.[42] Study is needed on the implications of neuroendocrine changes with repeated exercise tests in patient populations.

Knowledge of the patient's functional ability based on verbal report is useful and serves as a guideline for selecting the type of exercise test, its parameters, and the test termination criteria. Although these verbal reports do not replace an exercise test, they can be used as an adjunct. The diagram of oxygen cost is shown in Figure 19-3. This visual analog scale is constructed of a 100-mm line with physical activities hierarchically sequenced based on oxygen cost; the high end of the scale represents strenuous activity (walking briskly uphill) and the low end of the scale represents no activity, or sleep. The patient crosses the line at the point where breathlessness does not allow continuation at the patient's best (see Figure 19-3). Figure 19-4 shows incremental workloads associated with step increments in metabolic cost—that is, multiples of resting or near resting metabolic rate (resting metabolic rate = 1 MET, or 3.5 mL O_2/min/kg of body weight). Metabolic costs of activities range from very light to very heavy activities. One limitation of such charts in indicating the metabolic costs of various activities and exercises is that they can be used only as a general guide in patients with cardiopulmonary compromise, as they do not take into consideration the increased work of breathing and the work of the heart that is observed in patients with cardiopulmonary dysfunction, or the increased energy cost associated with abnormal biomechanics as observed in patients with neuromuscular and musculoskeletal conditions.

Exercise testing and training can be challenging in individuals with physical disabilities, such as those with stroke. Because of this limitation, many patients are denied the potential benefits of diagnostic exercise testing and exercise training. The use of external body supports is one means of providing support during standardized exercise testing on a treadmill. One study examined the metabolic effects of a 15% bodyweight support in individuals without impairments.[43] End-expiratory gas variables were not affected, except for maximal V_T, which was lower with body support; however, time to achieve peak values was increased. The responses of patient populations who would require variable levels of body support have yet to be determined. Another dimension of exercise

testing in people with disabilities is the assessment of gait speed, which is associated with physical independence and in activities such as crossing an intersection safely. In addition, gait speed has been proposed as a means of predicting discharge for people with acute stroke. Within the first 5 weeks following stroke, the 5-meter walk test at a comfortable pace (as opposed to the 10-meter walk test, the timed up-and-go test, and other common functional assessment indexes) is the measure of choice for detecting change in walking ability.[44] Finally, movement economy can be compromised in people with physical disabilities, given that their movements are biomechanically inefficient (e.g., people with the residua of poliomyelitis).[45] Abnormal postural alignment and movement asymmetry need to be considered in patient populations because these impairments can increase the energy cost of a given work rate based on norms.

Exercise testing has a role in preoperative assessment. In combination with other tests and examination, exercise testing in patients as a component of the workup for abdominal aortic aneurysm repair with measurement of $P\bar{v}O_2$ can identify patients at risk for perioperative complications.[46] Exercise testing has been used to define a gas-exchange threshold for patients with COPD who are being considered for thoracic surgery.[47] A $\dot{V}O_{2peak}$ of less than 20 mL O_2/kg/min has been recommended as the threshold for predicting perioperative complications. Routine preoperative exercise testing has been advocated. Exercise testing has also been recommended to assist in determining the operability of a patient with lung cancer.[48,49] Patients may be excluded from lung resection surgery based on conventional medical criteria, yet included based on their $\dot{V}O_{2peak}$. These patients have shown survival benefit.

Monitoring

Common variables measured during an exercise test include HR, ECG, systolic and diastolic BP, rate pressure product (RPP), RR, SpO_2, and subjective responses such as perceived exertion, breathlessness, discomfort, pain, and fatigue (see Chapter 18). Assessment of dyspnea is central to monitoring individuals with breathing and exertional impairments. The Borg scale and the visual analog scale are applicable to individuals with dyspnea, and if assessed in a systematic manner, they can provide valid and reliable measures when used in the patient groups for which they were designed, so they should be used routinely.[50] Measures are taken every few minutes after the patient has been exercising at a given intensity for a few minutes when a response to steady-rate exercise is being assessed. This allows for relative stabilization of oxygen kinetics during dynamic exercise. Subjective responses to exercise and daily activities are often the most important to the patient because these typically interfere with their social participation and its composite activities.

Pulse pressure (SBP − DBP) is known to be influenced by aging and arterial wall elasticity.[51] Pulse pressure is also influenced by lifestyle interventions, including exercise and diet.

Therefore it may serve as an index of changes in arterial wall stiffness with exercise training.

More detailed analysis can be done, depending on the testing or training goals. Noninvasive measures, including transcutaneous oxygen and carbon dioxide tensions, can be readily used to assess gas exchange during testing.[52] Invasive monitoring can be done in conjunction with metabolic testing. Such monitoring requires blood sampling through an intra-arterial line to examine serial changes in oxygen and carbon dioxide tensions, acid base balance, and arterial saturation, as well as to provide a means for conducting the thermodilution method that yields an index of CO.

The short- and long-term recovery responses, both quantitative and qualitative, in patient populations are important components of the exercise testing profile. The physical therapist must have a thorough understanding of normal physiological recovery responses in order to benchmark abnormal and atypical responses. Sustained elevated BP after cessation of exercise, for example, has been reported to be more sensitive than ECG for detecting myocardial insufficiency. Further, systolic BP after exercise is a strong predictor of hypertension, coronary artery disease, and cardiovascular mortality. An increase in systolic BP and the percent maximum systolic BP 2 minutes after exercise is directly and independently related to risk for stroke.[53]

Exercise Training Prescription

Physical therapists have a long history of prescribing exercise for health and rehabilitation. As mentioned previously, physical therapists are clinical exercise physiologists who are in a prime position to lead the charge against sedentarism, to utilize well-developed and monitored exercise programs for disease prevention, and to promote rehabilitation in any care setting. It must be stressed that exercise testing and prescription/training are essential components of the physical therapy assessment and treatment plan in every setting—from the ICU to the acute care hospital, to the community program, and finally to the private practice clinics. All patients, regardless of their illness and injury (with the exception of those for whom exercise is contraindicated, unsafe, or impractical), should first be encouraged to be as active as possible, and physical therapists play an essential role in providing comprehensive individualized prescription for each patient.

Exercise Prescription for Health and General Fitness

The components of exercise training for patients for general physical conditioning are the same as those for healthy people: selection of the type of exercise; its intensity, duration, and frequency; and the course of training and its progression. An individualized, rather than standardized, exercise prescription is essential to maximize outcomes in the same way that a physician individualizes a drug prescription.[54] The word *prescription* implies individualization to a person's needs and goals, including his or her social participation and its composite activities. The selection of the type of exercise used for training and the type used in the exercise test is based on the specific objectives of training.

Several expert organizations provide general guidelines for exercise prescription for health and general fitness. Arguably, the foremost of these organizations is the American College of Sports Medicine. The ACSM guidelines are well established and updated frequently; they provide enough guidance to give a comprehensive prescription, but allow enough flexibility to suit the demands of each individual patient. Table 19-6 provides a wide array of examples of how to approach exercise prescription for patients based on their individual level of habitual activity and physical fitness. The FITT approach (frequency, intensity, time, type/mode) to providing exercise prescription ensures that each prescription is detailed enough to be performed by each patient. Although guidelines are just examples, they provide a good starting point from which to design an exercise prescription. These principles are purposefully vague in terms of the exact numbers to use. This range of potential values, particularly for intensity, reflects the fact that improvements in cardiovascular health and fitness can occur with almost any type of exercise prescription within the designated ranges.

Intensity

The intensity of exercise is arguably the most important aspect of exercise prescription and is usually set at some proportion of the HR response or some other response, to a maximum or near-maximum work rate that was safely tolerated during an exercise test. The training intensity for a relatively fit individual who is able to tolerate several incremental work stages on a graded exercise test may be optimal between 65% and 85% of the heart rate reserve (HRR) achieved in the test. The HRR is calculated by taking the percentage intensity within the physiological range from rest to maximum. Thus HRR is equal to $(HR_{max} - HR_{rest}) \times$ intensity fraction + resting heart rate. HR_{max} can be estimated based on a predicted HR_{max} such as 220 − age. This predicted maximum is associated with significant error ± 10 beats (i.e., deviation from the actual HR_{max} achieved in a maximal test), thus the HR at which training is eventually conducted is refined on the basis of other indexes, such as the talk test and general responses. The ratio of HR_{max} (actual or predicted) and resting HR (the heart rate ratio method) provides a good estimate of $\dot{V}O_{2max}$ in healthy men and may have some application in some patient populations.[55]

A patient who is unable to tolerate a couple of increases in work stage is more likely to benefit from an exercise intensity range of 30% to 50% of HRR. In some patients, HR is an invalid indicator of exercise intensity because of the pathology or medications.[45,56] Thus other responses, such as BP, arterial saturation, or subjective parameters such as rating of perceived exertion or breathlessness, can be used. Use of subjective symptoms to supplement the training parameters is useful in patients whose objective exercise responses may be spurious and less valid (e.g., patients on medications that alter autonomic activity).

Time and Frequency

The duration (time) and frequency of the exercise program are established based on the patient's functional capacity, physiological reserve capacity, and exercise responses (see Table 19-6 for general guidelines). Patients with low

functional capacities but with adequate physiological reserve capacity respond quickly to a training stimulus (short training course), so they should be progressed accordingly. However, patients with low functional capacities and with limited physiological reserve capacity adapt more slowly (long training course). The shorter the training course, the sooner a retest is indicated to progress and reset the training parameters. To ensure that the patient continues to be trained safely and optimally, the training parameters should be progressed based on an exercise retest.

Type

The type or mode of exercise should be specific to the individual goals of the client, but should involve a large amount of muscle mass and should be relatively functional. For these reasons, walking, cycling, running, and swimming are often prescribed. Hemodynamic exercise responses depend on the type of exercise and the degree of static exercise and postural stabilization involved and on the muscle mass recruited. Depending on the patient's status and diagnoses, hemodynamic responses have to be considered. The HR response to ergometer rowing using the arms and legs, for example, is lower than running for the same relative workload.[57] Correspondingly, venous return, $\dot{V}O_{2max}$ and O_2 pulse are also greater in rowing.

Water exercise, including chair exercise in the water and running, are undergoing a revival in physical therapy for the management of chronic conditions. Water provides buoyancy, prevents injury, reduces spinal loading and lower extremity loading, minimizes muscle soreness, and optimizes temperature control to facilitate exercise performance. Long-term effects of water exercise such as deep-water running include increased blood volume, increased stroke volume, and increased cardiac output.[58] Water exercise for strength or cardiovascular endurance has benefits for training and for recovery from injury. Aquatic exercise programs have the advantage of being offered to groups as a way of improving fitness in healthy individuals and in people with pathologies such as stroke.[59]

Cross-training principles analogous to those used in athletes apply to patients.[60,61] Based on the assessment of oxygen transport deficits and threats and goals for the individual (e.g., function, health, fitness, prevention, or a combination), a decision is made regarding the prescription of a single mode or a dissimilar mode of training. Because of the specificity of exercise principles, the generalization of a single-mode exercise cannot be assumed; thus, other types of exercise, including task-specific exercise, may have to be included. Also, consideration should be given to the cross-transfer effects of exercising one side of the body. Cross-transfer between ipsilateral and contralateral limbs should be considered when focusing attention on one side of the body or to limit detraining during periods of unilateral immobilization.

Developing exercise programs for the masses of sedentary people in the community constitutes one of the greatest challenges to the physical therapist. Motivating people to be physically active in their daily lives and undertake a formal program of exercise is a skill in itself (see physical activity pyramid in Chapter 1). Intermittent bouts of exercise accumulated throughout the day are showing acceptance by the public and are producing favorable results. The 10,000-steps-per-day program encourages individuals to wear a pedometer and become conscious of how closely they approximate this guideline, which has been associated with an "active" lifestyle.[62] With this objective information, people may be more inclined to increase the number of their daily steps so as to improve their health by elevating the range of their daily steps from the inactive to the active lifestyle. Another creative public health initiative is a stair-climbing program in the community. Such a program has been directed toward sedentary young women.[63] The 7-week program of stair climbing involves progressing from one flight to several flights daily using a public-access stairway of 199 steps. This short-term exercise program resulted in aerobic conditioning as evidence by reduced $\dot{V}O_2$, HR, and lactate during stair climbing and by improved cholesterol levels. Such innovative approaches have enormous potential for improving public health.

Exercise Training to Improve Tasks or Performance

Contrary to the wide range of variables listed above related to exercise prescription for general health and fitness, performing exercise training for improvements in tasks or performance requires the use of a much more specific prescription. This specific prescription needs to be tailored to each individual patient and usually requires the use of specific exercise or functional tests. The use of the physical therapy history or interview, then, represents a crucial aspect of determining the tests and training program design. If there is a specific functional task or performance goal that is identified by the patient or the physical therapist, the exercise test(s) should attempt to, as closely as possible, reflect the requirements of the task or performance. Exercise training program design should then reflect the task/performance, as well as the results of the exercise test. For example, in a private practice setting, a worker who is recovering from a low back injury due to fatigue which caused abnormal lifting mechanics might have the goal of reducing fatigue so that he may maintain proper lifting mechanics throughout his day. Exercise testing, then, should mimic the movement pattern used (lifting) and attempt to determine his endurance in performing lifting related tasks. The training program should be suited to his current level of performance and progressed appropriately to allow optimal adaptation.

Another example of how training programs are designed might be a patient with obesity who needs to increase her sustained walking speed. An appropriate test might be to perform a graded exercise test with $\dot{V}O_2$ measurement to allow the estimation of this individual's anaerobic threshold (as a marker of maximal sustainable pace). The exercise training program would be designed to have the patient increase her anaerobic threshold (using an intensity of exercise at or around anaerobic threshold).

A significant difference between exercise prescription for health and training program design is that training programs often require long-term periodization in order to address multiple needs. Usually, this type of training design involves structuring periods of training that progress from more general to more task- or performance-specific. In the example of the patient wanting to increase anaerobic threshold, the physical therapist would usually begin the program with some lower intensity aerobic exercise for 3 to 8 weeks designed to

increase overall endurance and tolerance to walking. After this initial period of "aerobic base" training, the physical therapist would progress the program by prescribing training to increase anaerobic threshold. This type of training program design is complex, and a full description is beyond the scope of this chapter; however, physical therapists working with patients requiring improvements in specific tasks/performance should be competent in comprehensive program design.[64]

Emerging Alternate Types of Exercise Prescription

For many patients, continuous aerobic training as described above is either ineffective, inefficient, or intolerable (see Chapters 18, 34, and 35). There are a few promising methods of altering aerobic exercise prescription techniques that help to minimize these limitations. One example is the use of single-limb training (as opposed to double-limb). As mentioned in Chapter 18, patients who exhibit inability to exercise at high enough intensities to elicit significant physiological benefit due to impairments of central cardiovascular or respiratory responses can increase their muscle specific peripheral load by restraining exercise in one limb. Dolmage and Goldstein (2008)[65] found that single-limb cycling in patients with COPD allowed patients to rapidly progress single-limb workload, resulting in a significantly greater increase in $\dot{V}O_{2max}$ than the group who trained using two-legged cycling (22% versus 1%, respectively). This increase in $\dot{V}O_{2max}$ was achieved during a double-legged cycling GXT. What is most striking about this study is the fact that the overall training time between the two groups was the same. The double-legged training group cycled for 30 minutes continuously, whereas the single-limb group exercised one leg for 15 minutes, then switched legs for the remaining 15 minutes. There are two main conclusions that can be made in regard to the physiological adaptations achieved with single-limb training. First, it appears that progression of overall intensity beyond what is capable through double-legged training in this population is much more important than overall training time. Second, because $\dot{V}O_{2max}$ increased in the single-limb group on a double-limbed test, the mechanisms for increases in $\dot{V}O_{2max}$ are likely due to peripheral adaptations. It has been proposed that adaptations at the level of muscle mitochondria are most apparent with maximizing the amount of tissue oxygenation to minimize the circulating P_{O_2}.[66,65]

Another example of a promising method of exercise training is the use of high-intensity interval training. Although typically thought of as an "athletic" type of training, high-intensity interval training has been used successfully in patients with cardiovascular and respiratory disease. In patients with COPD, for example, ventilatory limitations prevent continuous exercise performance at high intensities.[67] As such, interval exercise models can be used to attempt to increase overall workload during exercise and to enhance muscular adaptation.[68,69] Interval exercise involves alternating periods of higher intensity work bouts (termed work phase) with those of lower intensity (termed recovery phase). The results of training studies reported to date in COPD indicate that high-intensity interval training (at a work phase of 90% to 100% of peak aerobic power) increases muscle performance and exercise tolerance to a similar degree as continuous training, with less ventilatory limitation and dyspnea.[68,69] In addition, the adaptations achieved in skeletal muscle are comparable to those achieved by continuous training. Meyer and colleagues (1996)[70] used high-intensity interval training at a work phase of approximately 120% of peak aerobic power compared with a continuous exercise protocol at 75% of peak power in patients with chronic heart failure. The interval exercise protocol resulted in greater exercise times, with reduced levels of ventilatory and cardiac stress and reduced symptoms of fatigue and dyspnea. After only 3 weeks of training at this high intensity, these patients achieved remarkable increases in maximal aerobic power and leg muscle performance, with reduced symptoms and stress during training.[70]

Recovery and Overtraining

The prescription of the parameters for optimal physiological recovery has not been described in detail. However, the practice of progressive, decremental exercise intensity in the form of a warm-up is supported. Such activity facilitates venous return and the return of HR and other exercise parameters to baseline values.[71] In addition, light activity after exercise promotes the degradation of circulating catecholamines. Priming exercise in athletes improves performance,[72] and this result can be expected in nonathletes as well. However, the parameters (i.e., exercise type, intensity, and duration) of an optimal warm-up have yet to be defined, and they may depend on the individual, general health and fitness, weight, age, and morbidity.

New advances in athletic training may have application to clinical populations, including titrating, or periodizing, training day by day, week by week, or month by month. Periodization has two primary goals: to structure a training program to achieve optimal, multiple physiological adaptations and to prevent overtraining. An overtraining phenomenon has been described in healthy people. Athletes whose performance has dropped off may improve performance outcomes with several weeks of rest.[73] Prevention of overtraining is achieved through a detailed analysis of the responses to and recovery from the previous exercise session. This method is based on modeling the effects of training, detraining, and overtraining.[74,75] This method does not assume that the interval between exercise sessions is the same across individuals or the same for a given individual from one day to the next. The proponents of the model believe that training is optimized by the avoidance of under- or overtraining and that training effects are better if they are accumulated over time, rather than according to the conventional methods that subscribe to a rigid exercise intensity, duration, and frequency over some interval (e.g., 6 to 8 weeks).

The role of overtraining in people with underlying pathology, whether induced by the pathology or resulting from an excessive therapeutic exercise prescription, is not well understood. The extent to which some severely compromised patients are, in fact, overtrained as a mere consequence of their activities of daily living is not known. It is possible that the syndrome of inability to maintain work performance, persistent fatigue, frequent illness (in particular upper respiratory tract infections), disturbed sleep, and altered mood states may reflect overwork in patients that is analogous to overtraining in athletes.[76,77] With respect to immunity, reduced neutrophil function may be implicated in both situations. In athletes, this overtraining syndrome due to excessive physical exertion and

inadequate recovery has been related to autonomic dysfunction and increased cytokine production. Because regular intense exercise can suppress mucosal immunity and because saliva is the most commonly used secretion for assessing mucosal immunity, monitoring the saliva of athletes during critical training periods provides an index of risk status. The usefulness of mucosal assessment in clinical populations warrants investigation. Relaxation has been shown to offset the exercise-induced suppression of secretory immunoglobulin associated with upper respiratory tract infection in healthy people.[78] The role of relaxation and its immune protection warrants exploitation in clinical populations. Immunity may be optimized with an appropriate balance of exercise, rest, and recovery. Achieving an optimal balance of exercise and rest or recovery warrants study in patient populations as a means of maximizing a patient's social participation.

Prescriptive rest periods between bouts of exercise and optimal sleep in patient populations, comparable to the training of athletes, should be considered as carefully as the prescriptive parameters of exercise itself to maximize functional performance.

Exercise Prescription

General Procedures

Before an exercise session, the patient needs to review a checklist to ensure that exercise is not contraindicated on that day. This is particularly important for patients whose conditions change rapidly or whose disease course tends to fluctuate, as in multiple sclerosis, cystic fibrosis, chronic fatigue syndrome, and congestive heart failure. Box 19-4 provides a checklist to be used in preparation for exercise testing and training sessions. Such a checklist, however, must be tailored to each patient. Aids and devices for older patients must provide assistance that is optimal and safe and promotes the most independence. Inappropriate aids are associated with poor patient outcomes in this population, and their use requires more surveillance by carers.[79]

Box 19-4 Patient's Checklist Before an Exercise Testing or Training Session

- Feeling well over the past 48 hours
- No infections (e.g., upper respiratory tract infection) or influenza
- No fever
- No unaccustomed muscle or joint discomfort or pain
- No chest tightness or pain
- No unaccustomed breathing difficulty or fatigue
- Adequate night's sleep
- Has not eaten heavily within past 3 hours
- Best time of day
- Wearing or using orthoses, walking aids, and devices
- Clothing appropriate for exercise conditions (indoors or outdoors)
- Appropriate socks and footwear that is comfortable, well-fitting, and has secured laces (double-knotted)
- Has water within reach
- Taken preexercise medications at specified time
- Has nitroglycerine within reach (patients with cardiac dysfunction)
- Has inhaler within reach (patients with pulmonary dysfunction)
- Has sugar supply within reach (patients with diabetes)
- Standardize and record the use of orthotics and walking aids

Active exercise is always selected to elicit optimal oxygen transport stress for improving aerobic and muscle power. Passive exercise, however, may have a limited role in some patients. Compared with active exercise, little is known about the physiological responses to passive exercise. When low-intensity active and passive cycling are compared in healthy people, inotropic changes are elicited primarily with active exercise, thus are dependent on mechanoreflexes stimulated by the metabolic products of skeletal muscle.[80] Cardiac output is increased by an increase in HR during active cycling and by an increase in stroke volume during passive cycling. It is interesting to note that blood lactate increases in both active and passive cycling but is higher during active cycling. These findings are of some physiological interest and may have potential therapeutic application; however, active exercise is the therapeutic priority, no matter how minimal the absolute intensity, duration, and frequency may be initially. The degree to which passive exercise could be exploited in individuals unable to cooperate with an exercise program, or whether passive exercise could augment active exercise, warrants further study.

Specific Procedures

In a supervised setting, the general procedures used in exercise training are comparable to those used for testing. Specifically, the patient prepares for the training session in a standardized manner and is monitored according to his or her condition. The components of the session are the same with respect to warm-up, cool-down, and recovery. The main part of the exercise program, however, will usually be steady-rate or interrupted exercise. Varying work rates may be indicated for some patients.

In the majority of situations, the goal is to transfer the responsibility of surveillance and monitoring from the physical therapist to the patient. Depending on the patient's pathology and ability to learn how to monitor exercise responses accurately, this process takes varying amounts of time. Planning of transition to home and the community is considered from the beginning. The patient's daily needs at home serve as the basis for the exercise program; his or her skills need to be transferred from the physical therapist and clinic to the home environment.

Monitoring

For safety reasons and to ensure that the patient is within the target training range of the variables selected to set exercise intensity, the patient must be closely monitored. This is particularly true if the patient has any risk for untoward or adverse reactions to exercise. If a patient is considered to be at any risk, exercise training should take place only in a supervised setting. A stable patient may begin an exercise program in a supervised setting, but with training and education can usually be transferred to an unsupervised setting. Education includes self-monitoring of exercise responses, maintaining

exercise intensity within the appropriate limits, and keeping a record of the details of their exercise sessions. When the patient is safely carrying out the exercise program independently in the community, some mechanism is needed to follow up on the patient's progress. If the objective is continued conditioning, the patient should be rescheduled for a retest. If the patient is on a maintenance program, the physical therapist is responsible for reminders about exercise and injury precautions and about notifying the physical therapist or physician if significant adverse effects are observed.

The HR, BP, RR, and other measure are taken according to standardized procedures. Electronic equipment and mechanical devices must be calibrated. A break point in the double product (HR × systolic BP) and work-rate relationship can provide a good estimate of the anaerobic threshold in patients with exercise intolerance as well as in healthy persons.[81]

Patients on sympathomimetic drugs or with various pathologies will have abnormal exercise responses. Thus knowledge of these factors is essential to determine whether a measure is valid.

The World Health Organization recommends repeated BP measurements be performed in the sitting or supine position followed by standing[82] and that the cuff be positioned at the level of the right atrium, irrespective of body position. One concern about this recommendation is that systolic and diastolic BP is lower in a sitting than in a supine position, so the two readings are not equivalent.[83] Blood pressure may be under- or overestimated if the level of the cuff is not at the level of the right atrium, regardless of body position. Further, this effect may be amplified in patients with autonomic dysfunction such as that found in patients with diabetes.

Nutritional status and rest/sleep status must be assessed in patient populations by physical therapists to maximize exercise capacity and function comparable to competitive athletes. Mobilization and exercise must be prescribed to maximize these effects during acute and chronic long-term exercise.

Most evidence related to exercise and health has focused on cardiovascular conditioning. The relationship between other dimensions of health is being increasingly studied—for example, immunological status[84] and mental health.[85] With respect to mental health, little is known about the parameters of exercise that are optimally antidepressive, other than benefits may be associated with regular physical activity, preferably engaged in with other people. Although there is an association between depressive symptoms and reduced activity in community-living older adults, research is needed to establish the role of exercise training in preventing or attenuating these symptoms.[85]

Summary

Although the principles of prescribing mobilization and exercise for their optimal preventive effects have not been scientifically elucidated in comparison with their general health benefits, physical activity and exercise in some form are indicated to offset the deleterious effects of deconditioning associated with lack of activity.

When the long-term effects of exercise are indicated, the exercise stimulus is defined in an appropriate prescription, generally involving higher intensity, longer duration, and less frequency when compared with the exercise prescription for acute effects. A long-term prescription is designed to be followed for several weeks or more before demonstrable physiological adaptation can be observed and the exercise parameters redefined based on an a subsequent exercise test for progression of conditioning. The precise parameters are based on considerations such as the patient's age, smoking history, body mass index, waist-to-hip ratio, cognitive status, the goals of physical activity and exercise for the patient, and his or her needs and wants,

The three levels of prescription of exercise are physiologically distinct and need to be prescribed specifically by the physical therapist for a given patient, taking into consideration the indications, contraindications, and side effects for that individual.

Finally, the physical therapist needs to be proficient in the assessment of nutritional status and sleep/rest status in every patient. These are important variables in facilitating and inhibiting response to exercise comparable to that in athletic training.

Review Questions

1. Describe the differences in exercise prescription parameters (i.e., type of exercise stimulus, intensity, duration, frequency, and course) when prescribing exercise for its (a) preventive effects, (b) acute effects, and (c) chronic effects.
2. Distinguish between submaximal and maximal exercise tests. Name two of each, their psychometric characteristics, their protocols, and their outcomes.
3. Describe the factors that can invalidate exercise test results and jeopardize test reliability and thus must be tightly controlled by the physical therapist.
4. Describe how the physical therapy assessment of nutrition and sleep/rest can be used to augment clinical outcomes.

The purpose of this chapter is threefold. First, therapeutic body positioning prescribed by physical therapists to optimize cardiovascular and pulmonary function and oxygen transport is differentiated from routine body positioning. Second, the physiological effects of static body positions as opposed to dynamic body position changes on cardiovascular and pulmonary function and oxygen transport are described. Third, the principles for prescribing therapeutic versus routine body positioning are presented.

Body positions that simulate the normal physiological effects of gravity and position change on oxygen transport are the clinical priority; being "upright and moving" is the physiological body position. When, because of disease or injury, patients are unable to be upright and moving consistent with the demands of normal living, the physical therapist simulates the patient's being upright and moving by means of specific body positions. Whether body positions are assumed actively by the patient or the patient is positioned passively by the physical therapist depends on the patient's status and needs.

Specific indications for body positioning and the decision-making process are highlighted. The chapter does not provide treatment prescriptions for given conditions because no specific patient is being considered. Understanding the physiological effects of body position on oxygen transport and how pathophysiology disrupts these normal processes is fundamental to prescribing body positioning for a given patient. An optimal body position can be prescribed only on the basis of consideration of all factors that impact on oxygen transport: the effects of the patient's pathophysiology and its specific presentation in that individual, the effect of restricted mobility and recumbency, the effect of extrinsic factors related to the patient's care, and the effect of intrinsic factors related to the patient (Chapter 17). It is only with an integrated analysis of these factors overall that (1) the most beneficial body positions can be predicted; (2) the least beneficial body positions can be identified and used minimally; and (3) the appropriate outcome measures can be selected.

Gravity and Normal Physiological Function: Physical Therapy Implications

The human is an orthograde organism. From moment to moment, gravity exerts its influence on the human body and particularly affects oxygen transport. The combined effects of gravity on the lungs, heart, and peripheral circulation are central to their interdependent function and to establishing normal oxygen transport. Knowledge of the effects of gravity on cardiovascular and pulmonary function in health and the deleterious effects of pathophysiological states on cardiovascular and pulmonary function (both primary pathology of the cardiovascular and pulmonary system and pathology of this system secondary to pathology in one or more other systems, as described in Chapter 6) provides a foundation for therapeutic body positioning as a primary intervention to optimize oxygen transport. Because of its potent and direct effect on oxygen transport, therapeutic body positioning can maintain or augment arterial oxygenation so that invasive, mechanical, and pharmacological forms of respiratory support can be postponed, reduced, or avoided—a primary objective of cardiovascular and pulmonary physical therapy.

In health, normal oxygen transport is maintained by being upright and moving—the physiological body position. A patient who may have prolonged periods of recumbency is also exposed to gravity continuously, but not to the same extent as in the upright position. Each body position the patient assumes differentially affects the steps of the oxygen transport pathway as a result of alterations in gravitational stress. Oxygen transport can be improved, maintained, or worsened with changes in body position. Despite being essential to normal cardiovascular and pulmonary function, gravity is the principal contributor to inhomogeneity of physiological function down the lungs.[1] Figure 20-1 illustrates the effect of this gradient with respect to alveolar ventilation ($\dot{V}_A$), perfusion (Q), ventilation and perfusion ratio ($\dot{V}_A/Q$), Pa_{O_2}, P_{CO_2}, P_{N_2}, oxygen content, carbon dioxide (CO_2) content, pH, and the flow of oxygen and CO_2 in and out of the lungs. Thus the lungs should not be likened to balloons, either physiologically or anatomically.

Based on a detailed analysis of all factors contributing to impaired oxygen transport and gas exchange (Chapter 17), the body positions that will have an optimal effect on oxygenation and those that may be deleterious must be distinguished from one another. In this way, a greater proportion of time can be spent by the patient in beneficial positions and less time in deleterious positions. Body positions themselves are associated with energetic stress, particularly in positions with greater gravitational stress, so the upright position can be more energetically demanding than supine positions, which are more demanding than lateral positions.[2] Compression forces also affect the heart and cardiac output. Lying on the left side, for example, can compromise cardiac output, particularly within 12 hours after surgery in patients whose cardiac index is less than 2.3 L/min/m^2.[3]

In health, gravitational effects and movement continually perturb the distributions of ventilation ($\dot{V}_A$) and perfusion (Q), and optimize $\dot{V}_A/Q$ matching commensurate with physiological demand. When body positions that are initially beneficial to the patient are assumed for too long, hydrostatic, gravitational, and compression forces acting on the heart, blood volume, lymphatic system, lungs, and chest wall, including the diaphragm, eventually compromise oxygen transport, offsetting any benefit. Therefore close monitoring is essential to ensure that the patient is turned to another position before the effects become detrimental. Frequent changes in body position and avoidance of prolonged periods in any single position minimize this risk.

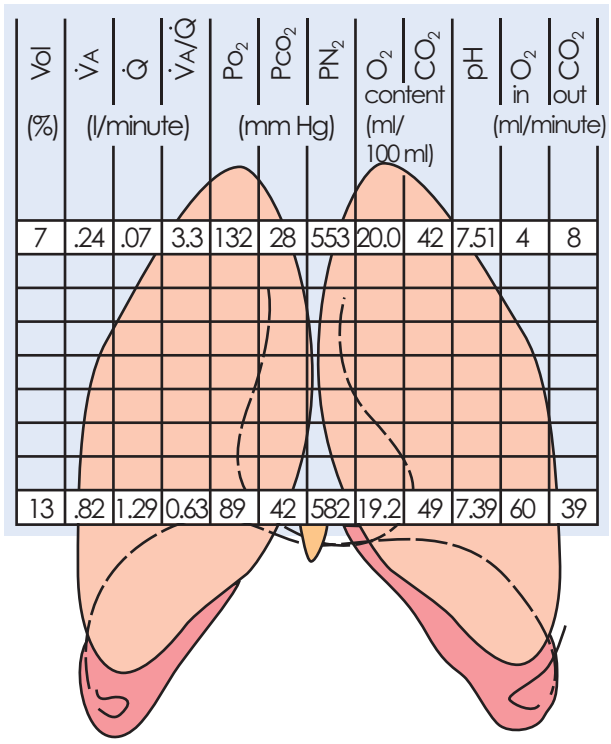

Fig. 20-1 Regional physiological differences down the upright lung. *VA,* Alveolar ventilation; *Q,* perfusion; $\dot{V}_A/Q$, ventilation-perfusion ratio. *(From West JB:* Respiratory physiology: The essentials, *ed 7, Baltimore, 2008, Williams & Wilkins.)*

The length of time a body position is maintained is response-dependent rather than time-dependent,[4] and it reflects individual differences, including pathology, severity, age, and body mass. Knowledge of the deleterious effects of prolonged periods in a single position supports the prescription of both frequent body position changes and extreme sequential body positions. These perturbations simulate the normal perturbations that the cardiovascular and pulmonary systems experience in health during normal mobility and body position changes in daily life. The ability to weigh the relative beneficial and deleterious effects of each possible body position (through 360 degrees in the horizontal plane and 180 degrees in the vertical plane, ranging from approximately 20 degrees head down to 20 degrees leaning forward) on a given patient's gas exchange is critical in prescribing body positioning.

Prescriptive Versus Routine Body Positioning

The literature supports the benefits of frequent body position changes, particularly for a patient who is relatively immobile, not alert, severely debilitated, obtunded, breathing at low lung

volumes, obese, aged or very young, or has lost the sigh mechanism. Even though the effectiveness of routinely turning patients every 2 hours has not been firmly established, it continues to be an accepted standard of care (although intensive care units fall short of this minimal guideline).[5] The practice is based on the belief that the deleterious consequences associated with assuming a static position for a prolonged period will be prevented. More frequent turning, however, may have greater physiological benefits in patients who are critically ill, and this suggests that patients who are less severely ill may also benefit from being gravitationally challenged systematically. The preventive effects of a routine turning regimen are distinct from the acute effects of body positioning on oxygen transport, which is the primary focus of this chapter.

Physiological Effects of Various Body Positions

Body positioning has potent and direct effects on most steps of the oxygen transport pathway, so it can be prescribed to elicit these effects preferentially. Because humans function optimally when upright and moving, therapeutic interventions that elicit or simulate being upright and moving (i.e., elicit both gravitational and exercise stress) are most justified physiologically (see Chapter 17). The recumbent supine position, a common position assumed by patients who are hospitalized, is nonphysiological and is deleterious to oxygen transport. The side-lying positions have an effect that is intermediate between that of upright and supine. The prone position, which is underutilized clinically, can have such a significant powerful effect on oxygen transport that a good rationale must be made for not incorporating this position into the treatment prescription.

The indications for therapeutic body positioning and for frequent body position changes to optimize oxygen transport are shown in Tables 20-1 and 20-2. For each of the indications listed, an optimal therapeutic body position can be selected for a given patient. A description of the physiological effects of several primary body positions follow, namely, the upright/supine, side-lying, head-down, and prone positions. However, this information cannot be applied out of context. The specific positions prescribed for a given patient are based on consideration of the multiple factors that impair oxygen transport (Chapter 17) in conjunction with a physiological analysis of the most justifiable positions.

Because of the potent and direct effects of body positioning on the steps in the oxygen transport pathway in health and in disease, it is unknown whether the beneficial effects reported with the use of postural drainage are attributable to enhanced mucociliary transport; or to the direct effect of positioning the good lung down on improving the gas exchange of that lung by increasing alveolar volume of the affected, nondependent lung; or to both of these mechanisms. Typically, studies evaluating conventional chest physical therapy, including postural drainage, have failed to control for the direct effect of body positioning on oxygen transport or for the direct effects of increased arousal and mobilization that occur when a patient's body position is changed.[6,7] This is a serious methodological problem that pervades the literature evaluating conventional practices, so-called chest physical therapy, and one that has to be considered when interpreting the results of studies of these

Table 20-1 Indications for Body Positioning to Optimize Oxygen Transport

Cardiopulmonary Indications	Decreased regional alveolar volume Decreased regional ventilation Decreased regional perfusion Decreased regional diffusion Compromised ventilation to perfusion matching Pulmonary shunting Decreased lung volumes and capacities, particularly functional residual capacity, vital capacity, and tidal volume Closure of dependent airways Abnormal breathing frequency Abnormal minute ventilation Monotonous pattern of tidal ventilation Suboptimal position of the hemidiaphragms Decreased respiratory muscle efficiency Airway resistance Suboptimal lung compliance Suboptimal flow rates Weak ineffective cough Poor biomechanical efficiency of cough's strength and productivity Increased work of breathing Abnormal arterial blood gases, gas exchange, and oxygenation Impaired mucociliary transport and mucus clearance Untoward gravitational, mechanical, and compression forces on the lungs, chest wall, diaphragm, and the gut Impaired viscerodiaphragmatic breathing Suboptimal pattern of breathing
Cardiovascular and Lymphatic Indications	Suboptimal preload and afterload Increased work of the heart Impaired systolic ejection fraction to pulmonary and systemic circulations Suboptimal venous return Untoward gravitational, mechanical, and compression forces on the myocardium, great vessels, mediastinal structures, and lymphatic system Suboptimal fluid shift from central to dependent areas (extremities) and vice versa to maintain fluid volume regulating mechanisms
Other Systemic Indications	Decreased patient arousal Undue energy expenditure Discomfort Pain Posturally increased muscle tone Increased intrathoracic pressure Increased intraabdominal pressure Increased intracranial pressure Biomechanically suboptimal body positions Decreased chest tube drainage Decreased urinary drainage Impaired peripheral perfusion

Table 20-2 Indications for Frequent Changing of Body Position

Cardiopulmonary Indications	Alter chest wall configuration Shift distribution of alveolar volume Shift distribution of ventilation Shift distribution of perfusion Shift distribution of diffusion Shift distribution of ventilation to perfusion matching Shift mechanical physical compression of the heart on adjacent alveoli Shift position of the heart, thereby altering chamber end diastolic filling pressures, preload, afterload, and work of the heart Shift distribution of mucus transport and accumulation Stimulate effective and productive cough Facilitate pumping action needed for optimal lymphatic drainage Perturb pattern of monotonous tidal ventilation Perturb breathing pattern Shift gravitational, mechanical, and compression forces on the lungs, chest wall, diaphragm, and gut Simulate normal inflation-deflation sigh cycles Shift intraabdominal pressure
Cardiovascular Indications	Shift gravitational, mechanical, and compression forces on the myocardium, great vessels, mediastinal structures, and lymphatic system Stimulate fluid volume shifts particularly to the dependent limbs
Other Systemic Indications	Alter arousal state Promote relaxation Promote comfort Control pain Prevent skin breakdown, risk for infection, and resulting positioning limitations Shift abnormal postural tone patterns Optimize chest tube drainage Promote urinary drainage

procedures. Unless these potent confounding variables are controlled, the degree to which conventional chest physical therapy has a beneficial effect over and above the effects of positioning, as well as of mobilization and increased arousal, cannot be established.[8]

Upright Positions

Although the upright position is common to the physiological and anatomical positions, movement in the upright constitutes the true physiological position in that the upright position coupled with movement (e.g., walking, cycling, or movement in sitting) is consistent with the requirements of daily activities. To meet the energetic demands of these activities, oxygen transport is optimized to the greatest degree, in that ventilation and perfusion are more uniform than they would be without the additional exercise stimulus. The upright standing position maximizes lung volumes and capacities, with the exception of closing volume, which is decreased.[9] Functional residual capacity (FRC), the volume of air remaining in the lungs at the end of end-tidal expiration, is greater in standing than in sitting and exceeds that in the supine position by as much as 50% (Figure 20-2). Maximizing FRC is associated with reduced airway closure and maximal arterial oxygenation.[10,11] Figure 20-3 illustrates the relationship of FRC and closing capacity as a function of age. Because of age-related pulmonary changes, the closing capacity of the dependent airways increases with age; this effect is further accentuated with recumbency. Airway closure is evident in the supine position in the healthy 45-year-old person and in the upright seated position in the healthy 65-year-old person.[12] Compression atelectasis results from cardiac weight, abdominal pressure, and pleural effusions, the effects of which are determined by the specific position of the patient.[13] These positional

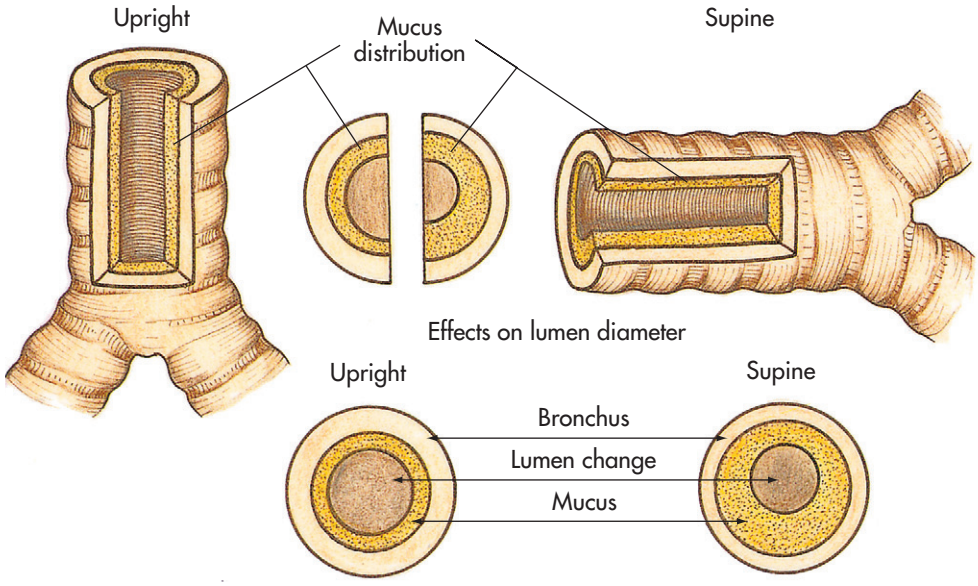

Fig. 20-4 Effect of recumbency and gravity on distribution of respiratory tract and diameter of bronchiolar lumen. *(From Gröer MW, Shekleton ME:* Basic pathophysiology: A holistic approach, *ed 3, St Louis, 1989, Mosby.)*

effects are further accentuated in patient populations with cardiovascular and pulmonary, thoracic, and abdominal pathologies, so the upright position is favored, and the supine position should be minimized so as to prevent airway closure and impaired gas exchange.

With respect to pulmonary function testing, the upright sitting position with legs dependent is the standard reference position.[14,15] When upright, the diameter of the main airways increases slightly. If the airways are obstructed, even small degrees of airway narrowing induced by recumbency can increase airway resistance (Figure 20-4). When a person is upright, the vertical gravitational gradient is maximal, the anteroposterior dimension of the chest wall is the greatest, and compression of the heart and lungs is minimized.[16] The shortened position of the diaphragmatic fibers is countered by an increase in the neural drive to breathe when a person is in the upright position.[17] Maximal expiratory pressure is augmented with progressively upright positions in patients with chronic obstructive lung disease, as well as in those in health; standing results in the highest values and head-down positions the lowest.[18] Thus coughing and other forced expiratory maneuvers should be encouraged when the individual is in the optimal erect, upright position.

The distribution of ventilation is determined primarily by the effect of gravity, which changes down the lung because of the anatomical position and the suspension of the lungs within the chest. At FRC in the upright position, the intrapleural pressure at the apex is −10 cm H_2O and at the base −2.5 cm H_2O (Figure 20-5). The intrapleural pressure is less negative in the base because of the suspended mass of the lungs. As a result of the greater negative intrapleural pressure in the apices, thus low compliance, these lung units have a larger initial volume; hence smaller volume changes occur during respiration. Because the lung units at the base have a smaller initial volume, thus high compliance, larger volume changes occur during respiration. Therefore, depending on their relative position with respect to gravity, different regions of the lung are at different points on the pressure volume curve.

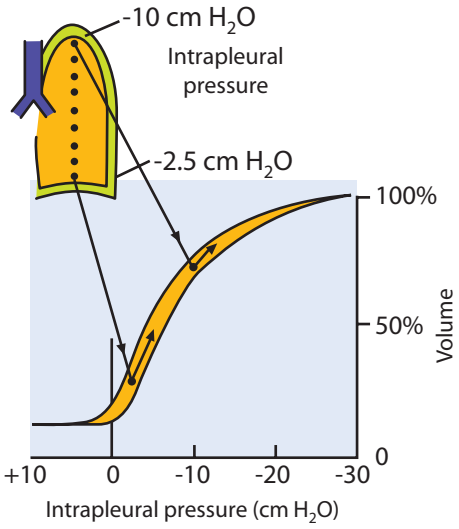

Fig. 20-5 Schematic of the regional differences in ventilation down the upright lung. *(From West JB:* Ventilation/bloodflow and gas exchange, *ed 4, Oxford, 1985, Blackwell Scientific.)*

A common clinical concern is patients breathing at low lung volumes—for example, patients in pain, patients who have undergone thoracic or abdominal incisions, older and younger patients, obese patients, pregnant patients, patients with gastrointestinal dysfunction (such as paralytic ileus and ascites, organomegaly, or intrathoracic or intraabdominal masses) patients who are malnourished, and patients who are mechanically ventilated or have spinal cord injuries). Breathing at low lung volumes reverses the normal intrapleural pressure gradient such that in the upright lung the apices have a negative intrapleural pressure compared with the bases, which have a positive intrapleural pressure (i.e., exceeding airway pressure) (Figure 20-6). This results in the apices being more compliant, thus better ventilated, than the bases. The bases are prone to airway closure in individuals breathing at low lung volumes.

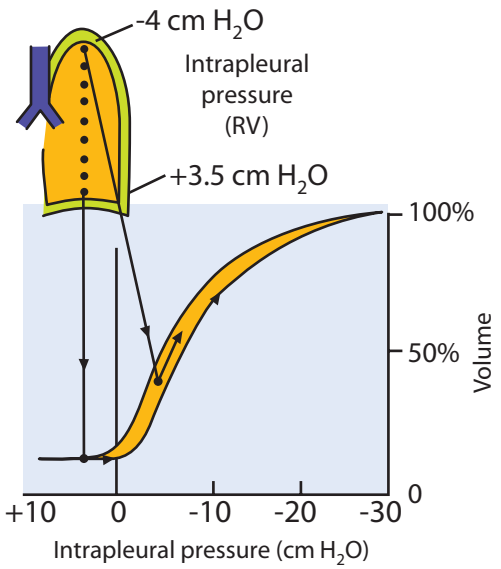

Fig. 20-6 Schematic of the regional differences in ventilation at low lung volumes. *(From West JB:* Ventilation/bloodflow and gas exchange, *ed 4, Oxford, 1985, Blackwell Scientific.)*

Another factor that reverses the normal intrapleural pressure gradient is mechanical ventilation. Despite its necessity in the management of patients in respiratory failure, mechanical ventilation can contribute to hypoxemia in several ways. First, it reverses the normal intrapleural pressure gradient so that the uppermost lung fields are preferentially ventilated. Because the dependent lung fields are preferentially perfused, $\dot{V}_A/Q$ mismatch is promoted. Positive pressure ventilation has the additional complication of increasing intrathoracic pressure and reducing venous return and cardiac output. These factors, in addition to the negative pressure required to open the inspiratory valve, can increase the work of breathing associated with mechanical ventilation.[19-21]

Although gravity is the primary determinant of interregional differences in the distribution of ventilation in the healthy lung, intraregional differences, secondary to differences in compliance and resistance of contiguous lung units, also contribute.[22] These effects are exaggerated in patient populations.[23]

The distribution of perfusion down the upright lung is also primarily dependent on gravity (Figure 20-7). The pressures affecting blood flow through the pulmonary capillaries and resulting in the typical uneven distribution (inhomogeneity) of blood flow are alveolar pressure and the arterial and venous pressures. In zone 1, at the apex, alveolar pressure predominates over arterial and venous pressures, so there is little or no blood flow. Zone 2, in the middle zone, reflects the blood flow from the recruitment of pulmonary vessels. Arterial pressure exceeds alveolar pressure and blood flow. Zone 3, in the lower area of the lung, reflects the blood flow from the distension of pulmonary vessels; arterial and venous pressures exceed alveolar pressure. And zone 4 (not illustrated), in the most dependent portion of the lung, has little or no pulmonary blood flow because of the interstitial pressure acting on the pulmonary blood vessels and creating a compression force.[1]

The matching of $\dot{V}_A$ and Q reflects the interfacing of the distributions of $\dot{V}_A$ and Q down the upright lung. Both $\dot{V}_A$ and Q increase down the upright lung; however, $\dot{V}_A$ increases disproportionately more than Q (Figure 20-8). As a result, the optimal area for $\dot{V}_A/Q$ matching is in the midzone, where the ratio is about 1.0.[24]

The upright position is associated with marked hemodynamic effects. These effects reflect primarily the central blood volume, which is shifted from the thoracic compartment to the dependent venous compartments when a person assumes the upright position from the supine.[25-27] End-diastolic volume and stroke volume are decreased, which results in a compensatory increase in heart rate.[28] Cardiac output is correspondingly decreased. The net effect of these physiological changes is a reduction in myocardial work.[29] This finding is corroborated by the observation that the anginal threshold is increased in patients with cardiac conditions when they are upright.[30] Further, intermittent gravitational stress following myocardial infarction or bypass surgery

maintains orthostatic tolerance and thereby prevents bed rest deconditioning.[31]

Peripheral vascular resistance increases and blood flow decreases with the assumption of an upright position greater than 45 degrees to offset dependent fluid shifts and potential blood pressure drop (Figure 20-9). An upright angle of at least 60 degrees is needed to optimize cardiac output and sympathetic tone.[32] Another important effect of body position on fluid volume is the promotion of urinary drainage from the renal pelvi to the bladder when in the upright position, as a result of the reduced area for urinary stasis when in this position as opposed to the supine position (Figure 20-10). Optimal renal function is essential to preserving normal hemodynamic status.

Older individuals who are relatively immobile tend to sit for prolonged periods. Without frequent exposure to standing upright, however, the phenomenon of seated postural hypotension may result.[33] In addition, dependent circulatory stasis and other consequences of restricted mobility such as deconditioning are promoted in this position.

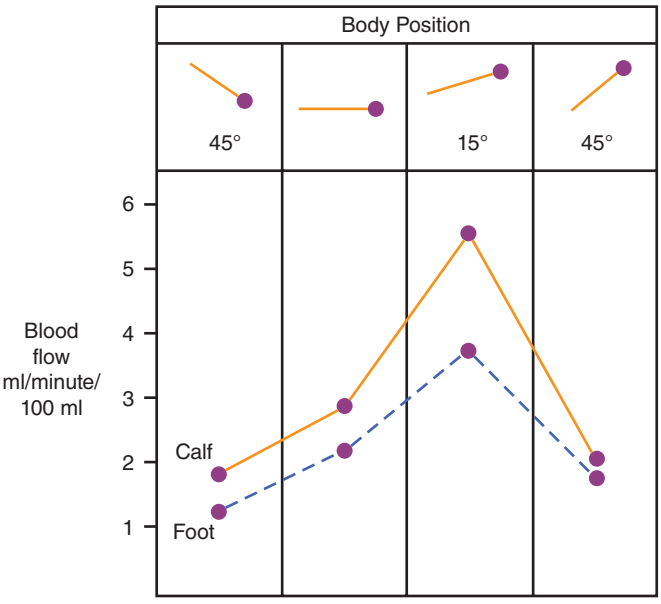

Fig. 20-9 *Effect of body position on peripheral blood flow.*

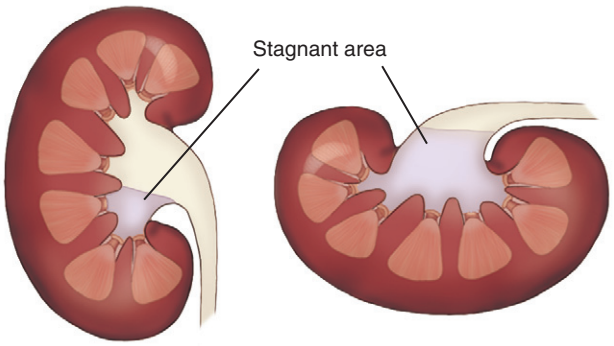

Fig. 20-10 Effect of body position on drainage from the pelvis of the kidney. *(From Browse NL:* The physiology and pathology of bed rest, *Springfield, Ill, 1965, Charles C. Thomas.)*

Supine Position

The indiscriminate use and overwhelming acceptance of bed rest evolved historically over the past 150 years. In the mid-1800s, the use of immobilization to heal bones and injuries was extended to the management of other conditions in the belief that internal organs could be rested as a therapeutic intervention as well. The injudicious application and overuse of bed rest to address medical problems has been challenged over several decades.[34-38] Although there has been a marked decrease in the use of prolonged periods of bed rest based on innumerable studies over the past several decades of its negative sequelae,[39] its use is still quite common despite the fact that its merits as a therapeutic modality and the parameters for its prescription (i.e., indications and specifications to achieving healing and recovery without deterioration) have not been scientifically established.

The supine position inherent in bed rest alters the configuration of the chest wall, the anteroposterior position of the hemidiaphragms, the intrathoracic pressure, the intraabdominal pressure secondary to the shifting of the abdominal viscera in this position, and the mechanics of cardiac function.[40-45] The normal anteroposterior configuration becomes more transverse. The hemidiaphragms are displaced cephalad, which reduces FRC in this position.[10] Prefaut and Engel[46] observed that hypoxic vasoconstriction secondary to closure of the dependent airways in the supine position contributed to preferential perfusion of the nondependent lung zones. Finally, in the supine position, excess pulmonary secretions tend to pool on the dependent sides of the airways. The upper side may dry out, exposing the patient to infection and obstruction (see Figure 20-4).

An increase in intrathoracic blood volume in the supine position also contributes to a reduction in FRC and lung compliance and to increased airway resistance.[47,48] Collectively, these effects predispose the patient to airway closure and an increase in the work of breathing. Although a healthy person can accommodate to these physiological changes, a healthy person does not assume this position for prolonged periods without unconsciously shifting. A hospitalized patient, however, is less likely to adapt to these immediate changes and their long-term effects. They may be less responsive to the need to shift position or unable to respond to afferent stimuli prompting a need to change position. These effects are accentuated in older people whose arterial oxygen tensions progressively diminish with age.[47,49] Compared with younger people, the arterial oxygen tensions of older people are particularly lower in the supine position compared with the reference sitting position.[50]

Several cardiovascular changes occur when the supine position is assumed (e.g., hemodynamic or intolerance to position change). A central shift of blood volume from the extremities to the central circulation initiates orthostatism.[27,51] This fluid shift increases both the preload and the afterload of the right side of the heart. This increased volume tends to distort the interventricular septum and reduce left ventricular volume and preload. The relatively increased central blood volume inhibits the release of antidiuretic hormone and atrial natriuretic peptide from the right side of the heart[52] and diuresis is stimulated.[53] Between 10% and 15% of fluid is lost within 24 hours,[27] which can manifest clinically as cardiac underfilling, orthostatic intolerance, and negative fluid balance.[54]

Altered autonomic nervous system function also has been implicated in the etiology of bed rest deconditioning.[55,56] Individuals with impaired autonomic control (those with high spinal cord lesions) exhibit greater reductions in mean arterial pressure and stroke volume compared with able-bodied individuals.[57] Because of local vascular regulation, cerebral circulation can be maintained. Finally, when individuals are confined to bed rest abruptly, they show more dehydration than do individuals confined to bed rest for a longer term, and it occurs faster, possibly because of less opportunity to compensate.[58] Although the prescriptive parameters regarding the optimal gravitational stress required to offset the hemodynamic changes that occur with the supine position have yet to be elucidated (degree of upright angle, duration, and frequency),[59] there are other effects of the upright position that support its frequent use in patients whose mobility is restricted. Anatomical regions adapt to the relative microgravity effects of the supine position differently according to the redistribution of transmural pressures and flows within the various vascular beds.[60] Knowledge of these physiological adaptations is essential for refining therapeutic countermeasures.

Although lower body negative pressure (LBNP) may have a role in space exploration for maintaining orthostatic stability and has been shown to offset change with bed rest such that exercise capacity is maintained,[61] LBNP will not likely be a feasible or practical modality in acute management. Despite its reported benefit in countering the adverse fluid shifts associated with recumbency, LBNP does not address other negative effects of bed rest.

Because of a reduction in the vertical gravitational gradient, and therefore in the intrapleural pressure gradient of the lung, in the supine position, the distribution of $\dot{V}_A/Q$ matching appears more uniform and evenly matched in horizontal positions.[62,63] These changes, however, must be considered in conjunction with other changes associated with the supine position: namely, reduced FRC, reduced vital capacity, reduced flow rates, increased area of dependent lung, and increased closure of the dependent airways, as well as its associated hemodynamic consequences. These deleterious factors offset any theoretical benefit of the supine position on V/Q matching.[64] However, in a patient who is unresponsive, hemodynamically unstable, and clinging to life, a recumbent position may be the only alternative (see end-of-life issues in Chapter 33).

The position of the diaphragm and its function are dependent on body position. Figure 20-11 illustrates the effect of body position on the level and movement of the diaphragm consistent with compromised lung function recorded in recumbent positions. In the supine position, the resting level of the diaphragm is influenced differentially by anesthesia and neuromuscular blockade.[65] Figure 20-12 illustrates these effects. In the spontaneously breathing subject, the excursion of the diaphragm is greater posteriorly because of the dependent viscera beneath the posterior portion of the diaphragm. During anesthesia with or without paralysis, the diaphragm ascends 2 cm into the chest. When paralysis is induced, the loss of diaphragmatic tone results in greater excursion of the nondependent rather than the dependent part of the diaphragm.

A study of hemodynamic postural effects in healthy subjects supports that the horizontal position maximizes central blood

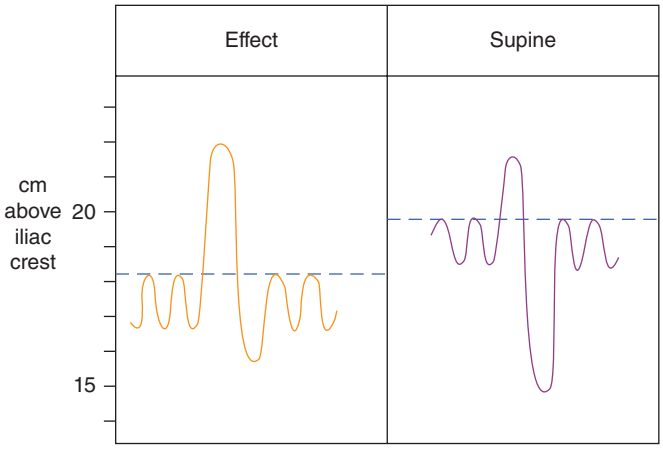

Fig. 20-11 Effect of body position on the level and movements of the diaphragm during respiration. *(From Browse NL:* The physiology and pathology of bed rest, *Springfield, Ill, 1965, Charles C. Thomas.)*

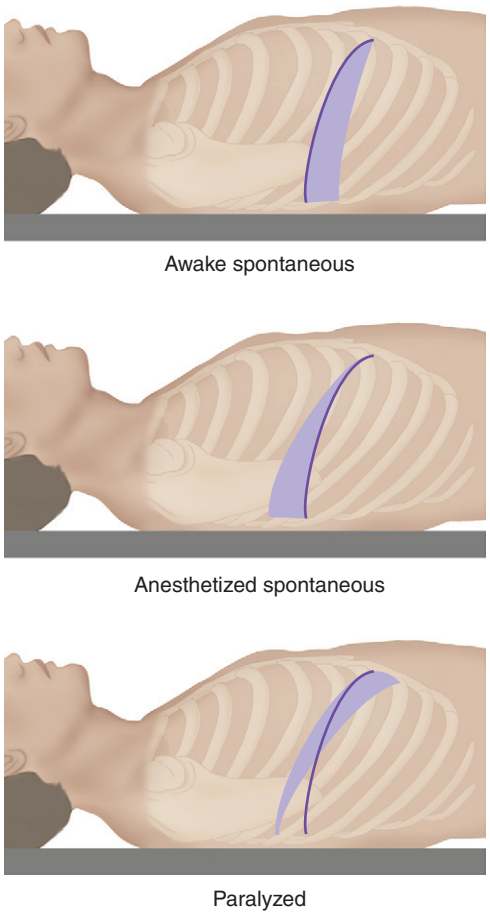

Fig. 20-12 Position of the diaphragm in an awake, spontaneously breathing subject and in anesthetized subjects with and without paralysis. The line is the end-expiratory position of the diaphragm in the awake state in the supine position. The shaded area shows the excursion of the diaphragm during inspiration and expiration. *(From Froese AB, Bryan AC: Effects of anesthesia and paralysis on diaphragmatic mechanics in man,* Anesthesiology *41:242-255, 1974.)*

volume.[66] This position, however, cannot be considered clinically optimal because of such effects as intrathoracic and intraabdominal compression.

Side-Lying Positions

Side-lying may be theoretically less deleterious compared with the supine position.[22,45,67] The side-lying position accentuates anteroposterior expansion at the expense of transverse excursion of the dependent chest wall. In this position, the dependent hemidiaphragm is displaced cephalad because of the compression of the viscera beneath it. This results in a greater excursion during respiration and to greater contribution to the ventilation of that lung and to gas exchange as a whole. The FRC in side-lying falls between that in the upright and supine positions. Compared with supine, in side-lying compliance is increased, resistance is reduced, and the work of breathing is reduced, whereas these measures are reversed when side-lying is compared with the upright position. Figure 20-13 illustrates the difference in lung volumes between maximal inspiration and FRC in a spontaneously breathing subject in right side-lying. Although ventilation is enhanced to the dependent lung, inspiratory lung volume and FRC are reduced. Compared with the reference sitting position, FEV_1 and FVC are reduced similarly in left and right side-lying, with no differential effects of side-lying on diffusing capacity and closing volume.[68] These lung-function effects in side-lying may reflect altered lung geometry with position change and a reduction in the vertical diameter of each lung in side-lying compared with that which occurs in the supine position.[69]

Side-lying increases end-diastolic ventricular pressure on the dependent side secondary to compression of the viscera beneath the diaphragm and to reduced lung compliance on that side.[70] Although such changes can be readily accommodated in health, they may further impair gas exchange in individuals with oxygen transport deficits.

Optimal $\dot{V}_A/Q$ matching occurs in the upper one-third of each lung in the side-lying position.[71] The total area for optimal $\dot{V}_A/Q$ matching, therefore, is likely greater than that in the upright position, which contributes theoretically to an improved $\dot{V}_A/Q$ matching. These apparent improvements, however, are offset by reduced lung volumes and airflow rates in this position.

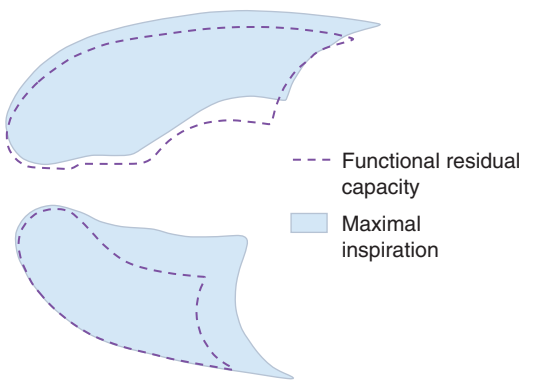

Fig. 20-13 Outlines of the lungs at two lung volumes in a conscious, spontaneously breathing subject in the right side-lying position. *(From Lumb AB, Pearl RG:* Nunn's applied respiratory physiology, *ed 6, Philadelphia, 2005, Butterworth Heinemann).*

In healthy people and in patients, arterial oxygen tension is greater in side-lying than in supine position.[72] This is true for patients receiving supplemental oxygen, as well as for those who are not. Thus side-lying can be used to enhance the efficiency of gas exchange and thereby minimize or avoid the use of supplemental oxygen. Arterial blood gases have been reported to be improved in patients with unilateral lung disease[73,74] when they are positioned with the good lung down and worsened when the affected lung is down. When lung pathology is bilateral, arterial blood gas values are better when patients lie on the right side than when they lie on the left. This can be explained by the greater size of the right lung and the reduced compression of the heart on the lung in this position compared with left side-lying.[75,76] The practice of "down with the good lung," however, has been questioned in patients with unilateral lung collapse secondary to central airway lesions.[77] Not all patients respond favorably when the good lung is down. Research is necessary to distinguish the characteristics of responders and nonresponders to refine the prescription of body positions.

The side-lying rather than the supine position is often a preferred position for patients who are hospitalized; yet its physiological consequences are not well understood. The pulmonary effects of side-lying have been reported for healthy older people.[68] FEV_1 and FVC are reduced comparably for right and left side-lying compared with a reference sitting position. Although diffusing capacity and homogeneity of ventilation appear to be unchanged, they may be adversely affected in patient populations with single and combined pathologies that affect oxygen transport.

Patients who are hemodynamically unstable require special consideration with respect to body positioning. These patients may be less able to benefit from active mobilization and are more reliant on positional perturbation than on movement to promote optimal gas exchange. In one study of patients with severe respiratory failure and receiving inotropic support, the extreme left lateral position contributed to a hyperdynamic state, and the right lateral position predisposed the patients to hypotension, likely as a result of impaired right ventricular preload.[78] Spirometric evidence from patients who were intubated supports decreased dynamic lung compliance in the lateral and prone positions compared with supine.[79] Body positioning warrants judicious prescription, with particular attention to the angle of the lateral position and the duration and to monitoring to observe the effect.

Prolonged side-lying has been shown to mobilize lung water in patients with pulmonary edema, and to a lesser extent in patients with pulmonary inflammation.[80] Physical therapy interventions that entail gravitational challenges, therefore, can have a direct effect on lung water distribution and possibly compartmentalization, which in turn, may affect pulmonary compliance and gas exchange. Similarly, pleural effusions respond to the effect of gravity. In patients with unilateral effusions, when the effusion is positioned lowermost in side-lying, oxygenation is lower than when the effusion is positioned uppermost.[81] This may be explained by the effusion impairing $\dot{V}_A/Q$ matching and gas exchange in the lowermost lung.

Head-Down Position

The head-down position augments oxygen transport in some patients by improving pulmonary mechanics. Patients with chronic airflow limitation, for example, tend to have hyperinflated chests and flattened diaphragms in which the contraction of the diaphragm is inefficient because of the position of its muscle fibers on the length tension curve. The head-down position causes the viscera to be displaced cephalad beneath the diaphragm. The diaphragm is positioned more normally and rests at a higher and more mechanically efficient position in the chest.[82,83] In this position, patients may experience relief from dyspnea, reduced accessory muscle use, reduced upper chest breathing patterns, and reduced minute ventilation. Patients with pathology in the lung bases may also benefit from the head-down position in that this position favors gas exchange in the more functional upper lung fields and promotes alveolar distension of bases, which are uppermost in the head-down position. Other patients, however, such as those with respiratory muscle fatigue, may have increased respiratory distress in this position due to the added resistive loading of the diaphragm because of the weight of the viscera beneath. These observations support the need to prescribe body positioning on an individual basis with consideration of the multiple factors that may impair oxygenation as well as enhance it.

Prone Position

There is mounting physiological and scientific justification for use of the prone position to enhance arterial oxygenation and reduce the work of breathing in patients with cardiovascular and pulmonary dysfunction who may or may not be mechanically ventilated. The prone position shifts the mobile structures of the thoracic and abdominal cavities.[84,85] The heart and great vessels are displaced anteriorly. The liver, spleen, and kidney shift anteriorly and caudally.

The prone position increases arterial oxygen tension, tidal volume, and dynamic lung compliance.[86-88] The pleural pressure gradient is homogenized; hence the distribution of $\dot{V}_A$ and alveolar inflation are augmented. Ventilation to perfusion matching has been shown to be more uniform in horizontal positions,[62] reflecting more uniform pleural pressure gradient and less lung compression by the heart.[89] In addition, the prone position reduces stroke volume, increases sympathetic activity, and augments urine output.[90] There has been increasing interest in exploiting these benefits in patients who are critically ill where mobilizing options are more limited (see Chapters 34 and 35). The prone position has some role in avoiding mechanical ventilation in patients who are conscious and alert, thereby reducing the risk for ventilator-associated complications.[88] Over the years, studies of prone positioning have been conducted largely in patients with acute respiratory distress syndrome (see Chapter 36).[91-93] Prone is associated with improving oxygenation in 70% to 80% of cases.[94] The effect of prolonged duration in the prone position has been studied, and the benefits appear to be dose-dependent.[95] The physiological outcomes of prone positioning in the management of acute lung injury are thought to reflect the particular pathoetiology.

Complications associated with prolonged periods in the prone position, particularly skin breakdown, are common; thus close monitoring of skin over bony prominences is essential. To prevent or manage these complications, intermittent prone positioning has been advocated. Intermittent prone positioning of patients with acute respiratory distress syndrome and best positive end-expiratory pressure (PEEP) therapy can reduce F_{IO_2} levels to less than 0.50, the critical level for oxygen toxicity.[96]

In a study using a canine model of acute lung injury, the prone position was observed to augment oxygenation in conjunction with low PEEP and to offset the negative hemodynamic effects of high PEEP.[97] This finding is consistent with clinical outcome studies. The two common variants of the prone position are prone abdomen-restricted and prone abdomen-free. Prone abdomen-restricted refers to lying prone with the abdomen in contact with the bed, whereas in the prone abdomen-free position, the patient's hips and chest are elevated so that the abdomen is free. Both prone positions augment gas exchange, but the prone abdomen-free position, comparable to the hands-and-knees position,[98] enhances lung compliance, tidal volume, FRC, and diaphragmatic excursion to a greater degree and minimizes compression of the heart and abdominal viscera on the lungs.[13] In one study, use of supplemental oxygen was reduced in four of five patients who were mechanically ventilated and whose positioning regimen included the prone abdomen-free position.[99]

Although patients in respiratory failure have been shown to benefit from the prone position, certain precautions must be observed. The patient must be positioned so that all pressure point stress (particularly on the head and face), as well as stress on the tubing and circuitry of the mechanical ventilator tubing, is minimized. The patient should be monitored continuously. A semiprone position can provide many of the physiological benefits of a full prone position and can minimize the risks, particularly in patients who are mechanically ventilated and those with cervical spine pathology. In addition, the semiprone position simulates the prone abdomen-free position. The semiprone position may be more conservative, more comfortable, and safer for the patient who is severely ill, potentially hemodynamically unstable, older, or has a protruding abdomen.

For patients unable to be mobilized, use of some variant of the prone position is even more important. Excessive recumbency, particularly in patients who are being positioned through a restricted arc (e.g., supine and one-quarter turns to either side), should be offset by some variant of the prone position, and this position should be incorporated often. Inevitably, patients exposed to a restricted arc of positioning may readily develop atelectasis in the dependent lung fields. Patients who are mechanically ventilated and have monotonous patterns of tidal ventilation are at particular risk. The only means of preventing and countering compression and hydrostatically induced atelectasis is by positioning dependent areas uppermost and repositioning the patient frequently.

The time course for the development of such hydrostatic complications is dependent on the patient's status, which may change from hour to hour in an individual who is critically ill. Although it is essential to monitor objective measures of oxygen transport and the adequacy of the steps in the oxygen transport pathway, subclinical changes will precede clinically measurable changes. By the time changes manifest in clinical measures, significant pathology may be present. Prevention, anticipation, and early detection are key.

Physiological Effects of Frequent Changes in Body Position

Table 20-2 lists some of the physiological effects of frequent changes in body position that are mediated primarily through their effects on respiratory mechanics, cardiac mechanics, airway closure, mucociliary transport, lymphatic drainage, and altered neural activation of the diaphragm. These effects, resulting from a change in position, are distinct from the benefits derived from a particular static body position. The benefits of changing position can be enhanced by moving to an extreme position (i.e., moving from supine to prone, rather than moving from supine to side-lying). Extreme body position changes simulate, but do not replace, the physiological "stir-up" and perturbations that occur with normal mobility and being upright. When the stir-up regimen was originally proposed, Dripps and Waters[100] did not appreciate fully the physiological implications of regular upright standing.[101] The net effect of changing body position is a stirring-up of the constituent distributions of $\dot{V}_A$, Q, and $\dot{V}_A/Q$ matching and shifting of internal organs and their compression on the structures of the cardiovascular and pulmonary unit. Areas of dependent atelectasis, physiological dead space and shunting, and mucus distribution are dramatically shifted.[102] The stir-up stimulates lymphatic drainage, surfactant production and distribution through stretching of the lung parenchyma, and the distribution and function of pulmonary immune factors.[103] Frequent physical perturbations also may inhibit bacterial colonization.[104] In addition, frequent body position changes shift and redistribute compression forces acting on the diaphragm, myocardium, and mediastinal structures and the compression of the lungs by the myocardium and mediastinal structures.

Frequent body position changes are used by physical therapists to stimulate the patient and increase arousal to a more alert and wakeful state (Figure 20-14). The more upright the patient, the greater the neurological arousal and the greater the stimulus to breathe; this effect is augmented by encouraging the patient to be self-supporting. Commensurate with an increase in arousal, the patient is stimulated to take deeper breaths and, hence, to increase $\dot{V}_A$. When body positioning is coupled with mobilization, vasodilation and recruitment of the pulmonary capillaries are stimulated, and this, in turn, improves the homogeneity of the distributions of $\dot{V}_A$ and Q, hence augmenting $\dot{V}_A/Q$ matching.

Prescription of Therapeutic Body Positions and Body Position Changes

Prescription of body positioning is based on an analysis of the factors that contribute to impaired oxygen transport for each patient.[105] Specific positions are selected to simulate as closely as possible the physiological function of the normal, healthy, upright cardiovascular and pulmonary unit and oxygen transport, and the perturbations and stirring-up that occurs hemodynamically during normal mobility and being upright.[101] A hierarchy of body positioning alternatives based on the physiological justification of the various positions appears in Table 20-3. These positions range from the most to the least physiological. The hierarchy is based on the premise that oxygen transport is optimal when upright and moving. Mobilization in the upright position increases tidal volume and respiratory rate, hence increasing minute ventilation, flow rates, and mucociliary transport and clearance and enhances the efficiency and effectiveness of airway clearance and coughing. Thus incorporating active movement into the body position change is optimal.

Despite the well-documented benefits of the judicious application of therapeutic body positioning to enhance oxygen transport, it does not replace the more physiological intervention of mobilization and exercise to maximize oxygen transport. Rather, once the effects of mobilization/exercise have been maximally exploited, body positioning is the next best physiological approximation to a mobilized upright state. However, even the mobilized patient benefits from therapeutic body positioning between mobilization sessions and during the night and rest periods. The progressive sequence of body positioning with movement is considered from the outset in planning for fully functional recovery and return to daily life.

Body position should first be exploited when coupled with movement followed by the erect sitting positions with legs dependent. Figure 20-15 illustrates several variants of the sitting position. Each of these positions has distinct effects on oxygen transport, so the specific upright position has to be prescribed specifically, because the supported and propped-up positions in bed do not substitute for upright, erect sitting. These variants have a role only when the patient deteriorates while being positioned upright or when in that position. Sitting with the feet down and supported is preferable to the propped up long sit because of the gravitationally induced

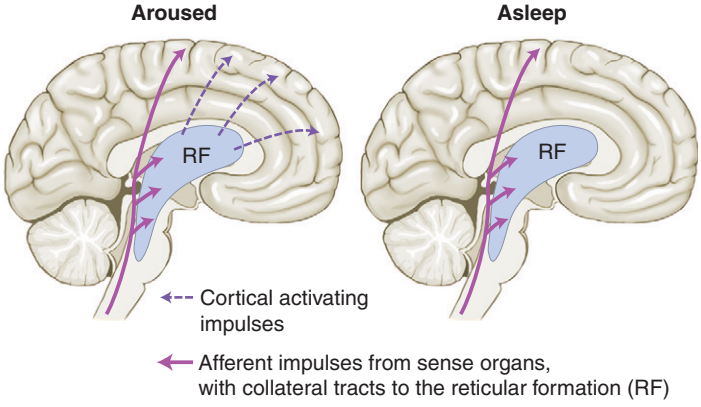

Fig. 20-14 Effect of arousal on cerebral activity. *(From Browse NL:* The physiology and pathology of bed rest, *Springfield, Ill, 1965, Charles C. Thomas.)*

Table 20-3 Physiological Hierarchy of Body Positions

Most Physiological Body Position	Least Physiological Body Position (Provisos)
Upright and moving in a 1-g gravitational field and exposed to a range of body positions and body-position changes over time	The upright erect sitting position implies that the back, head, and neck are vertical and aligned, with flexion only at the hips; the patient is not slumped or recumbent.
Relaxed erect standing (not too prolonged)	The less able the patient is to assist in positioning, the greater the need for more extreme positions and greater turning frequency.
Erect sitting (self-supported or with assist) with feet moving (e.g., active, active assisted, or passive cycling motion)	If the patient is totally unable to move (i.e., in a coma or paralyzed), extreme body positions are indicated if they are not contraindicated because of hemodynamic instability or increased intracerebral pressure.
Erect sitting (self-supported or with assist) with feet dependent	The upright position is used as much as possible, provided the patient is physically supported for safety and monitored in terms of treatment response.
Lean-forward sitting, with arms supported and feet dependent	Passive standing on a tilt table is hemodynamically questionable; it is preferable that patients be placed in a high Fowler position, with legs positioned dependently, using the knee breaks in the bed.
≥45-degree sitting with legs dependent	
Erect long sitting (legs nondependent)	
<45-degree sitting (legs nondependent)	
Prone and semiprone/side-lying	Regimens of 360-degree horizontal turning and 180-degree vertical turning (ranging from 20 degrees head-down to 20 degrees lean-forward) are used unless contraindicated. Positioning through a maximal arc simulates as closely as possible the three-dimensional movement of the chest wall during normal respiration.
Supine	

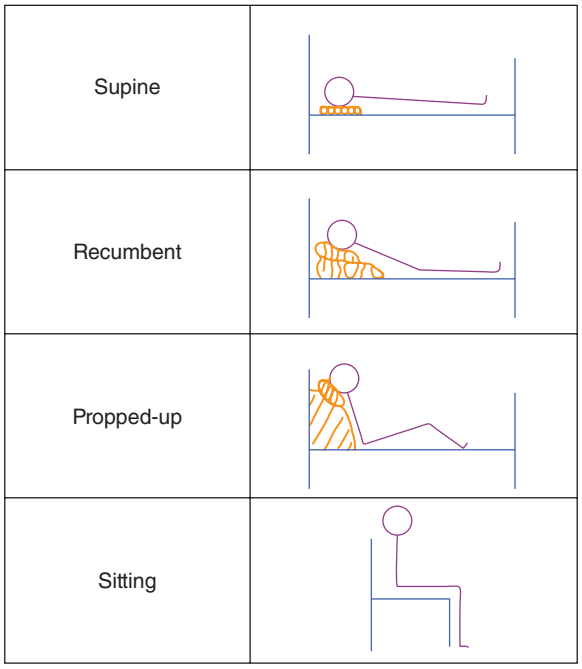

Fig. 20-15 Approximations of the upright position from supine. The recumbent and propped-up positions are not comparable physiologically to the upright sitting position. *(From Browse NL:* The physiology and pathology of bed rest, *Springfield, Ill, 1965, Charles C. Thomas.)*

hemodynamic benefits associated with this position. Sitting up in bed fails to position the patient in a perfectly vertical upright position. The head-up position in bed can be maximized, and the use of knee breaks in the bed provides a gravitational stimulus to the circulating blood volume.

One challenge when positioning patients in bed is the tendency to lose the position, usually from the compliance of the mattress and supporting pillows. Patients lose optimal positions in bed very quickly, so they should be monitored to ensure that the specific positions are maintained. An uncorrected slumped position can compromise pulmonary function and gas exchange. Pillows should not be used to maintain a body position because they are easily compressed and shifted. Blankets and sheets tightly rolled and secured with tape and rigid bolsters are more effective in maintaining a patient's body position.

Although there is a role for modified positions such as half side-lying, these positions are often overused at the expense of full turns to each side or prone or semiprone positions. Patients can be positioned safely (with appropriate supervision and monitoring) and comfortably in these full positions by observing the normal precautions of passive positioning.

A common practice is to progressively turn patients in one-quarter turns, such as from supine to side-lying and back to supine and so forth. However, the use of extreme positions and extreme position changes may yield greater physiological benefit with respect to the degree of perturbation and stir-up elicited.[106] Extreme position changes result in significant alterations in the distributions of $\dot{V}_A$, Q, and $\dot{V}_A/Q$ matching. Mucociliary transport is stimulated, and secretion accumulation and stagnation is minimized. In addition, the more extreme the body position, the greater the degree of arousal stimulated, particularly in the upright positions, and arousal is essential in patients who are critically ill.

Another important consideration is the time course of changes in oxygen transport with positions and position changes. There are three plausible outcomes: a favorable response, no response, or an unfavorable response. With the passage of time, all three outcomes will deteriorate. The specific time depends on the multitude of factors contributing to impaired oxygen transport. With judicious monitoring, the duration of a position can be maintained as long as the patient responds favorably, and it is modified before or at the first sign of deteriorating gas exchange.

Because of the marked changes that can be expected with body positioning and body positioning changes, the physical therapist has a narrow window of opportunity to assess and treat the patient before, during, and after position changes (immediate and delayed effects).

Mechanical Body Positioning

Kinetic or mechanically turning beds have long been known to benefit oxygen transport in patients who are severely ill.[107-111] These beds are indicated for those patients who are moderately hemodynamically unstable and on neuromuscular blockers and thus tolerate manual turns poorly. Such turning frames are contraindicated, however, for patients who are less ill. Even for patients who require multiple assistants and extra caution and time to turn and position effectively, these issues should never deny a patient a much-needed treatment with proven effectiveness.

The benefit of these beds on oxygen transport in patients who are critically ill has implications for the management of patients who are less severely ill. Continuous mechanical rotation can be simulated by increasing the frequency and arc of positions when manually positioning patients.

Practical Considerations in Positioning Patients

Prescriptive body positioning can require a significant amount of the physical therapist's time, as well as that of other team members. Such prescriptive positioning is based on clear indications and well-defined parameters; it is not to be confused with "routine" positioning. For any hospitalized patient who is recumbent and inactive, body positioning is a 24-hour concern, both during and between treatments. Such patients are at risk for impaired oxygen transport. The team as a whole has a responsibility to ensure that complications related to static positioning and restricted mobility are prevented.[112]

Despite the time and labor involved in turning a patient to the prone position, particularly if the patient is mechanically ventilated, the benefits of this position (even for short periods) outweigh the time and effort required. Given the benefits that can be derived from the prone position, justification has to be made for not doing so. Frequently, therapeutic body positioning can be effectively coordinated with nursing interventions and other procedures. With all body positions, but especially with the prone position in patients who are severely ill, potential inclusion and exclusion criteria should be reviewed, along with preturn considerations, the turning technique, assistants, monitoring the effectiveness of the prone position, passive movements, and limb positioning.[91] Finally, any problems or adverse responses to the prone, as to other positions, are documented.

Extreme body positions and body position changes are the interventions of choice after mobilization has been fully exploited or in the event that the role of mobilization is limited for a given patient. When extreme positions are less feasible, modified positions may be used. Even though the greatest benefits will be derived from extreme changes because they simulate the normal range of changes the human body is exposed to in health, small changes can be effective in altering intrapleural gradients slightly so that previously closed alveoli will be opened, even though previously opened ones may close. Although modified positions and small degrees of position change should not be relied on, their potential benefits should not be minimized in patients for whom extreme positions are contraindicated. Before and after each position change are prime opportunities to assess the patient and to encourage deep breathing and coughing or to suction the patient, as indicated.

Monitoring Responses to a Body Position or Position Changes

The prescriptive parameters of body positioning and body position changes include the positions selected, the duration in each position, the sequence of position changes, the cycle of all positions, and position changes overall. Because a patient necessarily assumes a body position at all times (is never free of gravitational forces), positioning patients between treatments can contribute as much to the overall treatment response as the treatment itself because the patient spends more time in the between-treatment positions than in the within-treatment positions.

The duration and frequency of the positions and the frequency of body position changes are response-dependent rather than time-dependent. Monitoring is the basis for defining and modifying the body positioning prescription. The physiological variables to be monitored depend on the patient's specific presentation and on cardiovascular and pulmonary dysfunction and its severity and distribution. Monitoring the patient who is not critically ill includes subjective and objective evaluation of indexes of the adequacy of oxygen transport (Part II). Among the most important are oxygen delivery, oxygen consumption, oxygen extraction, and gas exchange indicators such as the A/aO_2 difference and the PaO_2/PaO_2. Subjectively, the patient's facial expression, respiratory distress, dyspnea, anxiety, peripheral edema, discomfort, and pain are assessed. Objectively, heart rate, blood pressure, respiratory rate, SaO_2, flow rates, and bedside spirometry can be readily assessed. The appropriate standardization and procedures need to be used to ensure that the measures are both valid and reliable (see Chapter 7). Because physiological variables change from moment to moment, serial measures over a period of time should be taken to establish an average value, rather than using peak or discrete measures, which may misrepresent a treatment effect.

To interpret and compare various measures, the FIO_2 and any change in FIO_2 must be recorded. The use of the ratio PaO_2:FIO_2 enables comparison of gas exchange within and between patients when FIO_2 levels differ or change.[113] Similarly, for patients who are mechanically ventilated, any changes in the ventilatory parameters must be noted, in addition to other interventions that have a direct effect on oxygen transport. Only in this way will the clinician be able to reasonably conclude that the position or position change was instrumental in enhancing oxygen transport.

Measures and outcomes are recorded before (pretreatment baseline), during, and at periodic intervals following the treatment. A valid stable pretreatment baseline is essential to determine the therapeutic effect of a given position on oxygen transport. Variables monitored during the treatment are focused on ensuring that the treatment is having a beneficial effect, in addition to its not having any deleterious effect on the patient subjectively or with respect to any parameter of oxygen transport. As long as beneficial effects are being recorded, a position can usually be safely maintained in the absence of other contraindications; however, diminishing returns can be expected as the period becomes prolonged.

Patients maintained in static positions for more than 1 to 2 hours need to be monitored closely. A position change is physiologically defensible after this duration, rather than risking diminishing returns and potentially worsening the patient's condition.

The patient who is critically ill has the "advantage" of having more monitoring devices and lines in place. These provide access to several measures and indexes of oxygen transport, and certain hemodynamic and pulmonary variables are available continuously to ensure that the outcome is therapeutic and the patient is safe.

Summary

The premise underlying body positioning is that the physiological body position consistent with social participation and activity is "upright and moving." The specific purpose of this chapter is to differentiate therapeutic body positioning, which is prescribed by the physical therapist to optimize oxygen transport, from "routine" body positioning, which has the primary objective of maintaining gas exchange and preventing complications. The physiological effects on cardiovascular and pulmonary function and oxygen transport of different body positions and of changing body positions are described. The primary goal is to strive toward the physiological position for optimizing oxygen transport (i.e., upright and preferably moving). Issues related to optimizing the prescription of therapeutic body positioning and monitoring treatment outcome are presented.

This chapter focuses on the physiological effects of body positioning, an intervention that has well-documented, direct, and potent effects on oxygen transport. Establishing a clear rationale for prescribing a specific body position or body position changes is essential. The rationale, however, is based on multiple factors in addition to the physiological considerations presented. This chapter highlights the principles that must be considered in the decision-making process for prescribing therapeutic body positioning.

Review Questions

1. Relate the physiological body position of being upright and moving to the categories of participation and activity in the WHO International Classification of Functioning, Disability and Health.
2. Describe the effects of gravity on cardiovascular and pulmonary function and oxygen transport.
3. Distinguish prescriptive from routine body positioning.
4. In reference to the seated upright position, describe the effects of each of the following body positions on cardiovascular and pulmonary function and oxygen transport in health: supine, side-lying, head-down, and prone.
5. In reference to the seated upright position, describe the effects of each of the following body positions on cardiovascular and pulmonary function and oxygen transport in disease: supine, side-lying, head-down, and prone.
6. Explain how a physiologically ideal body position with respect to oxygen transport can be deleterious over time.
7. Distinguish between the prescription of therapeutic body positions and the frequency of body position changes.
8. Describe the principles of monitoring oxygen transport variables before, during, and after positioning a patient.
9. Explain why body positioning protocols cannot be defined for the management of specific pathological conditions, although this is often the way in which it is studied scientifically.

Summary 333
Review Questions 333
References 334

Oxygen transport from the lungs to body tissues can be limited in patients with an ineffective cough or an impairment of normal mechanisms of mucociliary clearance. An array of techniques for assisting the mobilization of airway secretions is available for patients and caregivers to augment a patient's own mechanisms. When prescribing an optimal method of airway clearance, the caregiver must consider the pathophysiology and the clinical manifestations of the disease, the physiological basis of the method, availability of the technique to the patient, and the patient's acceptance of the technique.

This chapter reviews the physiological basis of each airway clearance technique (ACT), the history of its use, and research on its effectiveness. An introduction to the application of these techniques to patients is presented. Also addressed are the benefits and burdens of each technique, contraindications and precautions, and practical concerns regarding patient care.

Evidence for the use of airway clearance techniques is often difficult to evaluate, in part due to agreement that top-level evidence on this topic is lacking.[1a-b] The components of a given treatment have not been standardized and the literature refers to ACTs using a variety of terms, including chest physiotherapy, chest physical therapy (CPT), bronchial drainage, postural drainage (PD) therapy, and bronchial hygiene. In addition, the availability of equipment and cultural differences in its application confound research results. Differences in the outcome measures for a given technique also occur—some studies use wet or dry (dehydrated) sputum volume or radioaerosol clearance, whereas other studies use pulmonary function tests, radiographic evidence, or arterial blood gases to asses the effectiveness of a specific technique. The majority of secretion clearance research has been focused on patients with cystic fibrosis, as the need for ongoing secretion removal is apparent in this population. However, results showing a treatment to be effective in one cross section of patients must not be generalized to apply to the treatment across all patients with pulmonary disease.

Historically, the gold standard of airway clearance has been a combination of postural drainage, percussion, and vibration with cough. This has been challenged[1b-c] as more techniques have been demonstrated to be effective. Postural drainage and percussion have been shown to be ineffective in some cases

© Copyright 2012 Elsevier Inc., Ltd., BV. All rights reserved.

and, in fact, to be detrimental to pulmonary status in others. Caregivers have also been shown to suffer from the performance of percussion; repetitive-motion injuries of the wrists have been documented as a result of regular performance of percussion.[2,3]

Alternative techniques have arisen out of the need to find effective methods for those patients not responsive to traditional methods. A desire to increase adherence with airway clearance, especially in patients approaching adolescence and adulthood, has led to an investigation of more independent techniques.[4] Many of these techniques have been practiced longer in other countries, but are now commonly used by practitioners in the United States.

It is important to remember, however, that secretion clearance is just one step toward realizing effective gas exchange in the complex oxygen transport pathway.[5] Airway clearance, when indicated, should be integrated into a comprehensive plan of care, including positioning and mobilization, to optimize oxygen transport.

Conditions That May Indicate Airway Clearance

Oxygen transport is the primary purpose of the cardiopulmonary system (see Chapter 2). Ventilation of the alveoli is an important step in the oxygen transport chain; it allows optimal delivery of oxygen to the tissues. Several medical and surgical conditions may interfere with this process. Retained secretions or mucus plugs in the airways may interfere with the exchange of oxygen. The secretions must be mobilized from the peripheral, or smaller, airways to the larger, more central airways, where coughing or suction may remove them.

The following conditions may be associated with difficulty in mobilizing airway secretions. Difficulty in effectively mobilizing secretions can result from a combination of factors including impaired ciliary motion, reduced lung inflation, impaired lung elasticity, impaired chest wall mobility and biomechanics, and weak or fatigued respiratory muscles. These factors can be coupled with increased viscosity of airway secretions.

- Cystic fibrosis
- Bronchiectasis
- Atelectasis
- Respiratory muscle weakness
- Mechanical ventilation
- Neonatal respiratory distress syndrome
- Asthma

Cystic Fibrosis

In this multisystem genetic disease of exocrine gland dysfunction, copious (often purulent), thick secretions and mucus plugs block the peripheral and central airways. Even infants diagnosed with cystic fibrosis, whether symptomatic or not, show evidence of small airway obstruction in the form of bronchial mucus casts.[6] Recurrent bacterial infections combined with this mucus hypersecretion in the lungs leads to destruction of the bronchial walls, or bronchiectasis. Airway clearance is recommended for all patients with CF and continues to be an important therapy in the treatment of cystic fibrosis.[1b,6a] This practice is supported by evidence of deteriorating lung function when regular treatments of postural drainage and percussion have been stopped.[7,8]

Bronchiectasis

This condition results in a breakdown of the elastic tissue in the bronchial walls, causing severe dilation. Inflamed mucosa and copious purulent secretions are present in this condition. Airway clearance has been shown to benefit patients with bronchiectasis in the mobilization of sputum.[9,10]

Atelectasis

This condition is caused by the collapse of alveolar segments, often by retained pulmonary secretions. It has been documented in patients who have undergone surgery under general anesthesia, especially in cases of thoracic or abdominal surgery. ACTs are indicated in cases of atelectasis due to mucus plugging.[11,12]

Respiratory Muscle Weakness

Many patients with neurological or metastatic diseases or general debilitation tend to hypoventilate or have increased work of breathing. They are unable to maintain adequate control of respiratory secretions and often have weak, ineffective coughing mechanisms.[13] This is especially true in patients with diminished diaphragm innervation resulting from spinal cord injuries.[14]

Mechanical Ventilation

Patients requiring ventilatory support for any reason, including patients who are obtunded or comatose, are at risk for atelectasis and are unable to manage their secretions independently.[15] Airway clearance is considered standard practice in the management of patients on mechanical ventilation.[15a]

Neonatal Respiratory Distress Syndrome

These infants are born lacking surfactant in the lungs, which results in atelectasis. ACTs may be useful in clearing secretions and preventing atelectasis, but there should be a clear indication for this procedure and it must be monitored carefully in this population.[16,17]

Asthma

This condition is characterized by the presence of hyperreactive airways and mucus plugging. ACTs may be beneficial to assist in the mobilization of mucus plugs but are not helpful in treating uncomplicated acute exacerbations.[18]

There are several conditions that do not appear to benefit from ACTs. Patients with pneumonia or chronic bronchitis without large amounts of secretion production do not appear to benefit from airway clearance. No differences in outcome were found when these populations were treated with postural drainage and percussion.[19-22] Viral bronchiolitis is an asthma-like lung disease occurring in infants less than 2 years of age. These patients do not appear to benefit from ACTs.[23] Also of little benefit, and possibly harmful, is the inclusion of airway clearance in the routine care of postoperative patients without

extensive secretions.[18] Even in patients with a history of lung disease, the use of ACTs has failed to affect the incidence of atelectasis as a postoperative complication.[24]

Airway Clearance Techniques

Airway clearance techniques differ with respect to equipment needs, the skill level required to perform them, and their usefulness with various clinical problems. Matching a patient with an appropriate method or combination of methods may increase effectiveness, reduce complications, and promote long-term adherence to the treatment. This will, in turn, assist with achieving the goals of airway clearance: reducing airway obstruction, improving ventilation, and optimizing gas exchange.

Preparation for any secretion removal technique should include evaluation of the patient's pulmonary status so that measures may be compared before and after a treatment is provided. A physical examination, including inspection, palpation, measurement of vital signs, and chest auscultation, provides assessment of a treatment's effectiveness. Other outcome measures include chest radiographs, arterial blood gas measurements, and pulmonary function studies. An adequate intake of fluids (as allowed) decreases the viscosity of the secretions, allowing easier mobilization.

Several factors must be taken into account when scheduling an optimal time for airway clearance. At least 30 minutes to 1 hour should be allowed for the completion of tube feedings or meals. The inhalation of bronchodilator medications should take place before airway clearance maneuvers to improve secretion removal by opening the airways. Inhaled antibiotics are best scheduled after airway clearance has taken place for optimal deposition of medication. If necessary, adequate pain control should be provided to receive a patient's best effort and cooperation with a treatment.

Exercise for Airway Clearance

In addition to improving many outcomes in patients with lung disease, exercise has been shown to assist in secretion clearance.[25-28] Exercise increases mucociliary transport in patients with chronic bronchitis.[28] Higher transpulmonary pressure with aerobic exercise may open closed bronchi, as well as increase collateral ventilation to allow mucus to be moved.[26] It has also been shown that exercise-induced hyperventilation is more effective than eucapnic hyperventilation in mobilizing bronchial secretions.[29] The contribution of increased expiratory airflow and exercise-induced coughing are other factors in improving secretion removal. Exercise for secretion clearance has focused on aerobic or endurance exercise; however, any form of exercise must be adapted to the individual patient's status and abilities.

Based on a lack of decrease in lung function following the cessation of PD and percussion but the continuation of an exercise program, or based on the improvement in pulmonary function, exercise has been recommended as a replacement for a conventional chest physiotherapy routine in some patients or at some stages of lung disease.[26,27,30,31] In hospitalized patients with cystic fibrosis, no significant change in pulmonary function was reported when exercise was substituted for two of three daily treatments of PD, percussion, and vibration, and the weight of the sputum produced was equivalent.[30] In terms of mucus cleared, no significant differences were found among exercise on a cycle ergometer, postural drainage, and PEP mask breathing.[32] Increases in sputum expectoration on exercise days as opposed to nonexercise days have also been reported.[27,33]

However, other studies conclude that exercise alone is not sufficient and recommend its use as a complement to other forms of airway clearance. Airway clearance using PD and FET was shown to be more effective than exercise with a cycle ergometer in inducing sputum expectoration.[34] Results from Bilton and colleagues[35] demonstrated that any modality that included the active cycle of breathing technique (ACBT) in PD positions alone or in combination with exercise is better than exercise alone at clearing sputum.

It is difficult to compare these studies, however, because the mode and length of exercise differ, as do the outcome measures of effectiveness of airway clearance. Exercise as an airway clearance technique is not suitable for the very young (younger than 4 to 5 years of age), for patients with neuromuscular limitations, or for patients with limited exercise tolerance. Moreover, the potential need for supplemental oxygen during exercise should be monitored. Nonetheless, evidence suggests that an exercise program, in addition to clearing secretions, may decrease morbidity and mortality by improving exercise capacity.[36,37]

Treatment with Exercise

- A walking program requires only a suitable pair of shoes and a safe location. Higher-impact exercise, because of increased stress on the knees, requires shoes specifically for that purpose. Clothing should be appropriate for the weather if exercising outdoors.
- Exercise equipment suitable for a patient who is beginning an exercise program includes the treadmill, bicycle ergometer, elliptical trainer, mini-trampoline, or arm ergometer. For more accomplished exercisers or patients with a higher exercise tolerance, equipment may include a stair climber, cross-country ski machine, or rowing machine. Numerous other exercise equipment options are available; the patient's interests should be the primary factor for choosing.
- Tools to monitor a patient's response to exercise include a sphygmomanometer, stethoscope, heart rate monitor, pulse oximeter, and a scale to measure patient's level of perceived exertion (Figure 21-1). In a home setting, patients should be knowledgeable in self-monitoring exercise intensity. For those patients who require closer monitoring, a pulse oximeter may be rented from an oxygen supply company. Monitoring of vital signs before and during exercise, and during recovery, will allow titration of the workload for optimal performance.
- Supplemental oxygen and oxygen delivery supplies will be necessary for those patients who exhibit oxygen desaturation during exercise.
- Patients with hyperreactive airways should be premedicated with a prescribed bronchodilator before an exercise session.
- The principles of an exercise prescription addressing mode, intensity, duration, and frequency, as well as principles of "warm up" and "cool down," should be followed

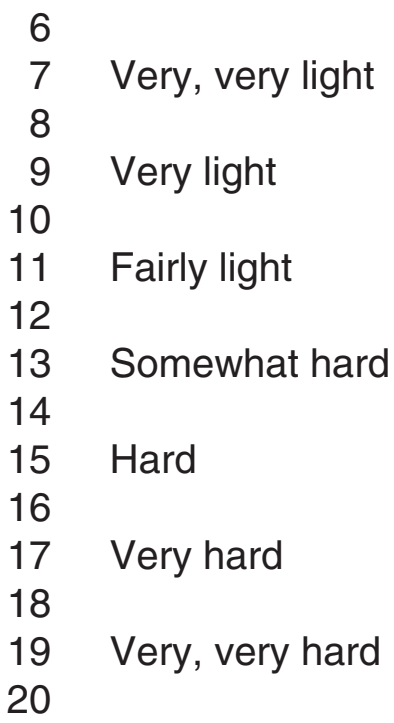

Fig. 21-1 Original perceived exertion scale. *(From Borg G: Psychophysical basis of perceived exertion,* Medicine and Science in Sports and Exercise *14:377, 1982.)*

when using exercise as a form of airway clearance. Individualizing an exercise program for each patient is of the utmost importance.

- Patients hospitalized for an acute exacerbation may not be able to initially perform endurance exercise. These patients should be started slowly and progressed as tolerated; consider using interval training.
- The patient should be instructed in huffing or controlled coughing to expectorate secretions as they are loosened.
- A regular, consistent program of exercise should be scheduled around the patient's daily activities to achieve adherence (e.g., walking the dog, sports at school, stopping by the health club after work).

Advantages and Disadvantages of Exercise

Exercise has the advantage of being the only airway clearance technique that is performed regularly by people without lung disease. This factor can make it appealing to those patients who do not want to call attention to their differences from their peers. Exercise may improve self-esteem, a sense of well-being, and quality of life. Higher levels of exercise tolerance in patients with cystic fibrosis have been demonstrated to improve survival.[37]

Some patients may not tolerate the amount or frequency of exercise necessary for this to be the sole method of airway clearance. Thus various airway clearance techniques can be used as adjuncts to exercise. This is particularly true during an acute exacerbation when activity tolerance is limited, or in infants or patients with neurological or musculoskeletal limitations. Andreasson[26] observed that regular contact with a caregiver seems to be necessary for successful exercise training, as does family support, especially in young children. This points out the difficulty with adherence to a home program. Adherence will also be affected by a patient's preference for a particular activity, scheduling conflicts, and commitment by friends and family members.

Precautions for Using Exercise

Several precautions must be observed when using exercise as a form of airway clearance. Care must be taken in prescribing exercise to patients with hyperreactive airways or a tendency toward oxygen desaturation. Desaturation has been shown to occur with exercise in individuals with pulmonary disease,[38,39] and therefore it becomes prudent to monitor oxygen saturation, providing supplemental oxygen for the exercise period when indicated. Exercise-induced bronchospasm must also be considered when pulmonary compromise is seen with exercise, especially with higher-intensity exercise.[40] When medication is indicated, it is recommended to provide an inhaled bronchodilator 20 to 30 minutes before exercise to alleviate this symptom.[41] Use of bronchodilator medication and supplemental oxygen may be necessary to improve exercise tolerance, but these patients require closer monitoring as well. Andreasson[26] reports a risk for pneumothorax associated with exercise in patients with extensive bullae.

Contraindications and Precautions for Manual and Mechanical Airway Clearance Techniques

In patients who are very young, who have limited ability to cooperate, or who are not adherent to other ACTs, percussion, shaking, and vibration offer methods for dislodging retained secretions. However, because of the force transmitted to the thoracic cage with these techniques, there are many precautions and contraindications to consider. The therapist should not make this decision alone but should seek direction from the medical team. These treatments are not completely benign and should not be performed in the absence of good indications.[42]

Percussion has been shown to contribute to a fall in PaO_2 in acutely ill patients,[43] especially in patients with cardiovascular instability[44] and in neonates.[45] The factor that seems most closely associated with or predictive of this effect is the patient's baseline PaO_2.[42] Cardiac dysrhythmias have been associated with chest percussion for bronchial drainage[11] and Huseby[46] hypothesizes that hypoxemia may be the underlying mechanism of CPT-caused cardiac arrhythmias.

Patients with hyperreactive airways (e.g., asthma) show intolerance for percussion as part of airway clearance. Campbell and colleagues[47] demonstrated a fall in FEV_1 associated with percussion; it was not evident when percussion was omitted. Administration of a bronchodilator before treatment with percussion precluded the fall in FEV_1. Wheezing has also been associated with percussion and vibration in patients with cystic fibrosis and COPD.[48,49]

Box 21-1 summarizes the precautions and contraindications for external manipulation of the thorax associated with percussion, shaking, and high-frequency chest compression.

Box 21-1 Contraindications to External Manipulation of the Thorax in Addition to Contraindications for Postural Drainage

- Subcutaneous emphysema
- Recent epidural spinal infusion or spinal anesthesia
- Recent skin grafts or flaps on the thorax
- Burns, open wounds, and skin infections of the thorax
- Recently placed pacemaker
- Suspected pulmonary tuberculosis
- Lung contusion
- Bronchospasm
- Osteomyelitis of the ribs
- Osteoporosis
- Coagulopathy
- Complaint of chest-wall pain
- Additional contraindications for percussion of a neonate
  - Intolerance to treatment as indicated by low oxygen saturation values
  - Rib fracture
  - Hemoptysis

From AARC Clinical Practice Guideline: Postural drainage therapy, Respiratory Care *36:1418-1426, 1991; and Crane L: Physical therapy for the neonate with respiratory disease. In Irwin S, Tecklin JS, editors:* Cardiopulmonary physical therapy, *St. Louis, 1985, Mosby.*

Vibration involves less force to the thorax and may be better tolerated than the aforementioned techniques. A nebulized bronchodilator may be administered during a treatment of high-frequency chest compression to avoid the consequences of hyperreactive airways.

Postural Drainage

Postural drainage, also known as bronchial drainage, is a passive technique in which the patient is placed in positions that allow gravity to assist with the drainage of secretions from the bronchopulmonary tree. PD is accomplished by positioning the patient so that the angle of the lung segment to be drained allows gravity to have its greatest effect (Figure 21-2). Positioning the patient to assist the flow of bronchial secretions from the airways has been a standard treatment for some time in patients with retained secretions.[50]

Knowledge of the anatomy of the tracheobronchial tree is vital to effective treatment. Each lobe to be drained must be aligned so that gravity can mobilize the secretions from the periphery to the larger, more central airways. The mechanism of postural drainage is considered to be a direct effect of gravity on bronchial secretions, although observations made by Lannefors (1992)[32] that gravity also influences regional lung ventilation and volume suggest that these mechanisms are also involved.

PD has been shown to be effective in mobilizing secretions in patients with cystic fibrosis,[51,52] bronchiectasis,[10] and other pulmonary diseases.[53,54] Other treatments, such as percussion, vibration, and the active cycle of breathing technique (ACBT), may be used while the patient is in postural drainage positions.

There are, however, many contraindications to gravity-enhancing positioning for PD. Recent studies have reported adverse effects of head-down or Trendelenburg positions required for the lower lobes. Modified positions should be used for head-down positions unless it has been shown to be effective in a particular patient. The head of the bed should remain flat instead of being tipped into the Trendelenburg (head down) position.

Preparation for Postural Drainage

- For the hospitalized patient, electric beds allow patients to be positioned more easily. Air therapy beds, most often used in the intensive care unit (ICU), are valuable aids for positioning, especially in patients who are large or unresponsive.
- In the ICU, it is imperative to be familiar with the multiple lines, tubes, and other devices attached to the patient (see Chapter 16). Allow enough slack from each device to position a patient for postural drainage.
- Ensure there are enough staff members to position the patient with as little stress to both patient and staff as possible.[55]
- For treatment in the clinic, have foam wedges or pillows available for positioning.
- For home treatment, aids in positioning might include pillows, sofa cushions, or a bean-bag chair.
- Nebulized bronchodilators or mucolytics before PD may facilitate the mobilization of sputum.
- For the patient with an adequate cough to expectorate secretions, have tissues or a specimen cup available. Have suctioning equipment ready to remove secretions from an artificial airway or the patient's oral or nasal cavity after the treatment. Refer to Chapter 43 for a discussion of suctioning.

Treatment with Postural Drainage

- After determining the lobe of the lung to be treated by auscultation and chest x-ray, position the patient in the appropriate position, supporting the patient comfortably in the position indicated (see Figure 21-2).
- If postural drainage is used exclusively, each position should be maintained for 5 to 10 minutes, if tolerated, or longer when focusing on a specific lobe. Coordinating the positioning with nursing care for skin pressure relief may allow the time spent in a position to be extended. If postural drainage is used in conjunction with another technique, the time in each position may be decreased. For example, if percussion and vibration are performed while the patient is in each PD position, 3 to 5 minutes is sufficient.
- A patient who requires close monitoring should not be left unattended, but this may be appropriate if a patient is alert and able to reposition himself or herself.
- It is not always necessary to treat each affected lung segment during every treatment; this may prove to be too fatiguing for the patient. The most affected lobes should be addressed with the first treatment of the day, with the other affected areas addressed during subsequent treatment(s).
- The patient should be encouraged to take deep breaths and cough after each position, if possible, and again after the

treatment is completed. Having the patient sit upright or lean forward optimizes this effort by allowing the use of the abdominals for a stronger cough.[55]

- Mobilization of secretions may not be apparent immediately after the treatment, but this may occur up to 1 hour later. The patient should be thus informed and reminded to clear secretions at a later time. A health care practitioner or family member should be included in this aspect of treatment, especially with patients who need encouragement.[55]

Advantages and Disadvantages of Postural Drainage

Postural drainage is relatively easy to learn; the patient and/or caregiver must be familiar with the appropriate positioning for the affected lung fields. Treatment in the hospital may be coordinated with other patient activities, such as positioning for skin pressure relief, bathing, or positioning for a test or procedure. Home treatment can be coordinated with activities such as reading or watching television.

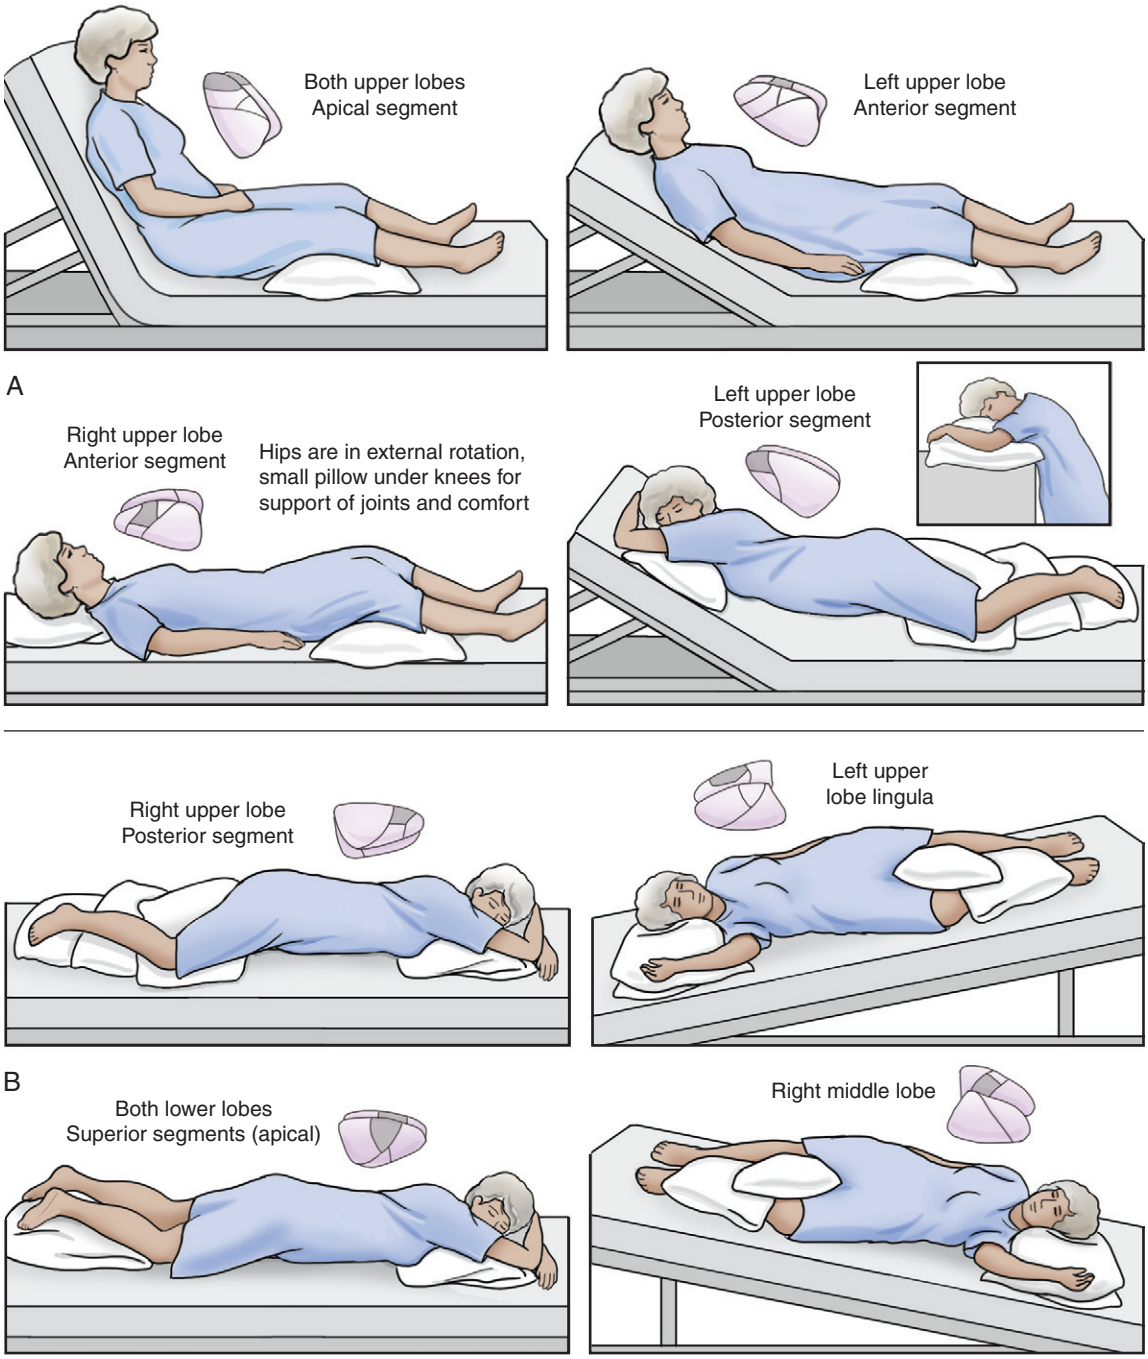

Fig. 21-2 Postural drainage positions. **A,** Upper lobes. **B,** Upper, middle, and lower lobes.

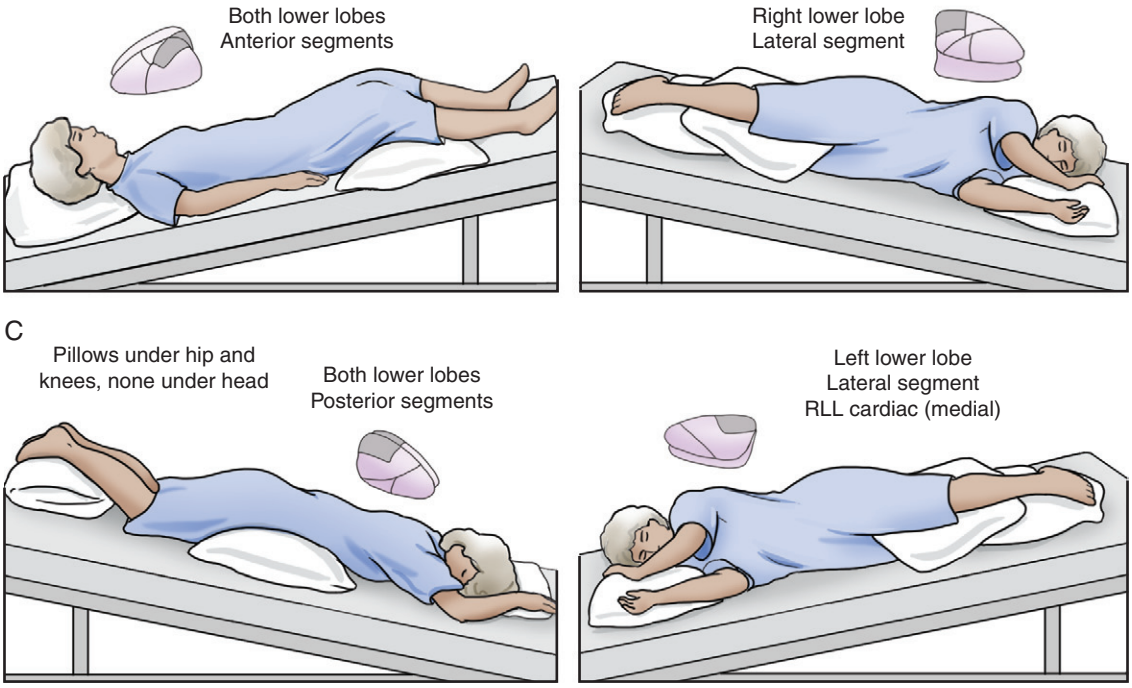

Fig. 21-2, cont'd C, Lower lobes.

For many patients, optimal PD positions will be contraindicated for a variety of reasons and modified positions should be used. Adherence to PD may be a challenge because of the length of the treatment; this is especially challenging in the pediatric population, who will require considerable distraction to maintain a desired position for the appropriate length of time. Children who are able to role-play the treatment—for instance, with a doll or stuffed toy—may better understand what is expected and be more cooperative with therapy.

The cost of the equipment required for PD is minimal. The cost of a caregiver's time to provide the treatment, however, especially in the case of a chronic disease, may be substantial. A family member should be taught the procedure, if possible, to decrease the cost and provide flexibility in scheduling.

General Precautions and Contraindications to Postural Drainage Positioning

It is essential that the therapist and the health care team discuss treatment priorities when deciding to use PD positions. A decision to use postural drainage might be made despite a contraindication if the benefits are thought to outweigh the risks in a particular case. For example, it is known that use of the Trendelenburg (head-down) position increases intracranial pressure in patients after neurosurgery.[56] However, if the patient develops atelectasis, the stress of respiratory embarrassment may also increase intracranial pressure. In this instance, the decision may be made to position the patient to clear the atelectasis and subsequently return to a modified conservative regimen.[55]

A fall in arterial O_2 saturation has been reported with the use of postural drainage for airway clearance, although the effects of PD were not separated from additional techniques.[46,57] Therefore O_2 saturation levels should be monitored during treatment, especially in patients with known low PaO_2 values.

Caution must also be used in treating a patient with end-stage lung disease in postural drainage positions because of the risk for hemoptysis.[58,59] Decreased cardiac output[60,61] has been associated with chest physiotherapy treatment; however, the effects of postural drainage were not separated from those of percussion and vibration.

Many physical therapists working with the pediatric population almost never use the head-down position in treating infants but rather a modified routine that excludes the Trendelenburg position. The head-down position has been shown to increase the incidence of gastroesophageal reflux in neonates.[16] Button and colleagues[62] found that the head-down position is associated with gastroesophageal reflux, distressed behavior, and lower oxygen saturation in infants with cystic fibrosis. It should be noted that a finding of gastroesophageal reflux can occur even 1 hour after treatment. A modified routine that eliminates head-down positioning is associated with fewer respiratory complications.[63] Box 21-2 summarizes the precautions and contraindications concerning postural drainage.

Percussion

Percussion, sometimes referred to as chest clapping, is a traditional approach to secretion mobilization. A rhythmical force is applied with a caregiver's cupped hands against the thorax, over the involved lung segments, trapping air between the patient's thorax and the caregiver's hands (Figure 21-3), with the aim of dislodging or loosening bronchial secretions from the airways so they may be removed by suctioning or expectoration. This technique is performed during both the inspiratory and expiratory phases of breathing. Percussion is

Box 21-2 Contraindications for Postural Drainage

All Positions Are Contraindicated for the Following:

- Intracranial pressure (ICP) >20 mm Hg
- Head and neck injury until stabilized
- Active hemorrhage with hemodynamic instability
- Recent spinal surgery (e.g., laminectomy) or acute spinal injury
- Active hemoptysis
- Empyema
- Bronchopleural fistula
- Pulmonary edema associated with heart failure (HF)
- Large pleural effusions
- Pulmonary embolism
- Older, confused, or anxious patients
- Rib fracture, with or without flail chest
- Surgical wound or healing tissue

Trendelenburg Position Is Contraindicated for the Following:

- Patients in whom increased ICP is to be avoided
- Uncontrolled hypertension
- Distended abdomen
- Esophageal surgery
- Recent gross hemoptysis related to recent lung carcinoma
- Uncontrolled airway at risk for aspiration

Trendelenburg Position Is Contraindicated for the Following Cases in Neonates:

- Untreated tension pneumothorax
- Recent tracheoesophageal fistula repair
- Recent eye or intracranial surgery
- Intraventricular hemorrhage (grades III and IV)
- Acute heart failure or cor pulmonale

From AARC Clinical Practice Guideline: Postural drainage therapy, Respiratory Care *36:1418-1426, 1991; and Crane L: Physical therapy for the neonate with respiratory disease. In Irwin S, Tecklin JS, editors:* Cardiopulmonary physical therapy, *St. Louis, 1985, Mosby.*

used in postural drainage positions for increased effectiveness[64,65] and may also be used during ACBT. For individuals with pulmonary disease, percussion in conjunction with postural drainage continues to be a mainstay of the treatment, especially for pediatric patients and patients who are unresponsive.

The proposed mechanism of action of percussion is the transmission of a wave of energy through the chest wall into the lung. This wave loosens secretions from the bronchial wall and moves them proximally, where ciliary motion and cough (or suction) can remove them. The combination of postural drainage and percussion has been shown to be effective in secretion removal.[66-68]

A handheld mechanical percussor can be used by a caregiver to minimize fatigue or may be used by the patient to self-administer percussion. The effectiveness of mechanical as opposed to manual percussion has been studied. Maxwell and Redmond[69] found mechanical percussion equivalent to manual percussion in effecting removal of secretions. Although there was a significant increase in pulmonary function with manual techniques, Pryor and colleagues[70,71] supported the use of mechanical percussion in patients, using the forced expiration technique. A study by Rossman and colleagues[72] was in disagreement, finding that mechanical percussion did not enhance postural drainage in secretion removal.

There are contraindications to percussion. If a patient's pulmonary status is of greater concern than the relative contraindications, a decision may be made to administer the treatment, with appropriate modifications.

Preparation for Percussion

- The only equipment required for manual percussion is the caregiver's cupped hands to deliver the force to mobilize secretions.
- For the adult and older pediatric population, electric or pneumatic percussors that mechanically simulate percussion are available. This enables a patient to apply

Fig. 21-3 Chest percussion.

self-percussion more effectively. Several models have variable frequencies of percussion, as well as different levels of intensity.

- Several devices, including padded rubber nipples, pediatric anesthesia masks, padded medicine cups, or the bell end of a stethoscope may be used to provide percussion to infants whose chest walls are too small to accommodate the size of an adult's hand.
- Placing the patient in appropriate PD positions (as the patient's condition allows) enhances the effect of percussion.
- A thin towel or hospital gown should cover the patient's skin where the percussion is to be applied. The force of percussion over bare skin may be uncomfortable; however, padding that is too thick absorbs the force of the percussion without benefit to the patient.
- Adjust the level of the bed so that the caregiver may use proper body mechanics during the treatment. The caregiver may become excessively fatigued or injured as a result of lengthy or numerous treatments if proper body mechanics are ignored.

Treatment with Percussion

- Position the hand in the shape of a cup with the fingers and thumb adducted. It is important to maintain this cupped position with the hands throughout the treatment, while letting the wrists, arms, and shoulders stay relaxed.
- The sound of percussion should be hollow as opposed to a slapping sound. If erythema occurs with percussion, it is usually a result of slapping or not trapping enough air between the hand and the chest wall.[73]
- The patient will better tolerate an even, steady rhythm. The rate of manual percussion delivered by caregivers can vary between 100 and 480 times per minute.[73]
- The force applied to the chest wall from each hand should be equal. If the nondominant hand is not able to keep up with the dominant hand, the rate should be slowed to match that of the slower hand. It might be helpful to start with the nondominant hand and let the dominant hand match the nondominant hand.[55] The force does not have to be excessive to be effective; the amount of force should be adapted to the patient's comfort.
- If the size of an infant does not allow use of a full hand, percussion may be done manually with four fingers cupped, three fingers with the middle finger "tented," or the thenar and hypothenar surfaces of the hand.[74]
- Hand position should be such that percussion does not occur over bony prominences of the patient. The spinous processes of the vertebrae, the spine of the scapula, and the clavicle should all be avoided. Percussion over the floating ribs should also be avoided because these ribs have only a single attachment.
- Percussion should not be performed over breast tissue. This will produce discomfort and diminish the effectiveness of the treatment. In the case of very large breasts, it may be necessary to move the breast out of the way with one hand (or ask the patient to do this) and percuss with the other hand.
- A patient may be taught to perform one-handed self-percussion to those areas that can be reached comfortably, either manually or with a mechanical percussor. This does, however, virtually preclude the treatment of the posterior lung segments.

Advantages and Disadvantages of Percussion

The addition of percussion to a PD treatment may enhance secretion clearance and shorten the treatment. Patients, especially young children and infants, often find the rhythm soothing and are relaxed and sedated by percussion.

Patients with chronic lung disease who have used PD and percussion for many years and have found it effective may be reluctant to try an alternative method of airway clearance. Acceptance of this method is dependent on the consistent availability of a family member or other caregiver to provide the treatment. Mechanical percussors allow a patient more independence or decrease fatigue of a caregiver, and they are especially useful in patients requiring ongoing treatment at home.

Percussion is not well tolerated by many patients postoperatively without adequate pain control. The force of percussion may also be contraindicated in patients with osteoporosis or coagulopathy. Percussion has been associated with a fall in oxygen saturation, which can be eliminated with concurrent thoracic expansion exercises and pauses for breathing control.[75]

Delivering percussion for extended periods on an ongoing basis can result in injury to the caregiver, whether a family member or a health care provider; repetitive motion injuries of the upper extremities may occur in long-term delivery of percussion for airway clearance.

The expense of a mechanical device for percussion is minimal compared with the ongoing cost of a caregiver to provide percussion and PD, either in the hospital setting or at home. In the case of young children or unresponsive patients, there are few choices for airway clearance. For other populations, however, a more independent method can prove to be more cost-effective if adequate adherence is achieved.

Vibration and Shaking

The techniques of vibration and shaking are on opposite ends of a spectrum. Vibration involves a gentle, high-frequency force, whereas shaking is more vigorous in nature. Vibration is delivered through a sustained co-contraction of the caregiver's upper extremities to produce a vibratory force while applying pressure to the chest wall over the involved lung segment. Shaking is similar in application to vibration, and is described as a bouncing maneuver, sometimes referred to as "rib springing," supplying a concurrent, compressive force to the chest wall. Like percussion, vibration and shaking are used in conjunction with PD positioning. Unlike percussion, they are performed only during the expiratory phase of breathing, starting with peak inspiration and continuing until the end of expiration. The compressive forces follow the movement of the chest wall. Both techniques require the assistance of a caregiver, but a mechanical vibrator may be used in place of manual vibration.

It is proposed that vibration and shaking enhance mucociliary transport from the periphery of the lung fields to the larger, central airways. Because the compressive force to the thorax is greater with shaking than vibration, it produces

increased chest wall displacement, and the stretch of the respiratory muscles may produce an increased inspiratory effort and lung volume.[76] The same relative contraindications for percussion should be observed for shaking, because it involves the application of force to the thorax.

Pavia[77] demonstrated a higher, though not statistically significant, rate of secretion clearance and sputum production with vibration. However, this study was conducted while subjects were in the upright position only, which does not replicate the use of vibration clinically. Many studies do not separate the effects of vibration from the components of PD and percussion because they are often used in conjunction. In fact, many studies describe the techniques of PD, percussion, and vibration or shaking as a single entity and refer to the treatment as chest physical therapy or postural drainage therapy. Mackenzie and colleagues[78] demonstrated significant improvement in total lung/thorax compliance after treatment with postural drainage, percussion, and vibration in mechanically ventilated patients. Feldman and colleagues[48] demonstrated improved ventilatory function by improved expiratory flow rates in patients receiving postural drainage, percussion, vibration, and directed coughing.

Preparation for Vibration and Shaking

- For manual techniques, the caregiver's hands are the only "equipment" required.
- Mechanical vibrators are available to administer the treatment and are useful for self-treatment by a patient or to reduce fatigue in the caregiver.
- For infants, a padded electric toothbrush may be used.[74]
- Place the patient in the appropriate PD position or modified position, as the patient's status allows.
- Place a thin towel or hospital gown over the patient's skin. The material should not be thick enough to absorb the effect of the vibration or shaking.
- Proper body position of the caregiver is important to deliver an effective treatment and to decrease caregiver fatigue.

Treatment with Vibration and Shaking

- For vibration, the hands may be placed side by side or on top of each other, as shown in Figure 21-4. As with shaking, the patient is instructed to take in a deep breath while in a proper PD position. A gentle but steady co-contraction of the upper extremities is performed to vibrate the chest wall, beginning at the peak of inspiration and following the movement of chest deflation. The frequency of manual vibration is between 12 and 20 Hz.[44,53]
- For shaking, with the patient in the appropriate PD position, place your hands over the lobe of the lung to be treated and instruct the patient to take in a deep breath. At the peak of inspiration, apply a slow (approximately 2 times per second), rhythmic bouncing pressure to the chest wall until the end of expiration. The hands follow the movement of the chest as the air is exhaled. The frequency of shaking is 2 Hz.[44,53]
- If the patient is mechanically ventilated, the previously described techniques needs to be coordinated with ventilator-controlled exhalation.
- If the patient has a rapid respiratory rate, either voluntary or ventilator-controlled, it may be necessary to apply vibration or shaking only during every other exhalation.
- A mobile chest wall is necessary to apply a compressive force without causing discomfort. If a patient has limited chest wall compliance, vibration will probably be better tolerated than shaking.
- Mechanical vibrators may be used by the unattended patient, although only limited attention can be paid to the posterior portions of the lungs.

Advantages and Disadvantages of Vibration and Shaking

The use of vibration and/or shaking in addition to PD may enhance the mobilization of secretions. Shaking or vibration may be better tolerated than percussion, especially in the post-surgical patient. Manual vibration and shaking allows the caregiver to assess the pattern and depth of respiration. The stretch on the muscles of respiration during expiration may encourage a deeper subsequent inspiration. A mechanical vibrator, more commonly used with pediatric patients, may be preferable for delivery of airway clearance in the long-term.

The patient cannot apply these techniques without assistance, except in a limited manner with a mechanical vibrator, so adherence and regular administration of vibration depends on caregiver availability.

The same contraindications for percussion apply because shaking and vibration involve compression to the thorax. The technique of vibration is less constrained by these contraindications than is shaking.

Manual Hyperinflation

The technique of manual hyperinflation was used more commonly in the past for patients requiring mechanical ventilation. However there is not enough evidence to promote the regular use of this technique that has many contraindications and that is not well known in the United States.[80] A brief description of the technique and its precautions follows. Two caregivers are needed to perform the technique with the patient placed in PD positions.[79] One caregiver uses a manual inflation bag to hyperinflate the lungs with a slow, deep inspiration and, after a short pause, provides a quick release to allow rapid exhalation. A second caregiver applies shaking or vibration at the beginning of exhalation to mobilize secretions. The technique is promoted to mobilize secretions and reinflate collapsed areas of the lung and is likened to simulating a cough—deep inspiration, pause, and forceful exhalation.

Clement[80] reported that this method of airway clearance enabled patients to be maintained on ventilators for long periods while retaining normal lung function. It was also demonstrated that the addition of positioning and vibrations enhanced the treatment of atelectasis by hyperinflation and suctioning.[81]

The risks to using manual hyperinflation are numerous. There are several adverse hemodynamic effects of this technique and hyperinflation has the potential to cause barotraumas.[61,80,83]

Active Cycle of Breathing Technique

In New Zealand, Thompson[85] described clearing bronchial secretions in patients with asthma by using a technique of forced expirations and diaphragmatic breathing. British physiotherapists modified the technique and further described it in the literature, first as the forced expiration technique (FET)[70] and later as the active cycle of breathing technique.[86]

As described by Webber and Pryor,[86] ACBT consists of repeated cycles of three ventilatory phases: breathing control, thoracic expansion exercises, and FET. Breathing control is described as gentle tidal volume breathing with relaxation of the upper chest and shoulders. The thoracic expansion phase consists of deep inspiration and may be accompanied by percussion or vibration performed by a caregiver or the patient. This phase helps to loosen secretions. The forced expiration technique involves one or two huffs, as when fogging a window or cleaning glasses with one's breath. Slow huffing from a middle lung volume (a medium-sized inspiration) down to a low lung volume moves secretions from the peripheral to the upper airways, whereas upper airway secretions may be cleared by a quicker huff from a high lung volume or deeper inspiration.[86]

The period of breathing control between the other phases is essential in order to prevent bronchospasm.[87] The period of thoracic expansion, which increases lung volume and promotes collateral ventilation, allows air to get behind secretions and assist in their mobilization.[88] Mead and colleagues[89] described the physiological theory of the equal pressure point (EPP), which is the basis for FET. EPP is the point in the airways where the pressure is equal to the pleural pressure. The forced expiratory maneuver produces compression of the airway peripherally to EPP. A huff from high lung volume causes compression within the trachea and bronchi, which moves secretions from these larger airways. A huff continued to low lung volume shifts the EPP more peripherally, which mobilizes more peripheral secretions.[84]

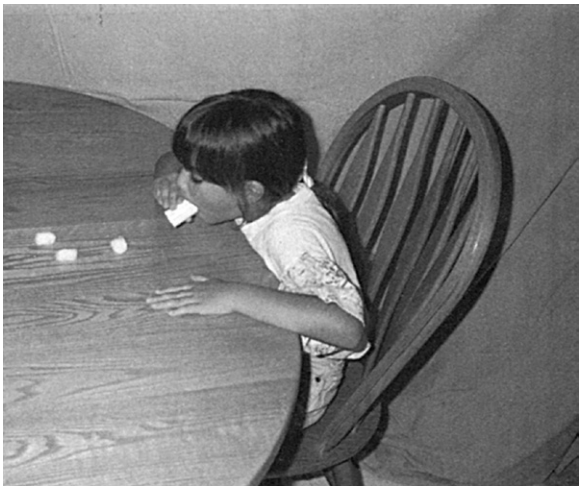

Fig. 21-5 Using a peak flow meter mouthpiece for huffing.

Because huffing has been shown to stabilize collapsible bronchial walls, it increases the expiratory flow in patients with obstruction without causing airway collapse.[90] Another benefit of this technique is its ability to maintain oxygen saturation. The decrease in oxygen saturation that has been demonstrated with postural drainage and percussion has been prevented by the use of ACBT.[75] Hassani and colleagues (1994)[91] showed that unproductive cough and FET resulted in the movement of secretions proximally from all regions of the lung in patients with mild hyposecretion. Therefore, FET may help to avoid prolonged retention of secretions, even in patients who produce little sputum.

ACBT may be performed in the sitting position but has been shown to be more effective in gravity-assisted positions; although horizontal side lying may have fewer adverse effects than the head-down position.[50,92] This method encourages active participation of the patient and has been shown to be as effective when performed by the patient alone or with the aid of a caregiver.[70] FET performed by patients independently has been shown to clear more sputum in a shorter amount of time than PD with self-percussion combined with percussion and shaking by a physical therapist.[70] Improvements in pulmonary function[93] and sputum clearance[94] have been demonstrated in patients with cystic fibrosis who incorporated FET into their postural drainage treatments. ACBT has been shown to be equally effective as positive expiratory pressure (PEP) in a year-long study.[50] Additionally, this method of airway clearance may be used with some children as young as 3 or 4 years of age. The sequence of ACBT is shown in Box 21-3.

Box 21-3 Active Cycle of Breathing Technique

- Breathing control
- Diaphragmatic breathing at normal tidal volume
- 3-4 thoracic expansion exercises
- Deep inhalation with relaxed exhalation at vital capacity, with or without chest percussion
- Breathing control
- 3-4 thoracic expansion exercises
- Breathing control
- Forced expiratory technique
- 1-2 huffs at middle to low lung volume
- Abdominal muscle contraction to produce forced exhalation
- Breathing control

Modified from Webber B, Pryor J: Physiotherapy skills: Techniques and adjuncts. In Webber B, Pryor J, editors: Physiotherapy for respiratory and cardiac problems, *Edinburgh, 1993, Churchill Livingstone.*

Preparation for Active Cycle of Breathing Technique

- The only equipment required for this manual technique is the patient's or caregiver's hands to percuss or shake/vibrate the chest wall during the thoracic expansion phase.
- Mechanical percussors or vibrators may be used during the thoracic expansion phase, either for self-percussion by the patient or for use by the caregiver.
- To teach the huffing maneuver (part of FET), it may be helpful to use a peak flow meter mouthpiece to maintain the mouth and glottis open (Figure 21-5). Young children may be taught games of huffing at cotton balls or tissue to improve the effect of the technique.[86] To help them focus on the expiratory maneuver, small children may also be taught to flap their arms to their lateral chest as they perform the huff, a technique referred to as the "chicken breath."[95]
- The patient should be in a PD position to stimulate drainage of a productive area of the lungs, although the entire treatment may also be performed in the upright sitting position. If PD positions are used, equipment for positioning will be required.
- Most patients tolerate treatment of two or three productive areas during one session.
- A minimum of 10 minutes in any productive position may be necessary to clear a patient with a moderate amount of secretions. Patients after surgery or with minimal secretions may not require as much time, and very ill patients may fatigue before optimal treatment is given.[86]

Treatment with Active Cycle of Breathing Technique

- During the breathing control phase, the patient is instructed to breathe in a relaxed manner using normal tidal volume. The upper chest and shoulders should remain relaxed, and the lower chest and abdomen should be active. The breathing control phase should last as long as is required for the patient to relax and prepare for the next phases, usually 5 to 10 seconds.
- The emphasis during the thoracic expansion phase is on inspiration. The patient is instructed to take in a deep breath to the inspiratory reserve volume; expiration is passive and relaxed. The caregiver or the patient may place a hand over the area of the thorax being treated to facilitate increased chest wall movement.
- Chest percussion, shaking, or vibration may be performed in combination with thoracic expansion as the patient exhales. For surgical patients or those with lung collapse, a breath hold or a sniff at the end of inspiration encourages collateral ventilation to redistribute air into collapsed segments and assist with reexpansion of the lung.
- The FET phase consists of huffing interspersed with breathing control. A huff is a rapid, forced exhalation without maximal effort. This maneuver is comparable to fogging a pair of eyeglasses with warm breath so they may be cleaned. Unlike a cough, in which the glottis is closed, a huff requires the glottis to remain open. In an effective huff, the muscles of the abdomen should contract to provide greater expiratory force. Other characteristics of effective versus ineffective huffing are shown in Box 21-4.
- Two different levels of huffing are characterized in FET. To mobilize secretions from peripheral airways, a huff after a medium-sized inspiration will be effective. This huff will be longer and quieter. To clear secretions that have reached the larger, proximal airways, a huff after a deep inspiration will be effective. This huff will be shorter and louder.
- The patient must pause for breathing control after one or two huffs. This will prevent any increase in airflow obstruction.
- ACBT should be adapted to the individual patient's needs. If secretions are tenacious, two cycles of the thoracic expansion phase may be necessary to loosen secretions before FET can follow. In a patient with bronchospasm or unstable airways, the breathing control phase may be as long as 10 to 20 seconds.[86] After surgery, the patient may be shown how to support the incision with her hands during FET to achieve sufficient expiratory force.
- When a huff from a medium-sized inspiration through complete expiration is nonproductive and dry sounding for two cycles in a row, the treatment may be concluded.[96]

Box 21-4 Effective Versus Ineffective Huffing

Effective Huffing	Ineffective Huffing
Mouth open, O-shaped to keep glottis open	Mouth half or almost closed
Forced expiration	Expiration always starting from high lung volume
From middle to low lung volume moves peripheral secretions	Abdominal muscles not used
From high to middle lung volume moves proximal secretions	Sound more like hissing or blowing
Muscles of the chest wall and abdomen contract	Mouth shaped as for "E" sound
Sound is like a sigh, but forced	Incorrect quality of expiration
Rate of expiratory flow varies with the following	Too vigorous or long, producing paroxysmal coughing
The individual	Too gentle
The disease	Too short
The degree of airflow obstruction	"Catching" or "grunting" at the back of the throat
Crackles heard if excess secretions are present	

From Partridge C, Pryor J, Webber B: Characteristics of the forced expiration technique, Physiotherapy *75:193-194, 1989.*

Advantages and Disadvantages of Active Cycle of Breathing

Incorporation of ACBT into a treatment of PD and percussion allows the patient to participate actively in secretion mobilization and offers the prospect of independently managing airway clearance. ACBT may be introduced at 3 or 4 years of age, with a child becoming independent in the technique at 8 to 10 years of age.

The technique may be adapted for patients with gastroesophageal reflux, bronchospasm, and an acute exacerbation of their pulmonary disease. A decrease in oxygen saturation caused by chest percussion may be avoided by using ACBT.[75] When the technique is performed independently, the cost of using ACBT for the long term is minimal.

In young children or extremely ill adults, it may be necessary for a caregiver to assist the patient with this technique. An assistant will also be required for the patient in whom percussion or shaking during the thoracic expansion phase increases the effectiveness of the treatment.

Autogenic Drainage

In Belgium in 1976, Chevaillier introduced autogenic drainage (AD), or self-drainage, for the treatment of asthmatic patients. He observed that during sleep, as well as while playing and laughing during the day, mucus was mobilized better than it was during PD and clapping. AD is an "antidyspnea" technique based on quiet expirations in a relaxed state and without use of postural drainage positions.[97]

Schoni[98] eloquently explained the physiology of AD's three phases, which use diaphragmatic breathing to mobilize secretions by varying expiratory airflow (Figure 21-6). The first phase starts with a normal inspiration and is followed by a breath hold to ensure equal filling of lung segments by collateral filling; then a deep exhalation is made into the expiratory reserve volume range. By lowering the middle tidal volume below the functional residual capacity level, secretions from peripheral lung regions are mobilized by the compression of peripheral alveolar ducts. Mid-expiratory tidal volume is lowered in the range of normal expiratory reserve volume. Chevaillier[97] named this phase the "unsticking" phase. The second phase of AD consists of tidal volume breathing

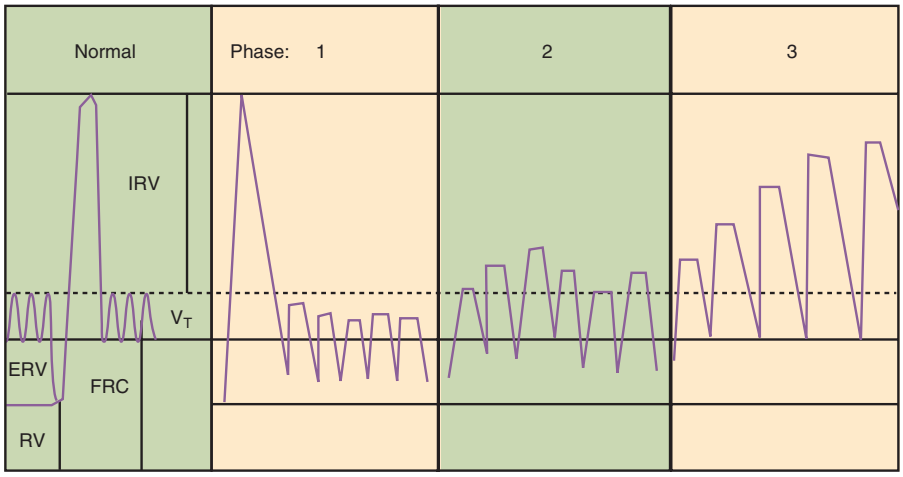

Fig. 21-6 Phases of autogenic drainage shown on a spirogram of a normal person. Phase 1: unstick; phase 2: collect; phase 3: evacuate. *VT,* Tidal volume; *ERV*, expiratory reserve volume; *RV*, reserve volume; *FRC*, functional residual capacity; IRV, inspiratory reserve volume; *IRV + VT + ERV,* vital capacity. *(From Schoni MH: Autogenic drainage: A modern approach to physiotherapy in cystic fibrosis,* Journal of the Royal Society of Medicine *82(Suppl 16):32-37, 1989.)*

gradually changing from the expiratory reserve volume into the inspiratory reserve volume range, which mobilizes secretions from the apical parts of the lungs. The velocity of the airflow must be adjusted at each level of inspiration so that the maximal expiratory airflow is reached without being high enough to cause collapse of the airways. Flow volume curves show that higher flows of longer duration can be achieved with AD,[99] demonstrating that mucus can be moved farther and at a faster rate. This is the "collecting" phase[97] The third phase consists of deeper inspiration into the inspiratory reserve volume, with huffing often used to help in evacuating the mobilized secretions. Control of airflow during this final phase is essential to the avoidance of uncontrolled, unproductive coughing. Chevaillier[97] named this phase the "evacuating" phase.

The Belgian method of AD has been modified by German practitioners using a combination of diaphragmatic and costosternal breathing in a treatment that is not separated into phases.[100] This modification resulted from the observation that many patients had difficulty breathing in the expiratory reserve volume range. The patient varies his or her mid-tidal volume in a passive exhalation followed by an active exhalation through pursed lips or through the nose. The German method of airway clearance includes other maneuvers in conjunction with AD, including inhalation therapy, FET, chest wall exercises, and physical activity.

Assisted AD has been described for use in treating infants and patients who are unable to participate.[50] Gentle manual pressure is applied to the chest during inspiration in an effort to vary the volume of breath inhaled; no pressure is applied during exhalation. This technique is often applied while gently bouncing the infant on a therapy ball.

AD has been compared with positive expiratory pressure and PD with percussion and/or vibration. It was reported that more sputum was produced with AD in patients with hyperreactive airways.[101] In a 2-year crossover trial, AD was found to be as effective as conventional CPT among patients with cystic fibrosis for improving pulmonary function.[102] However, patients exhibited a strong preference for AD over CPT, increasing the likelihood of adherence. Miller[103] showed greater clearance of inhaled radioisotopes with AD than with ACBT, with no significant differences in sputum weight, spirometry, or transcutaneous oxygen saturation. Giles[104] also studied oxygen saturation in AD and found greater levels with AD than with PD with percussion; there was also greater sputum evacuated with AD.

Preparation for Autogenic Drainage

- No equipment is needed for a patient to perform the technique of AD. The patient must possess good proprioceptive, tactile, and auditory perception of the mucus moving—this feedback makes it possible to adjust the technique of AD.
- To teach this method to a patient, a caregiver needs keen tactile and auditory senses to coach a patient to move between the phases by listening to and palpating the chest to identify the location and the quality of the secretions.
- The patient should be seated upright in a chair with a back for support. The surroundings should be devoid of distractions, allowing the patient to concentrate on the breathing technique.
- The upper airways (nose and throat) should be cleared of secretions by huffing or blowing the nose.
- The caregiver should be seated to the side and slightly behind the patient, close enough to hear the patient's breathing. One hand should be placed to feel the work of the abdominal muscles and the other hand placed on the upper chest (Figure 21-7).

Treatment with Autogenic Drainage

- In all phases, inhalation should be done slowly, through the nose if possible, using the diaphragm or lower chest. A 2- to 3-second breath hold should follow, allowing collateral ventilation to get air behind the secretions.
- Exhalation should occur actively with the mouth and glottis open, listening for the movement of mucus while avoiding a wheeze. The vibrations of the mucus may also be felt with the hand placed on the upper chest. The frequency of these vibrations reveals their location. High frequencies mean that the secretions are located in the small airways; low frequencies mean that the secretions have moved to the large airways.[97]
- In practice, inspiration is followed by a deep expiration into the expiratory reserve volume. The patient attempts to exhale as far into the expiratory reserve volume as possible, contracting the abdominal muscles to achieve this.

This low lung volume breathing continues until the mucus is loosened and starts to move into the larger airways.

- The second phase collects the mucus in the middle airways by increasing the lung volume to a greater level than in the initial phase. Tidal volume breathing is then changed gradually from expiratory reserve volume toward the inspiratory reserve volume range[98] so that the lungs are expanded more with each inspiration. The patient increases both inspiration and expiration to move a greater volume of air. This low to middle lung volume breathing continues until the sound of the mucus decreases, signaling its movement into the central airways to be evacuated.
- In the evacuation phase, the patient increases inspiration into the inspiratory reserve volume range. This middle-to-high lung volume breathing continues until the secretions are in the trachea and are ready to be expectorated. The collected mucus can be evacuated by a stronger expiration or a high-volume huff. Nonproductive coughing should be avoided, since it may result in collapse of airways. See Figure 21-6 for a diagram of the three phases of AD.
- Compression of the airways should be avoided. If wheezing is heard, the expiratory flow rate must be decreased. Beginners may have to use pursed lips to avoid airway compression.[97] Instructing the patient to roll the tongue (if possible) may assist in controlling the expiratory flow rate.
- In the simplified German procedure, the patient begins by varying the mid-tidal volume without excessive effort. After a passive but rapid expiration, an actively performed expiration follows, achieving exhalation to a low expiratory reserve volume (Figure 21-8).
- The duration of each phase of AD depends on the location of the secretions. The duration of a session depends on the amount and viscosity of the secretions. An average treatment will be 30 to 45 minutes in length. However, a patient who is experienced in performing AD will clear secretions in a shorter amount of time than a beginner.

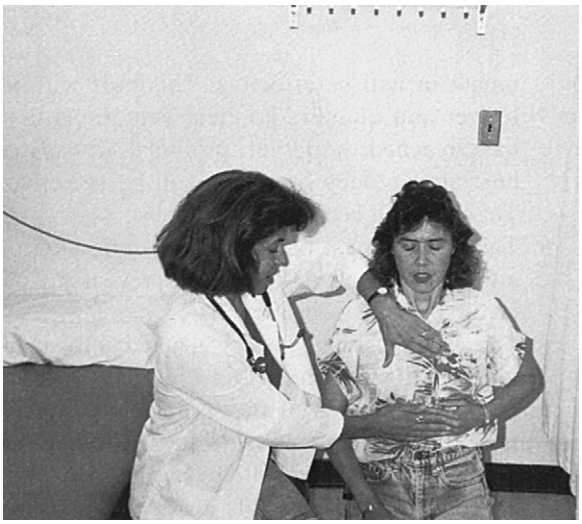

Fig. 21-7 Autogenic drainage.

Advantages and Disadvantages of Autogenic Drainage

When learned effectively, AD may be performed independently by patients over 12 years of age and requires no additional equipment. It is ideal for the adolescent or adult who prefers an independent method. Because it does not require the use of PD positions, it is appropriate for patients with gastroesophageal reflux. It is also recommended for use in patients with airway hyperreactivity.[105] The technique of AD requires attention to airflow and volume and to cough suppression until secretions are mobilized; this is a key factor to success.[106] Learning AD requires tactile and auditory feedback and continued modifications of the patient's technique, at least initially, to achieve a good result.

Although widely used in Europe, the use of AD in the United States is limited by the lack of trained caregivers but is growing in popularity. To learn this technique, patients must demonstrate good self-discipline and concentration. This method takes more practice than others. AD is not the treatment of choice for a patient who is unmotivated or uncooperative, and a study of flow volume curves suggests that AD would not be appropriate for small children even if they were cooperative.[99] A patient must also be available for periodic reevaluation and refinement of the technique. During early hospitalization for patients admitted with an acute exacerbation is a challenging time in terms of learning AD. Patients who are skilled in the technique may choose a more passive

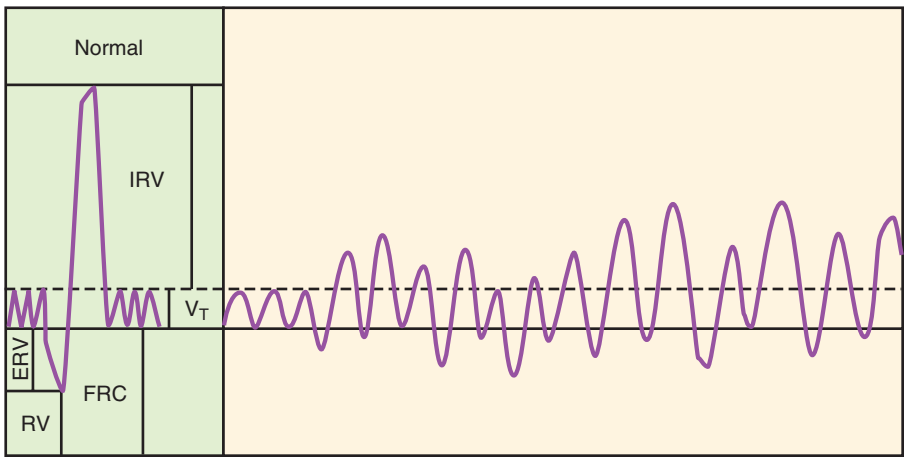

Fig. 21-8 Autogenic drainage: German method. Autogenic drainage shown on a spirogram of a normal person. form (one consuming less energy) of airway clearance at such times until they return to their baseline pulmonary status.

Positive Expiratory Pressure

The development and use of positive expiratory pressure (PEP) breathing came about in the 1980s in Denmark and is now widely used in the United States. Although high- or low-pressure PEP is prescribed worldwide, only low-pressure PEP is approved in the United States. Several devices deliver PEP in either oscillatory or smooth flow methods. Oscillatory PEP provides (1) positive expiratory pressure, (2) oscillation of the airways and (3) accelerated expiratory flow rates to loosen secretions and move them centrally.

Positive expiratory pressure includes a one-way breathing valve and an adjustable level of expiratory resistance that creates a back pressure to stent the airways open during exhalation. It is theorized that PEP breathing reinflates collapsed alveoli by allowing air to be redistributed through collateral channels—the pores of Kohn and the Lambert canals—allowing pressure to build up distal to the obstruction and promoting the movement of secretions toward the larger airways.[107,108] In addition, supplemental oxygen and nebulized medication can be effectively delivered during treatment with PEP.[109] A manometer in the circuit determines and monitors the pressure generated by the patient. In low-pressure PEP breathing, the resistance is regulated to achieve 10 to 20 cm of H_2O during slightly active expiration. The appropriate resistor is one that produces a flow volume curve demonstrating a maximal forced vital capacity, good plateau, and no curvilinearity.[88] Low-pressure PEP breathing is used more often than high-pressure PEP, as it offers equal effectiveness at a lower presumed risk for pneumothorax.

High-pressure PEP uses the same principles but at much higher levels of pressure (50 to 120 cm H_2O). Inspiration is performed to total lung capacity; this is followed by a forced expiratory maneuver against the PEP mask, which is connected to a spirometer. For high-pressure PEP therapy, the Pep/Rmt (Astra Tech Healthcare, Molndal, Sweden) mask is used. The equipment consists of a ventilation mask, a one-way valve, and various resistors. Spirometry is used to determine the appropriate resistance for each individual patient, but generally, a 1½-mm resistor is used for infants, a resistor of up to 2½ to 3 mm for older children and adults, and 3½ mm for adults with COPD.

Airway stability is maintained with PEP breathing, which results in improved ventilation and gas exchange as well as airway clearance.[110] PEP breathing has been shown to benefit patients at risk for postoperative atelectasis but has gained wider practice in the area of airway clearance, especially in patients with cystic fibrosis.[95] Numerous studies have demonstrated the effectiveness of PEP breathing. Tyrrell[111] has shown the PEP mask to be as effective as conventional physiotherapy over a 1-month period, with no difference in pulmonary function. Falk[112,113] demonstrated increased sputum production and clearance with the use of PEP over FET alone. However, Hofmeyer[114] found FET produced a greater quantity of sputum without the addition of PEP. Oberwaldner[115] evaluated lung function during 10 months of regular treatments with high-pressure PEP and found reduced pulmonary hyperinflation and airway instability and higher flow rates with PEP than with conventional CPT. These improvements in lung function deteriorated only 2 months after a return to conventional CPT. A study by Pfleger and colleagues[105] compared PEP with AD and found that PEP cleared higher amounts of sputum and demonstrated increased lung function. Finally, decreased duration of hospitalization has been cited as a benefit of using PEP breathing for airway clearance.[116]

Two of the most commonly used devices in the United States are the Acapella (Figure 21-9, *A* and *B*) and TheraPEP (DHD Healthcare, Wampsville, New York) (Figure 21-9, *C*). The TheraPEP device consists of a mouthpiece and an expiratory resistor that can accommodate many levels of expiratory flow. It comes with a detachable pressure monitoring port and indicator to show 10 to 20 cm of H_2O. The TheraPEP can accommodate a mask of different sizes. The Acapella has performance characteristics similar to those of the Flutter.[117] It comes in several models: green for patients who can maintain an expiratory flow of 15 L/min or more, blue for patients whose expiratory flow rate is less than 15 L/min, and the Acapella Choice. The Acapella Choice disassembles more easily than the original models for ease of cleaning (Figure 21-9, *D*). The Acapella consists of a mouthpiece attached to the body of the unit that uses a counterweighted plug and magnet to create airflow oscillation and a dial for expiratory resistance at the other end.

A device developed in Switzerland to deliver high-frequency oscillation PEP breathing and decrease the collapsibility of the airways is the Flutter VRP1 (VarioRaw, Aubonne, Switzerland). Axcan Pharma (Birmingham, Alabama) markets the Flutter VRP1 valve in the United States, the first oscillatory PEP device available in this country. This pipelike device consists of a steel ball, a plastic cone, a perforated cover, and a mouthpiece. Exhaled air causes the steel ball to roll up and down the cone causing airflow vibration. The PEP maintained by the Flutter (5 to 35 cm of H_2O) prevents dynamic airway compression and improves airflow acceleration.[118] The full effects of the vibration induced by the Flutter (6 to 20 Hz) may be received by changing the angle of the device. Movement of the Flutter upward increases the pressure and frequency while movement of the device downward results in lower pressure and frequency.[118] The vibration of the chest can be palpated to provide feedback as to the optimal angle of the device. The recommended procedure for use of the Flutter is shown in Box 21-5.

This early form of oscillatory PEP has been well studied. Konstan and colleagues[119] compared the amount of sputum expectorated with the Flutter with that expectorated with vigorous voluntary cough, with PD, with percussion, and with vibration. Subjects with cystic fibrosis produced more than three times the amount of sputum when using the Flutter than when using the other two methods, and no adverse effects were reported. The improvement in expectoration is based on the increase in airway diameter and the improvement in airflow acceleration.[120] Ambrosino[121] reported success in the treatment of patients with chronic obstructive pulmonary disease by using the device. When compared with AD, the Flutter was found to produce equal amounts of expectorated mucus.[122] The advantages of the Flutter device lie in its portability and the ease with which its use can be learned. Increased independence and better compliance have also been cited as advantages of this technique. However, frequent assessment of patient technique and appropriate level of resistance is recommended.[87]

Fig. 21-9 A-D, Positive expiratory pressure devices: TheraPEP and Acapella.

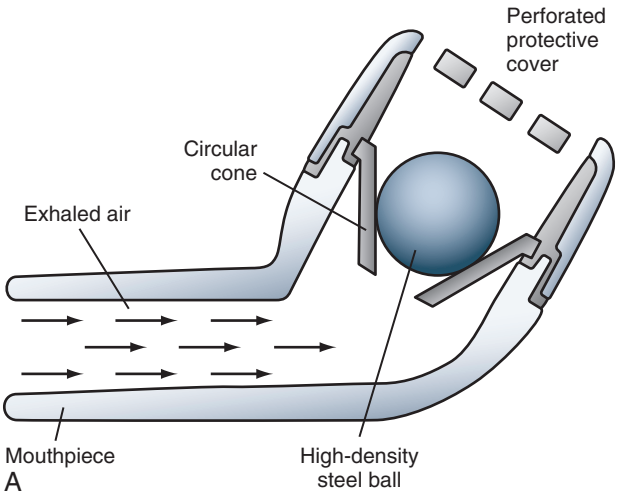
Another device that provides PEP with oscillations is the Quake (Thayer Medical, Tucson, Arizona), which consists of a mouthpiece integrated into the outer housing and a crank that interrupts airflow and allows the user to manually adjust the frequency of the vibration. This allows a wider range of oscillation frequencies than other devices, such as the Flutter. When using the Quake, it is recommended to rotate the handle at a steady and comfortable rate of about 1 to 2 rotations per second during exhalation. At the end of exhalation, the user may either remove the Quake from the mouth to inhale or continue to rotate the handle and slowly begin to breathe in deeply, then repeat the exhalation cycle. Both the inhalation and exhalation rate and the speed of the handle rotation may be varied to produce the ideal level of vibration in the lungs. This device can be used with a mouthpiece or a facemask, whereas the Flutter can only be used with a mouthpiece. The disadvantage of the Quake is that it requires both hands—one to hold the device and one to turn the crank. The other devices can be used with only one hand.

Preparation for Positive Expiratory Pressure

- Several different devices are available to deliver positive expiratory pressure with a steady level of resistance or oscillatory flow. The practitioner should be familiar with the specific device being used to provide adequate instructions to the patient and family.
- A mask can be used in place of the mouthpiece on most PEP devices (for adults and children) and is preferred by some practitioners. The rationale for using a mask is that the lung volumes should be increased during the entire phase of exhalation through the PEP device, which is more difficult to achieve when using a mouthpiece because the patient may open the mouth around the mouthpiece at the

Box 21-5 Proper Patient Technique for Using Flutter*

- Gather supplies, relax, and assume proper posture and position. Begin stage 1, mucus loosening and mucus mobilization.
- Slowly inhale beyond a normal breath, but do not fill lungs completely.
- Hold breath for 2 to 3 seconds.
- Place Flutter in mouth, adjust tilt, and keep cheeks stiff.
- Exhale through Flutter at a reasonably fast but not too forceful speed.
- Exhale beyond a normal breath, but do not empty lungs completely.
- Attempt to suppress cough.
- Repeat steps 2 through 7 for 5 to 10 breaths. Begin stage 2, mucus elimination.
- Slowly inhale, filling lungs completely.
- Hold breath for 2 to 3 seconds.
- Place Flutter in mouth, adjust tilt, and keep cheeks stiff.
- Exhale forcefully through Flutter as completely as possible.
- Repeat steps 9 through 12 for 1 to 2 breaths.
- Initiate cough (or "huff" maneuver). Return to step 2 and repeat full sequence until lungs are clear or therapy is over.
- Additional sessions may be added if necessary.
- Clean Flutter and store in clean, dry location.



*For more information about Flutter, contact Axcan Pharma, 22 Inverness Center Parkway, Birmingham, AL 35242; phone 205-991-8085

end of expiration causing a fall in lung volumes.[123] The use of nose clips is recommended when using a mouthpiece.

- A manometer can be placed proximal to the resistor in the initial stages of instruction in the use of PEP in most devices. First, the manometer helps to determine and monitor the appropriate level of resistance needed for the patient to achieve 10 to 20 cm of H_2O throughout exhalation. Second, the visual display of the manometer serves as feedback to assist the patient in mastering the technique.[95]
- Aerosol medication delivered by nebulizer may be placed inline in many devices to be delivered simultaneously with PEP for airway clearance, improving the deposition of medication.[109,124] If aerosolized medication is to be used simultaneously, the patient should be instructed in how to stop the flow of the aerosol when the mask or mouthpiece is removed during the PEP treatment session for coughing. Supplemental oxygen may also be placed inline in many devices for patients who require this.
- Bubble PEP is a variation of positive expiratory pressure that is particularly useful when treating children. Equipment needed includes a length of tubing 15 to 18 inches long and a plastic container filled with a column of water 13 cm high (this will generate a positive expiratory pressure of around 20 cm of H_2O). A few drops of food coloring and/or 3 to 6 squirts of liquid detergent or bubble liquid may be added to make the treatment more entertaining. Place the tubing at the very bottom of the container—it is important that the tube remain at the base of the column of water to generate the required expiratory pressure. If detergent or bubbles are included, place the container in a large bowl or on a towel to contain the overflow.[123]
- All PEP devices should be cleaned regularly with hot, soapy water; many can be cleaned in a dishwasher. In the hospital, the equipment should be sterilized according to infection control recommendations.

Treatment with Positive Expiratory Pressure

- To determine the correct level of resistance for PEP, the patient inhales using tidal volume and exhales actively into the mask or mouthpiece. The resistor valve is adjusted while the level of PEP is monitored on the manometer. The resistance is gradually decreased until the PEP level supplying 10 to 20 cm of water pressure has been identified.[113] Mahlmeister[95] reports most patients achieve this pressure range with flow resistors of 2.5 to 4.0 mm in diameter. Selection of the proper resistor produces the desired inspiratory to expiratory ratio of 1:3 or 1:4.[95] The use of too great a resistance will create an increased respiratory rate or too low a pressure, whereas too small a resistor will create a slow respiratory rate or too high a pressure.[125]
- For high-pressure PEP, appropriate resistance is determined by connecting the outlet of the PEP mask to a spirometer. The resistor producing the highest forced vital capacity through the PEP mask is selected for continued use.[115] The patient breathes in and out through the mask at tidal volume for 6 to 10 breaths; then inspiration is done to total lung capacity and a forced expiratory maneuver is performed against the PEP mask. This is repeated until all the mucus is mobilized.[125]
- For a PEP therapy treatment, the patient should be seated upright with elbows resting on a table. Use of a mask may require securing the device with both hands for a tight seal. If needed, the patient may be in a reclining position for all PEP devices except the Flutter, which is position dependent. To use the Flutter valve, the patient should be seated upright (Figure 21-10).
- The patient should be instructed to breathe into the mask or mouthpiece to tidal volume, using the lower chest and abdomen, and pause for an inspiratory hold for 2 to 3 seconds to equalize ventilation before exhaling.[123] Exhalation into the mask or mouthpiece should be slightly active but not forced. The patient continues breathing into the mask or mouthpiece for 10 to 15 breaths, using a normal respiratory rate. After a series of 10 to 15 breaths, the mask or mouthpiece is removed from the face and the patient performs a series of huffs and/or coughing to expectorate any mucus that has been mobilized.[126] It may be necessary to pause every 5 to 10 exhalations before resuming the session.[118]
- The series of PEP breaths followed by huffs should be repeated about four to six times. The total treatment lasts about 15 to 20 minutes and should be performed twice during the day or as needed. The frequency and duration of the treatment must be individualized for each patient. During periods of pulmonary exacerbation, patients are encouraged to increase the frequency of PEP treatments rather than extend the length of individual sessions.[95]

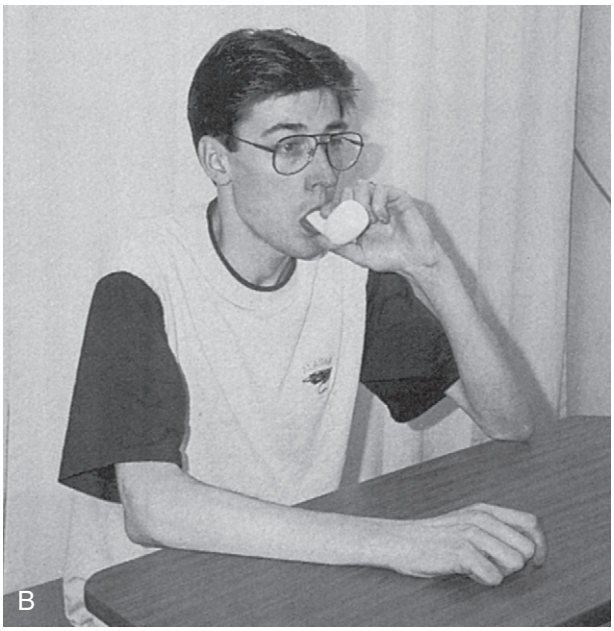


Fig. 21-10 Use of Flutter valve.

Some patients have a tendency to hyperventilate and become dizzy; an inspiratory pause will prevent this.[123]

- Initially, the patient and caregiver monitor the effort by means of the manometer, ensuring that a pressure of 10 to 20 cm of H_2O is achieved throughout exhalation (this is not possible with the Flutter). After the technique is mastered with the appropriate resistor, the manometer may be removed from the system. The appropriate resistance should be rechecked periodically during clinical visits or periods of hospitalization.
- For Bubble PEP, the patient is instructed to blow through the tube with enough force to cause the bubbles to rise up to the top of the container. After a number of breaths, the patient is asked to do huffing or coughing before resuming the treatment. The therapist may prescribe the height of the column of water to alter the pressure, the number of breaths taken, and the huffs or coughs needed to tailor the treatment to each patient.[123]

Advantages and Disadvantages of Positive Expiratory Pressure

PEP therapy does not possess some of the limitations of conventional PD and percussion for secretion clearance and is therefore applicable to a wider patient population. It is relatively easy to learn in one or two sessions and may be applied equally to the pediatric (children over 4 years of age) and adult populations. PEP is appropriate for use during acute episodes in hospitalized patients, as well as for long-term use for chronic pulmonary conditions. The expense of the equipment is minimal, and once the patient is competent in the technique, it provides independence (except for small children). All PEP devices are quite portable, making airway clearance easier to perform during travel or when away from home during the day. PEP devices can be used in any position except the Flutter, which is position dependent. Some musical instruments can provide a form of PEP therapy because of the manner in which they are played, with an inspiratory pause and resisted exhalation.[123] These instruments include the clarinet, oboe, bassoon, French horn, trumpet, flute, and voice. Low-pressure PEP is more commonly used in North America because it is believed to be not only as effective as high-pressure PEP, but also easier and safer to use and monitor. In those patients in whom PEP is an appropriate airway clearance technique, a high degree of acceptance has been shown.[112,117,127] This may translate into better adherence in the long term.

A decision to use PEP should be carefully evaluated in cases of acute sinusitis, ear infection, epistaxis, and recent oral or facial surgery or injury.[95] For PEP therapy to be effective, a patient should be able to cooperate and actively participate with the treatment. Although rare, pneumothorax has been reported with high-pressure PEP.[115]

Precautions for Positive Expiratory Pressure

The use of PEP for airway clearance carries an increased risk for pneumothorax.[115] Bronchodilator premedication should be considered when applying PEP in patients who show clinical or physiological signs of airway hyperreactivity.[105]

The increased airflow produced by the huff cough, as in the ACBT, may aggravate bronchospasm.[90] Additionally, Hietpas[90] cautions that the movement of secretions into the larger airways by the huff cough may precipitate spontaneous explosive coughing.

High-Frequency Chest Wall Oscillation

Efforts aimed at mucus clearance by creating a differential airflow rate led to the development of a high-frequency chest wall oscillation (HFCWO) system. Hansen and Warwick[128] designed a large-volume, variable-frequency air-pulse delivery system that can be used by patients with obstructive lung disease to promote mucus clearance.

High-frequency chest wall oscillation, also referred to as high-frequency chest compression, consists of an inflatable vest linked to an air-pulse generator. Although the sensation of the device is somewhat akin to mechanical percussion, it differs significantly in its mechanism of action. HFCWO works by differential airflow (i.e., the expiratory flow rate is higher than the inspiratory flow rate), allowing the mucus to be transported from the periphery to the central airways for

Fig. 21-11 SmartVest® high-frequency chest wall oscillation (HFCWO) system for airway clearance. *(Courtesy Electromed, Inc. New Prague, Minn.)*

expectoration (Figure 21-11). HFCWO has also been shown to decrease the viscosity of mucus, making it easier to mobilize.

The first HFCWO system developed was the Vest (Hill ROM, St. Paul, Minnesota), consisting of an inflatable fitted vest connected to an air-pulse generator by flexible tubing. This device provides oscillation of the entire thoracic cavity at varying frequencies (5 to 25 Hz). The lung volume expired tends to increase with lower frequencies (less than 10 to 12 Hz), whereas the flow rates tend to increase with higher frequencies (12 to 20 Hz). Continuous aerosolized medication or saline administered concurrently may assist with secretion mobilization.[129] The original, larger unit of the Vest is best used in a clinical setting; it can be placed on a wheeled stand for easy mobility. Newer models weigh as little as 17 pounds, providing more mobility than earlier models; these units fit under an airplane seat and are easier to manage during travel.

Two probable mechanisms of action have been offered to explain the significant increase in sputum mobilization that occurs with HFCWO.[130] One mechanism proposes that oscillatory airflow leads to changes in the consistency of mucus, which results in increased mobilization of secretions. Considerable decreases in mucus viscoelasticity were observed during administration of oscillatory airflow.[131] Another mechanism proposes that the difference between the expiratory and inspiratory velocities produces shear forces strong enough to move mucus. Chang and colleagues[132] demonstrated that nonsymmetrical airflow (peak expiratory flow rates greater than inspiratory flow rates) could be an important factor leading to increases in mucus clearance during the administration of HFCWO. The chest compressions produce a transient flow pulse similar to that observed during coughing, and by using the flows with the greatest rates and volumes, sufficient force is obtained to move mucus in the airway.[133]

HFCWO has been shown to increase mucus clearance rates in animal models, with the most pronounced effect in the 11 to 15 Hz frequency range.[134] Radford and colleagues[68] used bronchoscopy to demonstrate a marked increase in the speed and flow of mucus produced by oscillations at even higher frequencies than those attainable by manual percussion. Results of short-term use of the Vest have been mixed, but they show HFCWO to be at least as effective as conventional CPT. Robinson[135] showed no significant improvement or deterioration of lung function with its use. In additional studies, Kluft and Faverio[136,137] demonstrated increased wet and dry sputum weights using HFCWO as opposed to manual CPT, and Arens (1993)[138] showed similar dry sputum weight but an increase in wet sputum weight and a significant improvement in pulmonary function with HFCWO as opposed to conventional CPT. One 2-year study showed improved lung function and greater sputum production in subjects with cystic fibrosis with the use of HFCWO rather than manual CPT.[133] No adverse effects were observed with long-term use of the Vest. Hospitalized patients with acute exacerbation of lung disease have been shown to tolerate HFCWO well,[139] and the safety and tolerance of this method have been demonstrated in long-term mechanically ventilated patients.[140]

The fit of the vest requires attention because nausea, abdominal and chest wall discomfort, and complaints of urinary urgency may occur with an ill-fitting vest.[106] HFCWO systems are much more costly than other mechanical aids for airway clearance; thus expense may be a deterrent for some potential users. However, in a study of HFCWO users insured by Blue Cross and Blue Shield, a 49% reduction in health care costs was shown in the year following initial use of the vest as compared with the year before HFCWO use.[141] The impact of the use of the HFCWO device in a hospital department demonstrated a substantial savings resulting from therapy self-administration by patients.[142]

Preparation for High-Frequency Chest Wall Oscillation

- In order to provide adequate instructions to the patient and family, the practitioner should be familiar with the specific HFCWO device being used. The various models of inflatable vests are constructed to fit the thorax differently and are available in different sizes (from toddler to large adult). A full vest model should extend to the top of the thigh when the patient is sitting upright. A shorter vest (chest vest) is also available, resulting in less pressure to the abdominal area and less gastric discomfort. The vest should fit properly, but breathing should not feel restricted while the vest is deflated. A single layer of clothing or patient gown should be worn under the vest. For the hospital setting, adjustable vests are available for use with multiple patients (following appropriate infection control guidelines for cleaning). For home use, each patient should be fitted for his or her own vest.
- Simultaneous use of aerosolized medication is recommended for use throughout the treatment. This humidifies the air to counteract the drying effect of the increased airflow.

Treatment with High-Frequency Chest Wall Oscillation

- The patient should be seated upright in a chair, and the tubing should be securely connected to the air pulse generator. Start the aerosol therapy before turning on the HFCWO system.
- The pressure control setting should be adjusted according to patient comfort, opting for the highest pressure that is well tolerated.

- The treatment should progress through different frequencies, from low (7 to 10 Hz) to medium (10 to 14 Hz) and then to high (14 to 20 Hz), to achieve both higher flow rates and increased lung volume. Warwick[133] reported that the frequencies associated with the highest flow rates were usually greater than 13 Hz, whereas those associated with the largest volume were usually less than 10 Hz. The average length of time spent at each frequency is 10 minutes, but this will vary according to patient tolerance, amount and consistency of secretions, and the acuity of the patient's illness. After treatment at each frequency for the prescribed length of time, the patient should be instructed to huff or cough to clear loosened secretions.
- HFCWO has also been used with patients requiring long-term mechanical ventilation. Whitman and colleagues[140] found use of HFCWO to be safe and effective and concluded that it resulted in time savings over conventional PD and percussion.
- Patients with long-term central intravenous access such as a Porta-Cath or Hickman are able to use HFCWO with sufficient padding (such as a foam doughnut pillow) to relieve pressure around the access site.

Advantages and Disadvantages of High-Frequency Chest Wall Oscillation

This method of airway clearance allows independence and is easily learned in a short period. HFCWO can accommodate children as young as 2 years of age, and a vest may be custom-made for very large or obese adults. HFCWO is appropriate for those patients in whom PD positions are contraindicated, and it has also been used successfully in reclining patients who are unable to tolerate the upright sitting position. Use of HFCWO may result in time savings at home, as well as in a hospital or long-term care facility, because nebulized medications may be administered concurrently with the airway clearance treatment and all lobes of the lungs are treated simultaneously. The amount of time for patient contact required for a hospital caregiver is much less with this method than with conventional PD and percussion. This efficiency would also benefit families in which there is more than one member requiring airway clearance (such as siblings with cystic fibrosis). In those patients for whom it is appropriate (and reimbursable), HFCWO is an effective method of airway clearance. It provides independence for long-term use at home, as well as for acute exacerbations in the hospital.

A disadvantage of HFCWO as a method of airway clearance is the cost of the equipment. A study by Ohnsorg,[141] however, demonstrated a decline in total health care costs for the year after HFCWO was put into use by 11 patients. A study of the impact of the device in a hospital setting[142] reported a substantial savings as a result of therapy self-administration. Replacement of the equipment should not be a factor, because a lifetime warranty is available for the devices.

Intrapulmonary Percussive Ventilation

Intrapulmonary percussive ventilation (IPV) is an airway clearance method that simultaneously delivers intrathoracic percussion and aerosolized solution for bronchodilation.[143] An apparatus known as the Phasitron is the functional component in the intrapulmonary percussive ventilator. The Phasitron provides high-frequency impulses during inspiration, while positive expiratory pressure is maintained throughout passive exhalation. The pressure generated is between 10 and 30 cm of H_2O.

The intrapulmonary percussive ventilation device made by Percussionaire (Sandpoint, Idaho) works in a manner similar to that of the HFCWO except that a pneumatic device delivers the oscillation internally instead of externally. A mouthpiece delivers high flow rate mini-bursts of gases into the lungs at rates of 100 to 240 cycles per minute. Continuous pressure in the airways is maintained while pulsatile, percussive intraairway pressure rises and dilates the airways, enhancing intrabronchial secretion mobilization. This device provides percussion at 6 to 14 Hz, with a positive expiratory pressure of 10 to 20 cm of water pressure and simultaneous delivery of an aerosol. The aerosol mist within the lungs reduces adhesive forces of retained secretions.

It is theorized that changes in the frequency and pressure of the airflow delivered through the IPV device assist in stabilizing the airways and decrease the viscosity of the secretions; this results in increased sputum mobilization.[106] IPV has been found to be as effective as postural drainage and percussion in improving pulmonary function and sputum expectoration.[144] Marks[145] found no difference between IPV and Flutter in number of hospital or antibiotic days required to treat an exacerbation and reported good acceptance of this method of airway clearance by patients. IPV may be beneficial for patients with asthma and neuromuscular disease, as well as those with cystic fibrosis.[146,147]

Treatment with Intrapulmonary Percussive Ventilation

- One IPV model meant for institutional use is the Percussionaire Model IPV-1, which is powered by 50 psi of gas. Percussive rates or frequencies range from less than 100 to greater than 225 cycles per minute. This model has the capability to be used with an endotracheal tube and can be installed on a wheeled stand for greater mobility. Use of the hospital unit must be supervised by a respiratory care practitioner.
- The Percussionaire Impulsator is self-contained for home use and powered by a compressor, but it may also be used in a clinical situation. It generates 40-psi source pressure, which provides for efficient delivery of impulses and aerosolized medication. Condensation is minimal compared with institutional models, so maintenance on the unit is low. The patient and caregivers must receive training to use the home unit.
- A new model by Percussionaire, the HC Impulsator, is a portable IPV device that weighs less than 15 pounds, allowing patients to use it when traveling.
- Aerosolized medication in saline solution is delivered via the nebulizer component of the IPV unit.
- Treatment with IPV is titrated for patient comfort and visible thoracic movement. A thumb button is held for 5- to 10-second intervals to initiate the percussive impulses and released after an interval to allow exhalation. After each deep exhalation, the percussive interval starts again. When the patient needs to cough or expectorate, the thumb button is released until coughing is completed or secretions are cleared.

- The clinician or the patient at home programs each percussive interval. An average treatment lasts about 20 minutes.

Advantages and Disadvantages of Intrapulmonary Percussive Ventilation

IPV is available for home use and can be continued during hospitalization. IPV allows for greater independence for adolescents and adults with long-term need for airway clearance. Homnick[143] reported that three-fourths of the patients using IPV in one study estimated increased sputum production, and satisfaction was high for comfort and independence. IPV provides a safe and effective form of airway clearance.[148]

IPV is neither appropriate for nor tolerated by young children. In other patients, a feeling of claustrophobia or chest fullness may be a factor in deciding whether to use IPV.[106] The IPV device is more expensive than a PEP device but less costly than a unit for HFCWO. The availability of IPV in the clinical setting is not as common as other airway clearance devices; therefore, respiratory care practitioners may not be as familiar or comfortable with its application. The use of IPV may increase as more patients request alternative methods of airway clearance and as more research is done to demonstrate its benefits.

Acoustic Airway Clearance

A recent form of airway clearance uses acoustic vibrations to clear secretions from the lungs. The Frequencer (Dymedso Inc., Boisbriand, Quebec) is a device that provides mechanical vibration in addition to acoustic oscillation to mobilize secretions through a variety of tissue depths. The sound level (56-78 dB) generated at maximal power is below the level that would cause hearing damage.[149] Normal human hearing is limited to frequencies of 20 to 20,000 Hz, and the Frequencer operates between 20 and 65 Hz. The device adjusts to the resonant frequency of the airways of the lungs and is able to target small portions of the lungs as opposed to affecting the entire lung fields at once. It is similar to HFCWO in that the vibrations thin the viscosity of the pulmonary secretions. However, unlike HFCWO, which has an upper frequency of 25 Hz, the frequency of oscillation provided by the Frequencer is substantially higher at 20 to 65 Hz.

In a pilot study comparing the Frequencer with traditional postural drainage and percussion, the amount of sputum produced by the Frequencer was the same as or more than PD and patients reported less discomfort.[149] Another small study by Vallejos[150] described the use of the Frequencer in a clinical environment; treatment with the device produced sputum 75% of the time, and patients showed a preference for ACT by this method.

Treatment with Acoustic Airway Clearance

- The Frequencer consists of a control unit that generates acoustic waves in a range of frequencies and a transducer head to deliver the oscillation to a specific area of the lung. The treatment settings are changed by using a touch screen, and the settings can be locked to prevent accidental alterations. Intensity and frequency levels can be adjusted by sliding buttons up and down.
- Four sizes of adapters for the transducer are available to accommodate patients of varying body sizes. The control unit displays suggested levels of treatment for babies, children, and adults.
- There are six suggested chest treatment areas with a recommended 3-minute duration for each area.

Advantages and Disadvantages of Acoustic Airway Clearance

Use of the Frequencer does not require the patient to alter breathing patterns, and allows the treatment to be focused on the specific lung areas. It has the same effect of thinning the mucus as does HFCWO; furthermore, nebulized medication or supplemental oxygen can be administered concurrently. It appears to be appropriate for all ages and body sizes and can be applied in the upright position.

The Frequencer device is far more expensive than the PEP devices; the cost is similar to that of the HFCWO. In addition, it is less well known than other techniques. A relatively small number of patients with pulmonary disease has been exposed to acoustic airway clearance, and a few studies have been conducted on its efficacy across conditions.

Factors Affecting Selection of Airway Clearance Techniques

The process of prescribing an appropriate technique for secretion mobilization should be ongoing, with periodic reevaluation of the method and its effects on the patient. Mobilization and exercise are exploited to the maximal degree to mobilize secretions as indicated, and its effects may need to be augmented with manual or mechanical airway clearance techniques. Clinical judgment is needed to establish whether mobilization or exercise is sufficient or whether additional airway clearance support is needed. If it is determined that additional airway clearance techniques are warranted, clinical judgment must also be used to decide which specific techniques are indicated.

Among patients with pulmonary disorders, poor adherence to the performance of airway clearance on a regular basis has been well documented.[4,151-153] Litt[151] has shown that the complexity and increased duration of a prescribed treatment has a negative influence on patient adherence. It has been suggested that better adherence may be achieved if the treatment is specifically tailored to the individual patient's needs with regard to clinical status, family functioning, and family concerns (Box 21-6). Negotiation between the patient and the caregiver is also effective; patients are more likely to adhere to a prescribed treatment regimen to which they have agreed in collaboration with their caregiver.[154] The regular use of a particular ACT by a patient is governed by personal belief in the effectiveness of the method for his or her own disease process, the manner in which the method affects the family's life habits, and the patient's willingness to use the technique on a daily basis. Adherence is ultimately the best index of an ACT's effectiveness. For this reason, it is incumbent upon caregivers to consider the many factors that may alter a patient's adherence to a particular method when recommending a specific technique, especially in a patient with a chronic disease. These factors include the availability of the caregiver to teach the

technique and the willingness of the patient to learn it; the patient's concurrent medical problems; the effectiveness of the technique (subjective and objective); support for the technique from family, friends, and health care personnel; age and lifestyle of the patient; and the cost of the treatment.[106] Table 21-1 summarizes factors that can influence the choice of an airway clearance technique.

Box 21-6 Factors to Be Considered When Selecting an Airway Clearance Technique

- Motivation
- Patient's goals
- Physician/caregiver's goals
- Effectiveness (of considered technique)
- Patient's age
- Patient's ability to learn
- Skill of therapists/teachers
- Fatigue or work required
- Need for assistants or equipment
- Limitations of technique based on disease type and severity
- Costs (direct and indirect)
- Desirability of combining methods

From Hardy KA: A review of airway clearance: new techniques, indications, and recommendations, Respiratory Care *39:440-452, 1994.*

Availability

Accessibility of equipment or trained personnel limits the use of some ACTs. Some techniques of airway clearance that have been used in other countries for some time are new to health care providers and patients in the United States. Use of a method may be limited by the lack of caregivers trained to instruct patients in a particular technique. In the case of AD, the number of instructors available to teach the technique to patients and the time the health care team member must spend to learn it limits the method. AD takes longer for a caregiver to learn how to teach than does PEP or HFCWO. For IPV or acoustic airway clearance, the equipment and trained personnel must be available in the hospital; if a home unit is to be used, proper training of the patient and caregiver must be included. The ACBT is easily incorporated into conventional chest physical therapy by learning the FET and modifying the use of percussion or shaking. Exercise for airway clearance may be out of the realm of a respiratory therapist who is trained in respiratory care but not familiar with principles of exercise testing and prescription.

The patient's availability must also be taken into consideration. Proper instruction and review of a patient's technique are imperative to achieving optimal results. Instruction in PEP, ACBT, and HFCWO can be initiated during a single outpatient clinic visit, and further training can be provided during return visits. On the other hand, instruction in AD takes several training sessions. The patient needs to allow time to

Table 21-1 Considerations When Selecting an Airway Clearance Technique

Technique	Age of Patient	Assistant Needed	Equipment Needed	During Acute Exacerbation	Concurrent Nebulizer	Precautions	Cost
PD, percussion, vibration/ shaking	Any age	Yes	Positioning aids; percussor/ vibrator; devices for infants	Yes	Only in upright or side-lying	May need to modify positions; repetitive motion injuries	Expensive if performed by caregiver over long term
ACBT	Begin to teach at 3-4 years of age	Until 8-10 years of age	Positioning aids; percussor/ vibrator	Yes	Only in upright or side-lying	Precautions for head-down positions	Inexpensive if done independently
AD	Age ≥12 years	No	None	Best to use an alternative	No	Takes time to learn	No cost
HFCWO	Age ≥2-3 years	For young children	Air pulse generator; appropriately sized vest	Yes	Yes	Chest tube, indwelling catheter, or other device in chest area	Very expensive
IPV	Adolescents and adults	While in hospital	Home unit or hospital unit	May not be well tolerated	Yes	Titrate for comfort and visible chest movement	Moderately expensive
Acoustic Airway Clearance	All ages	For children	Acoustic generator and appropriate size transducer	Possibly; further studies are needed	Yes	Further studies are needed	Very expensive
Exercise	Children, adolescents, and adults	For young children	Variable	No	Premedicate before exercise	Exercise-induced bronchospasm; oxygen desaturation; adjunct to ACT	Depends on type of exercise

learn the method and be available and willing to fine-tune the technique with the therapist periodically. Unlike a clinic visit, hospital admission for an exacerbation of a pulmonary disease makes the patient a captive audience for instruction in a variety of techniques, including AD or a home exercise program after the acute stage has passed.

The key to success of airway clearance is the reevaluation of any technique used. The patient and caregiver must be available to demonstrate and review of the technique periodically so that modifications can be made. For example, in the case of PEP, reassessment of its resistance is recommended. A change in a patient's level of independence or motivation, a decline or marked improvement in pulmonary status, or a decrease in the effectiveness of a technique all necessitate reevaluation of the current method.

Effectiveness

The age of the patient can influence the effectiveness of a particular technique. Infants and very young children are limited to conventional postural drainage, percussion, and vibration performed by a caretaker, because they are not able to cooperate with other methods of airway clearance. A vest for HFCWO can be fitted for children as young as 2 or 3 years of age. After the age of 3 or 4, a youngster may be taught huffing and breathing control and can be assisted with the ACBT. PEP and exercise are also suitable for this age group, depending on the child's attention span and cooperation. As the child grows older and the variety of appropriate techniques increases, close supervision remains necessary. In the adolescent, even when physical assistance is no longer required, emotional support from family and friends is paramount to continued success with a technique. Children 12 years of age and older are capable of using any of the ACTs, including AD, which requires more concentration than a younger child is typically able to exhibit consistently. The company manufacturing the Frequencer claims that its device is suitable for all ages.

Another consideration in selecting a technique is the effectiveness of the technique measured both subjectively and objectively. A patient's subjective response to the treatment has implications for adherence to it. The ease of sputum mobilization and the quantity of sputum expectorated are important to a patient; this measure provides immediate feedback without a visit to the hospital or clinic. Although it is difficult to quantify, many patients rely on the amount of sputum production to guide their choices of secretion clearance methods. The effort that a treatment requires, or even more important, the amount of energy remaining after completion of the treatment, will affect the patient's willingness to continue with a technique.

Objective clinical measures to assess the effectiveness of an ACT can be followed during clinic appointments or periods of hospitalization. Radiographic changes, breath sounds, and pulmonary function tests may demonstrate adequate airway clearance or the need to reassess the appropriateness of the technique and its application. In addition to the quantity of sputum measured, other changes to monitor in sputum quality are color and viscosity. Hemodynamic values and measures of oxygenation—for instance, heart rate, blood pressure, O_2 saturation, changes in mechanical ventilator settings and arterial blood gas values—can be monitored to assess a patient's response to a particular intervention. The ultimate indicator of a favorable response is patient adherence, as this will determine to a degree to which benefit is sustained.

Clinical Status

The clinical status of a patient is key to determining the appropriateness of a particular ACT and the need to modify a technique. In addition, complications that occur as a result of a technique or precautions associated with a particular method must guide a patient and caregiver to find an alternate technique. For example, PD and percussion could worsen airway hyperreactivity, and although exercise should be preceded by an inhaled bronchodilator, in this case, HFCWO, PEP, acoustic airway clearance, and IPV can be performed concurrently with bronchodilator administration. AD lends itself well to use by patients with airway hyperreactivity. Gastroesophageal reflux prohibits patients from performing airway clearance in conventional PD positions. In this instance, AD, PEP, HFCWO, IPV, acoustic airway clearance and exercise, or ACBT in upright positions, are the preferred treatments. In infants or neurologically impaired patients in whom PD and percussion are the treatments of choice, modified PD positions are used, with exclusion of the Trendelenberg position, and sufficient time is allowed between a feeding and a treatment with PD. Sinus surgery may make use of a PEP mask intolerable, and the placement of a chest tube may necessitate a temporary replacement for HFCWO.

The severity of a patient's lung disease affects the choice of ACT. A patient hospitalized with an acute pulmonary exacerbation may need to be assisted with a passive method of secretion clearance until the patient's condition allows a return to a more independent technique. Similarly, a patient with end-stage lung disease might not have the energy to perform an ACT such as AD or ACBT, in which case a more passive technique would be appropriate. Also, a marked decrease in pulmonary function may limit the airflow control necessary for AD and PEP.

Lifestyle

A patient's living situation and the support of family and friends may influence a preference for a method of airway clearance. Many patients adopt a multifaceted approach to secretion clearance, becoming adept at several methods and using them as their conditions dictate. Patients who primarily use AD or exercise may use an alternate form of airway clearance during an acute exacerbation. Patients who use HFCWO at home may use a more portable technique when away from home. Patients who rely on assistance to perform percussion may need to learn a more independent method when assistance is not available. The lack of an assistant to provide airway clearance is a factor that prompts many patients to seek methods other than postural drainage and percussion. HFCWO, PEP, ACBT, acoustic airway clearance, exercise, and AD are techniques that provide independence from a caregiver. Adolescents eager for self-reliance, students away at school, and adults living alone frequently choose these independent methods. For optimal results, a health care team member who is skilled in airway clearance must regularly reevaluate each technique's effectiveness after it has been agreed that a patient exhibits independence in a given

technique. The support received from health care providers is vital to the patient's motivation to continue with a technique or to learn a new one.

When airway clearance is indicated daily, it becomes necessary to accommodate a patient's schedule. A patient may have a preference for the most effective treatment performed in the least time. A patient may also be interested in performing another activity during the airway clearance treatment—for example, AD or PEP may be performed while riding in a car (as a passenger); HFCWO can be conducted while studying for an examination or surfing the Internet; and a patient can be watching the news on TV while running on a treadmill or during percussion by an assistant.

Expense

In this era of skyrocketing health care costs, especially for long-term care and chronic disease, the expense of an airway clearance technique must be considered. The initial cost of equipment, replacement costs, and the expense of any required assistance all figure into the total cost of treatment. Often the choice of a technique is limited by the reimbursement available by a third-party payer. Nonetheless, the caregiver must strike a balance between economic and clinical considerations in choosing a mode of therapy. If several methods prove to be equally effective, it would be prudent to select the least expensive method. Although a common form of airway clearance in the United States continues to be postural drainage and percussion by a caregiver, this often proves to be quite expensive if a family member is not available for ongoing home treatments. Payment of a trained assistant for home use of PD and percussion is a great expense. Depending on the duration and frequency of treatment, this cost may outweigh that for other ACTs long-term. The equipment costs for ACTs vary. The generator required for HFCWO is more expensive to purchase or rent on a monthly basis than an IPV unit, but replacement should not be necessary. The Frequencer device used to deliver acoustic airway clearance is also expensive. Mechanical percussors or vibrators are moderately priced, and PEP devices are the least expensive of the techniques requiring equipment, with replacement of a unit expected to be necessary occasionally during a lifetime of use. A patient independently using ACBT or AD consumes the fewest financial resources.

Summary

Numerous ACTs have been shown to reduce obstruction, enhance mucociliary clearance, and improve ventilation, accomplishing the goal of improved oxygen transport. The effectiveness of various techniques has been demonstrated in multiple studies and evaluated with numerous outcome measures. In some cases, routine application of ACTs has not been shown to be effective in achieving improved oxygen transport. Acute asthma, bronchitis, pneumonia without copious secretions, bronchiolitis, and routine postoperative conditions were not shown to benefit from PD, percussion, and vibration.[18,21] ACTs are not without side effects or complications; routine use of these methods is not recommended without clear indications. Indications for ACTs have been established for acute illness and for chronic conditions. In acute illness, traditional methods (i.e., PD, percussion, and vibration) have been shown to be beneficial in patients with copious secretions and in the treatment of atelectasis.[155] For patients with cystic fibrosis, treatment with PEP and exercise in conjunction with PD, percussion, and vibration were also shown to be effective in an acute exacerbation.[156] In chronic disease states, patients with cystic fibrosis and bronchiectasis have been found to benefit from PD, percussion, and vibration, as well as PEP, autogenic drainage, ACBT, acoustic airway clearance, IPV, and exercise.[106,149,155,156]

The health care provider needs to consider many factors in recommending a technique of airway clearance for a patient. In addition to the availability of the technique and its effectiveness, these factors include consideration of several variables—physiological, psychological, and practical—that affect a patient's response to treatment. Treatments aimed at secretion clearance require monitoring the response of a patient to treatment and periodic reevaluation of this response. Caregivers need to incorporate this information into the real life situations presented by patients and choose a technique or combination of techniques that best suits each patient's needs. Acceptance of a specific treatment technique by the patient and family is paramount; adherence is the key to achieving effective treatment, especially in chronic lung conditions.

Health care providers are challenged to keep abreast of techniques and their modifications to best meet the patient's needs. The role of the caregiver involves more than technical expertise. The caregiver is uniquely positioned to simplify medical language for patients and families and encourage adherence to airway clearance. Support of a treatment by a health care provider can increase the benefit derived from the treatment.

Further research in the area of airway clearance is needed to compare and standardize techniques, follow long-term outcomes, and establish optimal treatment guidelines. This information will assist caregivers in evaluating and recommending a given technique of airway clearance for a particular patient or clinical population.

Review Questions

1. Which ACTs can be performed without purchasing specialized equipment?
2. Which ACTs would be appropriate to use during a hospitalization for a pulmonary exacerbation?
3. Which ACTs are most suited for instruction during a single outpatient clinic visit?
4. What outcome measures do you have at your disposal for evaluating the effectiveness of airway clearance?
5. Which ACT(s) would be appropriate for:
   - A 3-year-old newly diagnosed with cystic fibrosis?
   - An adolescent with bronchiectasis desiring independence from parental assistance?
   - A young adult with a spinal cord injury living alone?
   - An older adult with chronic bronchitis living in an extended care facility?
6. What are contraindications to chest percussion and/or postural drainage?
7. What factors should be considered in introducing a new method of airway clearance to a patient?

Cough truly serves many purposes: a therapeutic technique, a diagnostic signpost, and a social necessity. If it didn't already exist, we would have to invent it.

—Glen A. Lillington, MD

Cough is one of the most frequently reported symptoms in patients with pulmonary impairments. It is important to get a good history and physical examination to determine the cause and course of the patient's cough.[1] History should include sudden onset versus chronic; duration and type of cough—productive, nonproductive, or wheezy; whether the cough disturbs sleep and function; and what relieves or aggravates it. Diagnostic testing may include chest imaging, pulmonary function tests, bronchoscopy, and evaluation for gastroesophageal reflux (GER).[2] GER is said to be the causative factor in up to 41% of adults with chronic cough.[3]

The cough is an interesting phenomenon. It can either be a reflex or a voluntary action. Generally, in healthy individuals, a cough is rarely heard unless a person has a cold, or an irritant is inhaled and a sneeze or a cough ensues to evacuate the foreign body. The mucociliary escalator functions as the primary means to clear secretions and inhaled particulate matter. Except in certain circumstances—for instance, the mucus is very thick, as in individuals with dehydration or abnormal secretions; or a foreign body is inhaled; or a bolus of food "goes down the wrong hole," that is, into the trachea rather than the esophagus—a cough is not the usual mechanism to clear mucus. The mucus blanket and the support of the cough mechanism are the two means promoting normal airway clearance.

Frequent coughing or throat clearing may signal that the airways are irritated, that mucus is not clearing normally, or that the person is in an uncomfortable situation. This is something to be aware of, especially when treating patients with cystic fibrosis or asthma and patients with psychogenic issues. Depending on the reason for a cough, a variety of different approaches might be utilized. In most patients with primary pulmonary disease, the cough is related to the need for improved hydration and airway clearance. With patients who have psychogenic coughs, psychotherapy, biofeedback, and

relaxation techniques have proven to be effective.[4] Medications to suppress a cough are used rarely, primarily in the case of nonproductive, inflamed airways. Future directions are moving toward better medical management of cough reflex hypersensitivity through better diagnosis and medication.[5] If the cough is productive, hydration and coughing are necessary to expel secretions to prevent pneumonia from occurring.

Many people who have habitual coughs are unaware of their coughing. For example, when asked whether they cough, smokers with typical morning and ongoing smoker's coughs may deny coughing. Often, a spouse will chime in, saying, "He coughs and hacks all the time." An individual might constantly clear his or her throat and swallow mucus but will claim to be unproductive of mucus and free of a cough. It is important for therapists to be aware of both the reflex and the voluntary nature of their patients' coughs and observe for throat clearing and swallowing of mucus.

Frequent coughing or throat clearing may indicate other problems besides airway clearance deficits. For example, a patient may have postnasal drip from a sinus infection or allergy. When the mucus drips down into the back of the throat, it can cause a reflex cough to clear it. Other causes include bronchogenic carcinoma, nervousness, and smoking. Many over-the-counter products are marketed to improve environmental air factors, but there has been conflicting evidence for their effectivess.[6]

In a pediatric patient with a cough, a foreign body or object inserted or inspired into the nose or airway should be ruled out. Gastroesophageal reflux must be evaluated in children and adults with symptoms of cough.[7,8] GER is often overlooked in children. For example, if a child is beginning to prop-sit and pushes back to get out of that posture regularly, it may be because of GER irritation. This can delay developmental postures, so it is an important consideration for pediatric therapists.

A persistent cough or throat clearing might be indicative of asthma or other pulmonary diseases, but it may also be a result of GER and irritation to the upper airway. It is important to ask questions related to the patient's sleep. For example, does the person have heartburn or belching at least once a week after going to bed? Is there breathlessness at rest and nocturnal breathlessness? In a random group study in a large population of young adults, 4% were found to have GER. People with asthma and GER (9% of asthmatics had GER) had more nocturnal cough and morning phlegm with sleep-related symptoms.[9] The authors concluded that there was a strong association between asthma and GER.

Cigarette smoking is known to stop mucociliary clearance. It has been noted that for every cigarette a person smokes, the cilia are paralyzed for approximately 20 minutes. Many individuals are chain smokers and consequently must cough to provide any airway clearance. These smokers will often have significant amounts of phlegm raised first thing in the morning secondary to ciliary clearance while they slept.

Many patients with asthma find cough to be a more irritating, difficult symptom than wheezing and secretions. Yet cough is often not taken as seriously, even though it can be a life-interrupting symptom. Night cough can be a particularly difficult symptom in people with asthma and will make sleep difficult.[10] Persistent cough has also been reported following pulmonary resection. The cause seems to be unclear, but some studies have focused on the population of patients who have had a lobectomy and mediastinal lymph node resection, some of whom also had GER. These were at increased risk for continued cough, which was found to persist up to a year later. Of this group, 90% saw improvement in their coughing with medication.[11]

If a patient demonstrates retained secretions on radiography, encourage hydration (drinking water), use airway clearance mobilization techniques, and carefully evaluate the cough. Instruct the patient in controlled coughing when mucus is felt in the throat or upper airways (see Chapter 21).

Cough Associated with Eating or Drinking

If a cough is associated with eating, drinking, or taking medications, the patient's swallowing mechanism should be examined and evaluated. A barium swallow ("cookie swallow") is a fluoroscopic study in which the patient is given an opaque liquid, and a moving picture is observed to determine whether there is aspiration into the trachea. Populations commonly in need of evaluation of swallowing are patients with neurological disorders, such as those that occur with cerebrovascular accident (CVA), amyotrophic lateral sclerosis (ALS), cerebral palsy, Parkinson disease, and multiple sclerosis (MS). Patients who have tracheostomy tubes may experience difficulty in swallowing because the tube inhibits the normal movement of the larynx during swallowing. The use of a Passey-Muir valve has been found to be clinically effective in restoring a more normal swallow in patients with a tracheostomy. Older adults with chronic cough should be carefully observed and monitored, because the chronic cough may be a defense mechanism to prevent aspiration.[12] This is especially true if there are comorbidities such as a previous stroke. This list is not exhaustive; any patient who chokes when you offer fluids or who reports to you that food or water "goes down the wrong way" should be referred for evaluation of the swallowing mechanism.

Speech and language pathologists work with patients who have swallowing dysfunction (dysphagia) by helping them to learn techniques and procedures for safe swallowing. These specialists work with the patients, spouses, and parents to position patients for success, usually in a semi-Fowler sitting posture with head and neck flexion. In addition, the types and consistencies of food are evaluated. Many people have more difficulty with liquids than with puddings and other thicker consistencies. A thickening agent can be added to liquids to help patients swallow safely. Food may be ground up (pureed) if chewing is difficult. Every effort should be made to help patients eat and drink fluids successfully. However, if a patient is unable to swallow safely, alternative means of nourishment, such as feeding tubes and gastric tubes, must be used. The method can be revisited later and feeding tried again when the patient's condition improves.

Cough Pump

The cough pump is an intricate device. Mucus must be transported upward against the gravitational force and propelled cephalad by the expiratory gas flow. Generally, cough is the

most effective means, because it has a large inspiration and high expiratory flow rates. Cough will clear to approximately the sixth or seventh generation of airway segments (segmental bronchi). If a patient has retained secretions, distal airway clearance techniques such as postural drainage or use of the Acapella or other device must be used to move the secretions to an area where the cough can be effective. If the patient does not have the mechanical ability to have an effective cough (as in spinal cord injury), assistive cough techniques or mechanical methods, discussed later in this chapter, will have to be employed.

Complications of Coughing

Coughing can be hazardous to the patient and should never be repeated routinely. The irritation, inflammation, and possible airway narrowing that can occur during forced exhalation may cause bronchospasm. If the cough is dry and unproductive, do not encourage frequent coughing. This is especially true for people with asthma and chronic obstructive pulmonary disease (COPD). Do not ask patients with COPD to take a deep breath before they cough. These patients do not have trouble taking in air; on the contrary, a secondary condition of COPD is increased compliance, which causes alveolar destruction and decreased elasticity of their lungs. With a patient who has COPD, ask for a mid-sized breath, which will minimize air trapping (dynamic hyperinflation). If the patient demonstrates retained secretions, first employ an airway clearance device or treatment; then use an effective and controlled technique, such as the active cycles of breathing and forced expiratory technique (FET), to mobilize the secretions.

Tussive syncope can occur when a patient has a sustained series of coughs in which the intrathoracic pressure becomes so high that venous return to the heart is impaired. The cardiac output falls, leading to dizziness and then progressing to unconsciousness. Care must be exercised, especially in patients with primary and secondary cardiovascular and pulmonary disease. These patients must learn to control their coughing to prevent untoward side effects.

Patients with chronic cough can also experience stress urinary incontinence (SUI).[13] This is often not reported to the therapist or physician because the patient is embarrassed or considers this a problem of aging rather than a condition related to the chronic cough. Such patients often do not realize that physical therapy treatment is available for SUI. This knowledge deficit has been found in adolescents and teenagers with cystic fibrosis, as well as in adults with COPD. Asking patients with chronic cough about SUI should be a part of the routine examination and evaluation. Making a referral to a pelvic floor therapist can make a difference in their quality of life as SUI is managed.

Stages of Cough

Four stages are involved in producing an effective cough.[14] The first stage requires inspiring enough air to provide the volume necessary for a forceful cough. Generally, adequate inspiratory volumes for a cough are noted to be at least 60% of the predicted vital capacity for that individual. The second stage involves the closing of the glottis (vocal folds) to prepare for the abdominal and intercostal muscles to produce positive intrathoracic pressure distal to the glottis. The third stage is the active contraction of these muscles. The fourth and final stage involves opening of the glottis and the forceful expulsion of the air. The patient usually is able to cough three to six times per expiratory effort. A minimal threshold of FEV_1 (forced expiratory volume in 1 second) of at least 60% of the patient's actual vital capacity is a good indicator of adequate muscle strength necessary for effective expulsion (Figure 22-1). Bach

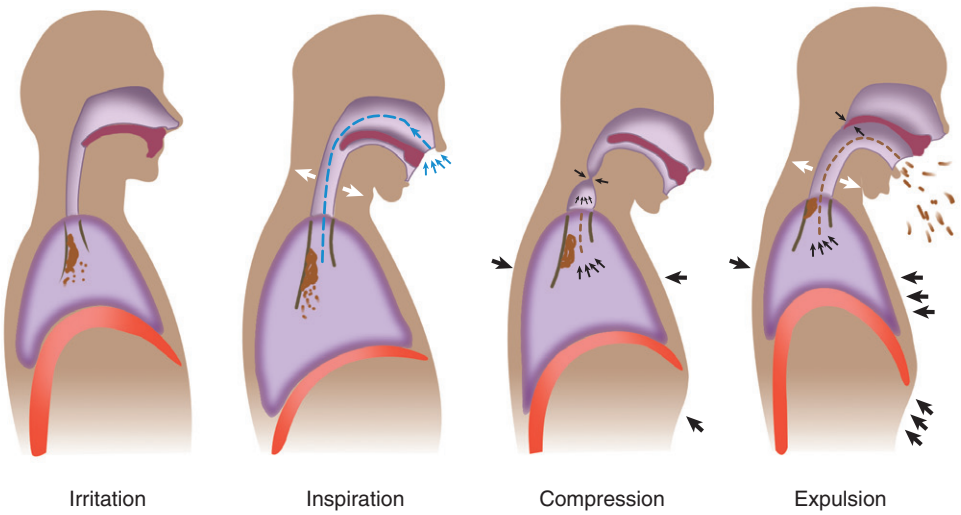

Fig. 22-1 Cough mechanics. **A,** Stage 1: adequate inspiration. **B,** Stage 2: glottal closure; stage 3: building-up of intrathoracic and intraabdominal pressure. **C,** Stage 4: glottal opening and expulsion.

and Saporito (1996)[15] established a minimal peak cough flow rate (PCFR) of 160 L/min to effectively clear secretions and to predict successful decannulation for patients with neuromuscular conditions. The use of a simple peak flow meter can help assess the cough. Drops in peak flow have been correlated in children, patients with spinal cord injury, and older adults who have a decreased ability to cough. Assessing PCFR is a simple clinical test that can objectively measure the patient's ability to provide the exhalation phase of the cough.[16-18] During a cough, alveolar, pleural, and subglottal pressures may rise as much as 200 cm H_2O.[14,19,20]

It is also important to identify the stage of the cough cycle in which the patient is having difficulty. Only then can the appropriate therapeutic intervention be directed at correcting that deficit.

Box 22-1 Positioning and Instruction to Improve Cough Effectiveness

- Position the patient for success, especially in regard to trunk alignment.
- Maximize inspiratory phase through verbal cues, positioning, and active arm movement.
- Improve hold stage through verbal cues and positioning.
- Maximize intrathoracic and intraabdominal pressures with muscle contractions, physical assist, or trunk movement.
- Instruct the patient in appropriate timing and trunk movements for expulsion.
- Make the procedure physically active on the patient's part.

Cough Evaluation

How do you assess whether a patient's cough is effective? The answer appears to be obvious: ask the patient to cough. However, the obvious answer often does not adequately analyze the functional performance of a cough, especially for a patient with neurological impairment. The clinician must first take time to prepare the patient for successful evaluation of cough. Here are guidelines for preparing the patient:

1. Do not disregard posture. Rather than simply asking the patient to cough from whatever position he or she happens to be in, ask instead, "What position do you like to be in when you feel the need to cough?" Then ask the patient to assume that posture, or assist the patient in assuming a posture as close to the preferred posture as possible. Pay close attention to the patient's choice. A patient should spontaneously choose a posture that lends itself to trunk flexion, which is necessary for effective expulsion and airway protection. A red flag, or inappropriate choice, would be a preference for coughing while supine, which involves the opposite: trunk extension and poor mechanical alignment for airway protection.
2. Now the patient is ready to demonstrate coughing. Do not make the mistake of asking a patient to "show me a cough" or he or she may simply "show you" a cough. It may not be the way the patient coughs to clear secretions. Instead, continue to set the patient up for success by asking him or her, "Can you show me how you would cough if you had secretions in your chest and you felt the need to cough them out?" With these instructions, you are asking the patient to show you something functional rather than theoretical.

Cough effectiveness can now be assessed (Box 22-1). Guidelines for objective evaluation with pulmonary function tests have been indicated previously. This section focuses on analyzing the movement patterns during all four stages of a cough. An effective cough should maximize the function of each individual stage. Thus in most patients (other than those with COPD or asthma), the clinician should see a deep inspiratory effort paired with trunk extension, a momentary hold, and then a strong cough or series of expiratory coughs on a single breath while the patient moves into trunk flexion.

Stage 1: Adequate Inspiration

Did the patient spontaneously inspire a deep breath before coughing, or did he or she cough regardless of the inspiration or expiration cycle? Did the patient spontaneously use trunk extension, an upward eye gaze, or the arms to augment the inspiratory effort? Did the patient take enough time to inspire fully before coughing? If the patient inspires adequately, he or she should be able to sustain two to six coughs per expiratory effort for a cascade effect. Neurologically impaired patients who have inadequate inspiratory efforts usually present with only one or two coughs per breath and generally produce a quieter cough.[21] If the patient cannot cough on demand (such as a young child or patient with cognitive impairment), ask the caretaker whether he or she has observed and/or heard the patient's inspiratory breath and hold before a cough. If so, how effective did the patient's process seem?

Stage 2: Glottal Closure

Did the patient hold his or her breath at the peak of inspiration before the expulsion phase, or did the patient go directly from inspiration to expiration? Did you hear a cough or a huff (a complete absence of a hold between inspiration and expiration)? If the patient intended to cough but instead produced a huff, this is an indication of insufficient glottal closure. This can result from a wide variety of situations, including glottal edema after prolonged intubation, partial or full paralysis of the vocal folds, hemiparesis of the vocal folds, or a timing or sequencing difficulty secondary to brain injuries, among other possibilities. A complete lack of glottal closure will not produce any cough sound because the vocal folds are not approximating (adducting). The huff technique may be encouraged when the patient tends to wheeze or after long-term intubation when there is vocal fold edema. However, in the "normal" population, a good hold and full cough are encouraged.

Stage 3: Building-Up of Intrathoracic and Intraabdominal Pressure

Did you see active contraction of the intercostal and abdominal muscles? Did the patient spontaneously move into trunk flexion during this phase? Did the cough have a low, resonant sound? Inadequate force is usually heard as a higher-pitched cough, often called a throaty cough. The sound is quieter

overall and does not produce as many coughs per expiratory effort. It is sometimes associated with neck extension rather than flexion as the patient attempts to clear the upper airway only. The air appears to leak out rather than being propelled out of the larynx during the cough. As with inadequate lung volumes, inadequate pressure prevents the patient from coughing more than once or twice during one expiratory effort.

Stage 4: Glottal Opening and Expulsion

The timing of the opening of the glottis and the forceful expulsion of the air is directly tied into the function of the third stage. During expulsion, does the patient appear to gag before successfully allowing the air to be expelled? Does the patient seem to get stuck holding his or her breath? Deficiencies in this area are often related to brain injuries and coordination difficulties. The opposite can also occur. Some patients get stuck at the end of expulsion, especially those with severe neurological impairments or bronchospasms, and may have difficulty initiating the next inspiratory effort.

If the patient is able to follow directions and has the muscular ability and cognition to learn cough techniques, patient instruction is the next step. If the person is unable secondary to neuromuscular weakness or frailty and cannot be independent in coughing, a decision must be made about the next step to be taken to provide airway clearance of secretions. Assistive cough techniques, the CoughAssist machine, and suctioning are possible considerations; these are discussed later in this chapter.

Patient Instruction

When working with patients, especially those with primary pulmonary disease or primary disease superimposed on secondary disease (i.e., a patient with CVA), the proper patient instruction can make secretion mobilization more effective. Multiple ideas are presented here because the therapist needs a "bag of tricks." Certain techniques work well for some patients but not for others. Try several with each patient and let him or her determine what works best. Objective tests can also be used to determine the most effective intervention, such as a change in oxygen saturation, improved breath sounds via auscultation, improved expiratory flow rates, chest x-ray clearing, and a reduction in the patient's perceived work of breathing (dyspnea scale).

As mentioned previously, patients with COPD and asthma are not encouraged to take a deep breath before they cough. These patients also tend to experience expiratory wheezing when they force and prolong exhalation. This can lead to bronchospasm and respiratory distress. Patients can be taught to do the pump cough, a variation on the huff technique. A huff is often encouraged to help patients produce controlled, less stressful coughs. It may be useful when patients have been intubated with an endotracheal tube for an extended time. The vocal folds, in this case, are swollen and inflamed and will not close and form the tight seal necessary to build up the pressure for a cough. Thus patients are instructed to huff rather than cough. The huff is done with more open vocal folds, a low sound, and less effort; yet it is quite effective in mobilizing secretions, especially when combined with FET.

Pump Cough

The pump cough extends the huff technique and, clinically, is more effective. The patient is instructed to take three mid-sized huffs followed by three short, easy coughs at low lung volume, not deep breaths or deep lung volumes. Three or four sequences are performed: (1) huff, huff, huff; cough, cough, cough; (2) huff, huff, huff; cough, cough, cough; (3) huff, huff, huff; cough, cough, cough. Usually, if secretions are present, a spontaneous cough occurs, or the secretions will mobilize with the small coughs.

Series of Coughs

Another variation that decreases stress on the patient is to use a series of coughs consisting of a small breath and a small cough, then a medium breath and a medium cough, and finally a large breath and a large cough. This is a good technique to use with postoperative patients, who often become fatigued trying to cough maximally each time. For these patients, it is an effort to get air distal to the secretions in various parts of the lungs, a form of autogenic drainage.

Patients with Neuromuscular Weakness or Paralysis

For patients with transient or permanent neuromuscular weakness or paralysis, further instructions may be necessary.[20,22-25] These patients must use every physical trait to maximize the function of each stage of the cough (see Figure 22-1). Physically assisting these patients during the expulsion stage of the cough addresses only one aspect.[26,27] Care must be taken to look at all four stages to maximize the airway clearance potential of any assistive cough technique. First, the patient must be positioned for success (stage 1). The beginning of any cough requires trunk extension or inspiratory movement to maximize inhalation, whereas the expulsion stage requires trunk flexion or expiratory movement to maximize exhalation.[28] Thus for any given posture, the clinician must assess the following:

- Whether the posture allows for both trunk movements
- Whether flexion and extension are possible, which movement is more important for that particular patient, and whether that posture facilitates its occurrence
- How gravity is affecting the patient's muscle strength and function in that posture
- Whether the patient can still protect the airway in this posture

When these questions have been answered satisfactorily, the clinician is ready to instruct the patient in the act of coughing. An example may provide the best illustration of these instructions. A clinician may pick a modified sitting position for a patient with generalized weakness (e.g., incomplete spinal cord injury, developmental delay, or temporary weakness or exhaustion after a medical or surgical procedure). The patient looks slumped, so the clinician places a lumbar support (e.g., a lumbar roll, a towel, or a pillow) behind the lower back to increase trunk extension in that position. The patient is asked whether he or she is comfortable and whether he or she can swallow safely. Next, the clinician tries to maximize the first cough stage by asking the patient to take a deep breath. Observing that the patient did not appear to take in as deep a

breath as the clinician thought possible, the clinician adds further instructions, such as the following:

- "Look upward while you inhale."
- "Raise both of your arms up over your head as high as you can while you inhale."
- "Squeeze your shoulders back while you inhale."
- "Straighten or extend your back while you inhale."

For patients with more limited arm function, apply appropriate ventilatory strategies detailed in Chapter 23. Very subtle movements can then be requested, such as the following:

- "Bring your arms up and out while you inhale."
- "Rotate your arms outward while you inhale."
- "Turn your forearm up while you inhale."

Although less dramatic than the larger movements described previously, these subtle motions may significantly increase the patient's inspiratory effort and provide a more active means for the patient to participate in his or her own coughing program.[29]

Stage 2 involves closing the glottis. For some patients with weakness or timing problems, a sharp loud command to "hold it" at the peak of inspiration, may be sufficient to facilitate closure. Remember to allow enough time for the patient to take in a deep inspiratory effort before being asked to "hold." Some clinicians rush the first phase by giving two instructions in quick succession, as in "Take a deep breath. Hold it." This unintentionally limits the time of the inspiratory effort. A more appropriate verbal cue would be "Take a deep breath in … in … in … in … and now hold it," allowing adequate time for the patient to inhale.

Stage 3 (building up pressure) and stage 4 (expulsion) are discussed together because their timing is interdependent. The patient now needs to move into trunk flexion, with or without the clinician's assistance, to maximize expulsion. Patients who are able to assist can be asked to do the opposite of stage 1:

- "Look down while you cough."
- "Pull both of your arms down to your hips as you cough."
- "Roll your shoulders forward while you cough."
- "Bend your trunk forward while you cough."

Likewise, patients with more limited arm function can be asked to do the following:

- "Squeeze your arms to your chest while coughing."
- "Roll your shoulders and arms inward while coughing."
- "Turn your hands down (pronation) while coughing."

In this manner the clinician has used every conceivable resource to maximize a voluntary cough. Even the weakest cough can be made more effective by applying these simple concepts:

- Position for success
- Maximize inhalation first
- Ask for a breath hold
- Encourage maximal intrathoracic and intraabdominal pressures
- Instruct the patient in appropriate timing and trunk movements for expulsion
- Make the procedure as active as possible for the patient

Objective and subjective assessments can confirm the improvement. However, even with excellent instructions, many patients with neurological disorders require a clinician's physical assistance to inhale more deeply or to exhale more forcefully because of muscle weakness or paralysis.[30]

Active Assisted Cough Techniques

If, after instruction and modification in the patient's cough, the patient still cannot produce an effective cough, then one of the following assistive cough techniques may be appropriate. However, a patient who needs some assistance to improve a cough is not excused from taking an active role in coughing. Keep the coughing process as active as possible for each patient, whether that is accomplished by adding a few verbal cues to improve overall timing or posture while the patient independently performs the cough, or whether it is accomplished by adding eye gazes for a very weak patient who cannot move the upper extremities and breathes with the assistance of a ventilator. Encourage the patient to be responsible for his or her own care by teaching the concepts involved in producing an effective cough.[31] In that manner, you will help the patient develop the problem-solving skills necessary for later modifications. Incorporate the guidelines and principles presented thus far with the specific cough techniques that follow. See Box 22-2 for a review of the techniques presented in this chapter.

Breath Stacking and Manual Chest Compression

Breath stacking is a technique that is achieved by a patient independently performing inspiration to maximal inspiratory capacity, then holding the breath and taking in 2 or 3 more breaths "on top" of the initial breath to increase vital capacity. This is followed by a cough. For a patient with neuromuscular weakness, a therapist or family member can do chest compression and assist the cough during exhalation.

In a study of patients with Duchenne muscular dystrophy, variations of breath stacking with a manual self-inflating bag were tested. One group simply used the self-inflating bag for breath stacking, whereas the other group used a combined technique of breath stacking with the bag plus manual compression for the exhalation. The combination technique proved to be most effective as measured by peak cough flow (see Figure 21-5).[32]

Manually Assisted Techniques

Costophrenic Assist

The first assistive cough technique, the costophrenic assist, can be used in any posture. After assessing the most appropriate position for the patient (most often sitting or side-lying) and

Box 22-2 Assisted Cough Techniques

Manually Assisted Techniques

1. Costophrenic assist
2. Heimlich-type or abdominal thrust assist
3. Anterior chest compression assist
4. Counter-rotation assist

Self-Assisted Techniques

1. Prone-on-elbows head-flexion self-assisted cough
2. Long-sitting self-assisted cough
3. Short-sitting self-assisted cough
4. Hands-knees rocking self-assisted cough
5. Standing self-assisted coughs

giving the patient instructions for maximizing all four coughing stages, the therapist places his or her hands on the costophrenic angles of the rib cage (Figure 22-2). At the end of the patient's next exhalation, the therapist applies a quick manual stretch down and in toward the patient's navel to facilitate a stronger diaphragmatic and intercostal muscle contraction during the succeeding inhalation. The therapist can also apply a series of repeated contractions based on proprioceptive neuromuscular facilitation (the PNF approach[33]) throughout inspiration to facilitate maximal inhalation. The patient may assist the maneuver by actively using his or her upper extremities, head and neck, eyes, trunk, or all of the above to maximize the inspiratory phase. The patient is then asked to "hold it." Just a moment before asking the patient to actively cough, the therapist applies strong pressure with his or her hands, again down and in toward the navel. In this manner the therapist is assisting both the build-up of intrathoracic pressure and the force of expiration. Of course, the patient should also actively participate by using his or her arms, trunk, or other body parts throughout the entire procedure (see Chapter 23).

This technique's obvious use would be for patients with weak or paralyzed intercostal or abdominal muscles. The therapist must remember to evaluate the effect of gravity and posture in each position for the appropriateness of this technique.[34] This technique is easy to learn and teach and can usually be used from the acute phase through the patient's rehabilitation phase, thus accounting for its popularity.

Heimlich-Type (or Abdominal Thrust) Assist

The second technique is the Heimlich-type assist, also known as the abdominal thrust assist. This method requires the therapist to place the heel of his or her hand at about the level of the patient's navel, taking care to avoid direct placement on the lower ribs (Figure 22-3). After appropriate positioning, the patient is instructed to "take in a deep breath and hold it." The therapist can then facilitate the inspiration. As the patient is instructed to cough, the therapist quickly pushes up and in, under the diaphragm with the heel of his or her hand, as in a Heimlich maneuver. The patient is instructed to assist with appropriate trunk movements as much as possible. Technically, this procedure is very effective at forcefully expelling the air,[22] as in a cough, but it can be extremely uncomfortable for the patient for several reasons:

Its concentrated area of contact

Its abrupt nature, which may elicit an undesired high neuromuscular tone response, or worse when combined with the sensory input supplied by the therapist's manual contacts

The force, which may cause gastrointestinal dysfunction such as GER

Because of its limited usefulness, the Heimlich-type, or abdominal thrust, assist should be used only when the patient does not respond to other techniques and the need to produce an effective cough is great.

The therapist can use a combination of the costophrenic and the Heimlich-type assists simultaneously when the patient is in the side-lying position. If the patient has a hemiplegic deficit or has a unilateral lung or thorax disease or trauma, emphasizing one side of the thorax over the other may be an appropriate focus during airway clearance treatments. One upper extremity is used to perform the Heimlich-type assist while the other does a unilateral costophrenic assist. In this manner, the therapist can compress simultaneously all three planes of ventilation in the lower chest. The possibilities of combining techniques and positions are numerous once the therapist understands the principles on which they were developed.

Anterior Chest Compression Assist

The third assistive cough technique is called the anterior chest compression assist because it compresses both the upper and lower anterior chest during the coughing maneuver. This is the first single technique thus far to address the compression needs of the upper and lower chest in one maneuver. The therapist puts one arm across the patient's pectoralis region to compress the upper chest; the other arm is placed parallel on the lower chest (avoiding the xiphoid process) or on the abdomen (Figure 22-4, *A*) or is placed as in the Heimlich-type

Fig. 22-2 Assisted cough techniques in supine position; costophrenic assist.

Fig. 22-3 Hand position for Heimlich-type (or abdominal thrust) assist.

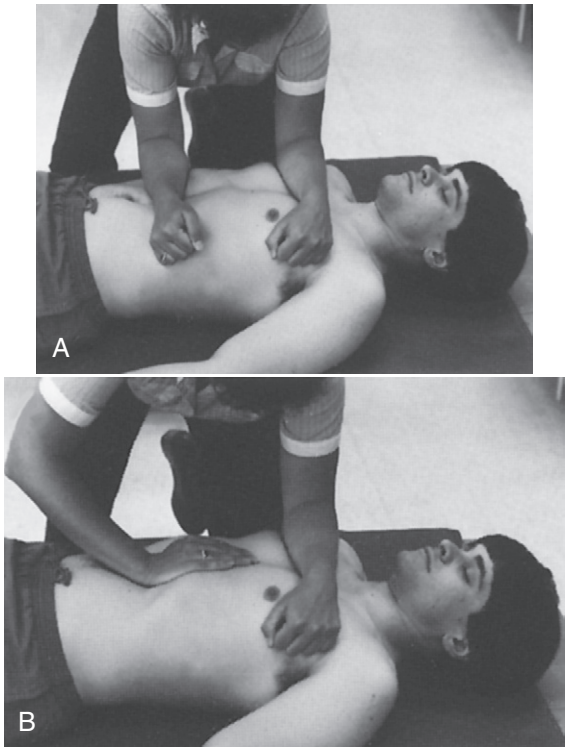

Fig. 22-4 Assistive cough techniques in supine position. **A,** Variation 1. **B,** Variation 2.

maneuver (Figure 22-4, *B*). The commands are the same as in the other techniques. Because of the direct manual contact on the chest, inspiration can be easily facilitated first, followed by a "hold." Thus the therapist can readily enhance the first two cough stages. The therapist then applies a quick force with both arms to simulate the force necessary during the expulsion phase. The directions of the force are:

1. Down and back on the upper chest
2. Up and back on the lower chest or abdominal arm

When performed together, the compression force exerted by both arms forms the letter V.

The anterior chest compression technique is more effective than the costophrenic assist for patients with very weak chest wall muscles because of the added compression of the upper anterior chest wall. These authors have found the side-lying or three-quarter supine position to be the most effective position for this technique. However, the anterior chest compression technique is not appropriate for a patient with a cavus condition of the upper anterior chest because it promotes further collapsing of the anterior chest wall.

Counter-Rotation Assist

In these authors' clinical experience, the most effective assistive-cough technique for the widest cross-section of patients with neurological disorders is the fourth and final method described: the side-lying counter-rotation assist.[18] The positioning and procedures required for the counter-rotation technique (described in detail in Chapter 23) apply for both the patient and the therapist (Figure 22-5). The therapist should recall that orthopedic precautions for the spine, rib cage, shoulder, and pelvis also apply for this technique.

The therapist begins by following the patient's breathing cycle, with his or her hands positioned over the patient's shoulder and pelvis (see Figure 22-5). The therapist then gently assists the patient in inhalation and exhalation to promote better overall ventilation. This sequence is generally repeated for three to five cycles or until the patient appears to have achieved good ventilation to all lung segments.

At this point, the patient is ready to begin the coughing phase of the procedure. The patient is asked to take in as deep a breath as possible, with the therapist assisting the patient in chest expansion (see Figure 22-5, *B*). Next, the therapist instructs the patient to "hold it" at the end of maximal inspiration. The patient is then commanded to cough out as hard as possible while the therapist quickly and forcefully compresses the chest with his or her hands in their flexion phase positions (see Figure 22-5, *A*).

The importance of following a true diagonal plane of facilitation during both the flexion and extension phases of this technique cannot be overemphasized. Failure to do so will result in the shifting of the air within the chest cavity rather than the desired forcing out of the air. This air shifting can occur to varying degrees when the upper chest and lower chest are not used together, as in all the other assistive cough techniques. When done properly, the counter-rotation assist is the only technique to rapidly close off the chest cavity in all three planes of ventilation in all areas of the chest. Unless the patient voluntarily closes his or her glottis, it is impossible to prevent the air from being forcefully expelled. However, a common mistake made by the therapist is pulling the patient back into trunk extension during the expulsion phase rather than into trunk flexion. A good rule of thumb: if you can see your patient's face when you are applying the compression force, you have pulled him or her into extension. The head and neck should stay forward and flexed so that only a facial profile can be seen.

Other effects of counter-rotation make this procedure particularly beneficial for patients with low levels of cognitive functioning:

1. The rotation component is a natural inhibitor of high tone. Thus this is the least likely of all techniques discussed so far to elicit an increase in abnormal tone during the coughing phase. In fact, the opposite usually occurs. Gentle rotation before passive coughing in a patient who is comatose can reduce high tone and frequently reduces a high respiratory rate. Both of these reduce the possibility of the patient's keeping his or her glottis closed during the expulsion phase.
2. Counter-rotation is an excellent mobilizer for a tight chest, which in itself can facilitate spontaneous deeper breaths. Tidal volumes (TVs) can therefore be increased for many patients by mobilizing the chest walls.
3. Finally, rotation can be a vestibular stimulator and may assist in arousing the patient cognitively, allowing him or her to take a more active role in the procedure.

The true beauty of the technique is the fact that no active participation on the part of the patient is required for success. Incoherent or unresponsive patients, such as patients with low functioning following a head trauma, CVA, or cerebral palsy, will still achieve good secretion clearance with this technique. The mechanics of the procedure dictate that the air within the lungs be rapidly and forcefully expelled, regardless of the patient's level of active participation. Obviously, patient

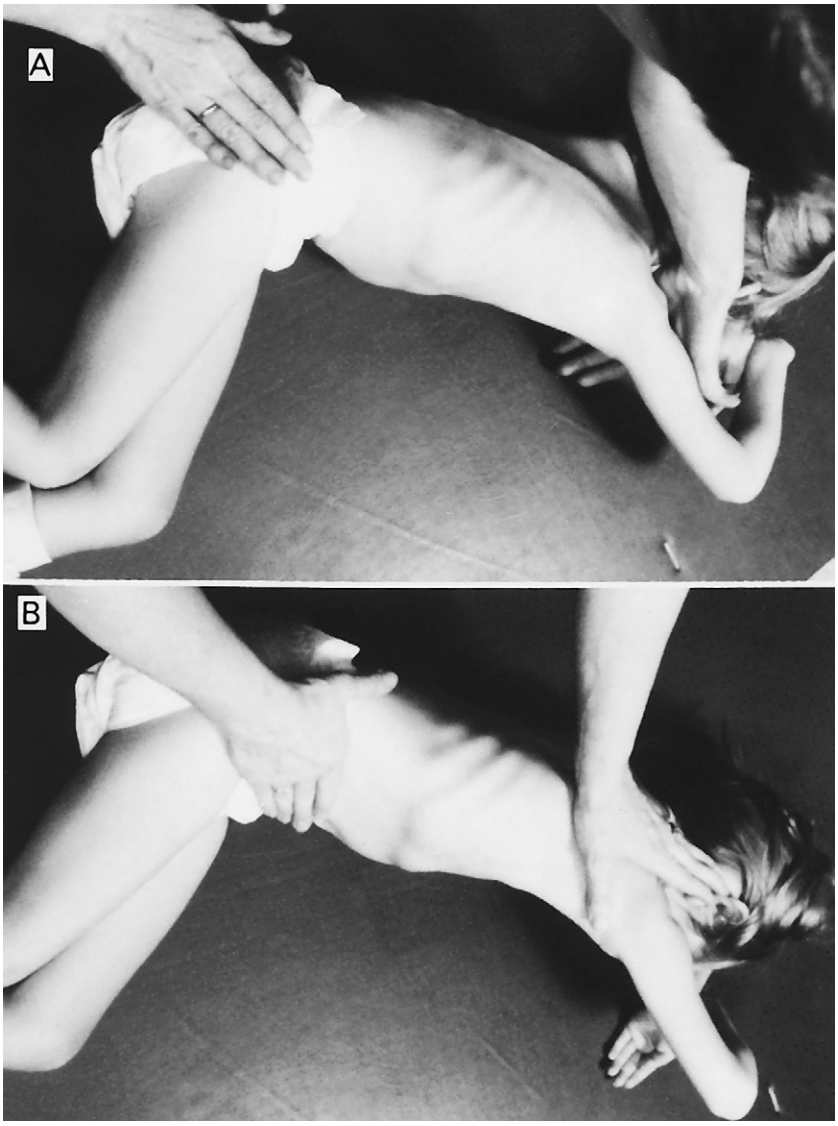

Fig. 22-5 Counter-rotation assist. **A,** Hand placement during expulsion phase. **B,** Hand placement during inspiration phase.

participation is desirable to clear secretions even more effectively and to teach the patient to eventually clear his or her own secretions, but it is not critical.

Clinical experience has demonstrated that in patients who have extremely tenacious secretions, the use of vibration may be more effective than quick chest compression during the cough itself. This prolongs the cough phase and gives the secretions time to be moved along the bronchi for successful expulsion. These patients may also require a series of three or four cough cycles before clearing most of their secretions. In general, patients from all the diagnostic groups discussed thus far, with or without good cognitive functioning, are appropriate candidates for this procedure. The majority of them find it to be the most comfortable and effective assistive means of expectorating secretions.

Self-Assisted Techniques

The coughing techniques discussed in this section are intended to be used as self-assisted procedures, so they are usually taught later in a patient's rehabilitation process. Five different techniques are presented in detail. Patients need to learn to cough in whatever position they are in for therapy or rest. Suggestions for variations are included. All self-assisted cough techniques can start out as physically assisted techniques; however, because they are more active and require greater gross motor movement, they lend themselves to self-assisted techniques.

Prone-on-Elbows, Head-Flexion Self-Assisted Cough

The prone position is not commonly used as a posture for coughing because the position itself inhibits full use of the diaphragm by preventing lower anterior chest and abdominal excursion following a neurological insult. This forces the patient to use an alternative breathing pattern that facilitates greater use of accessory muscles. Because this change in breathing patterns often occurs spontaneously, prone on elbows can be an effective posture for promoting spontaneous use of the accessory muscles during a more difficult activity (coughing). However, without the full recruitment of the

diaphragm, the resultant cough will be weaker than it would be in other postures. Prone on elbows should not be the exclusive posture for a self-assisted cough. After mastering the timing of the procedure, most patients move back to another posture, usually sitting or side-lying, and to other techniques to capitalize on the functional increase in chest expansion and compression. For the population of patients who can assume a prone-on-elbows posture independently (i.e., some patients with tetraplegia), this technique may be used functionally. In this position, they can assist their own coughs when the need arises, rather than wait for someone to assist them in a position change.

The head-flexion assist requires good use of head and neck musculature, seen in patients who have sustained a spinal level injury below C4 (e.g., spinal cord injuries [SCIs], spina bifida). It can be used either as a self-assisted or a therapist-assisted procedure, using the principles of trunk extension to facilitate inspiration and trunk flexion to facilitate expiration. With the patient prone on elbows, the therapist instructs him or her to bring the head and neck up and back as far as possible, inhaling maximally (Figure 22-6, *A*). The patient is then instructed to cough out as hard as possible while throwing the head forward and down (Figure 22-6, *B*). This head-and-neck pattern can initially be assisted by the therapist to establish the desired movement pattern and gradually progressed to a resisted pattern to promote increased accessory muscle participation and to strengthen those muscle groups.

Fig. 22-6 Head-flexion assistive cough in prone-on-elbows position. **A,** Extension and inspiratory phase. **B,** Flexion and coughing phase.

Long-Sitting Self-Assisted Cough

There are two variations of this technique, one for tetraplegic patients and one for those who are paraplegic. For the tetraplegic version of the long-sitting self-assist, the patient is positioned on a mat in a long-sitting posture (legs straight out in front) and with upper extremity support. The therapist instructs the patient to extend his or her body backwards while inhaling maximally (Figure 22-7, *A*). The therapist then tells the patient to cough as the patient moves his or her upper body forward into a completely flexed posture, using shoulder internal rotation if possible (Figure 22-7, *B*). Once again, the extension aspect of the procedure is used to maximize inhalation, whereas the flexion aspect is used to maximize expiration. The self-directed chest compression occurs mainly on the superior-inferior plane of ventilation only.

The second procedure, the paraplegic version of the long-sit assist, uses the same principles as those described for the tetraplegic patient. However, paraplegic patients have active spinal extension musculature and can achieve greater trunk extension and flexion safely, thus achieving greater chest expansion before the cough and greater chest compression on a superior-inferior plane during the cough. The patient positions his or her upper extremities in a butterfly position or uses elbow retraction, depending on the level of injury (Figure 22-8, *A*). During the flexion phase, patients throw themselves onto their legs, thereby compressing both the upper and lower chest (Figure 22-8, *B*). This can be taught very successfully to patients with paraplegia, provided they have adequate trunk balance control. If the patient lacks hip flexion or is worried about bony contact or skin injury, place a pillow (or two as needed) on the legs. This will limit the hip flexion and minimize trauma from the quick thrust onto the legs.

Short-Sitting Self-Assisted Cough

A third assistive cough technique can be done with the patient sitting. The short-sitting self-assist is typically performed in a wheelchair or over the edge of a bed. The patient is instructed to place one hand over the other at the wrist and place them in his or her lap. As in the previous technique, the patient is then asked to extend the trunk backwards while inhaling maximally, followed by a strong voluntary cough. During the cough, the patient pulls his or her hands up and under the diaphragm, resembling the motion of a Heimlich maneuver (Figure 22-9). The hands mimic the abdominal muscles, which would ordinarily contract to push the intestinal contents up and under the diaphragm to aid its recoil ability. This short-sitting technique uses the diaphragm more substantially than the long-sitting procedure and is therefore generally more effective as an assistive cough. It is an effective self-assisted method for patients who have weak diaphragms or abdominal musculature. Most patients with SCI or spina bifida at C5 or below can learn this technique successfully. Patients with tetraplegia usually require trunk support and/or a seat belt from their wheelchairs to perform it independently and safely, whereas most patients with lower-level lesions resulting in paraplegia can perform it from an unsupported short-sitting position. Patients who lack good upper extremity coordination, such as many patients with Parkinson disease and multiple sclerosis (MS), cannot perform the procedure

Fig. 22-7 Tetraplegic version of self-assisted cough in long-sitting position. **A,** Maximizing the inspiration phase. **B,** Maximizing the expiration, or coughing, phase. *(From Watchie J: Cardiovascular and pulmonary physical therapy, ed 2, St Louis, 2010, Saunders.)*

quickly or forcefully enough to make it effective and usually require assistance from another person.

Variations on all sitting techniques can be made readily. Clinicians are encouraged to use the concepts explained in the introduction to these cough techniques to develop techniques that work for their patients. For example, ask a patient in a wheelchair to lift his or her arms up while inhaling, hold, and then cough while throwing the arms down toward the feet or lap using maximum trunk flexion (use a seat belt for safety). Another idea is to have the patient hook one arm on a push handle of the wheelchair and move the other arm up and back (as in a pattern of shoulder flexion, abduction, and external rotation proprioceptive neuromuscular facilitation [PNF Pattern D2]);[35] make sure the patient's moving hand maximizes trunk rotation; have the patient inhale during the movement, hold, and cough while throwing the trunk and arm down toward opposite knee. When devising the most appropriate self-assisted cough for your patient, remember to look for a combination of trunk, arm, head, neck, and eye patterns that will maximize all four phases of the cough.

Hands-Knees, Rocking Self-Assisted Cough

The last assistive cough to be discussed is performed most commonly as a multipurpose activity to increase the patient's balance, strength, coordination, and functional use of breathing patterns (including quiet breathing and coughing) simultaneously. The patient assumes an all-fours position (hands-knees). He or she is then instructed to rock forward, looking up and breathing in while moving to a fully extended posture (Figure 22-10, *A*). After this, the patient is told to cough out as he or she quickly rocks backwards to the heels with a flexed head and neck (Figure 22-10, *B*). Once again, note the importance of the flexion and extension components of the cough. The rocking can be done with or without a therapist's assistance. For patients with generalized or spotty weakness throughout (e.g., some patients with SCI, head trauma, Parkinson disease, MS, cerebral palsy, or spina bifida), this method is perfect for incorporating many functional goals into a single activity. It can help prepare them for the more challenging respiratory activities they will undoubtedly face after their discharge from a rehabilitation center.

Fig. 22-8 Paraplegic version of self-assisted cough in long-sitting position. **A,** Inspiration. **B,** Expiration. *(From Watchie J: Cardiovascular and pulmonary physical therapy, ed 2, St Louis, 2010, Saunders.)*

For patients with limited lower extremity range of movement or skin concerns associated with a quick force, a pillow can be placed on the lower legs, thus restricting knee flexion and preventing direct contact of bony prominences.

Standing Self-Assisted Cough

Standing uses the same concepts as previously discussed and can be readily used for self-assisted coughs, provided the patient has adequate standing balance and upper extremity support. Any technique previously described can be modified for this posture. The number of possible combinations of trunk, head, and extremity movements during the cough maneuver is vast, so specific techniques are not detailed here.

CoughAssist Machine

As mentioned previously in the chapter, if patients are unable to be independent and assist in coughing to remove secretions, other options will be necessary. At this point, suctioning has been the most commonly used aid in secretion removal. However, it is not always tolerated well by patients. Mouth suction for oral secretions is usually appreciated and easy to use, but patients with tracheostomies and endotracheal tubes usually require more invasive—and more uncomfortable—suctioning into the trachea to remove secretions. Many patients have found a new device to be superior in comfort and in effectiveness in removing secretions; this piece of equipment, now readily available, is the CoughAssist machine.

Fig. 22-9 Assisted cough in short-sitting position. **A,** Hand position for patient with good hand function. **B,** Hand position for patient with only wrist function. *(From Watchie J: Cardiovascular and pulmonary physical therapy, ed 2, St Louis, 2010, Saunders.)*

Fig. 22-11 CoughAssist machine.

The CoughAssist, previously known as the Cofflator or Mechanical Insufflator-Exsufflator (MI-E), is a noninvasive machine used for airway clearance. A positive-pressure phase (insufflation) is followed by a negative pressure phase (exsufflation), simulating a cough. This device can be used as a face mask or attached to a universal adaptor for a tracheostomy tube (Figure 22-11).

Adults and children with neuromuscular disease are susceptible to recurrent chest infections, which are a major cause of morbidity and mortality. The suggested mechanism of action of the CoughAssist machine is to improve peak cough flow.[19] In a study of 22 patients ages 10 to 56 (median age 21), spirometry and respiratory muscle strength were measured. Peak cough flows were measured with maximal coughs unassisted, then randomly with assistive coughs, noninvasive mechanical ventilation, CoughAssist machine, and exsufflation alone. All the therapeutic techniques were well tolerated and showed similar patient acceptance. However, the CoughAssist machine produced greater increases in cough pressures than did the other cough-assist techniques.[23] Considering the workload of caregivers and the availability of the CoughAssist machine, many patients with neuromuscular weakness and artificial airways could well use this as an effective adjunct in the home, as well as in other settings.

The CoughAssist machine has been used primarily in adults, but it is being used more and more in children. In a study of 62 children (median age 11.3, ranging from 3 months to 28.6 years) with neuromuscular disease and impaired cough who were seen in a pediatric respiratory clinic, it was much preferred and was considered safe, well tolerated, and effective in 90% of this population for preventing pulmonary complications.[36] In a similar study, patients with spinal cord injury also preferred the CoughAssist machine and found it effective and more comfortable than other methods for removing secretions.[37] In a direct comparison of suctioning and the CoughAssist machine for adult patients with neuromuscular impairments, Massery and colleagues found no clinically significant difference between the two mechanical interventions; however, patients preferred the CoughAssist machine 10 to 1 over suctioning.[38]

Summary

In all postures and in all techniques, for both assisted and self-assisted coughs, initial positioning and ventilatory strategies are of utmost importance to the success of the airway clearance technique. Be creative in applying the concepts in this chapter to all patient populations. Also consider the mechanical needs of patients who are not able to assist or to be independent in the secretion removal that prevents pulmonary complications. From the tiniest postural change to full-body movements and physical assists, the most effective modification exists—the therapist just needs to find it so that all patients can improve their coughing.

Review Questions

1. What are the two mechanisms of airway clearance?
2. Which patients would a therapist need to assist in their coughing?
3. How does the CoughAssist machine work, and which patients would benefit from it?
4. What is a smoker's cough, and why does it occur?
5. What are the stages of a cough?

Individuals with breathing impairments (whether primary or secondary in origin) require a variety of interventions to optimize ventilation and oxygen delivery, as well as improving functional outcomes. Some interventions are passive in nature, such as the positioning of the patient or the application of an abdominal binder for better diaphragmatic positioning. Other interventions require very active participation on the part of the therapist, patient, or both, such as in assisted-cough techniques, in glossopharyngeal breathing instruction, or in learning a more efficient breathing pattern. Ideally techniques are incorporated into the patient's total physical rehabilitation program, such as the use of ventilation strategies pairing breathing with movement. All of these diverse aspects of treatment play an important role in the development of

a successful rehabilitation program to meet the needs of patients with pulmonary impairments. No single intervention or approach is appropriate in all cases. Sound clinical judgment and experience must be exercised when applying these ideas in each person. The interventions identified in this chapter are not inclusive. They are meant to provide examples and guidelines and to stimulate the clinician's creative talents in order to incorporate the interventions into a comprehensive treatment program determined by individual needs that improve the outcomes for each patient (Box 23-1).

Positioning Concerns

All patients spend some portion of the day in a horizontal position for rest or sleep. Some who are acutely ill or medically compromised spent extended time in bed, and major emphasis must be placed on the mobilization of patients early and often to prevent immobility from exerting its negative effects on all body systems (see Chapter 18). Studies have shown that patients who are medicated and spend extended time on ventilators in the ICU have developed critical illness neuromuscular syndrome or ICU-acquired weakness. Interventions shown to help prevent this problem are physical therapy/activity and daily interruptions of sedative medication.[1,2,3] These studies validate the need for intervention to prevent untoward effects of immobility and sedation.

Despite these problems, the time spent in a horizontal position can be used as an opportunity to assist patients in passive drainage and preventing the retention of lung secretions. It can be a natural beginning in the development of a patient's long-term respiratory program (e.g., the prevention of respiratory complications in a patient with tetraplegia). Specific postural drainage positions are covered under airway clearance interventions (see Chapter 21). Using a combination of these positions and the patient's position in bed, in the hospital or at home, can help to achieve multiple goals. First, various horizontal positions can assist patients in passively clearing secretions that they may have difficulty clearing actively. Pneumonia is still the leading cause of death in patients with spinal cord injury (SCI) who are tetraplegic.[4] Second, these position changes provide for skin relief and better circulation. Finally, they assist in retarding the development of joint contractures or other musculoskeletal abnormalities. A four-position rotation (i.e., supine, prone, and side-to-side) or a modified six-position rotation (supine, three-quarter supine, side-lying, three-quarter prone on each side) is usually an effective and reasonable means of incorporating these goals into a long-term prophylactic program.

Simple adaptations may make ventilation easier in each of these postures. For example, when the patient is in the supine position, placing the patient's arms up over his or her head facilitates greater anterior upper chest expansion.[5] Likewise, positioning the pelvis in a slight posterior tilt facilitates more diaphragmatic excursion. (Detailed explanations of positioning are discussed in Chapter 42.) Observation of all precautions and contraindications to passive positioning is still warranted, and positions should be modified based on the individual need of each patient.

Just as passive positioning of the patient in bed helps to maintain airway clearance and improve ventilation potential, optimal passive positioning of the patient's skeletal frame in an upright posture (sitting, standing) helps to maximize the mechanical advantages that facilitate breathing and improve cardiovascular fluid shifts. For example, patients with SCIs resulting in tetraplegia will be unable to support their intestinal contents properly under the diaphragm to allow for maximal expansion of the chest in all three planes of ventilation (see Chapter 39). The use of an abdominal support from the iliac crest to the base of the xiphoid process provides positive-pressure support to restore intestinal positioning to an upright position (Figure 23-1). Research has documented

well the significant improvements in vital capacity (VC), inspiratory capacity, and tidal volume (TV) in sitting with the use of a strong abdominal support.[6] These binders have also been used in nursing care to provide for better circulation and the prevention of hypotension.

The abdominal binder's value in cosmesis may be underrated. Many patients with neurological issues were once healthy individuals with high self-esteem who took great pride in their appearance. Many now present with protruding bellies (the anterior and inferior shift of the intestines resulting from flaccid abdominal muscles), which may be psychologically disturbing to them. Thus the use of a binder may greatly aid in the restoration of these patients' self-esteem, which should be a high-priority goal in any rehabilitation program.

A rigid type of abdominal support can be used when the vertebral column and the abdominal viscera need support. These are called body jackets or total contact thoracic lumbar sacral orthoses (TLSOs) (Figure 23-2). A TLSO is a rigid trunk support molded individually to the shape of the patient's entire trunk from the axilla down to the pubis. It is composed of two separate pieces, a front and a back, ideally with an anterior cutout in the abdomen to allow for normal diaphragmatic displacement of the viscera. In addition to these jackets, an elastic binder is applied around the abdomen to allow for

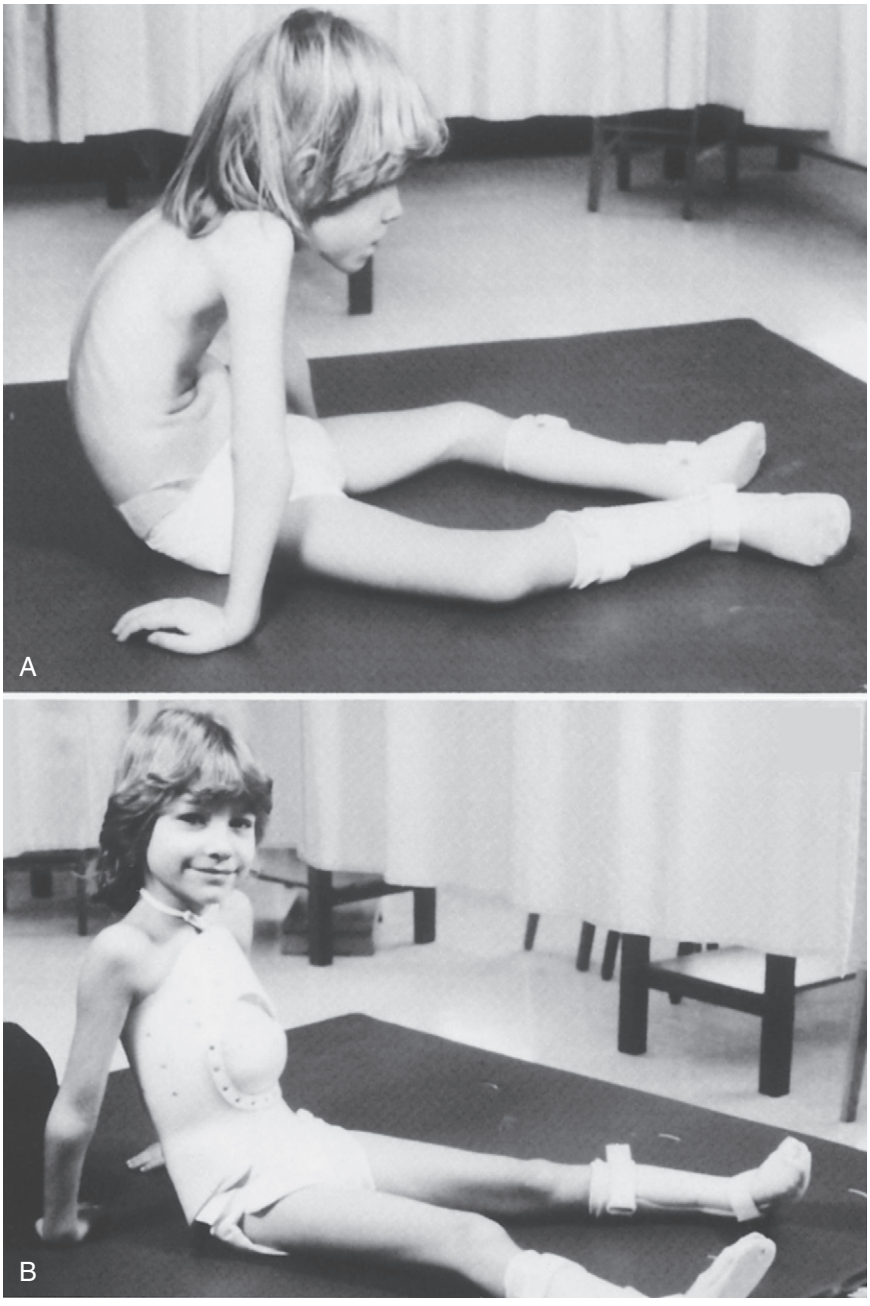

Fig. 23-2 **A,** Patient with C5 congenital tetraplegia, independent long-sitting. **B,** Long-sitting with body jacket support. Note the changes in head position and eye contact, hip alignment, and shoulder rotation.

diaphragmatic motion but minimize excessive displacement of the abdominal contents. This is particularly appropriate for a growing child who needs more spinal stability and for the completely flaccid patient with tetraplegia, who may also require the same support. Because head and neck positioning are so dependent on trunk positioning, a body jacket may make the difference for these patients between being dependent or independent in an upright posture. It may result in significantly better head control and eye contact and improved phonation. However, because the TLSO limits trunk movement, its usefulness for each patient must be assessed carefully.

The next consideration in passive respiratory techniques is proper wheelchair positioning. Optimal performance in ventilatory functioning, as well as many other areas of rehabilitation, depends on good alignment of the body against the force of gravity. Symmetry must be strived for through the use of a body jacket, lateral trunk supports in the wheelchair, abdominal binders, or some other means (Figure 23-3). This is especially important for patients with hemiplegia in whom habitual asymmetrical posturing leads to musculoskeletal problems later. Symmetrical breathing patterns and uniform aeration of all lung segments are augmented by careful upright positioning. Therefore everything from the type of neck and trunk support to the height and width of the arm rests to the length and type of the foot supports must be carefully analyzed for each patient.

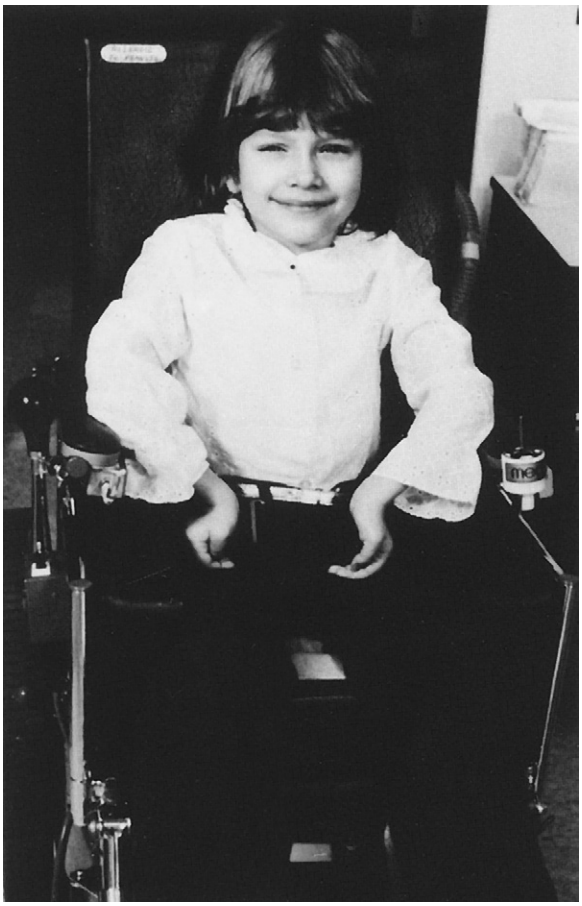

Fig. 23-3 Wheelchair alignment considerations.

Ventilatory and Movement Strategies for Improving Functional Outcomes

Observing patient movement and ventilation is inherent in the physical therapist's examination and evaluation of the patient. Patients often will hold their breath during activities. This will limit their ability to perform functional activities. When it is observed that breath holding is occurring or that the patient has dyspnea with activity, it is important to incorporate ventilatory strategies.

The patient is first positioned for successful ventilation. Then motor activities should be introduced. Interventions chosen will improve the patient's ventilatory support, or the therapist should capitalize on the patient's good ventilatory support to improve the motor activity. Using ventilatory strategies to improve motor performance or movement strategies to improve ventilation performance enables patients to achieve their functional goals sooner and have better health, including fewer respiratory complications. Generally, these simple concepts take no more than 1 to 2 additional minutes of therapy time, with no additional equipment costs other than a few extra pillows or towels. Therefore time and money are not mitigating factors. However, these ideas do require the practitioner to look carefully at the patient before beginning any treatment intervention and to ask, "Have I positioned my patient for ventilatory success?"; "Am I simply treating the patient in whatever position I found her or him in?"; and "Have I carefully chosen my verbal cues to include a ventilatory response and a functional response?" The practitioner must actively include ventilation in every activity to help the patient understand that breathing transcends all activities. Breathing is the bridge to function. A summary of the most important ventilation-movement strategies is listed in Box 23-2.

Incorporating Simple Therapy Tasks

Inspiration

After the patient has been carefully positioned for respiratory success, as described previously, begin the patient's therapy or daily-living activities. In a study looking at rhythmic pronation and supination wrist movements, inspiration and exhalation adapted and became coordinated with the arm movement (Table 23-1).[7,8] Accordingly, then, the simple task of passive

Box 23-2 Significant Ventilatory Movement Strategies

- Pair trunk extension activities with inspiration
- Pair trunk flexion activities with exhalation
- Pair shoulder flexion, abduction, and/or external rotation activities with inspiration
- Pair shoulder extension, adduction, and/or internal rotation activities with exhalation
- Pair upward eye gaze with inspiration
- Pair downward eye gaze with exhalation

Table 23-1 Anatomy of Inspiration and Expiration

	Inspiration	Expiration
Trunk	Trunk extension	Trunk flexion
Shoulders	Shoulder flexion, abduction, and external rotation movements	Shoulder extension, adduction, and internal rotation movements
Gaze	Upward eye gaze	Downward eye gaze

range of movement (ROM) can easily include the active goal of increasing ventilation by asking the patient to breathe in and look up when his or her arm is raised up into shoulder flexion. This encourages the patient to breathe in when the chest wall muscles are being stretched and the ribs are naturally opening up, causing both activities to be more successful. It also begins to teach the patient to use ventilatory strategies to optimize potential functional movement, such as in reaching up to a kitchen cabinet. Patients need to focus on avoiding breath holding and incorporating breathing during each activity.

Exhalation

Likewise, active or passive exhalation should be coordinated with the reverse upper extremity ROM pattern (i.e., the arm returning from flexion back to the patient's side). This can be done using all types of exhalation patterns, including the following:

- Passive quiet exhalation
- Forceful exhalation, as in blowing, coughing, or pursed-lips exhalation
- Vocalization patterns

Thus the therapist may ask the patient to slowly count out loud to 10 while the arm is being returned eccentrically to his or her side. The patient learns to correlate exhalation with shoulder extension while simultaneously learning a much more complex idea—that of controlling his or her rate and volume of expiration by including deliberate speech during exhalation maneuvers. Research is being done in the area of respiratory plasticity to evaluate changes with exercise and conditioning.[9,10] Clinical observation demonstrates that patients will incorporate new ventilation strategies and that these strategies become less cognitive and more based in habit as they are repeated.

In a recent study of strategies for respiratory exercise patterns with upper extremity movements in patients with chronic obstructive pulmonary disease (COPD), 15 patients were instructed in the reverse pattern. For example, with shoulder flexion they performed the activity with exhalation versus inhalation. The researchers concluded that there was less chest asynchrony and that it may be an important strategy for people with COPD to use the opposite pattern.[11] This study had only 15 patients with COPD; however, it may be noted that with ventilatory strategies, patients may try different ways of incorporating breathing. As long as patients are not breath holding, therapists should feel safe encouraging them to try techniques and see what works best for them.

To improve exhalation potential, increase the patient's relative trunk flexion alignment. While the patient is still supine and performing upper extremity ROM, ask the patient to lift his or her head and watch the hand as it returns to the side, which increases abdominal and intercostal activation. Or ask the patient to increase knee flexion, which increases posterior pelvic tilting and trunk flexion. Pairing trunk flexion with exhalation completes the trunk movement strategy for better ventilation.

Combining positioning with verbal cues for ventilation, as described in ROM activities, changes passive upper extremity ROM exercises into dynamic upper extremity ROM exercises. It encourages increased inspiratory and expiratory capacities, develops early functional motor planning strategies, and facilitates trunk mobility. In this manner the patient has the opportunity to learn from the beginning of his or her rehabilitation process that movement and breathing go hand in hand. Clinically, incorporating appropriate breathing patterns with movement early in the rehabilitation process discourages the development of Valsalva patterns or shallow breathing patterns when the motor activities become more difficult and complex. Patients who are mechanically ventilated on an assist mode or during a time of sedation interruption can accomplish this as well.

Dynamic Activities

Inhalation promotes trunk extension, exhalation promotes trunk flexion, and vice versa. This basic theme occurs naturally in all motor activities but may have ceased to become spontaneous after a neuromuscular or musculoskeletal insult. Valsalva, or breath holding, maneuvers during transitional movements, such as rolling or coming to a sitting or standing position, are often noted in these patients. By teaching them strategies that incorporate breathing into their motor plans for all motor activities, Valsalva patterns can be eliminated or minimized while simultaneously promoting better cardiovascular function.

The following activities are just a few of the common daily activities. They are typical gross motor activities, but the use of ventilatory strategies is a means of improving patients' abilities to perform them. Extrapolation of these concepts to all other motor activities should be carefully analyzed by each therapist for each individual patient, looking at the trunk patterns and type of muscle contraction that occurs in a given exercise or activity. At times there may be more than one effective ventilation strategy; there is no hard-and-fast rule. What is important is that patients breathe with the movement and not hold their breath.

Rolling

Ask patients to attempt to roll, and assess whether they tend to move with trunk extension or flexion to begin the roll. Those who roll in trunk extension patterns should be asked to breathe in while they roll and to look up. Those who roll with trunk flexion as their primary movement pattern should be instructed to roll first by inhaling, then blowing out and tucking the chin during the roll. In doing so, patients work with, not against, natural whole patterns of movements that increase the likelihood of success.

Coming Up to Sitting

Pushing up to sitting from side-lying should be evaluated in much the same manner. If patients are more effective in coming to the upright position when using trunk extension, have them inhale as they push up to sitting. Asking them to look up as they come to upright will reinforce the movement. If they are weaker and have more success in pushing up with trunk flexion, have them blow out and tuck the chin while moving. It may be helpful to allow patients to try both strategies and see which is most effective. The important consideration is that they do not hold the breath while changing the position.

Dressing

Patients often express how short of breath they become with dressing. These activities, too, can benefit from the concepts discussed here. Use of the upper extremities has been shown to involve an increase in oxygen consumption over lower extremity activities. For dressings, the recommended position is either sitting in a chair or the long-sitting position in bed for those with less trunk control (such as patients with SCI). While putting on lower extremity items such as pants, socks, and shoes in a long-sitting position, have the patient first take in a deep breath while extending his or her trunk. Then have the patient blow out, huff out, or cough while flexing the trunk to reach his or her toes. This combines the functional daily task of dressing with improving breath control, trunk control, and airway-clearance techniques.

Upper extremity dressing and upper extremity exercise can incorporate the same ideas. All movements should be coordinated with appropriate chest wall movements to maximize upper extremity tasks. Thus every time the arm is moving up above 90 degrees of shoulder flexion, the patient should be asked to breathe in, allowing for the normal shoulder/rib-cage rhythm to occur. Full shoulder flexion requires the opening of the intercostal spacing and the separation of the individual ribs.[12] Many patients with neurological impairments have lost the intrinsic mobility of the chest wall and thus may have lost some functional shoulder ROM as well. Not pairing inspiration with shoulder flexion is likely to limit the patient's shoulder ROM to approximately 140 to 150 degrees. It may also encourage Valsalva maneuvers during the activity and may cause more shoulder pain.

Coming Up to Standing

Coming up to standing requires both trunk flexion and trunk extension. Patients often use a rhythmic initiation (rocking) to begin the sit-to-stand transfer. This is a good opportunity to begin teaching breath control. Patients breathe in and then as they rock forward, they exhale; rocking backwards, they inhale as the trunk extends. There can be several cycles of rocking and breathing prior to standing before control is attained. Thus patients should initiate the forward trunk lean with exhalation and then initiate the standing phase with inhalation and trunk and neck extension. Active neck extension during assumption of standing not only facilitates greater inhalation but, along with the influence of the tonic labyrinthine reflex (TLR), also facilitates more significant contractions of the trunk and hip extensors. Clinically, this often results in a more noticeably upright posture and may make the difference between an assisted standing pivot transfer and an independent one. Returning to sitting should be accompanied by slow, controlled exhalation, such as in pursed-lips blowing or counting out loud, in order to maximize the body's controlled descent into gravity's influence.

Facilitating a Controlled Diaphragmatic Breathing Pattern

Why would a therapist want to change a patient's breathing pattern? The answer is simple—when the pattern being used is ineffective. Ordinarily, people use the pattern of breathing that is the most efficient for them. However, when the work of breathing increases and musculoskeletal, neuromuscular, or pulmonary impairment is present, abnormal patterns that are not efficient may be adopted. The patient knows that it requires hard work to breathe but often does not know how to do it with greater ease, especially during stressful situations when panic is present. The patient may spontaneously do pursed-lips breathing (PLB) but often in a forceful manner that may not relieve the dyspnea.

A healthy person uses approximately 5% of total oxygen consumption and 10% of vital capacity for the muscular work of breathing. Consequently, breathing at rest is generally perceived as effortless under normal conditions.

However, in the patients physical therapists evaluate and treat (often after surgery, respiratory disease, or dysfunction secondary to neurological insult or injury), the vital capacity may be significantly decreased and the oxygen consumption may be greatly increased because of the use of accessory muscles or the extra effort needed to breathe or cough.

Many patients with lung cancer also have COPD, which increases their postoperative complications because of impaired pulmonary function before surgery. In a study of patients with COPD who needed to undergo surgical resection for cancer, it was found that a preoperative pulmonary rehabilitation program of 10 visits over a 4-week period consisting of exercise prescription, inspiratory muscle training, and slow breathing technique improved patients' postoperative progress. The group in this program required a shorter period of time in the ICU and fewer days using a chest tube. Although this study was done with only nine patients, it has implications for improvement of postoperative success. However, in many cases, it may not be feasible to have 4 weeks of pulmonary rehabilitation before lung surgery. Some surgeons are hesitant to delay the needed surgery for pulmonary rehabilitation. A larger study would need to be conducted to demonstrate cost effectiveness, as well as the benefits and risks.[13]

Vital capacity is also affected in cases of tetraplegia, in which patients' vital capacity may be reduced to 1000 to 1500 mL from their normal 3000-mL vital capacity (50%). If the normal TV (normal volume of breathing) is 500 mL, this means that with each breath the patient would use 33% to 50% of his or her vital capacity (maximal inspiration followed by maximal exhalation). This would greatly increase the work of breathing and oxygen consumption just for normal quiet breathing. The patient would have little pulmonary reserve. This can lead to respiratory muscle fatigue. During exercise or stress, the patient would have an increased subjective feeling of shortness of breath and feel an increase in the work of

breathing. In addition, patients with spinal cord injury who are smokers experience excessive vital capacity losses.[14] Commonly used terms to describe breathing patterns are listed in Box 23-3. A listing of indications for teaching controlled-breathing techniques is provided in Box 23-4.

It should be appreciated that breathing comfortably and in a controlled manner is associated with wellness and a sense of ease. Even normal individuals who are under stress and have increased work levels are more cognizant of the increase in their work of breathing. For a patient who struggles with every breath and wonders how it will be possible to get through the day, ventilatory strategies and breathing-control techniques can be the key to maximizing potential. A list of goals for teaching controlled-breathing techniques is found in Box 23-5.

Breathing control has long been used in yoga to focus and to promote meditation. This is a key to maximizing rehabilitation. Patients who cannot breathe cannot function! It is of primary importance to assess patients' breathing at rest and during exercise. People often hold their breath with exertion, especially during new activities, so it is vital to assess the cardiopulmonary and neuromuscular response to each new activity. In many rehabilitation centers and health clubs, Pilates exercise regimens have been used to help patients achieve core strength and back stabilization. Pilates is a method of physical and mental conditioning combined with body, mind, and spirit integration; it has been also used by dancers and choreographers to improve postural control, increase ease of movement, and improve their performance. The first phase of Pilates incorporates diaphragmatic breathing *before continuing with the steps* to activate the muscles of the core (multifidus, diaphragm, pelvic floor, and transverse abdominis). The belief is that when the individual has a strong core, the posture will improve and the performance of other functional activities will be improved. This is similar to our concept of teaching diaphragmatic breathing control before functional activities in people with respiratory impairments. Joseph Pilates actually used the term *contrology* to define his concepts. That is what we are striving to teach our patients—breath control, then function.[15]

Box 23-3 Breathing Pattern Terminology

Eupnea: Normal breathing, repeated rhythmic inspiratory-expiratory cycles

Hyperpnea: Increased breathing; usually refers to increased tidal volume with or without increased frequency

Polypnea, tachypnea: Increased frequency of breathing

Hyperventilation: Increased alveolar ventilation in relation to metabolic rate (an increase in alveolar ventilation); seen as a decrease in the arterial P_{CO_2}

Hypoventilation: Decreased alveolar ventilation in relation to metabolic rate (a decrease in alveolar ventilation); seen as an increase in P_{CO_2}

Apnea: Cessation of respiration in the resting expiratory position

Dyspnea: The patient's subjective feeling of shortness of breath

Apneusis: Cessation of respiration in the inspiratory position

Apneustic breathing: Apneusis interrupted periodically by exhalation

Cheyne-Stokes respiration: Cycles of gradually increasing tidal volume followed by gradually decreasing tidal volume (usually followed by an apneic period)

Biot respiration: Sequences of uniformly deep gasps and apnea, followed by deep gasps

Modified from Comroe JH, Jr: Physiology of respiration, *ed 2, St Louis, 1974, Mosby.*

Box 23-4 Indications for Teaching Controlled-Breathing Techniques

Patients with any of the following:

- Pulmonary dysfunction, either primary or secondary causes
- Pain resulting from surgery, trauma, or disease
- Apprehension or nervousness
- Bronchospasm or impending bronchospasm in asthma
- Airway clearance dysfunction
- Restriction of inspiration resulting from musculoskeletal dysfunction, such as scoliosis, kyphoscoliosis, or pectus excavatum; obesity; pregnancy; pulmonary pathology such as fibrosis; scarring resulting from radiation therapy; neurological weakness such as spinal cord injury, Parkinson disease, or myasthenia gravis
- Congestive heart failure, pulmonary edema, or pulmonary emboli
- Rib fractures
- Ventilated patients on assist control or intermittent mandatory ventilation
- Metabolic disturbances that have a compensatory respiratory response
- Debilitated or bedridden patients, who tend to have constant volume ventilation and retain secretions and are prone to pneumonia and atelectasis due to poor airway clearance

Box 23-5 Goals of Teaching Controlled-Breathing Techniques

- To decrease the work of breathing
- To improve alveolar ventilation
- To improve airway clearance by improving cough
- To increase strength, coordination, and efficiency of respiratory muscles
- To improve phonation and the ability to express needs and wants
- To teach the patient how to respond to and control breathing
- To assist in relaxation
- To mobilize and maintain mobility of the thorax
- To enable patients to feel self-control and confidence in managing disease or dysfunction

Considerations in Teaching Breathing Control to Patients with Primary Versus Secondary Pulmonary Dysfunction

Patients with primary lung disease, such as COPD, asthma, bronchitis, or cystic fibrosis, present a picture very different from that of patients with secondary pulmonary deficits, SCI, Parkinson disease, myasthenia gravis, or Guillain-Barré syndrome. In general, patients with primary lung disease tend to overuse their accessory muscles and greatly increase the work of breathing secondary to shortness of breath or coughing. They often complain that they have difficulty "getting the air out," which demonstrates the decreased expiratory flow rates noted on pulmonary function tests. This can lead to dynamic hyperinflation, in which patients continue to gasp and increase the respiratory rate so more air is coming in, but there is not time for the air to be exhaled. Large volumes of air can get trapped in the lungs, which causes increased feelings of shortness of breath and panic. The goal with these patients is to teach them to relax the neck and chest accessory muscles and use more diaphragmatic breathing (abdominal and lateral costal breathing) to reduce the work of breathing in combination with relaxed pursed-lips breathing and prolonged exhalation. Their treatment programs focus on energy conservation, relaxation, and pacing activity with breath control. In pulmonary rehabilitation programs, exercise is a key component. Patients learn to coordinate their breathing with their activities and find that they have less dyspnea with exertion.[16,17]

There has been controversy in the literature about the effectiveness of diaphragmatic breathing. No standardized "norms" of how to perform diaphragmatic breathing exist. However, many skilled cardiovascular and pulmonary physical therapists would consider teaching the patient with COPD how to relax the accessory muscles and use the diaphragm as an important part of the patient's pulmonary rehabilitation. Dechman reported that in a search of the literature, pursed-lips breathing was considered most effective by people with COPD and that the literature does not strongly support the use of diaphragmatic breathing in people with COPD.[18] Cahalin found there are both positive and potentially detrimental effects to diaphragmatic breathing training.[19] Each individual patient needs to be evaluated to consider whether diaphragmatic breathing may be beneficial. For example, patients with severe hyperinflation and flattened diaphragms secondarily will most likely not benefit from diaphragmatic breathing because the muscle length tension relationship is abnormal and will not result in an appropriate movement of the diaphragm. With patients who have mild to moderate COPD and are overusing the accessory muscles, diaphragmatic breathing may be very helpful; it may require less oxygen consumption, decrease the respiratory rate, and increase the tidal volume.

Patients with secondary pulmonary dysfunction, such as SCI, have a more restrictive component to inspiration. In these cases, accessory muscles may be intact, but they are not being used to facilitate deep breathing or coughing. Patients may have strong diaphragmatic breaths, but the upper chest collapses on inspiration (paradoxical breathing; see Chapter 39). The goal is to teach these patients to use the accessory muscles to balance the upper and lower chest. This facilitates an increase in vital capacity that prevents atelectasis and pneumonia by increasing the volume of ventilation and improving the cough mechanism.

The choice of appropriate ventilatory strategies is determined by the individual patient's problem. The following questions should be considered when evaluating a patient:

- Does the patient have more difficulty during inspiration or exhalation?
- Is there a normal sequence to inspiration (i.e., abdominal wall rise, then lateral costal expansion, then upper chest expansion, with a full inspiration)? Or does the chest sink and the abdomen rise on inspiration?
- Does the patient appear to be working hard to breathe? Is the patient using the accessory muscles to an extreme?
- Does the patient frequently clear the throat, have trouble coughing, or have difficulty speaking at a normal volume and for the normal length of sentences?
- Is ventilation the limiting factor in accomplishing an activity (e.g., transfer, gait, or bed mobility)?

Patients with primary pulmonary disease generally benefit from ventilatory strategies that relax the accessory muscles and facilitate relaxed diaphragmatic breathing. On the other hand, patients with secondary pulmonary dysfunction usually benefit from the balanced use of the diaphragm and accessory muscles to increase vital capacity and breath support for activities.

Pursed-Lips Breathing

Pursed-lips breathing is a strategy that is often spontaneously used by people with COPD during episodes of dyspnea. Many patients feel this breathing pattern helps to decrease their breathlessness. The effect of PLB is an increase in the time of exhalation, which results in a decrease in the end-expiratory volume and an increase in the total time of the respiratory cycle. This results in a decreased respiratory rate and increased TV. According to studies, a decrease in the Borg scale of perceived exertion also occurs when PLB is used.[20] This technique has been acknowledged by many patients with respiratory impairments as being very easy to learn and yet very effective, quick to use, and readily incorporated into their activities to reduce dyspnea.[21]

When instructing a patient in PLB, emphasis should be placed on a relaxed, slow, prolonged, controlled exhalation. Often when patients initiate PLB spontaneously, they use a forceful exhalation, which tightens the neck musculature and oral area. This builds a significant pressure that can counteract the effectiveness of the technique and the subsequent relief of dyspnea. A relaxed head, neck, and mouth are essential. If patients have difficulty relaxing the mouth, they may be encouraged to try making an *sssss,* or hissing, sound, which will still prolong exhalation and provide back pressure.

Relationship of the Diaphragm and Posture

The respiratory action of the diaphragm and other respiratory muscles is normally coordinated with the need to provide postural control of the trunk during movement of the

extremities.[8] The diaphragm acts both as a muscle of respiration and as a muscle that works in providing core stability to the trunk. However, when respiratory demand increases, the diaphragm may not be able to continue to provide both of these functions.[22-27] Because the diaphragm is the primary muscle of respiration, postural control may be impaired. A complete discussion of this concept is provided in Chapter 39.

Facilitating Diaphragmatic Breathing

In the initial phases of breathing retraining, patients are taught to use the easiest intervention that facilitates diaphragmatic breathing; if it is not successful, a progression of specific facilitation and inhibition techniques will be tried. A summary of methods of facilitating diaphragmatic ventilation patterns is given in Box 23-6.

Diaphragmatic Controlled Breathing

Diaphragmatic breathing is the normal mode of ventilation. The diaphragm and intercostals are the normal muscles of quiet inspiration. When evaluating a patient's breathing pattern, the use of accessory muscles during quiet breathing should be noted; the patient with primary pulmonary disease needs to be instructed in relaxation of the accessory muscles to decrease the work of breathing. However, in a patient with a spinal cord injury or other neuromuscular disorder, these accessory muscles may assist in balancing ventilation and may also be useful in increasing vital capacity, improving the ability to cough, improving breath support for speaking, and increasing the potential for functional activities.

In general, controlled diaphragmatic breathing should be emphasized in each posture and in all therapeutic activities because carry-over of the breathing pattern from one posture to another or one activity to another is not necessarily present. If the patient is shown the pattern only when in the supine position, it may not carry over to sitting or to a sliding-board transfer, when the activity becomes more complex. A helpful sequence might be to teach the breathing pattern in side-lying, supine, sitting, and standing positions and in walking, stair climbing, and other functional activities, especially in patients with COPD. Patients with neurological impairment may require modification of the breathing pattern so that it fits well with their activity levels and capabilities.

Box 23-6 Diaphragmatic Facilitation Techniques

6. Upper chest inhibiting technique
7. Normal timing technique

Positioning Concerns

Position of Pelvis

The first step in facilitating any breathing pattern is to position the patient for ventilatory success. The details are discussed in this chapter and in Chapter 42. Often a patient's posture and pelvic position have dramatic effects on breathing. In general, a slight, relative posterior tilt of the pelvis facilitates diaphragmatic breathing, and a relative anterior tilt facilitates the opening of the anterior chest and upper chest breathing. It is helpful to see what difference a slight, relative change in pelvic position will do to a patient's ability to ventilate. This is especially true in secondary pulmonary problems related to neurological and neuromuscular dysfunction. A lumbar roll or a roll under the ischial tuberosities can facilitate an anterior pelvic tilt (see Chapter 42).

Relaxation of Upper Chest and Shoulders

Jacobsen's progressive relaxation exercises are familiar to physical therapists. Jacobsen proposed that a maximal muscle contraction would yield a maximal muscle relaxation. This technique can be applied to the upper chest and shoulders. The therapist places his or her hands on the patient's shoulder girdle. The patient is asked to shrug his or her shoulders up into the therapist's hands and hold it. "Don't let me push your shoulders down," is the therapist's command. Then, "Let your shoulders relax, let them go." The emphasis is on the relaxation phase. Verbal commands can be very important with this procedure. A strong command to "Raise your shoulders into my hands" is followed by a quiet, calmer, "Now relax and let them go," repeating quietly, "That's it, let them go, feel them relax." The addition of counter-rotation of the shoulder girdle can make this intervention more effective. Patients can learn the techniques independently and can relax their shoulders when they begin to feel tense. In addition, making shoulder circles in both directions, forward and backwards, can loosen the shoulder girdle. Sometimes the relaxation activity is all that it takes to resume a more natural pattern of breathing, and the therapist can move on to other therapeutic activities. If the patient starts to use accessory muscles again, the technique is repeated. The patient learns to feel the difference between tension and relaxation of the shoulders and can self-monitor and perform the relaxation independently.

Repatterning Technique

If a patient needs more support to gain control of breathing and is experiencing shortness of breath, a simple repatterning technique may be beneficial. An example might be a patient with asthma who has a high respiratory rate and is feeling panicky. When the patient is asked why he or she is breathing so fast, the reply will usually be, "I am not getting enough air. I can't catch my breath." The patient is asked to start with exhalation: "Try to blow out easily with your lips pursed. Don't

force it; just let it come out." A helpful technique for producing a prolonged, easy exhalation is to ask the patient to visualize a candle with a flame and then imagine exhaling in a way that makes the flame flicker but not go out. Doing this allows the respiratory rate to decrease automatically. When the patient feels some control of this step, then add, "Hold your breath at the top of inspiration just for a second or two." Make sure the patient does not bear down as in a Valsalva maneuver or hold the breath longer. Last, ask the patient to take a slow breath in, hold it, and let it go out through pursed lips. Patients learn that when they are short of breath, this technique often helps them to gain control, making them feel less panicky.

Sniffing

If working toward a generalized controlled-breathing pattern does not improve the patient's ventilatory pattern adequately, a technique that more specifically addresses the need to initiate breathing from the diaphragm can be attempted. Sniffing is a simple and effective means of teaching diaphragmatic breathing.[28] Sniffing is accomplished primarily by the diaphragm. This technique can be used first, before attempting more specific diaphragmatic training with patients who are capable of attempting sniffing because of its simplicity.

As with all procedures, the most important step is the first step: position the patient appropriately to increase the likelihood of increased diaphragmatic breathing resulting from musculoskeletal alignment. This includes the following:

- Choosing a gravity-eliminated position such as side-lying or a gravity-assisted position such as a supported semi-Fowler sitting position (supported spine)
- Choosing a relatively posteriorly tilted pelvis with flexed knees
- Choosing arm flexion below 90 degrees (in relative shoulder extension, adduction, and internal rotation)
- Choosing to use a pillow or pillows under the patient's head

For each patient, choices will be different (e.g., the amount of knee flexion or the number of pillows). Find the right combination of positioning characteristics that best facilitates diaphragmatic movement for that particular patient. (For details on positioning, see Chapter 42.) In this manner the therapist sets up the patient for ventilatory success before beginning the manual or verbal technique.

Initially, ask the patient to place his or her hands on the abdomen for increased proprioceptive feedback and the relative extension, adduction, and internal rotation position of the shoulders. In a quiet voice, ask the patient to "sniff in three times." Note whether the patient demonstrates more abdominal rise or lower chest expansion or both. If so, draw attention to this fact. During exhalation, tell the patient to "let it out slowly," which helps to prolong the exhalation and slow the respiratory rate (RR) and often encourages some relaxation. Progress the training by guiding the patient to "now sniff in twice, a little deeper." Do you still see greater diaphragmatic excursion and less upper chest excursion? If so, continue by asking for "one long slow sniff." If successful, follow with "now do it more quietly," then "now do it more slowly," then "even more quietly," or "less effort," and so forth. By this time, the patient should be demonstrating an easy-onset, slower RR and a diaphragmatic pattern with relaxed shoulders.

Clinical experience has shown this technique to be highly successful with about 80% of patients who have primary pulmonary pathologies or neurological impairments. The key to success seems to stem from the relaxed tones and words that the therapist uses, which decrease anxiety and imply relaxation and not "effort." Once the pattern has been established, the patient can easily be instructed to go through the training independently, as needed. The sequence (in whole or in part) may be appropriate for patients before getting out of bed if they become anxious and demonstrate excessive upper chest breathing during this activity. For other patients, it may be appropriate before or during eating or before climbing stairs. Obviously, the application of this technique will be individualized for each patient, depending on individual impairments.

Procedure for Teaching Controlled Diaphragmatic Breathing (Scoop Technique)

Minimal patient instruction is necessary to facilitate diaphragmatic breathing using the scoop technique. It allows the patient to feel the breathing pattern; then it is brought to the patient's cognitive awareness. The patient then learns to self-cue to incorporate the breathing pattern.

The following is a suggested sequence:

1. Position the patient for success, generally side-lying in a semi-Fowler position or supine in a semi-Fowler position, with a bend in the knees to achieve a relative posterior pelvic tilt and relaxation of the abdominal muscles.
2. Place your hand on the patient's abdomen at the level of the umbilicus. Tell the patient you want to feel his or her breathing. Follow the patient's breathing pattern for a few cycles until you are in synchrony with his or her respiratory rhythm. Do not invade the patient's breathing pattern; rather, at first, follow its movement.
3. After the normal end of the patient's exhalation, give a slow stretch and "scoop" your hand up and under the anterior thorax as shown in Figure 23-4, *A*. Then ask the patient, "Now, breathe into my hand," as the slow scoop stretch is done.
4. As the scoop stretch is performed, instruct the patient to "breathe into my hand" during the inspiration. Give a scoop at the end of exhalation with each breath. The verbal command can be effectively replaced after a few respiratory cycles with the therapist's audible breathing to facilitate the ventilatory pattern.
5. After achieving some success, call the patient's attention to the awareness of the breathing pattern. For example, ask, "Can you feel how your abdomen rises as you breathe in and your ribs go up to the side?" The patient's hand can be placed on the abdomen with the therapist's hand on top. Reinforce the breathing pattern, then remove your hand and allow the patient to feel independently the ventilatory pattern (Figure 23-4, *B*).

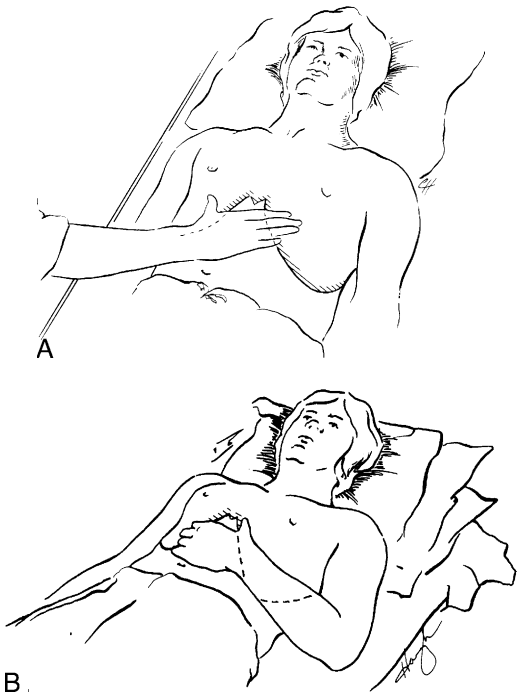

Fig. 23-4 Diaphragmatic breathing. **A,** Therapist's hand placement for diaphragmatic breathing. **B,** The patient is encouraged to continue practicing diaphragmatic breathing to become aware of his breathing pattern. This is usually the first position of the diaphragmatic breathing teaching sequence.

A few things should be taken into consideration. Don't ask patients to take too many deep breaths; they may begin to feel lightheaded because they may hyperventilate and blow off too much CO_2. The fact that they are breathing more with their diaphragms is the important consideration. Note also the position of the pelvis and trunk.

When the patient has mastered the breathing pattern in the side-lying position, try supine. Then progress to sitting (Figure 23-5, *A*), then standing (Figure 23-5, *B*), then walking (Figure 23-5, *C*) and, finally, stairs (Figure 23-5, *D*). Each position increases the difficulty in performing diaphragmatic breathing. In the side-lying or supine position, the patient is fully supported. The side-lying position is especially good for initial teaching of diaphragmatic breathing because the diaphragm is in a gravity-eliminated position. In the supine position, the patient must breathe against gravity. As he or she progresses to sitting, the patient must also provide trunk support and maintain stability against gravity, as well as relax the shoulders. In standing, the entire body must be supported, and when walking and stairs are added, the elements of breathing coordination, weight shifting, and balance increase the complexity of the activity.

Coordination of breathing for walking involves being careful not to allow the patient to hold the breath. It is important to keep inspiration and exhalation regular at a ratio of at least 1 to 1, preferably exhaling a little longer—1 to 2 or 1 to 4. In some yoga breathing techniques the exhalation is significantly longer—1 to 6, 1 to 8, or at times even longer.

In general, the preferred pattern for a patient with primary pulmonary dysfunction is as follows:

1. Have the patient pause at the base of the stairs to gain control.
2. Have the patient take a breath in and move up one step while exhaling.
3. The patient then pauses to inspire and exhales while walking up another step.
4. The patient should be encouraged to use the handrail and pace his or her movement slowly and with breath control.

A patient with neuromusculoskeletal issues who has lower extremity weakness may benefit from inspiration while ascending stairs and exhalation during descent. Going downstairs uses an eccentric muscle pattern, and exhalation is a relatively eccentric contraction of the diaphragm. Refer to the section on ventilatory and movement strategies in this chapter for additional information.

Lateral Costal Breathing

Lateral costal breathing also facilitates diaphragmatic excursion. It may be done bilaterally or unilaterally (Figure 23-6). Lower chest lateral costal expansion facilitates diaphragmatic and intercostal breathing in which the mid-chest recruits primarily intercostal activity.[29]

Upper Chest Inhibition

If all other manual facilitation interventions do not produce the desired increase in diaphragmatic breathing, inhibiting the upper chest during inhalation may be effective.

First, position the patient appropriately in a side-lying, three-quarter supine, or supine position. Begin by facilitating the diaphragm, usually with the diaphragm scoop. Slowly bring your other arm across the upper chest at about the level of the sternal angle. Leave it there for a couple of respiratory cycles without applying any pressure in order to feel the upper chest's movement.

After assessing this movement, gently allow your arm to follow the upper chest back to its resting position when the patient exhales. On the patient's next inspiratory effort, do not move your arm position. Thus your arm position will apply pressure or resistance to the expansion of the upper chest. This gentle pressure will cause postural inhibition to the anterior and superior movement of the upper chest. After each expiratory cycle, add more pressure until the patient subconsciously increases the lower chest breathing out of necessity.

When you note more diaphragmatic or lower intercostal muscle excursion, mention it to the patient. Ask the patient to try to reproduce this pattern. With your other arm, continue to facilitate the desired response, such as with the diaphragm scoop. Slowly, during each of the next series of inhalations, release your inhibition as the patient tries to maintain the improved lower chest-breathing pattern. If the patient is only partially successful, the inhibition can be partially reapplied to assist the patient. If the patient becomes anxious because the therapist's inhibition is preventing upper chest breathing, then decrease the inhibition to a comfortable level. This technique should never cause an increase in anxiety or it will only encourage more upper chest breathing rather than less. When the pressure is released on the upper chest, continue to facilitate diaphragmatic breathing and strive to have the patient do it independently.

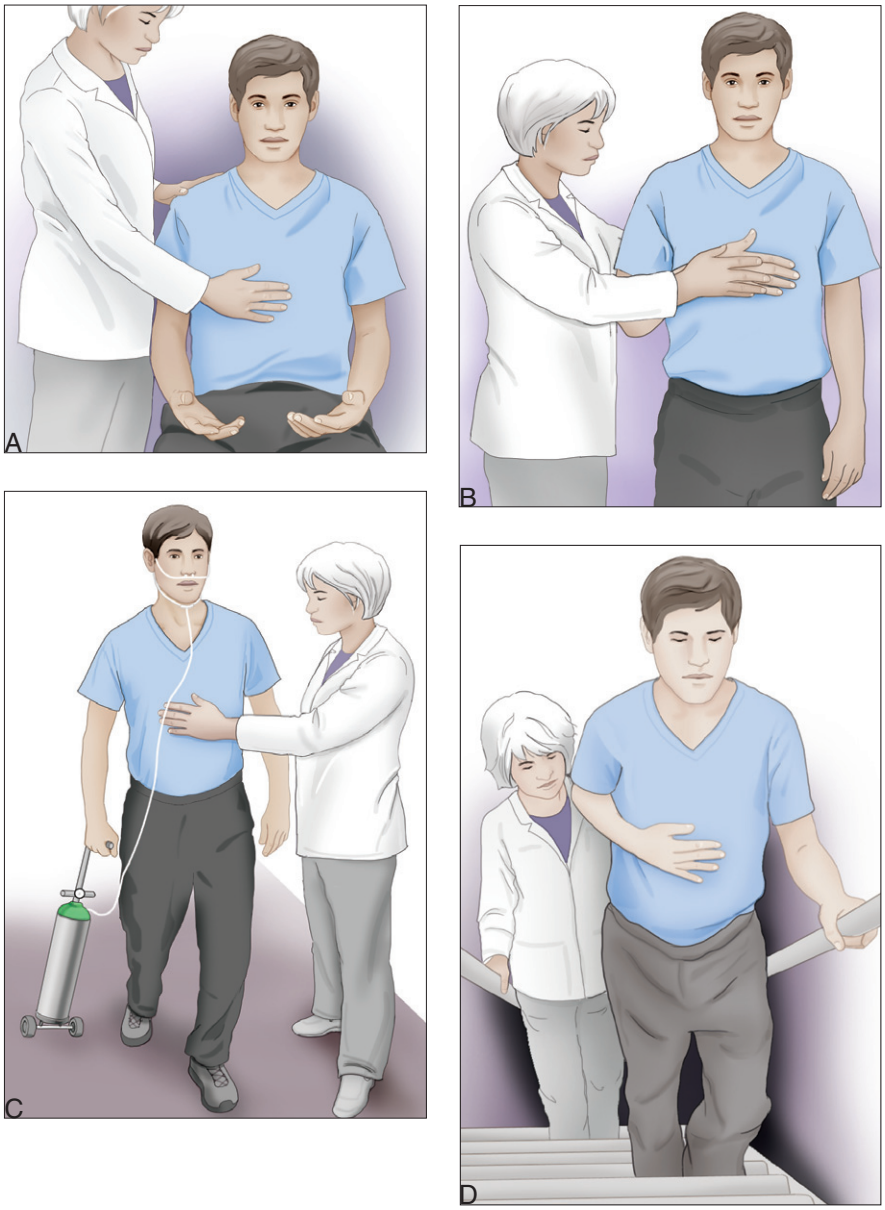

Fig. 23-5 Diaphragmatic breathing, supine. **A,** The patient advances to the sitting position for breathing retraining. Note the relaxed position of the patient's shoulders and hands. **B,** The third position in the sequence is standing. Full-length mirrors are helpful at this point. **C,** Walking is the fourth stage of retraining. The patient is encouraged to relax, control his breathing, take long steps, and slow down. **D,** Stairs are important, especially if the patient has them at home. He is instructed to pause slightly as he breathes in and to exhale as he climbs one to two steps.

Normal Timing

During normal quiet inspiration (controlled breathing), the diaphragm contracts, which is seen outwardly as a gentle rise of the abdomen. The second movement is seen as lateral costal expansion of the lower chest and, usually to a lesser extent, lower anterior chest expansion. Finally, the upper chest rises slightly, primarily in a superior-anterior plane, with less lateral expansion noted. A normal timing technique adapted from the physical therapy approach of proprioceptive neuromuscular facilitation (PNF) can help the patient work on this sequence. After the patient has learned to initiate inspiration with his or her diaphragm and lower chest wall muscles more consistently, this technique can help to put the whole sequence together. The diaphragm continues to be the primary mover, but the accessory muscles are encouraged to do what they should do, which is to assist the diaphragm for better overall ventilation.

Generally, the patient is positioned symmetrically in either a supine or a supported sitting position, with a neutral pelvic position. The therapist waits until the end of an expiratory cycle and then, using the hand placement of the diaphragm scoop, asks the patient to breathe in "here." With the other hand, the therapist moves up the chest wall to the lower sternum and touches the patient, giving instructions again to "now breathe here." Finally, the therapist uses the first hand to move up to the upper sternum (usually around the level of the sternal angle) and asks the patient to "now breathe here."

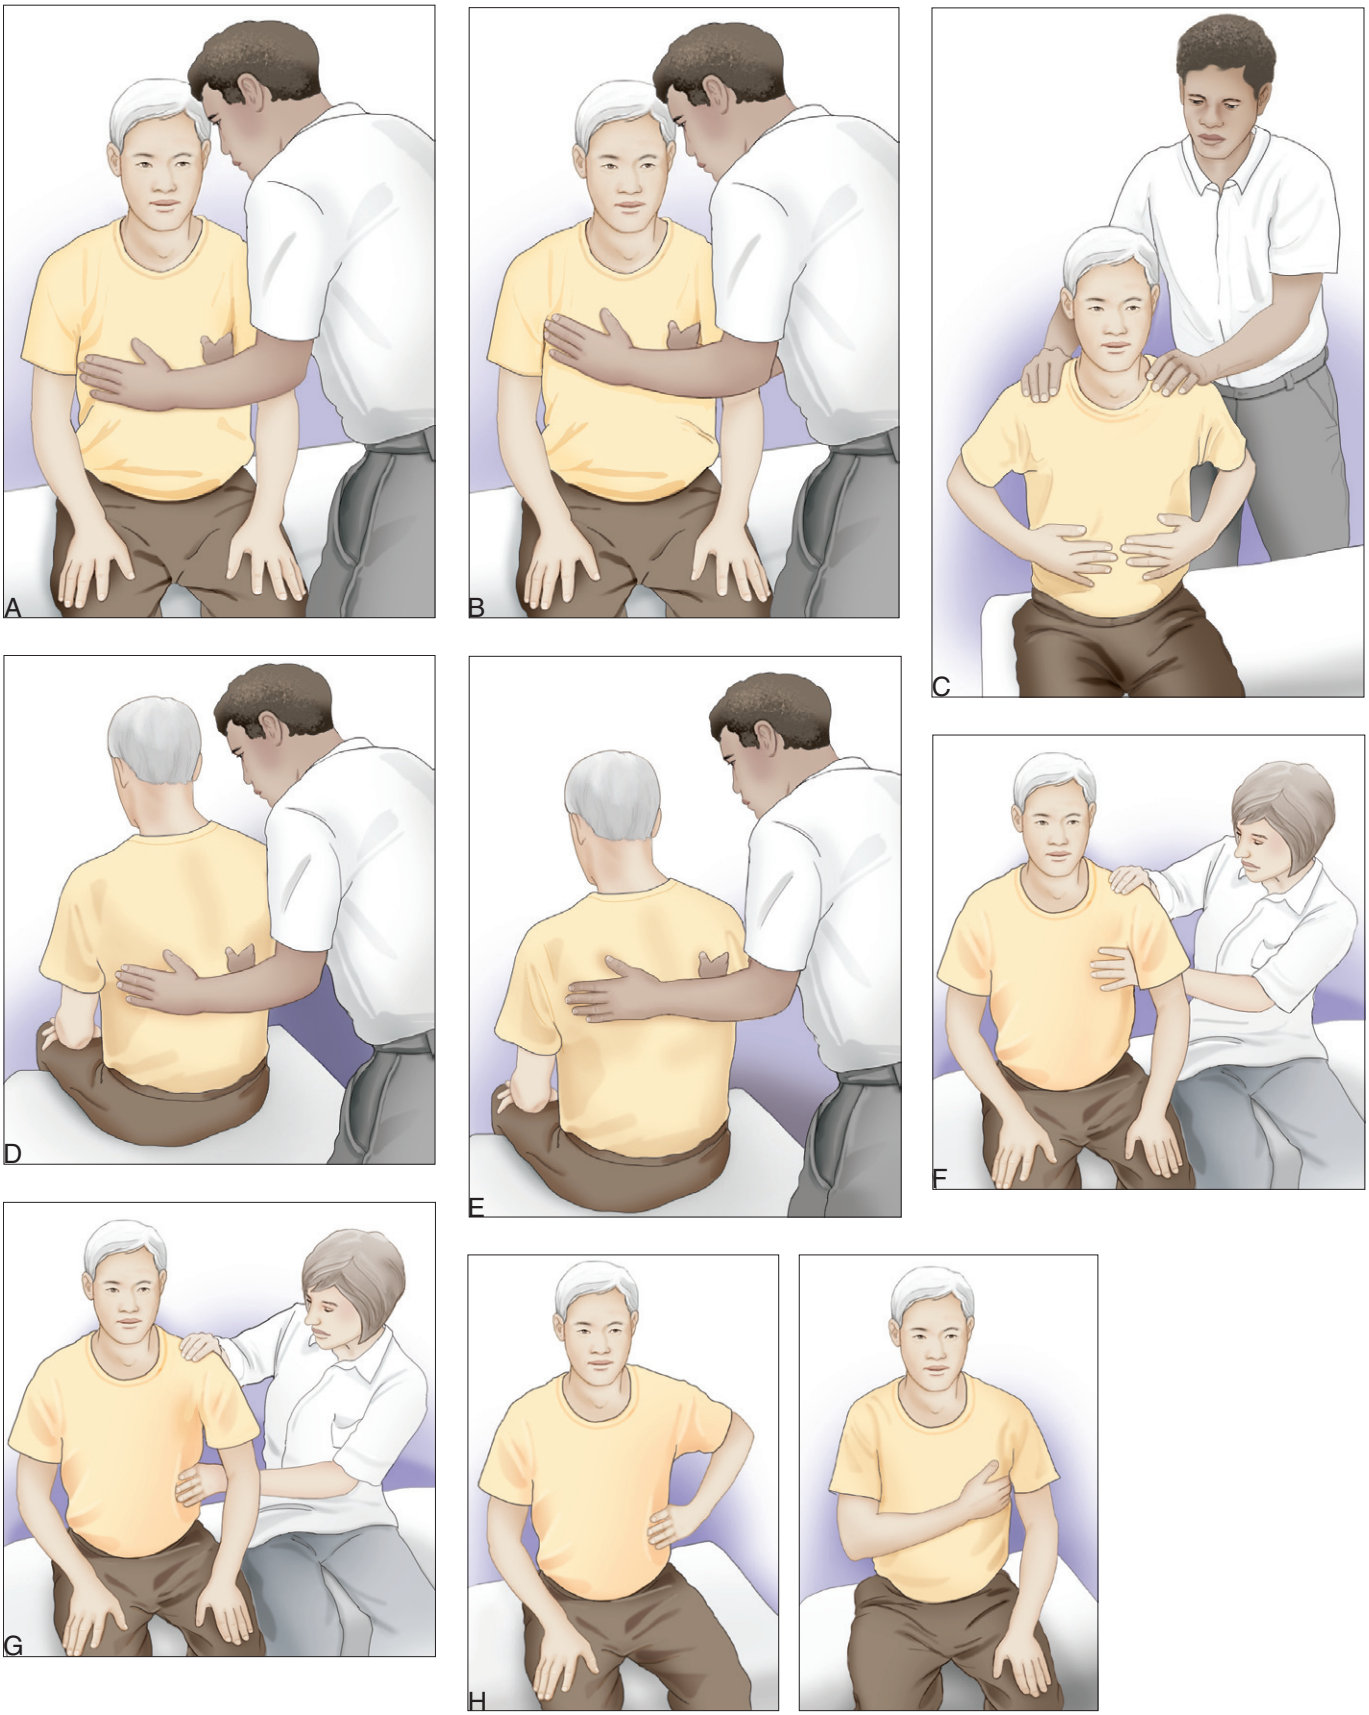

Fig. 23-6 A, Bilateral lower lobe expansion (this also facilitates diaphragmatic movement). **B,** Bilateral mid-chest expansion exercise. **C,** Self-assisted bilateral chest expansion exercise. Keep the patient's shoulders relaxed. **D,** Bilateral posterior chest expansion exercise. **E,** Bilateral posterior chest expansion exercise. **F,** Unilateral (segmental) breathing, left mid-lung field. **G,** Unilateral (segmental) breathing emphasizing the left lower lobe. Note that the patient's shoulder must remain down, with hands placed on ulnar border or palms up in his lap. **H,** The patient can perform unilateral (segmental) breathing by placing either hand on the side of the chest to be emphasized. The patient can also perform mid-chest expansion by moving the hand up.

It is important that the therapist smoothly transition from one hand to the next to assist the patient in developing a smooth motor transition from one area of the chest to the other. The manual cues provide tactile cueing rather than true motor facilitation. Because of this, the normal timing sequence is obviously a more advanced technique intended for use after success has been achieved in initial diaphragmatic training. It can address the functional need of the patient to take a quick deep breath in order to cough or a deeper breath in order to talk in longer sentences.

Mobilizing the Thorax

For some patients, controlled breathing alone may not alleviate inefficient ventilatory patterns, even with use of good positioning and appropriate ventilatory strategies. The thorax itself may be incapable of moving freely enough to allow for the adequate chest wall excursion necessary for that breathing pattern. For example, a patient with a spinal cord injury who is demonstrating an excessive diaphragmatic pattern that is unbalanced by the normal neuromuscular support of the intercostal and abdominal muscles can breathe using minimal chest wall expansion. This is often referred to as "belly breathing." It may be necessary to mobilize individual rib segments to gain the potential for chest wall expansion in all three planes of ventilation before facilitating a specific breathing pattern. If the potential for movement is not there, the breathing pattern cannot change. Likewise, a patient having primary pulmonary dysfunction and COPD, undergoing chest surgery, having chest tubes, or suffering from acute chest trauma may also find the rib cage stiff or sore and thus limited in its potential expansion. All these patients may benefit from the inclusion of rib cage mobilization in their therapy programs. The rib cage musculoskeletal limitation may be secondary to muscular atrophy or spasticity or to pain. Thus patients with either primary pulmonary dysfunction or secondary pulmonary dysfunction can benefit from the practice of chest mobilization.

It is beyond the scope of this textbook to detail all the numerous techniques involved in musculoskeletal mobilization of the thorax, but some simple techniques and suggestions for further study are presented. A summary of mobilization techniques is found in Box 23-7.

Box 23-7 Techniques to Mobilize the Thorax

- Use of towel rolls or pillows to mechanically open up the anterior or lateral chest wall
- Use of upper extremity patterns to facilitate the opening of individual rib segments
- Counter-rotation of the trunk
- Use of ventilatory-movement strategies to facilitate opening of the entire thorax
- Specific rib mobilization to free up an individual segment
- Myofascial release techniques to free up restrictive connective tissue on and around the thorax
- Soft-tissue release techniques to lengthen individual tight muscles

Once again, the therapist should note that the initial step toward achieving success is positioning. Starting with the patient in the supine position, anterior chest wall mobility can be improved by placing a vertical towel roll down the length of the thoracic spine and allowing gravity to pull the shoulders back to the bed. In this position, the anterior chest is opened up, stretching the intercostal and pectoralis muscles for easier facilitation of upper chest expansion.

In the side-lying position, the lateral aspect of the chest can be passively mobilized with gravity's assistance by placing one or more towel rolls or pillows under the lower chest (ribs 8 to 10) on the weight-bearing side. To determine an appropriate amount of side-bending, make sure that the patient's shoulder and pelvis are still in direct contact with the surface, even with the towel rolls in place. This maximizes the stretch of the chest without placing the patient in a position that is too advanced for his or her current chest wall mobility. Patients vary from tolerating only a single thin towel roll to tolerating three pillows under the lower ribs.

In both postures, active or passive stretching can be added after positioning for success. In the supine position, the patient is asked to move arms directly up over his or her head (shoulder flexion) as far as possible while watching his or her hands. Using the appropriate ventilatory strategy, the patient is also instructed to inhale during this movement. Because both full shoulder flexion and inspiration require the opening of the individual rib segments, pairing them in this gravity-assisted position promotes a greater passive chest wall stretch than either technique alone. If straight flexion is not a viable option, use a butterfly position, raising the arms up in shoulder flexion, abduction, and external rotation with elbows bent (like butterfly wings), again pairing this with voluntary maximal inspiration and upward eye gaze. Pairing inspiration and shoulder flexion maximizes the stretch on the chest and encourages better ventilatory strategies.

Ask the patient, who is in a side-lying position, to bring his or her arm up in straight flexion to maximize anterior chest expansion or to move the arm into abduction as a way of maximizing the lateral costal expansion. Pair either movement with inspiration and upward eye gaze. If upper extremity movement is not possible, passively use counter-rotation of the trunk to mobilize the chest while the patient is in the side-lying position over a towel or pillow. Continue to ask the patient to follow the movement with his or her eyes.

The same concepts can be used in upright postures, such as sitting or standing. Use a vertical towel roll along the thoracic spine, either along the back of a chair or wheelchair or along a wall. Move the patient's arms passively or actively up into the most extreme flexion or butterfly position possible. The patient will experience a more significant stretch in the anterior chest wall using the towel roll than without it. Precautions must be taken in patients with musculoskeletal problems along the spine and in patients with impaired skin tolerance.

If these general mobilization techniques do not produce enough chest wall mobility to allow freer breathing patterns to occur, more specific techniques must be considered, including the following:

- Specific rib mobilization
- Myofascial release of tight connective tissues (e.g., scar tissue secondary to areas of surgery or trauma)
- Soft tissue release in tight muscle groups (Note: Neurologically impaired patients often present with

tightness in the pectoralis, intercostal, and quadratus lumborum muscle groups, whereas orthopedically impaired patients tend to have more tightness in the neck and back muscles.)

Use the positioning and ventilatory strategies previously suggested (e.g., side-lying over a towel roll) during these specific interventions to maximize the potential gains in chest wall mobility. It is beyond the scope of this textbook to detail all the numerous techniques involved in musculoskeletal mobilization and release of the thorax. These three interventions are intended as suggestions for further study in other texts dealing primarily with musculoskeletal issues.

Facilitating Accessory Muscles in Ventilation

If the patient is still not demonstrating an optimal breathing pattern after experiencing appropriate positioning, appropriate ventilatory strategies, chest wall mobilization, and diaphragmatic retraining, specific facilitatory or inhibitory techniques should be initiated to stimulate the accessory muscles of ventilation. Specific techniques are discussed here in detail. A summary of interventions is listed in Box 23-8.

Because the diaphragm normally supplies the bulk of the inspired air during quiet breathing, diaphragmatic breathing is the preferred pattern of breathing. However, after certain neurological insults, strictly diaphragmatic breathing may not be possible or even preferred.[30] Unlike pulmonary rehabilitation programs for people with COPD or asthma, in which diaphragmatic breathing is almost always encouraged and use of accessory muscles discouraged, the restoration of independent, efficient breathing patterns for people with neurological impairment may require the regular use of accessory muscles.

Positioning continues to be the single most important aspect of all ventilatory facilitation techniques. If the patient is positioned for success, the probability of a successful response is much higher. By assessing the patient's head, upper extremity, trunk, pelvic, and lower extremity positions before every activity or technique, the therapist is empowered to use mechanical positioning and gravity to the patient's advantage rather than disadvantage. For example, a slightly posteriorly tilted pelvis tends to facilitate diaphragmatic breathing, whereas a slightly anteriorly tilted pelvis tends to facilitate upper chest breathing. Thus when the therapist is facilitating breathing with accessory muscles, the patient would be put in an advantageous posture by slightly tilting the pelvis anteriorly. In the supine position, this could be as simple as decreasing the amount of knee flexion that is present or using a small towel roll under the lumbar spine.

Box 23-8 Accessory Muscle Facilitation Techniques

1. Pectoralis facilitation
2. Sternocleidomastoid and scalenes facilitation
3. Trapezius facilitation
4. Diaphragm-inhibiting technique
   - Manual inhibition
   - Postural inhibition
5. Lateral costal facilitation
6. Serratus push-up

Pectoralis Facilitation

The pectoralis muscle group provides powerful anterior and lateral expansion of the upper chest and can substitute quite effectively for paralyzed intercostal muscles in the upper chest when trained to do so. Training usually begins in either a modified side-lying or a supine position. To increase the use of this muscle group during inspiration, the therapist should place his or her hand in the same direction as the contracting muscle fibers. Specific proprioceptive input is very important when facilitating a muscle, so make sure the hand is placed diagonally on the upper thorax (Figure 23-7).

The heel of the therapist's hand should be near the sternum and the fingers aligned up and out toward the shoulder in a diagonal pattern. The patient is asked to breathe into the therapist's hands while the therapist applies a quick manual stretch

Fig. 23-7 Hand placement for facilitation of the pectoralis muscles for upper chest breathing.

(as in repeated contractions in techniques of PNF to the muscle fibers (down and in toward the sternum). This elicits the quick stretch reflex of the muscle and simultaneously provides added sensory input, which facilitates a stronger and more specific muscle contraction. To emphasize an increase in lateral expansion, facilitation should gradually be transferred from the sternal area out toward the therapist's fingertips by the patient's shoulder. The verbal cues are stronger and require more effort than the quieter verbal cues for diaphragmatic breathing.

Sternocleidomastoid and Scalene Facilitation

The same principle can be applied to the sternocleidomastoid and scalene muscles.[31] When the patient is in the supine position, the therapist need change only the angle of hand alignment to more specifically facilitate the sternocleidomastoid and scalene muscles. Turning the hands parallel to the trunk so that the fingers are pointing up toward the neck rather than pointing out toward the shoulder, the therapist applies the same quick stretch and uses the same verbal cues. The altered hand position now specifically facilitates the sternocleidomastoid and scalene muscles and secondarily influences the pectoralis muscles. The sternocleidomastoid and scalene muscles expand the chest primarily in a superior and anterior plane, whereas the pectoralis muscles expand the chest primarily in a lateral and anterior plane, thus accounting for the slight difference in the facilitation positioning.

Trapezius Facilitation

The trapezius muscle assists in superior expansion of the chest. Facilitation can be initiated in the supine or side-lying position to decrease the resistance of gravity. It can be progressed to an upright posture, in which the patient would have to work against gravity.

Placing the hands on top of the patient's shoulders, the therapist gives a quick stretch to the trapezius in a downward direction to facilitate a stronger elevation response. Repeated contractions can be added to facilitate the contraction throughout the full ROM. The shoulder-shrug motion should be paired with inhalation and upward eye gaze to maximize the facilitation response.

Inhibition of the Diaphragm

Two techniques are described to inhibit the excessive use of the diaphragm during inspiration. Ideally, the therapist is venturing to balance the use of accessory muscles—especially the intercostal, sternocleidomastoid, scalene, and trapezius muscles—with the diaphragm's contraction. This is done to prevent paradoxical movements of the chest, or worse, to prevent adverse musculoskeletal changes in the chest wall, such as pectus excavatum, which can result from muscle imbalance.

Inhibiting the diaphragm may be necessary during breathing retraining for some patients with spinal cord injuries, polio, spina bifida, developmental delays, head traumas, and cerebral palsy. The diaphragm may be too weak to produce an adequate TV or VC without the assistance of accessory muscles. In these cases the diaphragm-inhibiting technique is used to encourage the use of the accessory muscles to assist in independent voluntary ventilation. Patients learn to use their weakened diaphragm muscles in concert with intact accessory muscles. Not only does this allow for increased TV and VC, but it also may provide better aeration of all lung segments and better mobilization of the entire thorax.

An unusually strong diaphragm, acting without support from surrounding musculature, specifically the intercostals and abdominal muscles, may also need to be inhibited. For example, patients with paraplegia or lower-level tetraplegia with intact diaphragm but absent abdominal and intercostal muscles may demonstrate a paradoxical breathing pattern (see compensatory breathing patterns, Chapter 39). In this case, the accessory muscles must be encouraged to keep the diaphragm in check, attempting to avoid the development of a pectus excavatum. The goal of this breathing retraining method is to stop the paradoxical movements of the upper chest during inspiration by balancing the use of the upper and lower chest. In some cases, spastic intercostal muscles, found in some spinal cord injuries, may intercede to prevent this paradoxical movement by maintaining the upper chest's position during inspiration in spite of the negative pressure within the chest and gravity's influence on the chest. Balancing the movement of the chest should produce an increase in TV and VC potential and mobilize a greater portion of the chest.

To perform the diaphragm-inhibiting technique, the patient is positioned in a supine, semi-sitting, or side-lying position, with the top arm positioned overhead or pulled back at the waist to open up the upper chest. If the patient can tolerate it, pillows are removed from under his or her head, the pelvis tilted anteriorly, and airway safety is assessed by checking to see whether the patient can still swallow comfortably. The heel of the therapist's hand is placed lightly on the patient's abdomen at about the level of the umbilicus. No instructions are given to the patient at this point. As the patient begins to exhale a normal breath of air, the therapist gently allows the heel of his or her hand to move up and in toward the central tendon of the patient's diaphragm (see Figure 23-4). When the expiration of that breath is complete, the therapist strictly maintains the hand position in that shortened expiratory position. During the following inspiratory phase, the diaphragm will experience some gentle resistance to its inferior descent, causing inhibition to its full ROM. On the next expiration, the technique is repeated, with the therapist carefully pushing the heel of his or her hand further up and in, maintaining greater inhibition during each inspiratory phase. After two or three ventilatory cycles, a patient usually begins subconsciously to alter his or her breathing pattern to include more upper chest expansion in order to reconcile the diaphragm's transient inability to produce enough chest expansion to yield an adequate TV. The therapist should carefully observe which accessory muscles the patient spontaneously chooses. Are they used symmetrically? What is the general quality of the movement? Is the onset harsh or smooth? Does the patient appear fatigued or uncoordinated?

It is not until this point that the therapist should verbally acknowledge any alteration of the patient's breathing pattern. Without changing the hand position, the therapist tells the patient what he or she observed that is encouraging about the new breathing pattern (e.g., balance between upper and lower chest expansion or less paradoxical motion of the sternum). Then the patient is asked whether he or she notices any

difference from before, bringing this breathing pattern to a conscious level. Only after some orientation to this pattern, usually no more than four to six breathing cycles in the full inhibiting pattern, should the therapist begin gradually to release the pressure being applied.

While slowly releasing pressure with each cycle of inspiration, the therapist asks the patient to try reproducing the desired pattern cognitively. It should take the same number of cycles to release the pressure as it did to apply it. This technique easily allows for gradations of inhibition, from full inhibition, when the patient is forced to use upper accessory muscles or risk becoming short of breath, to a barely proprioceptive reminder to change his or her breathing pattern. It also allows for gradation of inhibition while the patient is learning to assume control over the new breathing pattern. If, during the releasing phase of this technique, the patient begins to lose control over the new pattern, the therapist can gently reapply some pressure during the next expiratory phase to help the patient regain that control. At that point, the therapist can release or reapply pressure as necessary until the desired pattern is obtained and full release of pressure is acceptable.

This technique is particularly effective in patients who are having difficulty cognitively altering their own breathing patterns, such as small children, brain-damaged patients, or slow motor learners, because it requires no cognitive effort until success has already been achieved. Extra care must be taken to avoid initiating any applied pressure quickly because of the likelihood of eliciting unwanted abdominal contractions or spasticity[32] or eliciting a stronger diaphragmatic contraction resulting from the quick stretch reflex. The technique should never be painful. The therapist must keep his or her hand on the abdomen, not the rib cage, to properly influence the diaphragm. This technique can be progressed by changing postures, which requires greater trunk control. Can the patient still maintain the overall pattern? Can the patient breathe without paradoxical movements against gravity?

The second technique is for the more advanced patient and simply presents a physical block to diaphragmatic excursion. The patient is positioned in a prone-on-elbows position (Figure 23-8, *A*). In patients who are most severely impaired neurologically, the lower chest will be in direct contact with the surface, so lower anterior and inferior expansion is inhibited and lateral costal expansion is limited. The upper chest is positioned in extension and the upper extremities are fixed, optimizing the length-tension relationship of the anterior and superior accessory muscles for easy facilitation. In addition, anterior excursion of the upper chest is now in a gravity-assisted posture. Through the use of head and neck patterns, such as in PNF diagonals, or the use of static-dynamic activities, such as in weight shifting to one supporting limb while reaching out with the other extremity, the therapist can readily facilitate greater upper chest breathing (Figure 23-8, *B*). Therapists can use these same patterns to achieve other goals, such as increased head and neck control, increased shoulder stability, or increased upper body balance. Thus by helping patients to coordinate movement goals with ventilatory patterns, it becomes more likely that patients will incorporate these patterns functionally into their daily activities. This is the ultimate goal of any ventilatory retraining procedure.

The manual diaphragm-inhibiting technique is usually less threatening to the patient than is the prone-on-elbows inhibition technique. Prone-on-elbows position can inhibit the diaphragm so completely for neurological patients lacking spinal extensors that they become extremely short of breath. Consequently, do not position the patients in this more demanding posture until success appears likely.

Fig. 23-8 A, Diaphragm inhibiting in prone-on-elbows position. **B,** Static-dynamic upper extremity activities in prone-on-elbows position to encourage upper chest accessory muscle participation.

Serratus Push-Up

Facilitating greater posterior chest expansion can be achieved in a prone-on-elbows position. Gravity is now assisting anterior excursion of the chest and resisting posterior excursion. To emphasize the serratus anterior muscle's role in posterior expansion, the patient is instructed to perform an upper body push-up (with or without the therapist's assistance). The serratus anterior muscle causes lateral scapular movement, thereby facilitating maximal posterior excursion of the thorax. The patient is instructed to take in a deep breath during the push-up and to exhale the air (passively or forcefully) when returning to the starting position. Forceful exhalation in this activity can be used as a forerunner to effective cough retraining. Gentle or controlled exhalation can be used to encourage greater breath support for vocalization or for eccentric trunk muscle training.

Emphasizing posterior chest expansion during inhalation is the only occasion in which inspiration should be paired with

trunk flexion. In all other inspiratory situations, inspiration is paired with trunk extension and exhalation is paired with trunk flexion.

Patients with Asymmetrical Dysfunction

Patients with asymmetrical weakness need a different approach from the controlled or upper chest breathing patterns presented previously.[33] These patients need facilitation of the weaker side to promote symmetrical chest wall expansion in both the upper and lower chest. A summary of techniques is listed in Box 23-9.

Symmetrical Positioning

Symmetrical ventilatory patterns may be effortlessly achieved by altering the patient's position in each posture to maximize the chest wall's potential to move in a symmetrical pattern. This is especially true in an upright position, in which asymmetry is generally more pronounced. For example, a patient with hemiplegia may lean toward the involved side when sitting because of weakness or spasticity. Likewise, after thoracic surgery, a patient with primary pulmonary impairment may lean toward the surgical side to splint the area in order to avoid the pain caused by chest movement around the incision and the chest tubes. Both situations cause asymmetrical breathing patterns and decrease ventilation on the involved side. Improving chest wall alignment may alleviate the ventilatory deficit on the involved side. This may be achieved by the use of towel rolls or pillows to support the affected side as well as by good pain management postoperatively.

Postural Inhibition

For some patients, more aggressive positioning must be used to achieve greater chest wall excursion and ventilation on the involved side. This can be accomplished by inhibiting the chest wall movements on the uninvolved, or stronger, side. Usually, the best position in which to achieve this inhibition is side-lying. When the patient lies on his or her uninvolved side, with arms positioned below 90 degrees of shoulder flexion, lateral chest expansion into that side becomes inhibited because of the physical barrier. This forces the patient to find another way to meet his or her ventilatory needs, which indirectly facilitates chest expansion on the opposite side (the uppermost side). The therapist can then supply sensory and motor input through his or her hands to the patient's upper, middle, or lower chest on the involved or weaker side to facilitate increased ventilation on that side. Early in the rehabilitation process or soon after thoracic surgery, the patient may have difficulty performing lateral chest expansion against gravity when in a side-lying position (gravity-resisted movement). If so, place the patient in a three-quarter supine position to lessen the workload imposed by gravity. Gradually, work the patient up to a full side-lying posture to achieve the greatest strengthening benefits.

Timing for Emphasis

Another technique to promote symmetrical chest wall movements is performed in numerous postures, such as supine, sitting, or standing. The therapist places his or her hand symmetrically on the lower lateral chest wall, on the mid-chest, or on the upper anterior chest wall. At the end of exhalation, the therapist gives a quick stretch to the muscles being touched so as to facilitate a deep inspiratory effort in that area of the chest. Immediately after both sides begin to move into an inspiratory pattern, the therapist manually blocks (or inhibits) expansion of the chest on the stronger side while giving continued quick stretches to the weaker side. This facilitates greater expansion on the weak side by means of an overflow response. This technique, adapted from the PNFs timing-for-emphasis technique, uses the strength of the stronger side to facilitate movement on the weaker side. It can be applied to any area of the chest where symmetrical movements should be the norm.

Reducing Respiratory Rates

In addition to altering breathing patterns through facilitation and inhibition techniques, reducing RRs may also be necessary before arriving at an efficient breathing pattern for some patients. See Box 23-10 for a summary of techniques. Many patients with neurological impairment who have high neuromuscular tone increase their RRs to compensate for a decrease in their TVs or because of brainstem impairments that affect the respiratory centers. In addition, many patients who are anxious, such as people with asthma and those who have orthopedic or surgical conditions and are experiencing pain, may also demonstrate excessively high RRs. Attempting to restore ventilatory efficiency may require increasing TV while concurrently decreasing RR.

Box 23-9 Promoting Symmetrical Ventilatory Function for Patients with Asymmetrical Deficits

- Use of positioning to achieve more symmetrical alignment of the chest and trunk in both reclining and upright postures
- Use of postural inhibition of the stronger, or uninvolved, side to promote greater chest wall expansion on the weaker, or involved, side
- Timing-for-emphasis technique to promote active symmetrical breathing anywhere in the thorax

Box 23-10 Techniques to Reduce High Respiratory Rates

1. Previous techniques that increased tidal volume
2. Counter-rotation technique
3. Butterfly technique in sitting
   - Straight planes
   - Counter-rotation
4. Relaxed pursed-lips breathing with inspiratory and expiratory pauses

The techniques described in this chapter promote an increase in TV by improving the overall ventilatory patterns and often cause a secondary reduction in RR. Interventions such as PLB and repatterning, mobilization of the thorax, and upper chest breathing facilitation for neurologically impaired patients are often helpful in accomplishing slower, deeper, more controlled breathing.

Counter-Rotation

The technique described next has been developed specifically to promote a lower RR and improvement of chest wall mobility. The counter-rotation technique may help to reduce high neuromuscular tone and increase thoracic mobility, thus often resulting in an increase in TV and a simultaneous reduction in RR. This intervention is extremely effective for the following:

- Patients with decreased cognitive functioning after a neurological insult or after surgery
- Very young children (because verbal cues cannot be used)
- Patients with high neuromuscular tone

As described in Chapter 22, counter-rotation also can be easily adapted as a very effective assisted-cough technique. One medical contraindication for this technique, because of its rotary nature, is bony instability of the spine.

In bed or on a mat, place the patient in a side-lying position with knees bent and arms resting comfortably out in front of the head and shoulders. In this technique, the higher the upper extremities can be placed within a comfort zone, the better the result. Relaxed positioning of the patient is essential to the success of this technique, so the patient should be positioned in an open yet comfortable position. Normalizing neuromuscular tone is the first step in attempting to decrease a high RR. Patient discomfort is likely to elicit increased tone and an increased RR.

The therapist's own position is also important because it directs the force that is applied to the patient's chest. Initially, the therapist should stand behind the patient, perpendicular to the patient's trunk. If the patient is lying on the left side, the therapist places his or her left hand on the patient's shoulder and the hand on the patient's hip. The therapist then leaves the hands in place and simply follows the patient's respiratory cycle. This allows the therapist to assess the patient's subjective rate and rhythm and the patient's overall neuromuscular tone. Only after this assessment should the clinician begin the active phase of the technique. Using a PNF technique called rhythmic initiation, the patient is gently log-rolled in a small ROM in the side-lying position. The rolling is gradually increased achieving more ROM from side-lying toward prone. This progression of movement generally reduces high tone, which usually makes the second phase of the technique more effective.

During this phase, the therapist should audibly duplicate the patient's RR. As the patient moves into greater rolling ROM and begins to slow his or her RR, the therapist needs to use the patient's audible cuing as a facilitator for establishing a slower RR. Thus the therapist begins by having the patient establish the audible RR; then the therapist slowly takes over. Audible cues can be very strong facilitators of ventilatory rhythms.

The second phase requires the therapist to slowly change position. Transitioning to a diagonal posture, the therapist then stands or half-kneels behind the patient near his or her hips, turning to a diagonal position until facing the patient's head at roughly a 45-degree angle. Here the hand placement begins to get more specific. Assume again that the patient is side-lying on the left. At the beginning of the expiratory cycle, the therapist's left hand slowly glides over the patient's shoulder on the right pectoral region, with care being taken not to unintentionally use the thumb or finger tips; the right hand slowly glides back to the patient's right gluteal fossa (the hollow of the buttocks) (see Figure 22-6, *A*). The therapist can then manually compress the rib cage on all three planes of ventilation at the end of exhalation by gently pulling the shoulder back and down, while simultaneously pushing the hip up and forward. This movement promotes more complete exhalation.

When the patient begins the next inspiration, the therapist switches hand placement to capitalize on the improved potential for TV. The therapist's left hand slides back to the patient's right scapula, and the right hand slides forward just anterior to the patient's right iliac crest (see Figure 22-96, *B*). As the patient inhales, the therapist slowly stretches the chest to maximize inspiration TVs. The therapist's left hand pushes the scapula (or the thorax if the scapula is unstable) up and away from the spine, and the right hand pulls the pelvis back and down to maximize all three planes of ventilation, resulting in greater inspiration. The therapist should use the flat or heel of the hand whenever possible to avoid unintentional patient discomfort and to maximize the facilitated area.

Initially, the therapist begins and ends the respiratory cycle according to the patient's RR. However, as the patient's tone is relaxed and increased TVs are promoted by the effects of counter-rotation, the therapist gradually slows down the rate of rotation, giving the patient audible breathing cues to further facilitate a slower RR. The patient generally accommodates to a slower RR as the therapist gains more control over the patient's breathing pattern. With many patients, the results can be marked. If the patient can cognitively follow commands, he or she can be alerted to this change and encouraged to assist in voluntarily breathing at the slower rate.

The therapist can progress the technique by decreasing the manual input. The last facilitation to be removed should be the audible cues. As with the diaphragm-inhibiting technique, the therapist can reestablish control quickly if need be by simply reapplying stronger manual input. If the patient has an extremely fast RR (i.e., 50 to 60 breaths/min), the facilitation can be applied every two to three breaths to avoid fatiguing the patient or therapist.

It should be apparent that this technique need not be used exclusively for respiratory goals but rather can be incorporated into a patient's total rehabilitation program. It is a natural precursor to active rolling; it can also be used as a vestibular stimulator.

Butterfly Technique

If a patient has good motor control, an upright version of this technique may be appropriate. In unsupported sitting, stand behind or in front of the patient, depending on his or her balance needs, and ask the patient to bring the arms up into a butterfly posture (or assist the patient to bring the arms into this posture). Starting from a comfortable ROM position for that patient, begin to breathe audibly in time with the patient's

RR. When the patient inhales, raise the arms up into slightly more shoulder flexion. When the patient exhales, lower the arms slightly. Slowly begin to move in greater and greater increments of range, while breathing loudly with your patient. Through your audible breathing cues, begin to "ask" your patient to slow down the RR and take deeper slower breaths. The use of the following concurrent ventilatory strategies promotes deeper inhalations and exhalations: (1) shoulder flexion and trunk extension paired with inspiration; and (2) shoulder extension and trunk flexion paired with exhalation. Thus it becomes possible for the patient to increase TV and decrease RR.

As in the previous technique, the therapist begins by breathing loudly at the patient's respiratory rate and transitions to breathing audibly at a slower, more desirable pace. The patient picks up on this subtle cue and subconsciously reduces his or her own RR, even if unable to follow verbal commands.

This technique can be modified to encourage more intercostal and oblique abdominal muscle contractions by using a diagonal rather than a straight plane of movement. Have the patient look up and over one shoulder as he or she breathes in and brings arms up and behind the head. Then have the patient look down and away toward the opposite knee while breathing out and bringing arms down to the opposite knee (Figure 23-9).

Relaxed pursed-lips breathing can also be incorporated into the previously described techniques to reduce RR. By prolonging the expiratory phase through pursed lips, the patient secondarily decreases his or her RR automatically.

Glossopharyngeal Breathing

A small number of patients with neurological impairments require more than just promoting the use of accessory muscles or changing RR to meet basic ventilatory needs.[34] In the past decade, more people experiencing high-level SCIs (above C4) have survived the initial trauma because of advances in medical technology. The therapist in the rehabilitation setting is then faced with the difficult task of restoring quality of life. For these patients, as well as many older adult polio patients, mastery of the glossopharyngeal breathing (GPB) technique allows for greater voluntary ventilation, which many patients say improves the quality of their lives. This augmented

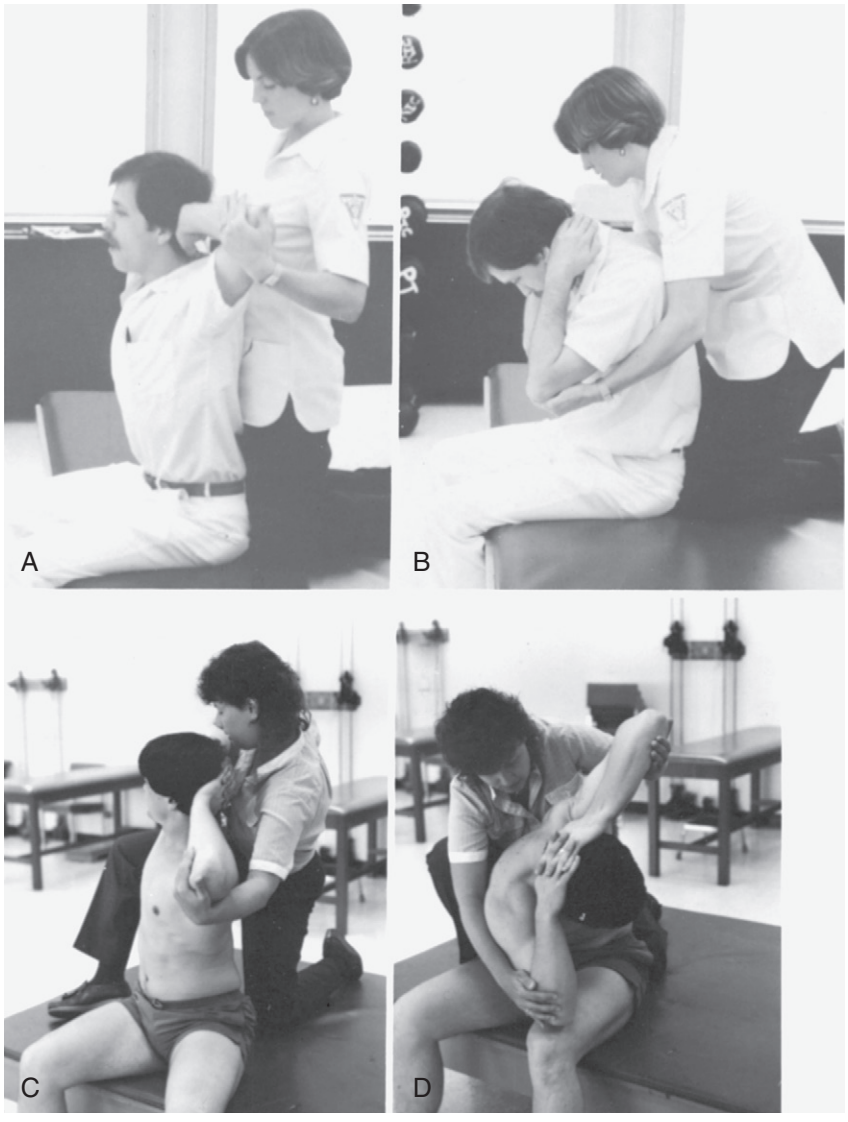

Fig. 23-9 A, Butterfly technique facilitating inspiration. **B,** Butterfly technique facilitating exhalation. **C,** Butterfly with trunk rotation facilitating inspiration. All three planes of respiration are stretched on the patient's right side. **D,** Butterfly with trunk rotation facilitating exhalation. All planes are compressed on the right side.

breathing pattern allows patients to regain some control over their lives and to regain control over their ventilation, which was lost as a result of severe neurological insult.

GPB is a technique developed in the 1950s by polio patients looking for a way to reduce their dependence on the iron lung for ventilation. It was found that by using the lips, soft palate, mouth, tongue, pharynx, and larynx, a patient could actually inhale enough air to sustain life without mechanical ventilation. Only intact cranial nerves are required. This method is sometimes referred to as "frog breathing" because it uses the principles of inspiration common to the frog. The patient learns to create a pocket of negative pressure within the buccal cavity (mouth) by maximizing that internal space, thereby causing the outside air to rush in. At that point, the patient closes off the entrance (the lips) and proceeds to force the air back and down the throat with a stroking maneuver of the tongue, pharynx, and larynx.

Research has shown consistently that use of this technique in patients who have severe neurological impairment can increase pulmonary functions significantly, especially TV and VC. If GPB is the only means of ventilation possible when a patient has been disconnected from a ventilator or phrenic nerve stimulator, mastery of this technique is critical to the patient's survival in case of mechanical or electrical failure. All attempts should be made to teach GPB to this patient population.

A clinical example may help to illustrate the usefulness of GPB. A 14-year-old male sustained a C1 complete SCI while racing in front of a train. After he was medically stable, two phrenic nerve stimulators were implanted in his chest. The patient had no unassisted means of ventilation. Neuromuscularly, the patient had limited use of one trapezius, the sternocleidomastoid, and intrinsic neck muscles. The patient and family worried that long-term nursing home placement would be inevitable because of their fear that his phrenic nerve stimulator would malfunction or a battery would wear out, causing immediate respiratory distress. The family believed it could not bear the psychological burden placed on them if the patient went home to live. GPB instruction was suggested and was begun slowly because the patient stated that he learned motor skills slowly. After a painstaking 2-month period, the patient learned to breathe without the use of his phrenic nerve stimulator for 3 to 5 minutes before becoming fatigued and hypoventilating. Within the next 1 to 2 months, he learned to breathe for up to 2 hours off of his stimulator, using GPB only. To the staff's surprise, he even learned to talk and operate his sip-and-puff wheelchair while using GPB. The patient was then successfully discharged to his home. This was not the only factor considered in his discharge planning, but it was perhaps the most significant.

Instruction in GPB takes time and concentration. It is best to start off in small time blocks of 10 to 15 minutes because it can be very fatiguing. However, for successful learning of the technique, it is also important that the patient get consistent, preferably daily, training. Once the patient has mastered the technique, practice sessions can be lengthened considerably, and the patient can be taught self-monitoring techniques. The specific goals of GPB training must be explained to the patient before the beginning of treatment in order to gain his or her support and cooperation. In addition to providing the ventilator- or stimulator-dependent patient with a TV necessary for gaining independence from mechanical assists, GPB has many other benefits. For the patient with tetraplegia who has a partially intact diaphragm (C3 to C4) or the loss of essential accessory muscles (C5 to C8), GPB can accomplish the following:

- Increase VC to produce a more effective cough
- Assist in a longer and stronger phonation effort
- Act as an internal mobilizer of the chest wall

The muscles used in this technique do not have the same internal proprioceptive, sensory, or visual feedback mechanisms as the trunk and limb muscles, so necessary adjustments in the technique are sometimes difficult to perceive. The patient cannot see his or her tongue pushing the air back or truly feel the pharynx swallowing the air into the lungs, so the therapist's external feedback system is very influential. Use of a mirror can greatly enhance the visual component of feedback. Small changes, like adjustments in posture or the suggestion of another sound to imitate, may be all that is needed for the patient to learn the stroking maneuver correctly. Success in GPB can be assessed objectively with a spirometer and a pulse oximeter. For patients incapable of breathing independently, any TV reading will indicate successful intake of air. For patients who are not ventilator dependent, a VC reading that is greater than 5% over the baseline indicates successful use of GPB. Patients with low-level tetraplegia (C5 to C8) have demonstrated increases in VC by as much as 70% to 100%.

Therapists can monitor their own successes with this technique by taking VC readings with and without GPB or by subjective analyses. Maximal inhalation, followed by three or four successful GPB strokes, will cause a feeling that the chest will burst if an attempt is made to inhale more air. Likewise, the sensation of "needing to cough" is another subjective indication of successful GPB. Conversely, a feeling of indigestion is usually indicative that air has been swallowed into the stomach instead of the lungs.

During the initial treatment session, the therapist demonstrates several times what a stroking maneuver looks like, giving the patient an idea of the motion required. The therapist continues to mimic the pattern as the patient attempts to duplicate it. This gives the patient an active model to mimic and decreases feelings of uneasiness surrounding the necessary but somewhat silly facial grimaces. If the patient is able to breathe independently, his or her ability to breath-hold and to close off the nasal passageway should be checked because air leakage is a common cause of failure. The patient is then instructed to take in a maximal inspiration before attempting the stroking maneuvers in order to eliminate the possibility of using other accessory muscles during the technique.

If possible, the patient is positioned in an upright or at least a symmetrical position. Specifically, the patient is instructed to bring the jaws down and then forward as if reaching the bottom lip up for a carrot dangling just in front and above the upper lip (Figure 23-10, *A*). Slight cervical hyperextension is necessary to allow for maximal temporal mandibular joint (TMJ) excursion. (A contraindication for this technique is a TMJ disorder.) The lips should be shaped as if they were making the sound *oop*. The patient is then told to close the mouth, reaching the bottom lip up to the top lip (Figure 23-10, *B*). The tongue and jaw are drawn back toward the throat, with the mouth and tongue formed as though saying *up* or *ell* (see Figure 23-10, *B*). The lower jaw moves in a roughly rectangular pattern. Most patients learn the stroking

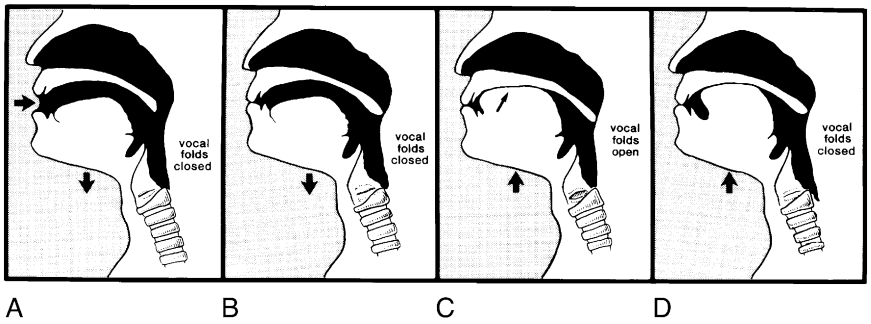

Fig. 23-10 Glossopharyngeal breathing. **A,** Mouth opened to draw in air. **B,** Jaw closed to entrap the air. **C,** Air pushed back with tongue into trachea. **D,** Vocal folds closed to prevent passive air leaks. Entire maneuver is then repeated.

Box 23-11 Common Problems in GPB Instruction

- An open nasal passage or glottis that allows the air to escape
- A feeling of indigestion, indicating that the air is being swallowed into the esophagus rather than the trachea
- Incorrect shape of the mouth as the air is being drawn in (usually not puckered enough)
- Uncoordinated backward movement of the tongue
- Inadequate jaw mobility, TMJ dysfunction, or decreased cervical ROM;
- Incorrect sounds while performing the technique, such as the word *gulp* or the sound *em*

maneuvers by making the sounds; as they become more proficient, the sounds and excessive head and neck motions diminish. Often, the students (patients) outperform the teachers (therapists) because through consistent use, they learn all of the technique's finer subtleties.

Although this technique can be broken down into several stages, as it has been here for the purpose of description, most of the literature cautions the therapist against doing so.[35] Simple, minimal instructions seem to accomplish more, perhaps because the continuity of movement is so essential to the success of the inhalation. Specific instructions can be given later if necessary.

Common problems encountered with GPB instruction can be found in Box 23-11. Avoiding any instruction for the tongue seems to produce better results. Concentrate on assisting the patient in learning the external physical movements.

Tolerance of GPB can be increased when mastery of a single stroke becomes consistent. For patients using it as an assist to their own voluntary ventilation, three to four strokes on top of a maximal inspiration is usually sufficient. Ventilator- or stimulator-dependent patients may need to use as many as 10 to 14 strokes per breath. These figures should be used only as rough guidelines. Each patient will use a slightly different technique and a different number of strokes; the only important factor is a method that works for the individual. Fatigue after long trials of GPB can be monitored effectively by an oximeter. The oxygen saturation level should stay above 90% to maintain adequate Pa_{O_2} levels. For example, if the patient begins the GPB session with an oxygen saturation level in the upper 90s, fatigue can be monitored and anticipated by watching to see whether the oxygen level decreases. If the level begins to fall to the mid-90s and then the low 90s, you can anticipate when they will reach 90%. At that point, end the GPB training and put the patient back on the previous ventilatory support system. Pulse oximetry not only allows for accurate monitoring but also provides an objective means of monitoring progress over time. In addition, a spirometer objectively measures improvements in using GPB. It gives the patient concrete indications of success or failure in mastering the technique.

Enhancing Vocalization Skills

In contrast to procedures that assist a patient in inhalation, procedures intended to improve a patient's phonation skill must focus on elongating the expiration phase. Coughing is a gross-motor skill that relies more on force than on fine control of the ventilatory muscles for its effectiveness. Conversely, phonation requires precise, fine-motor control of these muscles and demands that the vocal folds provide a consistent air flow through the larynx. Both are expiration activities and they depend on the preceding inspiration for optimal performance; however, coughing uses concentric contractions of the expiratory muscles to force the air out, whereas quiet talking uses primarily eccentric contractions of the inspiratory muscles to slowly release the air during expiration. Because of these differences, procedures to improve coughing and phonation are different in focus. Considering the relationship between speaking and breathing and the concepts of shared respiratory control, it is notable that speaking can lead to shortness of breath and shortness of breath can alter speaking ability.[36] Previous discussions of posture and use of abdominal binders in patients with spinal cord injury should also be considered when speaking is impaired.[37] A summary of techniques is listed in Box 23-12. Coughing is covered in detail in Chapter 22.

Because the patient's TV and total inspiratory capacity are the power source for phonation, they become important concerns in a phonation program. Generally, a normal TV is adequate for conversational speech. However, larger volumes of air, thus greater inspiratory capacities, are required for singing, loud talking, or professional speaking. Therefore the breathing pattern facilitation techniques described earlier in this chapter are ideal for use before instructing the patient in better expiration control. For example, facilitating diaphragmatic and accessory-muscle breathing techniques, along with the use of quick stretches or repeated contractions, can facilitate the desired deeper inhalation.

Box 23-12 Enhancing Vocalization Skills through Increased Breath Support

1. Position to achieve a neutral chin tuck and optimal vocal fold alignment
2. Manual techniques
   - Vibration or shaking
   - Percussion or tapping
3. Eccentric resistance
   - Agonistic reversal technique
   - Functional resistance
4. Verbal techniques to refine breath support
   - Singing and whistling
   - Games
   - Wind or brass instruments
   - Stopping and starting vocalizations

Positioning Concerns

Consistent with all previous techniques, the first aspect of improving breath support for vocalization is to optimize the patient's position. The vocal folds have an ideal muscle length-tension relationship when the head is in a neutral chin tuck. In addition, an open anterior chest wall allows for the greatest potential for chest wall excursion and thus the largest VC. Use the previously described suggestions for positioning to determine whether a particular patient needs positioning to encourage a more diaphragmatic, upper chest, or unilateral breathing pattern.

Manual Techniques

Several simple techniques can be used to improve eccentric control of the diaphragm and intercostal muscles in preparation for speech. Vibration or shaking of the lower chest during expiration helps to produce a slower, more controlled recoil of the diaphragm. Why this occurs is not fully understood. It may be that the sensory and proprioceptive stimulation that the vibration or shaking provides augments the patient's concentration on those muscles, resulting in longer phonation. The patient is instructed to phonate an *ah* or *oh* sound for as long as possible. The therapist simultaneously vibrates the patient's chest with an even and gentle force throughout and slightly beyond the full expiration phase, placing his or her hands on the lateral costal borders of the thorax, the mid-chest, or the pectoral area, depending on which area of the chest needs the most help in controlling exhalation. This is very different from the rapid, forceful pressure that is applied to the patient's chest when promoting a deep cough. Be certain that the patient understands this important difference. Emphasize that the patient should not let air escape before vocalizing and should try to keep voice intensity consistent throughout the procedure. This will promote slow, eccentric release of the inspiratory muscles during the entire course of the vocalization. Progress can be readily monitored by timing the patient's vocalization before, during, and after this technique. About 10 to 12 seconds of vocalization at 8 to 10 syllables per breath is generally considered adequate for functional use in speech.

For a child, this technique can be modified. The child is asked to say *ah* or *oh* for as long as possible while the therapist percusses or taps lightly with his or her hands on the child's upper or lower chest so as to produce a series of staccato sounds. Usually, a child enjoys the new sound that this makes and tries repeatedly to phonate longer and louder to accentuate the different intensities. Therapeutically, this requires the child to take a deeper inhalation before vocalizing, followed by an elongated expiratory phase, both of which are necessary for functional speech. As the child becomes more adept at it, the therapist can apply more pronounced clapping over the chest, accomplishing a wider range of voice intensities and doubling as a means of percussion for postural drainage.

Eccentric Resistance Techniques

More specific facilitation can be used to increase breath support. Ideally, the patient is positioned symmetrically in a supine or supported-sitting position, allowing for maximal chest wall expansion. The patient is instructed to visualize his or her chest being pulled up toward the ceiling and held there. Next, the patient is told to vocalize slowly, trying not to let the chest "fall." Meanwhile, the therapist is applying consistent pressure to the patient's chest to try to force a quicker exhalation. The patient is told to resist this motion by trying to control and prolong expiration. As with the antagonistic reversal technique described in PNF, the therapist is resisting the patient's attempt to eccentrically contract and control the trunk muscles. This strengthens the eccentric phase of exhalation and promotes greater breath control for vocalization.

The same concept can be applied to functional tasks. Moving into gravity (i.e., coming down to sitting from a standing posture, lying down from a sitting posture, or bringing an arm down from reaching into a high cabinet) requires eccentric control of the muscles involved in the activity in order to slow the body's descent into gravity's influence. Because quiet speech uses a similar muscular contraction, teaching the patient to count out loud or otherwise vocalize when performing an overall eccentric activity usually improves both activities. For example, the patient can be instructed to reach up to a high shelf while inhaling. Then, using gravity to provide the eccentric resistance, the patient is asked to bring the arm back down to his or her lap or side while slowly counting out loud and controlling the rate of the arm's descent. The activity can be progressed several ways. The activity can include lifting something heavy off the shelf and controlling it along with the arm and trunk while lowering the object to a table or to the patient's lap. Or the postural demands of the activity can be increased. The patient could be asked to lift the same heavy object but to do so while standing, which increases the demands on the musculoskeletal system.

Verbal Techniques

Speech activities that do not require a therapist's physical assistance can be done in a group or individual setting. Singing, for instance, promotes strong and prolonged vocalization with maximal inspiration, which is a significant goal in a phonation program. Similarly, whistling or playing a kazoo or harmonica promotes long, even exhalations but is nonverbal. Both are easily incorporated into a group activity on the nursing floor, in therapy, or in the community.

Along recreational lines, games that promote controlled blowing further the refinement of motor control of the respiratory muscles. This can be accomplished by blowing bubbles (especially large ones), blowing out candles (especially trick candles), blowing a ping-pong ball through a maze, or blowing air hockey disks across the table rather than pushing them with the hand. Patients with musical inclinations should be encouraged to learn to play wind or brass instruments, in which refined breath control is mandatory for success. Obviously, the possibilities in recreational activities are endless and simply require imagination on the part of the therapist.

Further refinement of breath control for speech can be promoted by interrupting the outgoing air flow. This procedure is geared toward improving functional communication skills. Functional speech is a series of vocal stops and starts. The therapist tells the patient to take a deep breath and count out loud to 100. After a few numbers, the patient is told to "hold it" and is then told to start up where he or she left off; the therapist periodically interrupts. Because this activity requires the patient to stop and start the inhalation and exhalation phases at will in all aspects of the ventilatory cycle, it is more advanced and should be used only after some control of exhalation has been mastered.

Summary

The use of appropriate choices in positioning, together with use of an appropriate ventilatory and movement strategy for any given task, will make success in mastering that task all the more likely. If these simple, time-efficient methods of facilitation do not produce adequate ventilatory changes by themselves, it is then appropriate to add the next layer of facilitation—manual facilitation techniques. Specifically, the techniques that are described in this chapter assist in facilitating the following:

1. Greater diaphragmatic breathing patterns (or controlled breathing)
2. Increased chest wall mobility
3. Greater accessory-muscle breathing patterns (or primarily upper chest breathing)
4. More symmetrical breathing patterns (in unilateral disorders)
5. Reduction in high respiratory rates
6. Auxiliary techniques (GBP)
7. Improved phonation support

Obviously, not all techniques are appropriate for any single patient. It is up to the therapist to determine which techniques will best address a particular patient's deficits.

Positioning is vital to increasing ventilation potential and functional skills. From the beginning of the patient's respiratory program, optimizing ventilation and breath control through passive and active positioning techniques should be a priority of all health team members, not just the physical therapist. As patients progress, the clinician can and should assist them in developing better and more efficient movement strategies for higher-level activities by coordinating appropriate breathing patterns, such as trunk extension-inhalation or trunk flexion-exhalation strategies, into all activities. After these quick and easy suggestions are used, a therapist who has been exposed to numerous methods of manual facilitation and techniques to promote more effective and efficient breathing patterns can choose the most appropriate interventions. In some cases, increasing diaphragmatic breathing may be the desired outcome. In other patients, increased upper chest breathing or increased movement on one side of the chest may be more desirable. Some may benefit even more from techniques to reduce the high RR or to mobilize the thorax. For a select patient population, instruction in GPB may be necessary to support breathing without mechanical ventilatory support. Finally, the therapist can choose to use techniques to assist the patient in developing adequate breath support for vocalization and communication.

As therapists come to understand how profound the influence of effective ventilation can be on a patient's recovery from disease or trauma, they will incorporate breathing and ventilation strategies into all patient treatment. Understanding that facilitating effective ventilation goes far beyond diaphragmatic exercises, therapists can be empowered to incorporate other techniques and strategies to help their patients become healthier more quickly and to assist them in reaching their highest potential and prevent future respiratory complications.

The take-home message is that the cardiovascular and pulmonary system will be either an asset or a detriment to a patient's function. Examination and evaluation of breathing patterns and breath control will promote improved patient outcomes.

Review Questions

1. Why would a therapist want to try to change a patient's breathing pattern?
2. How can ventilatory strategies be incorporated into a treatment session?
3. When would a therapist not teach diaphragmatic breathing?
4. What is the role of relaxation in breathing control?
5. When would a therapist consider teaching the patient to use his upper chest accessory muscles more in breathing?
6. When would a unilateral breathing pattern be taught?

Cardiac and Pulmonary Rehabilitation: Future Directions 401
Summary 401
Review Questions 401
References 402

The principles of physical therapy practice in the management of individuals with primary cardiovascular and pulmonary conditions can be applied in formally structured programs or in one-on-one sessions. Exercise testing and training are primary components of comprehensive physical therapy management, which is detailed in Chapter 31. This chapter describes these principles. Structured cardiac and pulmonary rehabilitation programs are therapeutic multidisciplinary programs that encompass the essentials of the best physical therapy practice (Box 24-1). The distinctions among structured programs lie in the primary patient populations they serve rather than in the principles of physical therapy management, which are comparable when applied on a one-to-one basis. The general principles of comprehensive care include

Box 24-1 Definition of Cardiovascular and Pulmonary Rehabilitation

- The goal of cardiovascular and pulmonary rehabilitation is to maintain or return an individual with cardiovascular and pulmonary dysfunction to full participation in life with a high level of life satisfaction.
- Cardiovascular and pulmonary rehabilitation consists of a comprehensive interdisciplinary management program, including physical activity and exercise, education, and behavioral change designed to improve the physical and emotional status of individuals with cardiovascular and pulmonary dysfunction or their risk factors.

teamwork, patient education, exercise testing and training, long-term sustainable lifestyle change, and follow-up, and these are common across patient groups. This chapter extends the basic principles of exercise testing and training outlined in Chapter 19. The chapter highlights state-of-the-art literature and the physical therapist's central role as clinical exercise physiologist and health educator in addressing the needs of individuals with primary cardiovascular and pulmonary conditions.

The role of the physical therapist as health coach and advocate to promote lifelong health and well-being is further emphasized in the management of these patient groups. These principles are also applied when primary cardiovascular and pulmonary dysfunction is a secondary diagnosis—that is, for example, in a patient whose primary diagnosis is a frozen shoulder but who has history of ischemic heart disease or its risk factors. This underlying condition has major implications for the modification of an exercise program for the frozen shoulder in addition to implementing management to specifically address it.

Over the past decade, an extensive number of position statements, clinical practice guidelines, and consensus statements have been published to guide contemporary practice in cardiac and pulmonary rehabilitation programs. The major goal of these programs is to improve quality of life and tolerance of daily activities. An overriding objective is to institute lifelong healthy practices, including secondary prevention.[1] The application of these principles is central to the management of cardiovascular and pulmonary conditions, whether they are primary or secondary conditions. In general practice today, patients (including children) presenting to the physical therapist with musculoskeletal or neuromuscular complaints have a high probability of having underlying cardiac or pulmonary pathology, or one or more associated risk factors (see Chapter 1). Established guidelines for cardiac rehabilitation programs do not replace the expert clinical judgment of rehabilitation professionals and goal-directed, patient-centered service delivery.[2] Consistent with the World Health Organization's definition of health (see Chapter 1), both cardiac and pulmonary rehabilitation programs focus on the enhancement and maintenance of cardiovascular and pulmonary health through individualized programs designed to optimize physical, psychological, social, vocational, and emotional status overall. In addition, they promote secondary prevention through risk-factor identification and modification in an effort to prevent disease progression and the recurrence of cardiovascular and pulmonary events.[2]

A criticism of conventional cardiac and pulmonary rehabilitation programs is that they are structured with little individualization.[3] The physical therapist, who is uniquely qualified as an applied clinical exercise physiologist and health coach, needs to ensure that all components—in particular, exercise—are prescribed to meet the specific needs and comorbidities of each individual. For reference purposes, we include elements of international standards and guidelines for cardiac and pulmonary rehabilitation programs in Appendixes A and B. We caution, however, that these elements need to be tailored to an individual (based on a detailed history, assessment, and examination, and ongoing evaluation) and that such standards may change as new evidence emerges. Nonetheless, they will provide useful guidelines to physical therapists involved with setting up facilities related to cardiac and pulmonary rehabilitation.

This chapter extends the information in Chapter 31 concerning the management of chronic, primary cardiovascular and pulmonary dysfunction. In the review of the state-of-the-art literature, $\dot{V}O_{2max}$ was often reported in studies and was used to mean $\dot{V}O_{2peak}$ (see Chapter 18 for elaboration of this physiological distinction). Despite this, we have retained the term used by the original investigators in each study in our summary of these studies.

Cardiac and Pulmonary Rehabilitation: Evidence Base, Efficacy, and Practicalities

Although an interprofessional team approach is fundamental to both cardiac and pulmonary programs, individuals who regularly participate in moderate exercise experience greater control of symptoms and increased functional capacity than do those treated with drugs alone.[4] Self-management strategies learned in a pulmonary education program also contribute to perceived control of symptoms and to self-confidence.[5] This sense of control is perhaps the single best argument supporting the exploitation of noninvasive interventions for the management of chronic conditions. This component may be singularly important in determining long-term outcomes, such as reduced demands for health care and lower health care costs.[6]

The effectiveness of cardiac and pulmonary rehabilitation has been established at the highest level of evidence[2,7-19] and this is true irrespective of stage of disease.[20,21] With the aging of the population, cardiac rehabilitation has been shown to benefit octogenarians as well as younger people. Because of the issues associated with exercise testing older people, the use of a mobility index, such as the Rivermead Mobility Index, to evaluate exercise performance has been proposed even in absence of a formal exercise test.[22] Because of common lifestyle behaviors, ischemic heart disease as a primary lifestyle-related condition will remain prevalent for the foreseeable future.

These interprofessional programs have internationally recognized standards that are well described and are recommended for all patients with cardiovascular and pulmonary conditions. They specialize in patient education (including smoking cessation, nutrition and weight control, and promotion of self-management and training) that has sustained,

lifelong, positive effects on cardiovascular and pulmonary status and sense of well-being.[23-26] The term *end stage* needs to be revisited, given the efficacy of rehabilitation in severely compromised individuals.[27] Considering these benefits and the enormous economic implications of keeping people healthy and out of hospitals and physicians' offices, rehabilitation can be supported as a primary intervention rather than a secondary priority after suboptimal effects of pharmacotherapy or surgery.[28]

Noninvasive cardiac and pulmonary rehabilitation is more cost-effective than medical and surgical treatments, and it offers long-term health benefits and reduced risk. However, there is a significant discrepancy between the actual provision and practice of cardiac rehabilitation and that advocated in published guidelines. These evidence-based, noninvasive, cost-effective interventions are being grossly underused, and participation rates are low.[29] Referral to cardiac rehabilitation has been reported to reflect selected groups, namely, younger age groups, those who have participated previously, those admitted to hospital with outpatient cardiac rehabilitation services, and those having a discharge diagnosis of myocardial infarction or coronary artery bypass surgery.[30,31] Significant barriers also have been reported to exist with respect to availability, referral, and utilization of these programs; payment issues are another factor.[32] Only a small proportion of individuals are referred, and of those, only a small proportion can access the programs.[33-35] Phase I inpatient cardiac rehabilitation has been reported to be a declining trend.[36] Physicians and surgeons may not have knowledge and awareness of the effectiveness of noninvasive approaches to health problems that have been managed primarily with drugs and surgery, so suitable candidates are not always referred.[37] In addition, there are psychosocial reasons for underutilization of these resources. Women are referred less commonly than men, and their drop-out rates are higher.[38,39] Thus there is a selection bias in the individuals sampled for studies of cardiac rehabilitation.[40] The participation of women is associated with insurance, level of education, bypass surgery, and transportation availability.[41] Cost containment and increasing accessibility are two primary barriers to participation in cardiac rehabilitation.[42] Low participation rates (particularly by women, minority group members, and older people) and means of increasing access have become primary areas of interest.[43]

Of the multiple facets of a cardiac rehabilitation program, different components may have different effects on individual heart health. In addition, physiological distinctions between men and women affect the incidence and manifestation of cardiovascular conditions between the two sexes and, in turn, their responses to cardiac rehabilitation. Women tend to have lower systolic blood pressure and pulse pressure than men and to have more favorable lipid and homocysteine levels.[44] However, the compliance of women's small blood vessels tends to be lower, which may reflect female sex hormones and the higher mortality rates of premenopausal women hospitalized for myocardial infarction. Women also tend to have more "silent" ischemic heart disease than men, which is more often associated with sleep disturbance in women. The results of one descriptive study also showed that women were less likely to adhere to diet and exercise modification guidelines compared with regimens for smoking cessation, medication, and stress management.[45]

Special attention needs to be paid to motivating individuals to participate in rehabilitation programs (identify facilitating factors and barriers to participation), to generalize their new skills to home activities and the community, and to continue their new lifestyle behaviors beyond formal enrollment in the program.[4] Given that education and exercise are core components of cardiac and pulmonary rehabilitation, physical therapy is uniquely positioned to implement care for individuals with cardiac or pulmonary conditions as primary or secondary diagnoses and to mobilize an interprofessional health care team for a given individual if no formal program exists. Education materials should be individualized to the learner's needs and capacities; otherwise, resources will be wasted. A marked disparity exists between the average American's reading ability (eighth grade level) and the readability levels of cardiac rehabilitation materials.[46] The large number of polysyllabic words is a primary factor.

Cardiac and pulmonary rehabilitation programs are typically conducted in formal centers in large communities. The vast majority of patients, however, do not have access to cardiac and pulmonary rehabilitation. Furthermore, long-term participation and adherence to the principles of the program have been disappointing, particularly for women.[47] The principles of these programs reflect fundamental physical therapy practice, which can be implemented on a one-to-one basis in a private practice (in a large or small community) or in a hospital that does not have a formal program in cardiac or pulmonary rehabilitation; in such settings, the outcomes are comparable to those in formal programs.[48-50] A close-to-home philosophy of care is emerging in the field of health care, including cardiac rehabilitation, in an effort to improve access to underserved people and groups.[51] When well constructed, a home-based cardiac rehabilitation program can have long-term outcomes comparable to those of a center-based program—for example, improved total cholesterol, smoking reduction, anxiety reduction, and self-reported improved physical activity and diet.[52] Patients who are stable after bypass surgery do as well (in terms of improved exercise capacity and risk reduction) in an individualized detailed home program as those participating in a supervised center-based rehabilitation program.[53]

As patients become more active, their pharmacokinetics change. Medications must be reviewed on an ongoing basis and prescriptions modified accordingly.[54] These changes reflect the long-term metabolic effects of exercise, in addition to improved health and potential weight loss. Close teamwork is needed to monitor a patient's medications and ensure that drug prescriptions are changed so that they promote weaning from medication commensurate with the benefits of noninvasive intervention, including education and exercise. Eliminating or reducing the needs for medication and pharmacological support is an important physical therapy outcome consistent with the philosophy of exploiting noninvasive care as much as possible.

Formal exercise testing and training—primary physical therapy skills—are warranted in patient diagnosis, evaluation, and exercise prescription. Early intervention with exercise for heart and lung conditions has become an established practice to counter the deleterious effects of deconditioning and the loss of cardiac and pulmonary function and to maximize remaining oxygen-transport reserve.[55]

Addressing the psychosocial components of care in cardiac and pulmonary rehabilitation is an element of the internationally accepted definition of rehabilitation. Psychosocial factors, however, constitute few, if any, aspects of the workup and assessment of an individual with heart or lung disease. A structured assessment tool to assess and monitor psychosocial factors and changes in patients with heart disease has been proposed.[56] Guidelines concerning the psychosocial component of cardiac rehabilitation are the sole focus of a position paper currently being developed in Europe. This position paper is designed to promote active psychological as well as physical well-being.[57] Given the aging of the populations of high-income countries, cardiac rehabilitation programs must pay particular attention to the needs of older adults with respect to nutrition, physical activity and exercise, program adherence, smoking cessation, psychological issues, and methods of teaching the older learner.[8] Doing so will help to reduce the high exclusion rate of this cohort of the population from cardiac rehabilitation programs.

Finally, with the advent of databases and outcome measures, projects such as the Wisconsin Society for Cardiovascular and Pulmonary Rehabilitation (WISCVPR) Web-based Outcomes Project, which focuses on outcomes for cardiac rehabilitation, are being used to develop benchmarks and further refine best practice guidelines.[58] Outcomes of pulmonary rehabilitation include quality of life, which for those with chronic lung disease, is reflected in the St George's Respiratory Questionnaire and the 36-item Short-Form Health Survey. A simple linear analog quality-of-life scale has also been shown to be valid in evaluating disease-specific, health-related quality-of-life issues in older individuals with chronic lung disease.[59] With databases and outcomes evaluation, physical therapists will be able to individualize programs to promote more immediate, more effective, and more long-lasting effects.[60] In addition, programs are being evaluated that will enhance the quality of prevention strategies initiated by health care providers through hospital-based programs for patients at risk.

Quality-improvement initiatives are becoming a focus in the literature. In 2008, one such initiative that used interactive training of hospital teams with Web-based teaching tools, enhanced adherence to prevention guidelines in hospitalized patients with cardiac disease.[61] From baseline to 1 year, this initiative reported marked improvements in smoking cessation, lipid control, blood pressure control, and cardiac rehabilitation referral. Quality-improvement initiatives for activities related to cardiac rehabilitation produce marked benefits. In addition to structured exercise, cardiac rehabilitation focuses on counseling and teaching about risk reduction in order to promote lifelong health; however, long-term studies are needed to address the issue of deterioration with respect to risk factors and lifestyle behaviors over time.[62] In 1998, a multistate outcome program for cardiovascular and pulmonary rehabilitation was shown to be feasible; it was possible to benchmark data across programs.[21] Outcomes included the SF-36 Health Survey, a patient knowledge test, and a 6-minute-walk test distance. All outcomes improved in both cardiac and pulmonary rehabilitation programs. Such outcomes are needed to systematically evaluate the effects of cardiac and pulmonary rehabilitation programs.

Although cardiac rehabilitation reduces cardiac deaths, it remains unclear whether exercise alone or the comprehensive range of interventions associated with cardiac rehabilitation is responsible.[63] The answer to this question is singularly important in refining the principles and practices of cardiac rehabilitation programs.

Studies of the efficacy of cardiac rehabilitation have been methodologically marred by selection bias: subjects tend to be low-risk, middle-aged men, whereas those who might benefit most are often excluded, namely, those who are older, at high risk, and have multiple comorbidities.[63] Those individuals who do not attend cardiac rehabilitation programs tend to be older, less aware of their cholesterol values, and less likely than attenders to believe their condition was controllable and that their lifestyle may have contributed.[64] Attention to exercise and motivational profiles has been proposed as a means of enabling rehabilitation program participants to continue with exercise.[65] Promoting self-efficacy should therefore be an important focus in tailoring cardiac rehabilitation programs. Finally, the ethnicity of program participants is rarely reported. Given the needs of the aging population, the number of people with multiple conditions, and the increasing ethnic diversity in the United States and Canada, the reports on the effects of cardiac rehabilitation, to date, have relatively limited generalizability.

As a handy reference for clinicians, key points in the assessment, evaluation, and exercise testing and prescription of patients with primary cardiovascular and pulmonary conditions are summarized in Appendix C.

Patients with Chronic Cardiac Dysfunction: Exercise Responses

Cardiac dysfunction includes a range of types of pathology, causes (acquired or congenital), and severity that may be managed medically, surgically, or in both ways (see Chapter 31 for the principles of comprehensive physical therapy management). The most common cause is ischemic heart disease and myocardial infarction. The muscle that is infarcted never recovers, so remodeling of the heart occurs, and that alters the heart's electrical functions (as shown on an electrocardiogram [ECG]) and mechanical functions (evidenced by ECG and echocardiogram). Remodeling takes place over time and with exercise. Ejection fraction (right ventricle) at rest is a poor indicator of cardiac function and exercise capacity.[66] In fact, heart failure can occur in the presence of a normal ejection fraction,[67] a form of disorder that typically occurs in women who have histories of hypertension and increased left ventricular mass.

Patients can range from being asymptomatic and having risk factors to being in severe distress and having minimal functional capacity, requiring high levels of supplemental oxygen and pharmacological support, and awaiting heart transplantation. Patients with extremely severe disease may require mechanical ventilation. To be able to classify patients' functional capacity in a semi-quantitative manner, the New York Heart Association classification of function is commonly used (see Box 31-2). Exercise is now considered an essential component in the management of individuals with stable heart failure and in those who have undergone transplantation.[68] Surgical options include keyhole surgery, open-heart surgery (e.g., coronary artery bypass surgery, valve repair, and aneurysm repair), and heart transplantation.

There is an interaction between circadian rhythms and the pathogenesis of heart rate and blood pressure variability. These rhythms are under the influence of adrenal, autonomic, hypothalamic, and pituitary activity. Thus physical exertion, sleep deprivation, emotional stress, and high-fat meals are major triggers of myocardial ischemia, angina, infarction, sudden cardiac death, and stroke, which have a higher incidence in the second quarter of the day, between 0600 and 1200.[69] Heart rate and blood pressure variation have been implicated in the pathogenesis and progression of atherosclerosis, heart failure, and thrombosis, and are independent risk factors. During this period, vitamins C and E are lower than during the rest of the day; it has been postulated that regulating the intake of these vitamins and exercising may minimize the variability of heart rate and blood pressure. Whether such regulation can then modulate cardiovascular events warrants further study.

Although dyspnea is a common limiter to exercise in cardiac failure, the other factors that contribute to exercise limitation are multiple. In addition to central hemodynamic impairments, exercise capacity is affected by impaired ventilatory control, lung function, peripheral circulation, and skeletal muscle function.[70] Exertional dyspnea has been attributed to the regulation of arterial pH during exercise.[71] Pulmonary hypertension and systemic hypotension can also limit exercise performance.[72] Explanations for these limiters include baroreceptor dysfunction, beta-receptor downregulation, abnormal vascular adaptation, and poor cardiac output in relation to elevated right ventricular afterload. The delayed $\dot{V}_{O_2}$ responses (delayed oxygen kinetics or time constant for this variable) are associated with lactate production and early anaerobiosis.[73] Maladaptive gait changes have been ruled out as a factor influencing ventilation in patients with chronic heart failure.[74]

The physiological capacity of patients with cardiac dysfunction to adapt to exercise depends on the type and severity of impairment in the heart and in other steps in the oxygen transport pathway. Reduced alveolar-capillary membrane-diffusing capacity[75] and a ventilation to perfusion mismatch have been proposed[76] and may reflect chronically elevated pulmonary capillary pressure. A primary ventilation-perfusion mismatch defect in patients with heart failure may explain their increased ventilatory response to exercise, but this theory has been questioned.[77] Patients with severe left ventricular dysfunction enhance their aerobic capacity primarily by improving oxygen extraction at the tissue level rather than by means of central adaptation. Similarly, with aerobic exercise, these patients improve the collateralization of peripheral capillaries so as to improve blood flow to working muscles and increase nitric oxide production in the blood vessels, which mediates endothelium-dependent relaxation.[78] This effect is correlated with functional capacity. Thus evaluation of vasomotor reactivity has been proposed as a means of explaining the effects of interventions, including exercise and medications. Aortic wall elasticity modulates left ventricular function and coronary blood flow. Pulse wave velocity is a marker of arterial stiffness and is an independent predictor of $\dot{V}_{O_{2peak}}$.[79] The exercise intolerance observed in individuals with dilated cardiomyopathy may be explained by an increase in arterial stiffness.

Although guidelines for exercise prescription have been commonly adopted for people with uncomplicated heart disease, the optimal prescription is still being refined. Moderate aerobic exercise performed alternate days for 20 to 40 minutes is generally accepted. Nonetheless, despite the general health benefits that are associated with this level of exercise, more moderate levels including brisk walking have been reported to be equally protective.[80] Such findings are important particularly for individuals who are disinclined to formally exercise at the recommended level for cardioprotection. Brisk walking is more easily integrated into daily life hence likely to be adhered to.

Individuals with Chronic Cardiac Dysfunction and Failure

The cardiac dysfunction managed by physical therapists can range from mild to severe. With increasing severity of disease, an individual's response and adaptation to exercise are altered markedly, which has major implications for exercise testing and training. Today, patients with even severe heart dysfunction may be able to participate in some level of exercise.[19] However, this needs to be done under the supervision of a competent health care team to ensure the benefits are maximized and the risks minimized.

Chronic heart failure is usually hallmarked by left ventricular dysfunction. In health, normal left stroke volume coupled with increased heart rate leads to greater cardiac output and greater metabolic demand, as during exercise. As the left ventricle becomes increasingly compromised, the individual with heart failure depends more on heart rate to increase cardiac output and peripheral oxygen extraction. Left ventricular ejection fraction during exercise is not consistently associated with resting ejection fraction,[81] even in people with objective signs of myocardial ischemia and increased heart rates during exercise. Thus the left ventricular ejection fraction at rest must be interpreted cautiously in the context of exercise and predicted exercise responses.

Determining which patients will benefit from a rehabilitation program has been the subject of debate. Goebbels and colleagues (1998)[82] reported that patients with depressed left ventricular function benefit, whereas patients whose left ventricular function has been preserved, such as may occur after myocardial infarction and coronary artery bypass surgery, tend to improve spontaneously within 3 months.[83] Proponents of selecting patients for cardiac rehabilitation however, have failed to address the past history of patients, their comorbidities, access to rehabilitation, return to work, and secondary prevention strategies to maximize their care and long-term outcomes. Noninvasive practices need to be exploited before, during, and after a myocardial event or surgery to maximize long-term gains, including reduced recurrence of the problem and need for doctor- and hospital-based care, reduced risk factors and morbidity, and prolonged quality of life. Physical therapy has a commitment to long-term outcomes, including reduced doctor- and hospital-based care, reduction or elimination of medications, and reduced probability of repeat surgeries.

Conservative management of patients with heart failure who utilize physical therapy has emerged as a major focus in the literature, in part because of the cost of surgery and an inadequate supply of organ donors. The benefits include reduction of deconditioning, including restoration of normal autonomic balance and, potentially, some primary effects on

the underlying pathology.[84] Patients with chronic heart failure respond to aerobic exercise favorably, showing improvement in functional class as defined by the New York Heart Association.[85] Both $\dot{V}O_{2max}$ and anaerobic threshold improve. In addition, there is a reduction in the exaggerated ventilatory response at maximal and submaximal work rates that is usually observed in these patients. As a result, symptoms are reduced. Exercise benefits persist after patients shift from a supervised center-based to a home-based program. This finding has important practical and economic implications.

Over recent years attention has turned to exercise training of patients with cardiac failure and the role of ventilatory changes in exercise-induced dyspnea. The periodic breathing of patients with cardiovascular disease is well known clinically; however, the mechanism underlying the cycling hyperpnea and hypopnea is not clear. Fluctuations in pulmonary blood flow have been proposed as a mechanism for this periodic breathing.[86] With respect to other ventilatory correlates of heart failure, ventilatory efficiency, the ratios of $\dot{V}_E$ and $\dot{V}CO_2$, have yielded important prognostic information.[87] When used in combination with $\dot{V}O_2$ (≥15 mL/kg/min), $\dot{V}_E/\dot{V}CO_2$ (≥50 L/L) can be useful in defining a high-risk group that should be prioritized for heart transplantation.[88]

At rest, individuals with more severe heart failure have more restrictive lung pathology and impaired gas exchange.[89] During exercise, these patients have increased dead space, impaired gas exchange, and greater submaximal ventilatory responses than individuals whose disease is less severe. Exercise limitation in patients with chronic heart failure correlates with reduced FEV_1 and FVC, implicating airway resistance in the increased work of breathing in exercise intolerance.[90] In addition, an exercise-induced diffusion defect has been identified.[91] Alveolar-capillary membrane conductance has been identified as the best lung function predictor of $\dot{V}O_{2peak}$ in patients with chronic heart failure.[92] The impairment in ventilatory efficiency is associated with reduced exercise tolerance and pulmonary artery pressures.[93] Pulmonary vasoconstriction has been implicated in leading to pulmonary hypertension and alveolar hypoperfusion. Overall, exertional dyspnea observed in patients with heart failure is not the result of abnormal ventilatory function.[94]

Ventilatory exercise parameters, including $\dot{V}O_{2peak}$, $\dot{V}_E/\dot{V}O_2$, and $\dot{V}_E/\dot{V}CO_2$, are strong predictors of mortality.[95,96] $\dot{V}O_{2peak}$, however, may be underestimated, given the slowed O_2 kinetics in this population.[97] Gas exchange, therefore, should continue to be monitored throughout recovery. Submaximal respiratory gas indexes have been proposed as being more sensitive than peak $\dot{V}O_2$ for assessing functional impairment[98] and for predicting survival in ambulatory patients with chronic heart disease.[99] Nonetheless, ventilatory capacity is not likely to limit exercise performance in patients with stable chronic heart failure.[100] Ventilatory and heart rate responses are, however, strong and powerful predictors of mortality in these patients, and they are superior to the use of $\dot{V}O_{2peak}$.[101] Inspiratory capacity varies inversely with pulmonary capillary wedge pressure in individuals with chronic heart failure, and it is a strong independent predictor of functional capacity.[102]

Patients with severe chronic heart failure often have high ventilatory demands during exercise, and they have respiratory alkalosis, which is consistent with significant wasted ventilation on exertion,[103] and increased respiratory drive;[104] only a relatively small effect is attributed to ventilation-perfusion mismatch. However, increased ventilatory drive, as evidenced by the ventilatory equivalent of carbon dioxide ($\dot{V}_E/\dot{V}CO_2$), has been reported to occur infrequently.[105] Knowledge and understanding of which patients exhibit this response and which do not would be clinically useful.

Patients with severe chronic heart failure have a reduced ratio of increase in $\dot{V}O_2$ to increase in work rate during incremental exercise.[106] The reduced DO_2 due to severely compromised cardiac output is not fully compensated by an increase in oxygen extraction. These patients do tend to show improved exercise response through improved peripheral oxygen extraction. Changes in cardiac performance may reflect the Frank-Starling effect rather than changes in contractility.[107] Low cardiac output, particularly in less intense exercise, does not necessarily result in lower exercise capacity.[108] This phenomenon has been attributed to a unique mechanism that regulates arteriovenous oxygen content difference to optimize DO_2 to the tissues in patients with severe heart failure. At peak exercise, fractional oxygen extraction in the muscle is greater in patients with chronic heart failure than in healthy people in proportion to the level of the patient's impairment.[109] This observation supports the importance of peripheral adaptation to aerobic training in patients with heart failure.

Heart failure can be categorized as either diastolic or systolic; the former may be the dominant form in elderly people.[110] In stable outpatients, mortality due to diastolic failure is about half that of mortality due to systolic failure. However, when patients are hospitalized, the rates are comparable. Because of its strong prevalence among the elderly, diastolic failure exceeds systolic failure in being the cause of mortality. In diastolic failure, the Frank-Starling mechanism is impaired, causing reduced maximal cardiac output, heart rate, stroke volume, and left ventricular filling pressure. Vascular stiffness is also increased. Acute exacerbations result in pulmonary edema and are associated with hypertension, sodium intake, and lack of adherence to medication schedule. A primary goal is to reduce blood pressure, which improves symptoms and reduces exacerbations.

Exercise testing is an important means of establishing the prognosis of an individual with chronic heart failure with respect to treatment response, morbidity, and mortality. Peak $\dot{V}O_2$ pulse, ($\dot{V}O_2$/heart rate), and lean body mass adjusted for O_2 pulse are useful prognosticators.[111] Postexercise blood pressure response has shown to be a reliable and valid predictor of adverse cardiac events in individuals with dilated cardiomyopathy.[112] The postexercise blood pressure response is defined as the ratio of systolic blood pressure at 3 minutes postexercise to that at peak exercise, with a criterion of 0.79 or greater to predict complications. The 6-minute walk test has been reported not to replace $\dot{V}O_{2peak}$ as a prognosticator in individuals with advanced heart failure.[113]

Prediction of the prognosis of individuals with chronic heart failure can be improved with a two-step exercise-test protocol.[114] This test combines maximal and low-intensity exercise to improve accuracy and reproducibility. In addition, a distance of less than 300 meters walked in the 6-minute walk test (see Chapter 19) has been reported to be a useful prognostic marker of subsequent cardiac death in individuals with mild to moderate heart failure.[115] Exercise testing has also been reported to provide good prognostic value in determining postoperative outcomes (mitral and aortic regurgitation).[116] An important role for exercise testing in prognosis is emerging.

Although tests of $\dot{V}O_{2max}$ can be used to stratify patients with cardiac failure according to risk factors, these tests can be invalid as a result of premature termination by the tester or lack of motivation by the patient. Tests of anaerobic threshold may be less influenced by these factors in such a potentially compromised group.[117] Rather, the combination of a $\dot{V}O_2$ at an anaerobic threshold (gas exchange threshold) of less than 11 mL/kg/min and a $\dot{V}_E$ versus $\dot{V}CO_2$ slope of more than 34 is a better predictor of mortality at 6 months than is $\dot{V}O_{2max}$, and it may provide a guide when prioritizing patients for heart transplantation. Submaximal and endurance tests and determining the anaerobic threshold have been advocated over maximal tests for clinical evaluation of patients with heart failure because they are relatively easy to perform, are associated with less risk, and are more valid indexes of a patient's capacity for daily activity.[118,119]

Individuals with heart failure have a higher incidence of glucose intolerance compared with healthy individuals (20% lower).[120] After an aerobic exercise program, glucose uptake can increase by 25%. The mechanism of the reduction in glucose tolerance in individuals with heart failure and the remediating effects of aerobic exercise have yet to be elucidated. Whether secondary improvement in insulin sensitivity from aerobic exercise occurs in these individuals comparable to that in healthy people warrants clarification.

Body position may be an important factor to consider when exercising patients with chronic heart failure who often complain of orthopnea. However, when exercise responses in the erect and supine positions were compared in one study, no change was reported in breathlessness, and no change occurred in $\dot{V}_E/\dot{V}CO_2$. However, $\dot{V}_{Epeak}$ was greater in the upright position.[121]

Patients with chronic heart failure can benefit from aerobic training. Exercise training of patients with impaired left ventricular function is associated with improved ventilatory function.[122] In addition to improved cardiac output, long-term high-intensity exercise resulted in reduced ventilatory dead space and improved ventilatory efficiency. In men with reduced left ventricular function, high-intensity exercise (2 hours of walking daily in combination with high-intensity, monitored cycle ergometry at 70% to 80% of peak capacity for 40 minutes, four times a week for 8 weeks) has been reported to result in marked increases in $\dot{V}O_{2max}$ secondary to increased cardiac output and widening of the A-aO_2 difference.[123] No improvement in myocardial contractility tends to be observed in these patients after such an exercise program. High-intensity exercise does not impair hemodynamic status or lead to further myocardial damage. Low-intensity exercise in individuals with chronic heart failure has been shown to improve autonomic tone and reactivity to vagal and sympathetic stimulation.[124]

The effects of exercise training on pulmonary function in individuals with heart failure are becoming better understood. After training, individuals with coronary artery disease have been reported to show no change in pulmonary function, with the exception of the respiratory exchange ratio at peak exercise.[125] Also, alveolar-capillary diffusing capacity may contribute to improvement in exercise tolerance after training.[126] Pretraining pulmonary function is not correlated with improvement in exercise performance.

With aerobic exercise training, respiratory muscle endurance improves, and that contributes to improved overall exercise capacity.[127] Breathlessness is also reduced. The reverse occurs too—that is, respiratory muscle training can improve $\dot{V}O_{2peak}$, as well as respiratory muscle endurance in patients with chronic heart failure. The combination of muscle and endurance training is superior to endurance training alone in this patient cohort with respect to improved left ventricular function, $\dot{V}O_{2peak}$, and strength.[128,129]

An understanding of skeletal muscle function in individuals with chronic heart failure is important because improvements in aerobic capacity may be largely dependent on maximizing peripheral oxygen extraction. Strength training in combination with aerobic training improves walking distance in the 6-minute walk test, which is an independent prognosticator in individuals with chronic heart failure.[130] Regular endurance exercise increases oxidative enzymes in the working muscles and is associated with a shift from type II to type I fibers.[131] These skeletal muscle adaptations are independent of peripheral circulatory adaptations.

Adaptation to resistance muscle training reflects changes in the myosin heavy chain of peripheral skeletal muscle and a shift from slow aerobic to fast glycolytic and fast oxidative characteristics.[132] These findings are associated with $\dot{V}O_{2peak}$, O_{2pulse}, and tidal volume. Reduced strength of the knee flexors and extensors in patients with chronic heart failure is associated with impaired ventilatory response to exercise; thus muscle dysfunction has been proposed as a contributing factor to symptoms.[133] Improved functional outcomes, increased walking distance, and reduced muscle area with increased interstitial space after exercise training support the theory that these effects are mediated by improved capillary density and flow reserve to exercising muscle.[134]

Peripheral myopathy in individuals with chronic heart failure may contribute to exercise intolerance and training capacity.[135] Features include reduced proportion of type I fibers, shift to type II fibers, biochemical shift consistent with increased muscle fatigability, reduced mitochondrial density, and reduced capillary density.[136] However, some of these changes, such as altered capillary density, appear to be gender-specific, which may have implications for training.[137] Skeletal muscle appears to adapt to central impairment of oxygen transport in heart failure. There is histochemical and gas exchange evidence showing that physiological recovery is delayed in patients with heart failure.[138] Interestingly, markers of skeletal muscle oxygenation, including myoglobin and its derivatives, are reduced during incremental aerobic exercise to maximum, and during the recovery. As the capacity for aerobic exercise declines, patients may have greater reliance on anaerobic metabolism (but this cannot be sustained/attained in the same way), which is consistent with increasing reliance on anaerobic pathways for metabolism during exercise. Inflammatory cytokines have been implicated in the myopathy associated with heart failure.[132] However, the possibility that this outcome reflects deconditioning cannot be ruled out because patients typically are unable to achieve high exercise intensities.[139]

The recovery process in patients with heart failure has important implications for optimizing exercise training parameters and, thereby, training effects. However, further study of differences in exercise recovery characteristics between patients with heart failure and healthy people is warranted.[140,141] Evidence supports the idea that exercise intolerance in these patients is characterized by slower adaptation to acute exercise

and recovery and to reduced maximal exercise capacity compared with healthy people.[142]

After angiography, positioning and mobilization have important roles after several hours of bed rest.[143] Limiting restricted mobility after cardiac catheterization to 2 hours from 6 hours has been reported to be safe, and it may limit complications.[144]

Different types of exercise stress (aerobic or resistance) have differential effects on the heart and circulation.[145] In health, for example, static exercise exerts a pressure load on the heart that can be distinguished from the normal hemodynamic response to dynamic exercise, which involves a volume load on the heart. Static exercise leads to concentric cardiac hypertrophy (left ventricular), and dynamic training is associated with eccentric hypertrophy. Static exercise can produce effects that have been associated with aerobic training. Isotonic exercise using hand weights has been reported to be associated with increases in systolic and diastolic blood pressure, rate pressure product, serum norepinephrine, and perceived exertion.[146] Pulmonary capillary wedge pressure, incidence of dysrhythmias, and ST-segment changes do not differ from rates recorded at rest. Generally, isotonic exercise is tolerated well by individuals with heart failure, and no angina or dyspnea occurs.

Low to moderately intense strength training may cause fewer cardiovascular complications than aerobic exercise training in individuals who have undergone myocardial infarction.[147] Resting blood pressure can be reduced, albeit to a lesser extent, suggesting reduced sympathetic and baroreceptor activity. In addition, lipid profiles may improve. These benefits can be observed in patients with cardiac and circulatory pathology without adverse effects. Even older, frail patients may tolerate weight training at 40% to 60% of maximal voluntary contraction. Qualitatively similar hemodynamic responses occur in response to resistance exercise, as in aerobic exercise in individuals with heart failure.[148] In general, resistance training with multiple repetitions of moderate weight produces the most beneficial effects. To ensure that a patient is able to perform optimally the activities of daily living, which require a certain degree of muscle strength, strength training is considered an integral component of a cardiac rehabilitation program.

The effect of cardiac dysfunction on regional circulation has been of interest, particularly with respect to cerebral perfusion. A recent study has shown that patients with left ventricular dysfunction can have impaired cerebral perfusion. During exercise, the adequacy of cerebral perfusion is dependent on the adequacy of cardiovascular and pulmonary function; it is compromised in patients whose cardiac output fails to increase appropriately in response to exercise.[149]

Some individuals with chronic heart failure have been reported to have sick euthyroid syndrome, in which serum-free triiodothyronine is reduced in the presence of normal free L-thyroxin and thyrotropin.[150] Sick euthyroid syndrome is a sign of poor prognosis in individuals with chronic heart failure. Exercise, however, can normalize the free triiodothyronine levels and reverse the syndrome, in turn improving exercise capacity.

Individuals with persistent life-threatening cardiac rhythms may require artificial pacemakers. Advances in this area have included biventricular pacing for individuals with systolic left ventricular failure with prolonged duration of the QRS complex. Preliminary reports suggest that these pacemakers are safe and effective.[151] Further, biventricular pacing can improve symptoms and quality of life by improving walking times and ejection fraction.[152] These effects persisted at the 6-month follow-up, and the 2-year survival rate was excellent. There are few specific guidelines for these individuals with respect to exercise testing and prescription. Similarly, there are few guidelines for individuals with automatic implantable cardioverter defibrillators.[153] Preliminary reports suggest that exercise and lifestyle recommendations are needed for individuals with pacemakers and implanted cardioverter defibrillators and that with due modification, exercise testing and training are feasible.

Ventricular dysrhythmias contribute to a significant number of deaths. Despite improved survival, this cohort of high-risk individuals may be considered inappropriate for cardiac rehabilitation. With careful patient screening and monitoring, however, some patients with ventricular dysrhythmias may safely participate in cardiac rehabilitation.[154]

Individuals after Heart Transplantation

Heart transplantation has become an accepted therapy for end-stage heart failure over the past 20 years, with its ultimate goal being the return of function and a good quality of life (see Chapter 17). Postoperatively, the resting heart rate for heart transplant recipients is higher than normal. In the early postoperative period, the peak $\dot{V}O_2$ and work rate of people who have had heart transplants are 50% of those of healthy people.[155] At ventilatory threshold, the $\dot{V}O_2$ and work rate were also 50% of normal. Peak heart rate, which increases for up to 3 minutes after peak exercise, is also significantly lower. This evidence supports the need for mandatory rehabilitation so as to maximize the benefits of this high-risk surgery, including optimizing functional work capacity, return to work, and life satisfaction.

Without training, exercise tolerance remains severely limited over the first 16 months postoperatively. This has been explained by the reduced capacity to respond to the Frank-Starling mechanism and the residual low cardiac index.[156] Rehabilitation begins preoperatively and continues for 1 year after discharge.[157] The principles of cardiac rehabilitation are applied; however, response of the denervated heart to exercise requires extended warm-up and cool-down periods and limits the maximal heart rate and $\dot{V}O_2$ that can be achieved. Reinnervation of the sympathetic nerves to the heart is associated with improved heart rate response to exercise and contractile function.[158] Hemodynamic responses to exercise are initially dependent on exogenous catecholamines rather than on the fast-responding sympathetic release from nerve endings. Systolic blood pressure is more appropriate than heart rate for assessing exercise response and recovery.[159] Anaerobiosis is achieved early. The degree to which neuroplasticity can be influenced by exercise training to promote autonomic reinnervation to the heart after transplant has yet to be established.

When compared with patients after bypass surgery in postoperative cardiac rehabilitation programs (phase II; up to 3 months postoperatively), patients with heart transplants have comparable functional outcomes.[160] However, after graduation from this program and being on a home-based program for 9 months, patients with transplants had lower $\dot{V}O_{2peak}$ and

were significantly more limited at the 1-year follow-up. Thus phase I only, combined with recommendations for a home program, may be inadequate for patients after heart transplantation; they may benefit from long-term supervised training programs.

Persistently low $\dot{V}O_{2max}$ after transplant reflects in part intrinsic skeletal muscle abnormalities.[161,162] In addition to intensive aerobic exercise, resistance muscle training has an important role in countering the effects of corticosteroid-related osteoporosis and peripheral myopathy. With respect to predicting the prognosis of patients with heart failure who undergo heart transplantation, $\dot{V}O_{2peak}$ is considered a superior indicator of submaximal indexes of exercise capacity.[163]

Isometric exercise and activities requiring postural stabilization are largely avoided in people who have had heart transplants because of potential hemodynamic stress. Light isometric exercise (handgrip) attenuates increases in heart rate, blood pressure, and systemic vascular resistance. Whole-body isometric exercise also attenuates these hemodynamic variables.[164] At rest, heart rate, blood pressure, and rate pressure product are higher in individuals who have had transplants than those rates in healthy people.

Some patients who receive heart transplants have low pulmonary diffusion capacity, and this is associated with lower exercise tolerance than is found in patients who do not have this impairment.[165] Poor diffusion capacity, however, is not associated with exercise-induced hypoxemia and thus is not considered a primary contributor to impaired exercise tolerance.

Individuals with Left Ventricular Assist Devices

Left ventricular assist devices have become more common as an interim intervention for an individual awaiting heart transplant. The donor pool is small, so many individuals may not survive the wait for surgery. The Jarvik heart is a left ventricular device designed as a long-term solution for heart failure. In an initial case study describing a patient with a Jarvik heart, exercise tolerance, myocardial function, and end-organ function all improved 6 weeks after surgery.[166] The Jarvik heart shows some promise for the management of end-stage heart failure; however, its success will depend on its mechanical dependability.

Individuals with Congenital Heart Disease

Guidelines for individuals with congenital heart disease warrant development. Barriers to exercise in this cohort have been reported to be their perceived physical limitations, lack of interest, and fear.[167] Currently, guidelines are suboptimal.

Individuals with Intermittent Claudication

Intermittent claudication (IC) is the symptom of exercise-induced muscle ischemia of peripheral arterial disease. IC is a systemic complication of atherosclerosis with or without overt ischemic heart disease. The disabling pain during walking results from muscle ischemia. The risk for cardiovascular morbidity and mortality far exceeds that of severe limb ischemia or limb loss.[168] A patient with IC must be managed as a patient with heart disease as well as one with peripheral arterial disease. Conservative management is a priority and should include physical activity and exercise programs, smoking cessation, weight loss and optimal nutrition, and stress management.

Claudication symptoms may mask cardiac symptoms. In addition, a comorbidity such as arthritis can complicate the clinical picture in such a way that the underlying vascular condition is neither manifested peripherally nor centrally. During exercise testing and training, arthritis may limit the capacity of the patient who may have well been restricted by claudication pain.[169] Even in this cases, exercise training can improve exercise tolerance in the absence of improved peripheral blood flow.[169] Exercise effects include reduced submaximal heart rates and oxygen cost and reduced postexercise lactate levels. In addition, lipid profiles can be improved.

The exercise responses of patients with IC also exhibit a slowed $\dot{V}O_2$ response related to impaired muscle perfusion.[170] The associated delayed ventilatory response has been associated with the hyperemic response in the exercising muscle rather than with ischemia.

Outcome measures, including ankle-brachial index performed in a vascular laboratory to assess changes in peripheral stenoses with exercise training, are useful.[171] Ultrasound can be used to assess pulses, particularly when they are weak. Palpation of skin temperature is a crude indicator of perfusion in that skin is highly sensitive to ambient temperature. Using the back of the hand, however, and scanning bilaterally down the legs, so that skin temperature can be compared in the legs, may have some utility for identifying gross differences in blood supply.

Individuals with Anemia

The exercise responses of patients with anemia have not been well described. The capacity of the blood to transport oxygen is determined by the hemoglobin concentration and the binding characteristics of the hemoglobin. Patients who develop acute anemia are more likely to complain of dyspnea than patients who develop anemia gradually. Rather than a primary cardiac, pulmonary, or muscle compensatory mechanism, this adaptation is mediated by increased diphosphoglycerate, which decreases the affinity of hemoglobin for oxygen in the tissue. Patients with sickle cell anemia have a low $\dot{V}O_{2peak}$ and a low anaerobic threshold in the presence of a high heart rate reserve but no gas exchange abnormalities.[172] The disease is characterized by restrictive lung pathology, increased alveolar dead space, and hypoxemia.[173] Increased dead space may reflect impaired pulmonary capillary perfusion due to the sickle cells. Exercise hyperventilation is thought to be associated with increased anaerobiosis.

Individuals with Hypertension

Hypertension remains the silent killer for which effective nonpharmacological interventions are underused. Hypertension is associated with sedentary lifestyle, diet, obesity, smoking, and stress. Further, hypertension has long been linked to type 2 diabetes mellitus as well as vascular changes typically seen with aging.[174,175] Modifying one or more of these factors can reduce high blood pressure and its lethal sequelae and eliminate, or at least reduce, the need for medication. Chronic sympathetic overdrive associated with hypertension promotes

left ventricular hypertrophy, cardiac dysrhythmias, and atherogenesis.[176] Further, inhibiting sympathetic overactivity may help reduce cardiovascular risk. Regular physical activity and a formal exercise program reduce the risk for hypertension or modify it. This effect is likely mediated through a decrease in total peripheral vascular resistance. African American men are particularly at risk for hypertension, and this risk can be detected by an exaggerated blood pressure response to exercise.[177] Endurance training reduces this exaggerated response and thereby may reduce the risk for developing hypertension. Along with eating a healthy low-salt diet and not smoking, exercise is a potent noninvasive intervention that can prevent, as well as control, high blood pressure. Despite the efficacy of many antihypertensive medications, potential deleterious effects of low perfusion to the vital organs with intensive blood pressure control cannot be overlooked clinically.[178]

Individuals with Type 2 Diabetes Mellitus

Type 2 diabetes mellitus is a strong risk factor for coronary artery disease and sudden cardiac death. This condition is associated with reduced baroreceptor sensitivity and heart rate variability, which are also risk factors for morbidity and mortality. Exercise training improves baroreceptor sensitivity in people with type 2 diabetes as well as glucose sensitivity, exercise tolerance, and muscle strength.[179] Prognosis may well be improved with exercise.

Type 2 diabetes mellitus results in multiple deficits to exercise capacity, both central and peripheral. Muscle blood flow may be impaired at the level of microcirculation in the absence of overt peripheral vascular disease.[180] In patients with chronic diabetes, exercise capacity is compromised by reduced oxygen delivery. A reduction in the arteriovenous oxygen difference may contribute to a reduction in $\dot{V}O_{2peak}$.[181] When smoking is controlled, individuals with diabetes mellitus who are insulin dependent and have complications have been reported not to exhibit impaired pulmonary gas exchange during exercise despite thickening of the alveolar basal lamina.[182] Individuals with non–insulin-dependent diabetes mellitus have reduced glucose transport in skeletal muscles, and this may contribute to exercise intolerance.

Diabetes mellitus is an independent risk factor for reduced left ventricular ejection fraction during exercise, as is severity of coronary artery disease.[183]

Role of Medications: Augmenters and Attenuators of Outcome

Among the factors that can confound exercise responses of patients are medications. Medications can enhance, limit, or have no effect on exercise performance. Patients with cardiovascular dysfunction, particularly those under a physical therapist's care, are likely to be taking one or more potent medications. The timing of their ingestion of these medications in relation to their performing an exercise test should be recorded in order to standardize testing procedures from one time to the next; at the very least, it is important to be aware of the confounding effects of a medication that could explain improved or worsened responses. Beta blockers are commonly taken by patients with cardiac dysfunction to improve the rhythm and contractile force of the heart. Long-term use of beta blockers causes no significant improvement in delayed heart rate recovery, which is a predictor of mortality in patients with heart failure.[184] These drugs can contribute to fatigue and exercise intolerance. Many patients are taking angiotensin-converting enzyme (ACE) inhibitors to enhance cardiac function. This classification of drug improves diffusion capacity and exercise capacity, an effect mediated through prostaglandin activity. However, this activity can be mitigated by aspirin, another drug commonly taken by patients with heart failure.[185] Thus a change in aspirin administration in combination with ACE inhibitors can worsen exercise tolerance. Captopril, a commonly prescribed ACE inhibitor, has a demonstrable beneficial effect on exercise responses in patients after myocardial infarction.[186] Ventilatory efficiency is improved, as is evidenced by a reduction in $\dot{V}_E/\dot{V}CO_2$ at submaximal workloads. Reduced perception of exertion and improved capacity to perform the activities of daily living may result from a reduction in ventilatory demand. Concurrent with physical therapy management, an inventory of the patient's medications and medication changes should be maintained and considered when conducting an exercise test or interpreting exercise test data.

Individuals with Chronic Pulmonary Dysfunction: Exercise Responses

Of individuals who participate in pulmonary rehabilitation programs, the largest proportion is made up of those with emphysema. Smoking is the primary cause of emphysematous changes in the lungs and the associated systemic complications (see Chapter 5). Patients with moderate or severe pulmonary distress may be referred to pulmonary rehabilitation. Other groups that may be referred are individuals with cystic fibrosis, asthma, interstitial lung disease, and alpha$_1$-antitrypsin deficiency. Patients with lung cancer are typically underrepresented in rehabilitation programs and warrant being targeted as a group that could benefit.

Like patients with chronic cardiac dysfunction, those with chronic pulmonary dysfunction may have a history of being managed pharmacologically or surgically. Surgical options include lung volume reduction surgery, segmentectomies, lobectomies, pneumonectomies, and lung transplantation.

Individuals with Chronic Obstructive Lung Disease

Deconditioning in patients with chronic lung disease is an anticipated consequence of the downward spiral of pathophysiological compensation for the structural and functional damage to the lungs. In individuals with severe disease, exercise intolerance may reflect limited peripheral perfusion and oxygen extraction due to the disproportionate demand on the respiratory muscles.[187] These individuals are unable to exercise at an intensity that induces a high level of aerobic conditioning, and they experience early onset of dyspnea. On experiencing dyspnea with exercise, a person with chronic obstructive pulmonary disease (COPD) reduces his or her activity level, which leads to deconditioning. With impaired aerobic capacity, anaerobic glycolysis has an increasingly important role in supporting physical activity. This leads to increased blood lactate, which needs to be buffered with bicarbonate, thereby producing additional carbon dioxide. This further increases

ventilatory load and dyspnea and leads to further inactivity and deconditioning. These individuals frequently have secondary cardiac and hematological changes. The goal of physical therapy is to relieve dyspnea and increase exercise tolerance, hence, quality of life. After smoking cessation, exercise is the single best intervention for controlling dyspnea in individuals with COPD.

Exercise testing has become an established component of the workup of an individual with impaired functional capacity, including patients with chronic lung disease. Although estimating the ventilatory capacity of patients with COPD on the basis of whether a patient can climb one or two flights of stairs is no longer considered a tenable test, symptom-limited stair climbing can be used to evaluate cardiovascular and pulmonary reserve.[188] Stairs climbed in a symptom-limited stair-climbing test correlate with $\dot{V}_{O_{2peak}}$, $\dot{V}_E$, heart rate, and respiratory rate in response to a maximal cycle ergometer test.

During acute exercise, patients with COPD have elevated heart rates and blood pressures and show increased hypoxemia and desaturation with incremental or prolonged constant work-rate exercise. Impaired exercise capacity reflects physical damage to the lungs, including impaired pulmonary vasculature[189] as well as cardiac and skeletal muscle abnormalities. Exercise capacity is marked by a disproportionate ventilatory response and differences in FEV_1, but these responses explain only a fraction of the variability in $\dot{V}_{O_{2max}}$.[190] Variability in the ventilatory response to exercise is a primary determinant of variability in the exercise capacity of patients with COPD. In the absence of right heart failure, right ventricular end diastolic volume is highly correlated with $\dot{V}_{O_{2max}}$ and cardiac index in patients with COPD, suggesting that right ventricular end diastolic volume compensates optimally.[191]

As in other conditions, in the management of patients with COPD, individualized training programs based on heart rate as the gas exchange threshold (anaerobic threshold), as opposed to standard protocols based on 50% of heart rate reserve, produce superior therapeutic outcomes; that is, they reduce ventilatory requirements and are safer.[192] Supervised training of individuals with COPD has been reported to have advantages over self-monitored exercise programs.[193] When two to eight programs were compared, the supervised treadmill program was superior to a community-based walking program with respect to training intensity in terms of improved $\dot{V}_{O_2}$, $\dot{V}_{CO_2}$, $\dot{V}_E$, and heart rate in response to moderate-intensity workloads. Research is needed to design home-based programs for selected patients in order to maximize these programs' effectiveness.

The 6-minute walk test is useful in the assessment and management of patients with COPD, for whom the test was originally developed. The discriminating capacity of the test can be increased by considering factors in addition to walking distance. Four factors based on an evaluation of 15 variables accounted for 78% of the variances in distance walked:[194]

1. Heart rate
2. Endurance
3. Impaired oxygen transport
4. Perceived exertion

Based on a walking-distance test, the effect of an exercise program can be predicted on the basis of low pretraining walking distance and higher FEV_1.[195]

Symptom-limited tests are used to estimate the effects of training on patients with COPD. In patients with low functional work capacity, objective submaximal indexes of training effects are useful. With respect to oxygen kinetics during constant work rate, the time constant of $\dot{V}_{O_2}$ after training is reduced, and it reverts after detraining.[196] The O_2 pulse similarly increases and decreases with training and detraining, respectively, and serum lactate decreases with training and increases with detraining.

Rigorous training (80% of peak work rate, for 45 minutes, 3 times a week, for 6 weeks) results in significant training responses in individuals with severe COPD.[197] Peak work rate and exercise endurance increase. In response to constant work rate, the kinetics of O_2 uptake, CO_2 production, $\dot{V}_E$, and heart rate are reduced. Improved exercise tolerance may reflect changes in breathing pattern, specifically, increased tidal volume and reduced respiratory rate.

During the past decade, research that sought to elucidate the training responses of individuals with COPD and their adaptation to exercise has focused on peripheral muscle pathophysiology and adaptation. With refinement in exercise testing and training procedures and in measurement, changes in peripheral muscles have been found to be associated with the underlying disease. In addition, aerobic training responses reflect both central and peripheral adaptations.

Compared with healthy people matched for activity level, individuals with COPD have less muscle strength (70% to 80% of age-matched healthy people), which may be explained by deconditioning, a disease-related myopathy, or both.[198] In addition, mechanical efficiency may be impaired. Patients have large numbers of less efficient type II muscle fibers, but cross-sectional fiber area, capillarization, and mitochondrial density are comparable or reduced.[135,199] Although metabolic capacity is unchanged, differences in fiber type in COPD may explain the reduced mechanical efficiency.

Systemic factors contributing to exercise intolerance have been identified in individuals with chronic lung disease, and they appear to resemble those observed in individuals with chronic heart disease.[200] Some individuals with COPD have impaired peripheral perfusion and oxygen extraction, which may be explained by the redistribution of cardiac output from the peripheral to the respiratory muscles during increasing work rates.[187] This may be a primary exercise limiter in these patients. In a study designed to distinguish central from peripheral limitations in the exercise responses of patients with COPD, central factors rather than peripheral muscle limitations were reported to be responsible (although not wholly) for their exercise intolerance.[201] Endurance training is associated with increased skeletal muscle activity and recruitment of slow-twitch fibers.[202]

Individuals with Primary Pulmonary Hypertension

Patients with primary pulmonary hypertension have impaired exercise responses that may resemble those of patients with COPD and secondary pulmonary hypertension. During incremental exercise, the lungs become less efficient as gas exchangers because of impaired lung perfusion.[203]

Individuals after Lung Volume Reduction Surgery

Lung volume reduction surgery has become a topic of increasing interest as an invasive means of correcting the hyperinflation in the lungs of patients with COPD. A good quality of life is correlated with reduced lung hyperinflation after surgery,[204] and these improvements have been maintained for at least 18 months on follow-up.[205] A commensurate reduced work of breathing appears to facilitate performance of activities of daily living. Improvement in functional capacity after surgery has been attributed to improved breathing mechanics during exercise, as well as at rest,[206] and to improved respiratory muscle strength.[207] Specifically, higher maximum levels of tidal volume and $\dot{V}_E$ are achieved; in turn, these lead to improvements in $\dot{V}O_2$ and $\dot{V}CO_2$.

Individuals with Interstitial Lung Disease

Performing exercise testing in individuals with interstitial lung disease can elucidate the extent of the pathology and its functional consequences—diffusing capacity and alveolar arterial oxygen tension difference.[208] These patients have less ability than healthy people to recruit the pulmonary capillary bed during increased exercise stress, so they can desaturate readily.[209,210] $\dot{V}O_{2peak}$ is correlated with impairment of gas exchange and circulation, rather than with ventilatory impairment. Thus the pathophysiology of the pulmonary vasculature is considered more important than impaired ventilatory mechanics in patients with interstitial lung disease.[211] Abnormal exercise responses in individuals with pulmonary sarcoidosis may reflect subclinical right heart dysfunction.[212]
