- Right lower extremity (RLE): PROM: WFL
- Right shoulder subluxation: 1/2 inch (1 finger width)

TONE
- LUE and LLE: WFL
- RUE: Decreased at shoulder; minimal increase: elbow flexors, pronators, wrist and finger flexors, modified Ashworth Scale (mAS) = 1
- RLE: decreased at hip and knee, minimal increase: ankle plantarflexors (PF) (mAS=2)

STRENGTH/ACTIVE ROM
- LUE and LLE: WFL
- RUE: exhibits minimal active control of shoulder flexion, abduction, external rotation with elbow flexion against gravity (flexion synergy pattern)
- RLE: exhibits flexion and extension synergy patterns, can move limb against gravity

BALANCE
Sitting:
- Good (G) static: able to maintain position without handhold support, minimal sway
- Fair (F) dynamic: able to accept only minimal challenge

Standing:
- Poor plus (P+) static: requires handhold support and moderate assistance
- Poor (P) dynamic: unable to accept challenge or move without loss of balance

POSTURAL CHANGES
- Kyphosis
- Forward head position

GAIT
- Able to ambulate 10 feet in parallel bars with moderate assistance
- Gait deviations: unsteady, requires verbal cues for sequencing; decreased foot clearance on right slides RLE forward or hip hikes on right to advance RLE; will benefit from an ankle-foot orthosis (AFO)

PERCEPTUAL
- Spatial awareness: WNL

SKIN
- Dry
- Intact

PSYCHOLOGICAL FUNCTIONING
- Affect: appropriate, no symptoms of depression, emotional distress
- Adjustment to medical condition: good
- Motivation for rehabilitation: good

FUNCTIONAL: FUNCTIONAL INDEPENDENCE MEASURE (FIM) ADMISSION SCORES
- Eating = 6
- Grooming = 4
- Bathing = 4
- Dressing: upper body = 4; dressing lower body = 4
- Toileting = 5

- Bladder management = 5
- Bowel management = 5
- Transfers: bed, chair, wheelchair = 3
- Transfers: toilet = 2
- Transfers: tub-shower = 2
- Locomotion: walk = 1; wheelchair = 5
- Locomotion: stairs =1
- Comprehension = 7
- Expression = 5
- Social interaction = 7
- Problem solving = 7
- Memory = 5

BED MOBILITY

- Patient requires minimal assist to roll onto the sound side and push up into sitting

PATIENT GOALS

- "I want to walk as before"

GUIDING QUESTIONS

1. Identify/categorize this patient's problems affecting locomotion in terms of direct impairments, indirect impairments, and activity limitation.
2. Identify an anticipated goal (within 2 weeks) and expected outcome for LT.
3. Identify three interventions complementary to LT.
4. Identify three LT environments that could be used to improve walking and indicate a training progression.

For additional resources, including answers to the questions for review and case study guiding questions, please visit **http://davisplus.fadavis.com**

Ambulatory Assistive Devices: Types, Gait Patterns, and Locomotor Training

TYPES AND GAIT PATTERNS

There are three major categories of ambulatory assistive devices: *canes, crutches,* and *walkers.* Each has several modifications to the basic design, many of which were developed to meet the needs of a specific patient problem or diagnostic group. Assistive devices are prescribed for a variety of reasons, including problems of balance, pain, fatigue, weakness, joint instability, excessive skeletal loading, and cosmesis. Another primary function of assistive devices is to eliminate weight-bearing fully or partially from a lower extremity (LE). This unloading occurs by transmission of force from the upper extremities (UEs) to the floor by downward pressure on the assistive device. Prescribing an appropriate assistive device requires knowledge of the patient's weight-bearing status. Common clinical descriptors used to identify weight-bearing status are presented in Box 11A.1. Considerations specific to the bariatric population are presented in Box 11A.2.

Canes

Most canes used in clinical practice are constructed of lightweight aluminum. Evidence supports the effectiveness of canes to improve balance[1,2,3] and improve postural stability.[1,4,5,6] Although canes reduce biomechanical load on LE joints,[2,7] they are not intended for use with a restricted weight-bearing status (such as non–weight-bearing [NWB] or partial weight-bearing [PWB]). Patients are typically instructed to hold a cane in the hand *opposite the affected extremity.* This positioning of the cane most closely approximates a normal reciprocal gait pattern with the opposite arm and leg moving together. It also widens the BOS with less lateral shifting of the center of mass (COM) than when the cane is held on the ipsilateral side.

Several investigations have confirmed that contralateral positioning of the cane reduces hip abductor activity on the side opposite the cane.[4,8,9,10] During normal gait, the hip abductors of the stance extremity contract to counteract the gravitational moment at the pelvis on the contralateral side during swing. This prevents tilting of the pelvis on the contralateral side but results in compressive forces acting at the stance hip. Use of a cane in the UE opposite the affected hip will reduce these forces. The floor (ground) reaction force created by the downward pressure of body weight on the cane counterbalances the gravitational movement at the affected hip.[3] Thus, the need for tension in the abductor muscles is reduced, with a subsequent decrease in joint compressive forces.

Several components of floor reaction forces that create joint compression at the hip can be reduced by use of a cane. In an early study by Ely and Smidt,[11] contralateral use of a cane was found to decrease the vertical and posterior components of the floor reaction force produced by the affected foot. They noted that the reductions in vertical floor reaction peaks were probably due to a shifting of body weight toward the cane, which was a contributing factor in reducing contact force at the affected hip. In a study of patients with total hip arthroplasty (THA), Neumann[8] found that contralateral use of a cane reduced average hip abductor electromyography (EMG) activity to 31% below that generated when not using a cane. Cane use contralateral to a THA, with the addition of carrying an ipsilateral load, decreased hip abductor activity by 40% compared to walking without carrying a load or using a cane.[10]

Research supports use of a cane as an effective method for reducing forces acting at the hip.[4,8,9,10] This reduction is particularly important for activities such as stair climbing, when the forces generated at the hip are significantly

Box 11A.1 Clinical Descriptors of Weight-Bearing Status

- *Full weight-bearing* (FWB): There are no restrictions on weight-bearing; 100% of body weight can be borne on the LE.
- *Non–weight-bearing* (NWB): No weight is borne on the involved limb; foot/toes make no contact with floor/ground surface.
- *Partial weight-bearing* (PWB): Only a portion of weight can be borne on the extremity; sometimes expressed as a percentage of body weight (e.g., 20% or 50%).
- *Toe-touch weight-bearing* (TTWB) or *touch-down weight-bearing* (TDWB): Only the toes of the affected extremity contact the floor to improve balance (not to support body weight).
- *Weight-bearing as tolerated* (WBAT): Weight-bearing is limited by patient tolerance of weight borne on extremity.

Box 11A.2 Bariatric Ambulatory Assistive Devices

As with all patients, safety and function are paramount concerns in selection of assistive devices (canes, crutches, and walkers) for patients who are morbidly obese. Important considerations include the following:

- Selecting devices with the appropriate *weight capacity*. Manufacturers of bariatric equipment typically include the maximum weight designation for each product. Standard devices have a weight capacity of 250 to 350 pounds; bariatric equipment carry weight capacities in the range of 400 to 1,000 pounds.
- Identification of the needed dimensions (height and width) of the equipment; this requires knowledge of the anthropometric characteristics (measurements and proportions) of the patient's body.
- Large patients often walk with a wide-based gait owing to lower extremity limb girth and the need to increase the base of support to carry body weight and maintain balance. If a disproportionate amount of weight falls anterior (e.g., abdominal region), upright postures will be further challenged by the need to counteract the anterior effects of gravity.[a]

Following are general characteristics and features of commercially available walkers, crutches, and canes designed for the bariatric population. The information presents a range of available options and is not representative of any individual assistive device. As new products are continually introduced to the market, consultation with a durable medical equipment (DME) supplier will help ensure prescription of the optimal device for an individual patient.

Note: For labeling or identifying bariatric equipment in patient care settings, the term *expanded capability* (EC) is recommended over less desirable terms such as *oversized, extra- large,* or *heavy duty*.[b]

Walkers

- Bariatric walkers typically include deeper and wider frames.
- May accommodate user heights from 5 feet 3 inches to 6 feet 10 inches.
- Overall walker height adjustments range from 31 to 41.25 inches.
- Available widths: 23.5 to 30 inches.
- May include double anterior cross bracing to increase stability.
- Weight capacity range: 500 to 700 pounds (without seat); 400 to 500 pounds (with seat).
- Walker weight: 7 to 12 pounds (without seat); 19 to 26 pounds (with seat).
- Seat dimensions: height, 22 inches; width, 17.5 to 18 inches; depth, 13 to 14 inches.
- Some models are constructed using a reinforced steel frame; for rolling walkers, large casters are typically used.

Axillary Crutches

- Bariatric axillary crutches are generally constructed of heavy-duty steel.
- May accommodate user heights from 5 feet 2 inches to 7 feet 4 inches (youth sizes available).
- Overall crutch height adjustments range from 44 to 60 inches.
- Weight capacity range: 550 to 1000 pounds.
- Crutch tips: 2-inch diameter.
- Crutch weight: 4 pounds, 6 ounces to 5 pounds each.

Forearm Crutches

- Bariatric forearm crutches are generally constructed of heavy-duty steel.
- May accommodate user heights from 5 feet to 6 feet 7 inches (youth sizes available).
- Crutch height adjustments (handle to floor) range from 28 to 42 inches and forearm piece adjustments (handle to center of cuff) range from 8 to 9.5 inches; as with standard forearm crutches, the leg and forearm sections adjust independently.
- Weight capacity range: 500 to 700 pounds.
- Crutch tips: 2-inch diameter.
- Crutch weight: 2 pounds 6 ounces to 5 pounds 7 ounces.

Canes

- Bariatric canes are generally constructed of stainless steel or heavy-duty steel tubing; most incorporate an offset handle and a reinforcing cuff tightened by a rotation sleeve.
- May accommodate user heights from 4 feet 10 inches to 6 feet 4 inches.
- Overall height adjustments range from approximately 25 to 46 inches.
- Weight capacity range: 500 to 700 pounds.
- Cane weight: 1.8 to 2 pounds.

Continued

Box 11A.2 Bariatric Ambulatory Assistive Devices—cont'd

Quadruped Canes

- Bariatric quadruped canes are generally constructed of steel and often incorporate a double-plated base; most incorporate an offset handle and a reinforcing cuff tightened by a rotation sleeve.
- May accommodate user heights from 4 feet 11 inches to 6 feet 5 inches.
- Overall height adjustments range from approximately 29 to 39 inches.
- Weight capacity range: 500 to 700 pounds.
- Weight: 4 to 5 pounds.
- Footprint size: small base, 6 × 8 inches; large base, 8 × 12 inches.

increased. Contralateral cane use has also been found to reduce knee pain in patients with osteoarthritis (OA).[7,12] Clearly, use of a cane has important implications for hip and knee involvement such as joint replacements or degenerative joint disease. Box 11A.3 Evidence Summary presents studies addressing the impact and function of canes.[1,4,7,12,13,14]

Maguire et al[4] found that contralateral cane use reduced gluteus medius activity by 21.86% and tensor fascia lata activity by 19.14% in patients with subacute stroke. This finding has important implications for patients with stroke, who often use canes, because strategies to improve postural control and balance reactions may be adversely affected by reduced hip abductor activity.

In addition to altering the forces on the affected extremity, canes are selected on the basis of their ability to improve gait by providing increased dynamic stability and improving balance. This is achieved by the increased base of support (BOS) provided by the additional point(s) of floor contact. The level of stability provided by canes is on a continuum. Broad-based (four-point) canes provide the greatest stability and standard (single-point) canes provide the least. The following section presents several of the more common types of canes in clinical use and identifies their advantages and disadvantages.

Types of Canes

Standard Cane

This assistive device also is referred to as a single-point or straight cane (Fig. 11A.1A). It is made of wood or acrylic and has a half-circle ("crook") or T-shaped handle.

- *Advantages*. This cane is inexpensive and fits easily on stairs or other surfaces where space is limited.
- *Disadvantages*. The standard cane is not adjustable and must be cut to fit the patient. With a half-circle

Box 11A.3 Evidence Summary Canes

Reference	Subjects	Design Intervention	Duration	Results	Comments
Jones et al[7] (2012)	64 patients with knee OA; 89% female (F) and 11% male (M) randomly assigned to either experimental group (EG) or control group (CG); groups homogeneous for demographic and clinical characteristics	Single-blind parallel group RCT; EG used a single-point cane; CG did not use cane; outcome measures (OMs): pain (VAS), function (Lequesne knee questionnaire and WOMAC); general health (SF-36); and energy expenditure (6MWT/ATS)	Two months; OMs performed at baseline, again at 30 and 60 days	Compared to CG, EG showed significant improvement in pain (ES 0.18), function (ES 0.13), two SF-36 items (physical functioning [ES 0.07] and bodily pain [ES 0.08]) and energy expenditure (ES 0.21)	For patients with OA, a cane can be effective in decreasing pain, improving function, and improving quality of life. Patients should be advised that an initial adaptation period to the cane is required before gains in function, reduction in pain, and diminished energy expenditure are achieved.

Box 11A.3 Evidence Summary Canes—cont'd

Reference	Subjects	Design Intervention	Duration	Results	Comments
Maguire et al[4] (2010)	13 patients with hemiplegia following first unilateral stroke; 5 F and 8 M; mean age: 64 (SD = 14) years; mean time since stroke: 9.2 weeks (range 5–16 weeks; SD = 3.8)	Randomized within-subject experimental design; subjects walked at self-selected pace under three conditions: (1) with cane; (2) with TheraTogs* (elastic orthosis providing vertical support to increase stability); and (3) with taping for GM and TFL; OMs: Peak EMG from baseline and temporal/spatial gait characteristics	Baseline data and testing of three conditions occurred in single experimental session	Use of cane reduced GM activity by 21.86%; TheraTogs increased it by 16.47%; tape increased it by 5.8% Use of cane reduced TFL activity by 19.14%; TheraTogs reduced it by 1.10%; tape reduced it by 3% Gait speed (m/sec): baseline = 0.44; cane = 0.45; tape = 0.48; TheraTogs = 0.49	Following stroke, cane use reduced hemiplegic hip abductor activity; hip abductor taping and TheraTogs increased hemiplegic hip abductor activity and gait speed; cane use may not be optimal during early stroke rehabilitation; TheraTogs and taping may be more beneficial in promoting muscle activity and balance reactions; examination of long-term effects warranted
Bohannon[1] (2011)	11 consecutive qualifying patients obtained from review of author's patient records who were not habitual cane users; 7 F and 4 M; mean age: 79.1 (SD = 12.0)	Descriptive study to determine if use of a single-point cane increases unipedal (single limb) balance time during static standing OM: time in single limb balance (30-sec cutoff)	Bilateral single limb balance times measured using a stopwatch under two conditions: (1) with a cane; and (2) without a cane	Balance times were significantly higher with the cane for both the left (t = (4.99; p <.001) and right (t = (7.82; p <.001) stance times as compared to without the cane	Confirms use of canes for increasing single limb balance time; for patients reluctant to use a cane, study presents a simple method using readily available equipment (stopwatch) to reinforce the increased stability provided by a cane
Beauchamp et al[13] (2009)	14 male inpatients with stroke; based on a gait-symmetry calculation patients divided into 2 groups: symmetrical (n = 5) and asymmetrical (n = 9)	Within-subject experimental design; subjects walked on a pressure-sensitive walkway under three conditions: (1) no cane; (2) single-point cane; and (3) quadruped (quad) cane OMs: spatial and temporal measure of gait using GAITRite† system	Testing of three conditions occurred in single experimental session	Standard cane significantly improved symmetry in asymmetrical subjects (p = 0.028); use of a quad cane did not improve symmetry (p = 0.36); for symmetrical subjects, there was no effect on symmetry with either standard (p = 0.88) or quad (p = 0.32) canes	A standard cane is effective in improving temporal gait symmetry in asymmetrical patients; further research is warranted into the impact of canes on early stroke rehabilitation and the long-term effects of ambulatory assistive devices on gait symmetry

handle, the point of support (shaft of cane) is anterior to the hand, not directly beneath it. The T-shaped handle shifts the point of support only slightly closer to hand.

Standard Adjustable Aluminum Cane

This assistive device (Fig. 11A.1B) has the same basic design as the standard cane. It is made of aluminum and has a half-circle handle with a molded plastic covering. The telescoping design of this cane enables the height to be adjusted using a push-button mechanism. Variations in available height range differ slightly with manufacturers. However, they are generally adjustable within the range of approximately 27 to 38.5 in (68 to 98 cm). (*Note:* Most adjustable aluminum assistive devices [e.g., canes, crutches, walkers] use a push-button mechanism to alter height; many include a reinforcing cuff tightened by a thumbscrew or rotation sleeve.)

- *Advantages*. This cane is quickly adjustable, facilitating ease of determining appropriate height. It is lightweight and fits easily on stairs.
- *Disadvantages*. The point of support is anterior to the hand, not directly beneath it. This cane is more costly than a standard wooden cane.

Adjustable Aluminum Offset Cane

The proximal component of the shaft of this cane is offset anteriorly, creating a straight *offset* handle. It is made of aluminum with a plastic or rubber molded grip-shaped handle (Fig. 11A.1C). Using a push-button mechanism, the telescoping design allows the height to be adjusted from approximately 27 to 38.5 in (68 to 98 cm).

- *Advantages*. The design of this cane allows pressure to be borne over the center of the cane for greater stability. This cane also is quickly adjusted, is lightweight, and fits easily on stairs.
- *Disadvantages*. This cane is more costly than standard or adjustable aluminum canes.

Note: For standard and offset canes, the diameter of both the distal rubber tips and shaft of the cane is generally at least 1 in (2.54 cm).

Quadruped (Quad) Cane

This assistive device is constructed of aluminum and is available in a variety of designs depending on the manufacturer. Both large-based quad canes (LBQCs) and small-based quad canes (SBQCs) are commercially available (Figs. 11A.2 and 11A.3). The characteristic feature of these canes is that they provide a broad base with four points of floor contact. Each point (leg) is covered with a rubber tip. The legs closest to the patient's body are generally shorter and may be angled to allow foot clearance. On many designs the proximal portion of the cane is offset anteriorly. The hand piece is usually one of a variety of contoured plastic grips. A telescoping design allows for height adjustments. Quad canes are generally adjustable from approximately 28 to 38 in (71 to 91 cm).

- *Advantages*. This cane provides a broad-based support. Bases are available in several different sizes. This cane is also easily adjustable.

Figure 11A.1 Shown here are (**A**) standard wooden cane, (**B**) standard adjustable aluminum cane, and (**C**) adjustable offset cane.

Figure 11A.2 Shown here are a variety of large-based quadruped canes.

Figure 11A.3 A variety of small-based quadruped canes.

- *Disadvantages*. Depending on the specific design of the cane, the pressure exerted by the patient's hand may not be centered over the cane and may result in patient complaints of instability. As a result of the broad BOS, some quad canes may not be practical for use on stairs. Another disadvantage of broad-based canes is that they warrant use of a slower gait pattern. If a faster forward progression is used, the cane often "rocks" from rear legs to front legs, which decreases effectiveness of the cane. Patients should be instructed to place all four legs of the cane on the floor simultaneously to obtain maximum stability.

Hemi Cane

The hemi cane also is constructed of aluminum (Fig. 11A.4). It provides a very broad base with four points of floor contact. Each point (leg) is covered with a rubber tip. The legs farther from the patient's body are angled to maintain floor contact and to improve stability. The handgrip is molded plastic around the uppermost segment of aluminum tubing. Hemi canes fold flat and are adjustable in height from approximately 29 to 37 in (73 to 94 cm).

- *Advantages*. Hemi canes provide very broad-based support and are more stable than a quad cane. These canes also fold flat for travel or storage.
- *Disadvantages*. As with the quad canes, the specific design of a hemi cane or handgrip placement may not allow pressure to be centered over the cane. Hemi canes cannot be used on most stairs. They require use of a slow forward progression and are generally more costly than quad canes.

Figure 11A.4 Hemi cane.

Rolling Cane

Constructed of aluminum and aluminum tubing (Fig. 11A.5), this cane provides a wide, wheeled base allowing uninterrupted forward progression. It includes a contoured handgrip, height adjustment from 28 to 37 in (71 to 94 cm), and a pressure-sensitive brake built into the handle engaged using pressure from the base of the hand.

- *Advantages*. The wheeled base allows weight to be continuously applied as the need to lift and place the cane forward is eliminated. This also provides for a faster forward progression. The second and third handles placed between the uprights can assist in rising to standing (brake engaged).
- *Disadvantages*. This cane is more costly than standard quadruped canes and requires sufficient UE and grip strength to engage the braking mechanism. This cane is not suitable for patients displaying a propulsive gait pattern (e.g., Parkinson's disease).

Laser Cane

This cane incorporates a bright red laser line projected across the floor designed to assist with overcoming freezing episodes while walking (Fig 11A.6). A walker with a laser is also available (Fig 11A.7). Donovan et al[15] examined 26 patients with Parkinson's disease using either a laser cane or walker (selection based on type of device habitually used). The Freezing of Gait Questionnaire (FOG-Q)[16,17] was used as an outcome measure (lower scores suggest improved function). Subjects were instructed not to look at the visual cue (laser beam) unless experiencing a freezing of gait (FOG) episode, at which

Figure 11A.5 Rolling cane. *(Courtesy of Full Life Products, LLC, Moorestown, NJ 08057.)*

Figure 11A.6 The Laser Cane projects a bright red laser beam across the floor in front of the patient. During a freezing of gait episode, the beam provides a visual cue for the patient to step over. *(Courtesy of In-Step Mobility Products Corp, Skokie, IL 60076.)*

Figure 11A.7 The U-Step II walking stabilizer includes both visual (laser) and auditory (beat pattern for gait speed) cues. U-shaped base surrounds the individual for increased stability. It also includes a seat, a small projection over posterior casters to assist moving onto a curb, and a control to set rolling resistance. *(Courtesy of In-Step Mobility Products Corp, Skokie, IL 60076.)*

time they were instructed to "step over" the light. Findings indicated a small but significant mean reduction in FOG-Q scores of 1.25 (±0.48; $p = 0.0152$). The mean reduction in fall frequency was 39.5% (±9.3%; $p = 0.002$). No significant changes in gait speed were noted. Although additional research is warranted, these initial findings suggest that assistive devices incorporating a laser beam may hold potential for addressing FOG episodes common in patients with Parkinson's disease.

Handgrips

A general consideration relevant to all canes is the nature of the handgrip. A variety of styles and sizes are available. The type of handgrip should be judged and selected primarily on the basis of patient comfort and on the grip's ability to provide adequate surface area to allow effective transfer of weight from the UE to the floor. The more common types of handgrips are (1) the *crook* handle, (2) the straight *offset* handle, and (3) the *T-shaped* handle, which conforms to the patient's hand. It is useful to have several handgrip styles available for examination and trial with individual patients.

Measuring Canes

In measuring cane height, the cane (or center of a broad-based cane) is placed approximately 6 in (15.24 cm) from the lateral border of the toes. Two landmarks typically are used during measurement: the *greater trochanter* and the *angle at the elbow.* The top of the cane should come to approximately the level of the greater trochanter, and the elbow should be flexed to about 20 to 30 degrees. Because of individual variations in body proportion and limb lengths, the degree of flexion at the elbow is generally considered the more important indicator of correct cane height.

The 20 to 30 degrees of elbow flexion serves two important functions. It allows the arm to shorten or to lengthen during different phases of gait, and it provides a shock-absorption mechanism. Finally, as with all assistive devices, the height of the cane should be considered with regard to patient comfort and the cane's effectiveness in accomplishing its intended purpose.

Gait Pattern for Use of Canes

As discussed, the cane should be held in the UE opposite the affected limb. For ambulation overground on level surfaces, the cane and the involved (or more involved) extremity are advanced simultaneously (Fig. 11A.8). The cane should remain relatively close to the body and should not be placed ahead of the toe of the involved extremity. These are important considerations, because placing the cane too far forward or to the side will cause lateral and/or forward bending, with a resultant decrease in dynamic stability.

When bilateral involvement exists, a decision must be made as to which side of the body the cane will be held. This question is most effectively resolved by using a

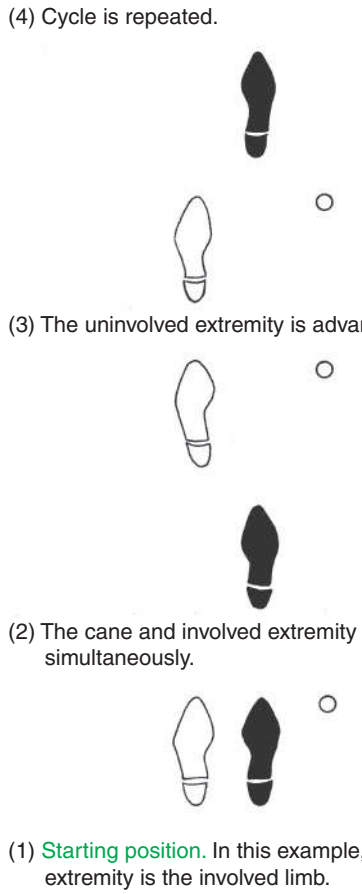

Figure 11A.8 Gait pattern for use of cane.

Figure 11A.9 The client is ambulating using bilateral offset canes with a four-point gait. One cane is advanced and then the opposite LE is advanced. For example, the right cane is moved forward, then the left LE, followed by the left cane and then the right LE.

problem-solving strategy with input from both the patient and therapist. Questions to be considered include the following:

- On which side is the cane most comfortable?
- Is one placement superior in terms of improving balance and/or ambulatory endurance?
- If gait deviations exist, is one position more effective in improving the overall gait pattern?
- Is safety influenced by cane placement (e.g., during transfers, stair climbing, or overground in community)?
- Is there a difference in grip strength between hands?
- Are two canes needed for stability?

Consideration of these questions will generally provide sufficient information to determine the most effective cane placement and use when bilateral involvement exists.

For some patients, optimal function is achieved using canes bilaterally (Fig 11A.9). In these situations, a two- or four-point gait pattern is used. For example, with a four-point pattern, the contralateral cane is moved forward and then the ipsilateral LE steps forward. Using a two-point pattern, the contralateral cane and ipsilateral LE are moved forward simultaneously. These gait patterns are described in the following section on crutches.

Crutches

Crutches are used most frequently to improve balance and to relieve weight-bearing either fully or partially on an LE. They are typically used bilaterally and function to increase the BOS, to improve lateral stability, and to allow the UEs to transfer body weight to the floor. This transfer of weight through the UEs permits functional ambulation while maintaining a restricted weight-bearing status. There are two basic designs of crutches in frequent clinical use: *axillary* and *forearm* crutches.

Types of Crutches and Attachments

Axillary Crutches

These assistive devices also are also referred to as standard crutches (Fig. 11A.10, *left*). They are made of lightweight wood or aluminum. Their design includes an axillary bar, a hand piece, and double uprights joined distally by a single leg covered with a rubber suction tip (which should have a diameter of 1.5 to 3 in [1.5 to 3 cm]). The single leg allows for height variations. Height adjustments for wooden crutches are accomplished by altering the placement of screws and wing bolts in predrilled holes. The design of most aluminum crutches incorporates a push-button pin mechanism for height adjustments similar to those found on aluminum canes. Some aluminum crutches also have

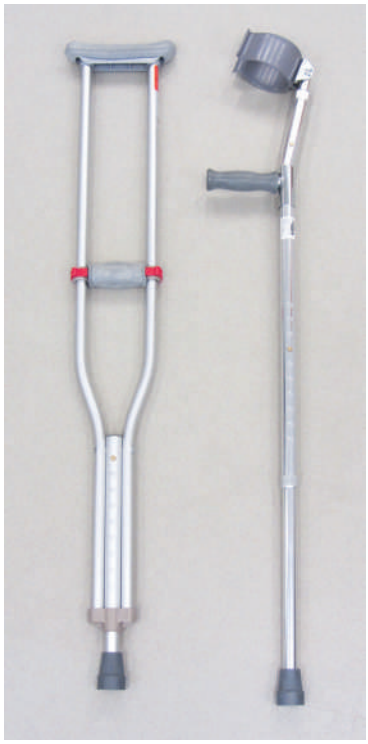

Figure 11A.10 Axillary crutch (*left*) and forearm crutch (*right*).

patient height markers adjacent to the notches to assist in adjustment. The height of the handgrips for wooden and some aluminum crutches is adjusted by placement of screws and wing bolts in predrilled holes. The handgrip height on some aluminum crutches is adjusted using a push-button mechanism with a reinforcing clip-lock (Fig. 11A.11). Both the overall height of the crutch and the height of the handgrip typically adjust in 1-in (2.54-cm) increments. Axillary crutches are generally adjustable in adult sizes from approximately 48 to 60 in (122 to 153 cm), with children's and extra-long sizes available.

- *Advantages.* Axillary crutches improve balance and lateral stability and provide for functional ambulation with restricted weight-bearing. They are easily adjusted, inexpensive when made of wood, and can be used for stair climbing.
- *Disadvantages*. Because of the tripod stance required to use crutches and the resultant large BOS, crutches are awkward in small areas. For the same reason, the safety of the user may be compromised when ambulating in crowded areas. Another disadvantage is the tendency of some patients to lean on the axillary bar. This causes pressure at the radial groove (spiral groove) of the humerus, creating a situation of potential damage to the radial nerve, as well as to adjacent vascular structures in the axilla.

Platform Attachments

These attachments (Fig. 11A.12) are also referred to as *forearm rests* or *troughs*. Although they are described here, they also are used with walkers. Their function is to allow transfer of body weight through the forearm to the assistive device. A platform attachment is used when weight-bearing is contraindicated through the wrist and hand (e.g., arthritis, Colles' fracture). The forearm piece is usually padded, has a dowel or handgrip, and has hook-and-loop straps to maintain the position of the forearm.

Forearm Crutches

These assistive devices are also known as *Lofstrand* and *Canadian* crutches (Fig. 11A.10, *right*). They are

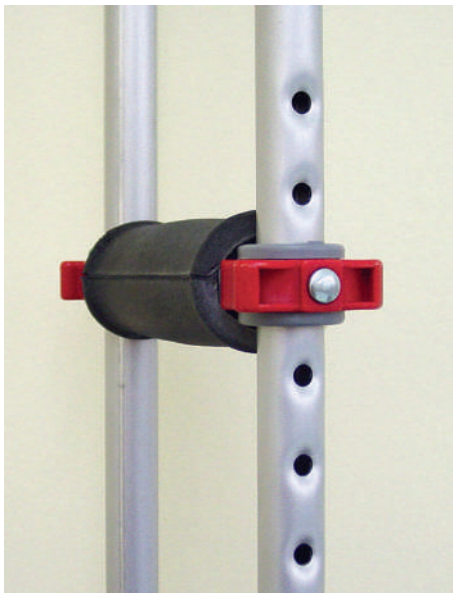

Figure 11A.11 Push-button handgrip adjustment with reinforcing clip-lock.

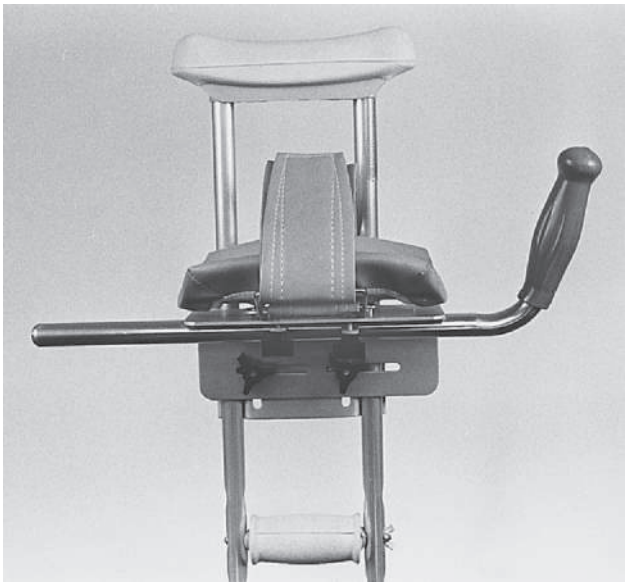

Figure 11A.12 Platform attachment to axillary crutch. These attachments can also be used on walkers.

constructed of aluminum. Their design includes a single upright, a forearm cuff, and a handgrip. This crutch adjusts both proximally to alter position of the forearm cuff and distally to alter the height of the crutch. Adjustments are made using a push-button mechanism. The available heights of forearm crutches are indicated from handgrip to floor and are generally adjustable in adult sizes from 29 to 35 in (74 to 89 cm), with children's and extra-long sizes available. The distal end of the crutch is covered with a rubber suction tip. The forearm cuffs are available with either a medial or anterior opening. The cuffs are made of metal and can be obtained with a plastic coating.

- *Advantages*. The forearm cuff allows use of hands without the crutches becoming disengaged. They are easily adjusted and allow functional stair climbing activities. Many patients feel they are more cosmetic and they fit more easily into an automobile owing to the overall decreased height. They are also the most functional type of crutch for stair climbing activities for individuals wearing bilateral knee-ankle-foot orthoses (KAFOs).
- *Disadvantages*. Forearm crutches provide less lateral support owing to the absence of an axillary bar. The cuffs may be difficult to remove.

Measuring Crutches

Axillary Crutches

Several methods are available for measuring axillary crutches. The most common use a standing or a supine position. Measurement from standing is most accurate and is the preferred approach.

- *Standing*. From a supported standing position, crutches should be measured from a point approximately 2 in (5.08 cm) below the axilla. The width of two fingers is often used to approximate this distance. During measurement, the distal end of the crutch should be resting at a point 2 in (5.08 cm) lateral and 6 in (15.24 cm) anterior to the foot. A general estimate of crutch height can be obtained before standing by subtracting 16 in (40.64 cm) from the patient's height. With the shoulders relaxed, the hand piece should be adjusted to provide 20 to 30 degrees of elbow flexion.
- *Supine*. From this position the measurement is taken from the anterior axillary fold to a surface point (mat or treatment table) 6 to 8 in (5.08 to 7.5 cm) from the lateral border of the heel.

Forearm Crutches

Standing is the position of choice for measuring forearm crutches. From a supported standing position, the distal end of the crutch should be positioned at a point 2 in (5.08 cm) lateral and 6 in (15.24 cm) anterior to the foot. With the shoulders relaxed the height should then be adjusted to provide 20 to 30 degrees of elbow flexion. The forearm cuff is adjusted separately. Cuff placement should be on the proximal third of the forearm, approximately 1 to 1.5 in (2.5 to 3.8 cm) below the elbow.

Crutch Gait Patterns

Gait patterns are selected on the basis of the patient's balance, coordination, muscle function (strength, power, endurance), and weight-bearing status. The gait patterns differ significantly in their energy requirements, BOS, and the speed with which they can be executed.

Before initiating instruction in gait patterns, several important points should be emphasized to the patient:

- During axillary crutch use, body weight should always be borne on the hands and not on the axillary bar. This will prevent pressure on both the vascular and nervous structures located in the axillary region.
- Balance will be optimal by always maintaining a wide (tripod) BOS. Even when in a resting stance, the patient should be instructed to keep the crutches at least 4 in (10 cm) to the front and to the side of each foot. The foot should not be allowed to achieve parallel alignment with the crutches. This will jeopardize anterior–posterior stability by decreasing the BOS.
- When using standard crutches, the axillary bars should be held close to the chest wall to provide improved lateral stability.
- The patient should also be cautioned about the importance of holding the head up and maintaining good postural alignment during ambulation.
- Stepping in a small circle rather than pivoting should be used when turning.

Three-Point

In this type of gait three points of support contact the floor (two crutch points and a single LE). It is used when a non–weight-bearing status is required on one LE. Body weight is borne on the hands through the crutches instead of on the affected LE. The sequence of this gait pattern is illustrated in Figure 11A.13.

Partial Weight-Bearing

This gait is a modification of the three-point pattern. During forward progression of the involved extremity, weight is borne partially on both crutches and on the affected extremity (Fig. 11A.14). During instruction in the partial weight-bearing gait, emphasis should be placed on use of a normal heel–toe progression on the affected extremity. Patients may interpret "partial weight-bearing" as meaning that only the toes or ball of the foot should contact the floor. Use of this positioning over a period of days or weeks will lead to heel cord tightness. Limb load monitors are often a useful adjunct to partial weight-bearing gait training and are described in the section, Adjunct Training Devices. These devices provide auditory feedback to the patient regarding the amount of weight borne on an extremity.

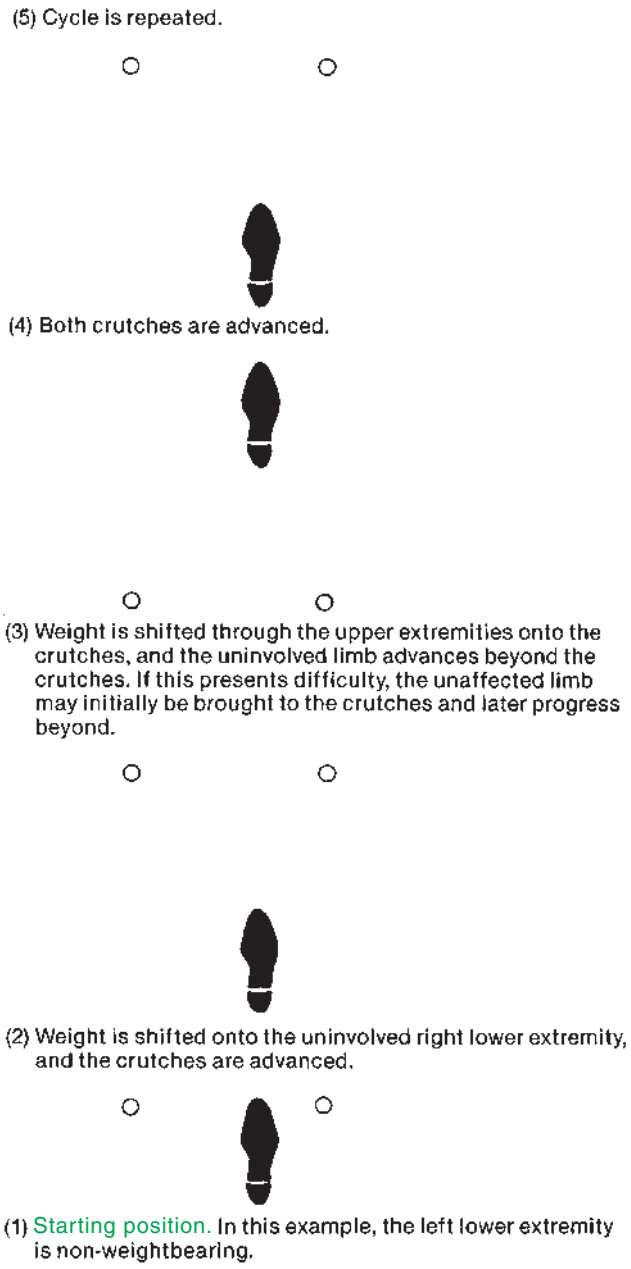

Figure 11A.13 Three-point gait pattern.

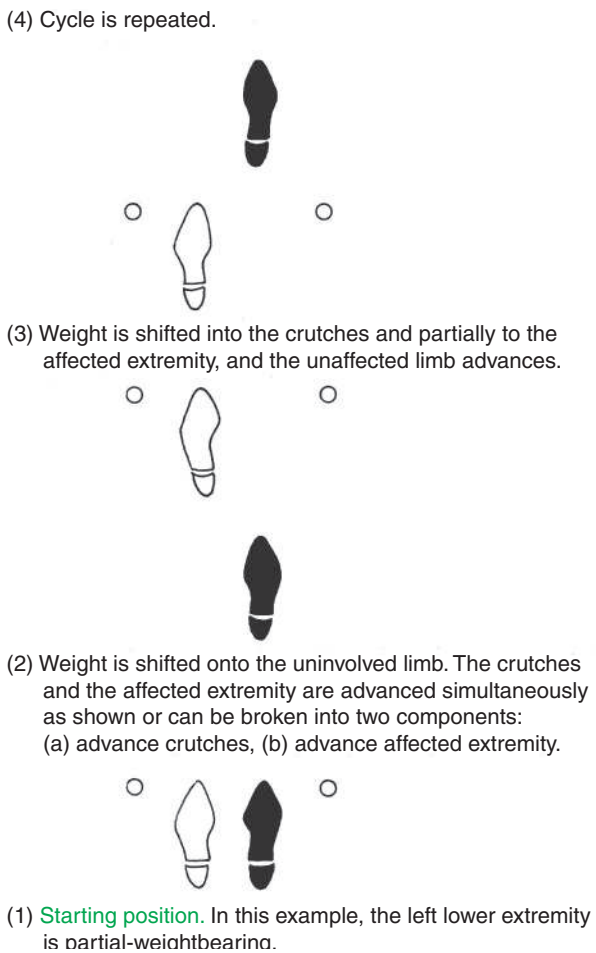

Figure 11A.14 Partial weight-bearing gait; modification of the three-point gait pattern.

Four-Point

This pattern provides a slow, stable gait as three points of floor contact are maintained. Weight is borne on both LEs and typically is used with bilateral involvement due to poor balance, incoordination, or muscle weakness. In this gait pattern one crutch is advanced and then the opposite LE is advanced. For example, the left crutch is moved forward, then the right LE, followed by the right crutch and then the left LE (Fig. 11A.15).

Two-Point

This gait pattern is similar to the four-point gait. However, it is less stable because only two points of floor contact are maintained. Thus, use of this gait requires better balance. The two-point pattern more closely simulates normal gait, inasmuch as the opposite LE and UE move together (Fig. 11A.16).

Two additional, less commonly used crutch gaits are the *swing-to* and *swing-through* patterns. These gaits are often used when there is bilateral LE involvement, such as in spinal cord injury (SCI). The swing-to gait involves forward movement of both crutches simultaneously, weight is shifted onto the hands, and the LEs "swing to" the crutches. In the swing-through gait, the crutches are moved forward together, weight is shifted onto the hands, and the LEs are swung beyond the crutches.

Walkers

Walkers are used to improve balance and relieve weight-bearing either fully or partially on an LE. Of the three categories of ambulatory assistive devices, walkers afford the greatest stability. They provide a wide BOS, improve anterior and lateral stability, and allow the UEs to transfer body weight to the floor.

Walkers are typically made of aluminum with molded vinyl handgrips and rubber tips. They are adjustable in adult sizes from approximately 32 to 37 in (81 to

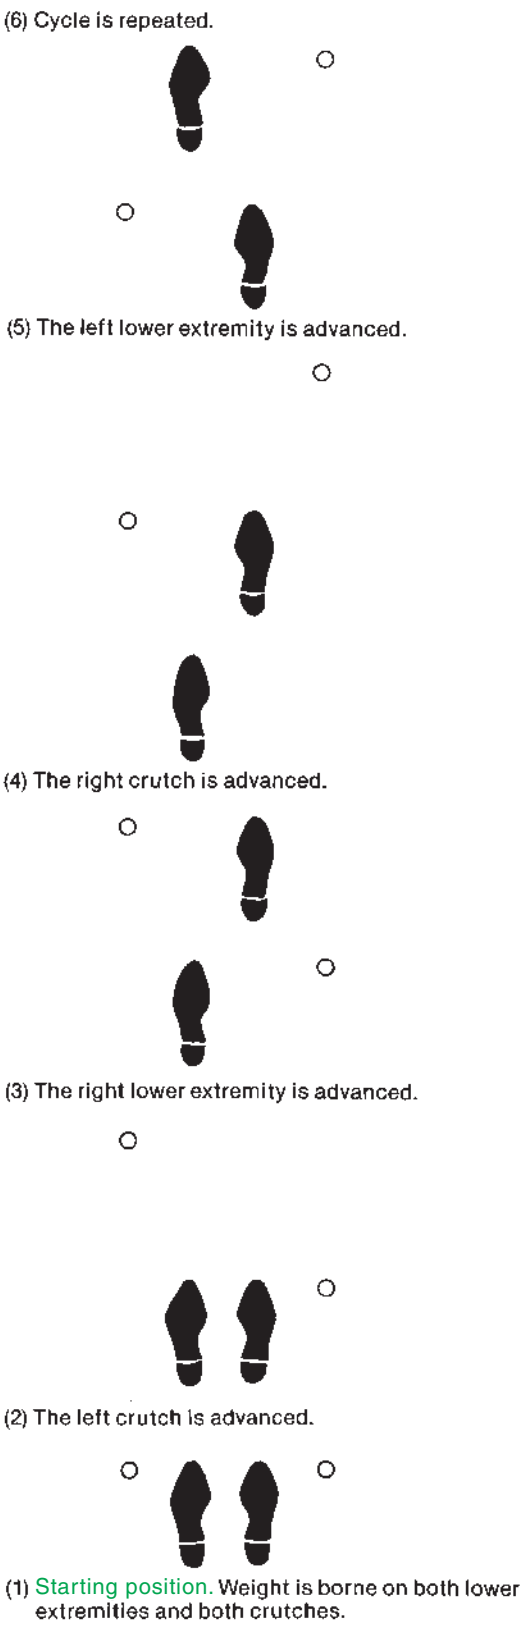

Figure 11A.15 Four-point gait pattern.

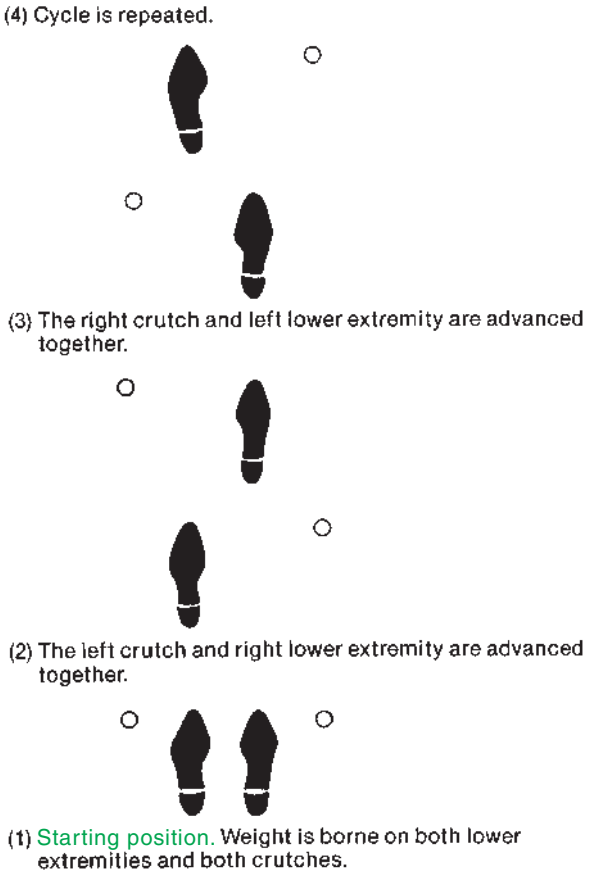

Figure 11A.16 Two-point gait pattern.

92 cm), with children's, youth, and tall sizes available. Several design variations and modifications to the standard design are available and are described below.

Types of Walkers and Features

Glides

Glides are small, plastic attachments placed on the posterior legs of walkers typically in combination with wheels on the front legs (Fig. 11A.17A). They promote a smooth forward progression without having to lift and place the walker with each step. They are typically made of high-density plastic in an inverted-mushroom shape. Other common glide designs include a 1-in (2.54 cm) diameter "disk" with a central stem that slides into the tubular leg and is tightened into place with a screwdriver, and a fitted cap that is placed directly onto the walker leg (in the same manner the rubber tip is attached). Another style of glide incorporates a tennis ball within a fixed housing (Fig. 11A.18).

Folding Mechanism

Folding walkers are particularly useful for patients who travel. These walkers can be easily collapsed to fit in an automobile or other storage space (see Fig. 11A.17B).

Handgrips (Handles)

Enlarged and molded handgrips are available, and may be useful for some patients with arthritis. Some walkers

A

B

Figure 11A.17 Walker in (**A**) open and (**B**) folded position. The features on this walker include plastic posterior glides, a built-in seat with a molded back bar to support the user during rest intervals (the seat flips up for folding), large front wheels (6 in) to improve ease of use on multiple terrains, a second set of handles set at approximately the seat level to assist sit-to-stand transitions in the absence of chair armrests or for movement on and off a toilet, and a removable walker pouch for storing personal items. Handle height adjusts using a collar and pin mechanism that eliminates having to turn the walker over to change the height. *(Courtesy of Full Life Products, LLC, Moorestown, NJ 08057.)*

Figure 11A.18 The design of these walker glides incorporates a tennis ball within a fixed housing, a spring-loaded brake for intermittent braking during walking, and brake lock-out clips used to deactivate the braking feature for uninterrupted forward motion. The tennis ball can be manually rotated to unworn areas or completely removed to "snap in" a replacement. *(Courtesy of Invacare Corp, Elyria, OH 44036.)*

offer a second set of handles to assist with sit-to-stand transitions (see Fig 11A.17A).

Platform Attachments

This adaptation is used when weight-bearing is contraindicated through the wrist and hand (described in crutch section; see Figure 11A.12).

Wheel Attachments

This adaptation to walkers (often called *rolling* walkers) includes the addition of wheels (either to the two front wheels only or to all four wheels). The addition of wheels frequently allows functional ambulation for patients who are unable to lift and to move a conventional walker (e.g., frail elderly). *Swivel wheels* turn freely in a complete circle (Fig. 11A.19). *Fixed wheels* rotate around a central axis (Fig. 11A.20A). Wheels are generally available in 3-, 5-, and 6-in (7.62-, 12.7-, 15.24-cm) diameters. Eight-inch-diameter (20.32 cm) wheels are also available and can be used to add height for tall users.

Braking Mechanism

A braking system is an essential feature of walkers designed with wheels. Walkers with four wheels frequently include handbrakes that lock the rear wheels (see Fig. 11A.19). *Spring-loaded locks* can be placed on the rear walker wheels (Fig. 11A.20A). These locks engage when weight is placed on the posterior walker legs through the handgrips. Posterior pressure brakes are effective when wheels are placed only on the front walker legs.

Figure 11A.19 The front wheels of this walker swivel freely in all directions. The back wheels rotate around a single axis. Handbrakes allow locking the rear wheels. A seat surface accommodates rest intervals. *(Courtesy of Invacare Corp, Elyria, OH 44036.)*

Tripod Rolling Walkers

Three-wheel walkers incorporate a tripod design (Fig 11A.21); some manufacturers refer to these as *rollators*. A major advantage of this device is ease of maneuverability and turning. Height adjustments are made at the handles; the unit folds for storage and travel.

Storage Attachments

The ability to transport items is an important consideration for many patients and is often essential for those needing frequent access to medications, a cordless or cellular phone, or remote control device. A variety of sizes and styles of attachable baskets and pouches are available (Fig. 11A.22). These storage attachments should be used judiciously and only for essential items. Overuse of the attachment creates an excessive anterior load that may pose a safety hazard and/or alter the patient's gait or ability to effectively use the walker.

Seating Surface

A variety of walker seat designs are available that fold out of the way when not in use. The structural design of many walkers also includes a contoured back support (see Figs 11A.19 and Fig 11A.20A). Seats are an important consideration for individuals with limited endurance (e.g., postpolio syndrome), as well as for community ambulators who require periodic rest intervals. Walker seats should be carefully examined for stability and safety with respect to individual patient needs. Patient practice in use of the walker seat should be provided.

A

B

Figure 11A.20 Walker seat (**A**) positioned for use and (**B**) flipped up for ambulation. The 5-inch fixed front wheels of this walker rotate around a single axis. Features of this walker include rear spring-loaded brakes, a flexible backrest for sitting, a dual-paddle folding mechanism, and adjustable seat-to-floor height. *(Courtesy of Invacare Corp, Elyria, OH 44036.)*

Reciprocal Walkers

These walkers are designed to allow unilateral forward progression of one side of the walker (Fig. 11A.23). A disadvantage of this design is that some inherent stability of the walker is lost. However, they are useful for patients incapable of lifting the walker with both hands and moving it forward (in situations in which a rolling walker might be contraindicated).

- *Advantages*. Conventional walkers provide four points of floor contact with a wide BOS. They provide a high level of stability. They also provide a sense of security for patients fearful of ambulation. They are relatively lightweight and easily adjusted.
- *Disadvantages*. Walkers tend to be cumbersome, are awkward in confined areas, and are difficult to

Figure 11A.21 Three-wheel walker with handbrakes and polyurethane tires to improve performance on a variety of terrains. *(Courtesy of Invacare Corp, Elyria, OH 44036.)*

maneuver through doorways and into cars. They eliminate normal arm swing and generally cannot be used safely on stairs.

Measuring Walkers

The height of a walker is measured in the same way as that of a cane. The handgrip or handle of the walker should come to approximately the greater trochanter and allow for 20 to 30 degrees of elbow flexion.

Gait Patterns: Conventional Walkers

Before initiating instruction in gait patterns using a conventional walker (four points of floor contact without wheel attachments), several points related to use of the walker should be emphasized with the patient:

- The walker should be picked up and placed down on all four legs simultaneously to achieve maximum stability. Rocking from the back to front legs should be avoided because it decreases the effectiveness and safety of using the assistive device.
- The patient should be encouraged to hold the head up and to maintain good postural alignment; forward flexion of the trunk, neck, and head should be avoided.
- The patient should be cautioned not to step too close to the front crossbar. This will decrease the overall BOS and may result in a fall.

Three types of weight-bearing gait patterns can be accomplished with conventional walkers: full weight-bearing (FWB), partial weight-bearing (PWB), and non–weight-bearing (NWB) gait (rolling devices are generally not recommended for patients with altered weight-bearing status). The sequence for each pattern with a walker follows.

Figure 11A.22 Walker basket *(top)* and walker pouch *(bottom)*. *(Courtesy of Sunrise Medical, Longmont, CO 80503.)*

Full Weight-Bearing

- The walker is picked up and moved forward about an arm's length.
- The first LE is moved forward.
- The second LE is moved forward past the first.
- The cycle is repeated.

Partial Weight-Bearing

- The walker is picked up and moved forward about an arm's length.
- The involved PWB limb is moved forward, and body weight is transferred partially onto this limb and partially through the UEs to the walker.

Figure 11A.23 Reciprocal walkers allow unilateral movement of one side of the walker while the opposite side remains stationary.

- The uninvolved LE is moved forward past the involved limb.
- The cycle is repeated.

Non–Weight-Bearing

- The walker is picked up and moved forward about an arm's length.
- Weight is then transferred through the UEs to the walker. The involved NWB limb is held anterior to the patient's body but does not make contact with the floor.
- The uninvolved limb is moved forward.
- The cycle is repeated.

Note: Rolling walkers generally allow use of a reciprocal gait pattern because the walker can be rolled forward while walking. As the need to lift the walker forward following each step is eliminated, a smoother forward progression can be achieved.

LOCOMOTOR TRAINING USING ASSISTIVE DEVICES

Overground Indoors

Several important preparatory activities should precede locomotor training (LT) on level surfaces with the assistive device. These activities may be completed in the parallel bars for added security. However, if the width of the bars is not adjustable, the BOS of the assistive device may make movement within the bars difficult and unsafe. An alternative is to move the patient outside but next to the parallel bars (or oval bar) or near a treatment table or wall. These preparatory activities include the following:

1. **Instruction in assuming the standing and seated positions with use of the assistive device. These techniques are outlined in Box 11A.4 for each category of assistive device.**

2. **Standing balance activities with the assistive device (similar to those using the parallel bars, described earlier).**

3. **Instruction in use of assistive device (with selected gait pattern) for forward progression and turning.**

As mentioned, demonstrating these activities by assuming the role of the patient during verbal explanations is an effective teaching approach. Following the demonstration, manual contacts, verbal cueing, and explanations can be used again to guide performance of the activity. Following these preliminary instructions gait training using the assistive device can be begun overground on level surfaces. The following guarding technique (Fig. 11A.24) should be used:

1. **The therapist stands posterior and lateral to the patient's weaker side.**

2. **A wide BOS should be maintained with the therapist's leading LE following the assistive device. The therapist's opposite LE should be externally rotated and follow the patient's weaker LE.**

3. **One of the therapist's hands is placed posteriorly on the guarding belt and the other anterior to, but *not touching*, the patient's shoulder on the weaker side.**

Should the patient's balance be lost during training, the hand guarding at the shoulder should make contact. Frequently, the support provided by the therapist's hands at the shoulder and on the guarding belt would be enough to allow the patient to regain balance. If the balance loss is severe, the therapist should move in toward the patient so that the therapist's body and guarding hands can be used to provide stabilization. The patient should be allowed to regain balance while "leaning" against the therapist. If balance is not recovered and it is apparent the patient must be moved to the floor, further attempts should not be made to hold the patient up because this is likely to result in injury to the patient and/or the therapist. In this situation, the therapist should continue to brace the patient against his or her body to break the fall and to protect the head and move with the patient to a sitting position on the floor. It is also important to talk to the patient (*"Help me lower you to the floor"*) so

Box 11A.4 Assuming Standing and Seated Positions With Assistive Devices

I. Cane

A. *Coming to standing*

- Patient moves forward in chair.
- Cane is positioned on uninvolved side (broad-based cane) or leaned against armrest (standard cane).
- Patient leans forward and pushes down with both hands on armrests, comes to a standing position, and then grasps cane. With use of a standard cane, the cane may be grasped loosely with fingers before standing and the base of the hand used for pushing down on armrests.

B. *Return to sitting*

- As the patient approaches the chair, the patient turns in a small circle toward the uninvolved side.
- The patient backs up until the chair can be felt against the patient's legs.
- The patient then reaches for the armrest with the free hand, releases the cane (broad-based), and reaches for the opposite armrest. A standard cane is leaned against the chair as the patient grasps the armrest.

II. Crutches

A. *Coming to standing*

- The patient moves forward in the chair.
- Crutches are placed together in a vertical position on the affected side.
- One hand is placed on the hand pieces of the crutches; one on the armrest of the chair.
- The patient leans forward and pushes to a standing position.
- Once balance is gained, one crutch is cautiously placed under the axilla on the unaffected side.
- The second crutch is then carefully placed under the axilla on the affected side.
- A tripod stance is assumed.

B. *Return to sitting*

- As the patient approaches the chair, the patient turns in a small circle toward the uninvolved side.
- The patient backs up until the chair can be felt against the patient's legs.
- Both crutches are placed in a vertical position (out from under axilla) on the *affected* side.
- One hand is placed on the hand pieces of the crutches; one on the armrest of the chair.
- The patient lowers to the chair in a controlled manner.

III. Walker

A. *Coming to standing*

- The patient moves forward in the chair.
- The walker is positioned directly in front of the chair.
- The patient leans forward and pushes down on armrests to come to standing.
- Once in a standing position, the patient reaches for the walker, one hand at a time.

B. *Return to sitting*

- As the patient approaches the chair, the patient turns in a small circle toward the stronger side.
- The patient backs up until the chair can be felt against the patient's legs.
- The patient then reaches for one armrest at a time.
- The patient lowers to the chair in a controlled manner.

that the patient does not continue to struggle to regain balance.

Overground indoor activities on level surfaces should include instruction and practice in passage through doorways, elevators, and over thresholds. When using crutches, doorways are most easily approached from a diagonal. A hand must be freed to open the door and one crutch must be placed in a position to hold it open. The patient then gradually proceeds through the doorway, using the crutch to open the door wider if necessary.

Because many patients using a walker or cane may have balance problems, careful examination will determine the safest methods for passage through doorways. A patient using a conventional walker with sufficient balance may be able to use a technique similar to that described above.

Stair Climbing

Several general guidelines should be relayed to the patient during instruction in stair climbing. First, if a railing is available it should always be used. This is true even if it requires placing an assistive device in the hand in which it is not normally used. For stair climbing with axillary crutches using a railing, both crutches are placed together under one arm. Second, the patient should be cautioned that the stronger LE always leads going up the stairs, and the weaker or involved limb always leads coming down (*"up with the good and down with the bad"*).

Figure 11A.24 Anterior (*left*) and posterior (*right*) views of guarding technique for level surfaces, demonstrated with use of crutches. The same positioning is used with canes and walkers.

Stair climbing techniques are presented in Box 11A.5. The therapist should use the following guarding technique during stair climbing.

Ascending Stairs (Fig. 11A.25)

1. **The therapist is positioned posterior and lateral on the affected side behind the patient.**
2. **A wide BOS should be maintained with each foot on a different stair.**
3. **A step should be taken only when the patient is not moving.**
4. **One hand is placed posteriorly on the guarding belt and one is anterior to, but not touching, the shoulder on the weaker side.**

Descending Stairs (Fig. 11A.26)

1. **The therapist is positioned anterior and lateral on the affected side in front of the patient.**
2. **A wide BOS should be maintained with each foot on a different stair.**
3. **A step should be taken only when the patient is not moving.**
4. **One hand is placed anteriorly on the guarding belt and one is anterior to, but not touching, the shoulder on the weaker side.**

Should the patient's balance be lost during stair climbing, the following procedure should be followed. First, contact should be made with the hand guarding at the shoulder. Next, the therapist should move toward the patient to help brace the patient (the patient should never be pulled toward the therapist on stairs) or leaned toward the wall of the stairwell (if available). Finally, if needed, the therapist can move with the patient to sit the patient down on the stairs. Remember to inform the patient of your intentions ("*I'm going to sit you down*").

Locomotor training using assistive devices should also include outdoor training and practice with curb climbing, negotiating ramps, and sloped surfaces; even and uneven terrains; walking with imposed time requirements (e.g., crossing street at a stoplight); walking for long distances, dual-task training while walking, walking at various speeds, and negotiating open community environments with distractors, as well as outside doors and thresholds; and transportation vehicles.

Adjunct Training Devices

Limb Load Monitors

A limb load monitor is a form of biofeedback used clinically as an adjunct intervention during gait training. The limb load monitor incorporates a strain gauge attached to the sole or heel of the shoe. When a force or pressure is applied, the strain gauge is deformed and an auditory signal provides feedback to the wearer. As pressure increases, the signal becomes louder or more rapid. This feedback provides information about the

Box 11A.5 Stair-Climbing Techniques*

I. Cane

A. *Ascending*

1. The unaffected lower extremity leads up.
2. The cane and affected lower extremity follow.

B. *Descending*

1. The affected lower extremity and cane lead down.
2. The unaffected lower extremity follows.

II. Crutches: Three-Point Gait (non–weight-bearing gait)

A. *Ascending*

1. The patient is positioned close to the foot of the stairs. The involved lower extremity is held back to prevent "catching" on the lip of the stairs.
2. The patient pushes down firmly on both hand pieces of the crutches and leads up with the unaffected lower extremity.
3. The crutches are brought up to the stair that the unaffected lower extremity is now on.

B. *Descending*

1. The patient stands close to the edge of the stair so that the toes of the unaffected lower extremity protrude slightly over the top. The involved lower extremity is held forward over the lower stair.
2. Both crutches are moved down *together* to the *front* half of the next step.
3. The patient pushes down firmly on both hand pieces and lowers the unaffected lower extremity to the step that the crutches are now on.

III. Crutches: Partial Weight-Bearing Gait

A. *Ascending*

1. The patient is positioned close to the foot of the stairs.
2. The patient pushes down on both hand pieces of the crutches and distributes weight partially on the crutches and partially on the affected lower extremity while the unaffected lower extremity leads up.
3. The involved lower extremity and crutches are then brought up together.

B. *Descending*

1. The patient stands close to the edge of the stair so that the toes protrude slightly over top of the stair.
2. Both crutches are moved down *together* to the *front* half of the next step. The affected lower extremity is then lowered (depending on patient skill, these may be combined). *Note:* When crutches are not in floor contact, greater weight must be shifted to the uninvolved lower extremity to maintain a partial weight-bearing status.
3. The uninvolved lower extremity is lowered to the step the crutches are now on.

IV. Crutches: Two- and Four-Point Gait

A. *Ascending*

1. The patient is positioned close to the foot of the stairs.
2. The right lower extremity is moved up and then the left lower extremity.
3. The right crutch is moved up and then the left crutch is moved up (patients with adequate balance may find it easier to move the crutches up together).

B. *Descending*

1. The patient stands close to the edge of the stair.
2. Both crutches are moved down together. Alternatively, the right crutch is moved down and then the left. This pattern must be used with caution as crutch placement on two different steps can introduce excessive and unwanted trunk rotation.
3. The right lower extremity is moved down and then the left.

*The sequences presented here describe stair-climbing techniques without the use of a railing. When a secure railing is available, the patient should be instructed to use it always.

amount of weight-bearing on a limb. Limb load monitors can also be used to reinforce the correctness or timing of a movement. For example, an audible noise or buzzer sounding when the heel makes contact with the floor can provide immediate feedback on foot placement. Similar devices can also be attached to a cane (often referred to as a ***biofeedback cane***). The principle of operation is the same and incorporates a strain gauge. Auditory signals provide the patient with information on placement, as well as pressure applied to the cane.

Chronic Pulmonary Dysfunction

Julie Ann Starr, PT, DPT, CCS

Chapter 12

LEARNING OBJECTIVES

1. Define the disease processes (including definition, etiology, pathophysiology, clinical presentation, and clinical course) of chronic obstructive pulmonary disease, asthma, cystic fibrosis, and restrictive lung disease.
2. Describe examination procedures (including patient interview, vital signs, observation, inspection, palpation, auscultation, and laboratory tests) for a patient with pulmonary disease.
3. Identify the anticipated goals and expected outcomes of pulmonary rehabilitation.
4. Describe the rehabilitative management of a patient with chronic pulmonary dysfunction.
5. Value the therapist's role in the management of a patient with chronic pulmonary dysfunction.
6. Analyze and interpret patient data, formulate realistic goals and outcomes, and develop a plan of care when presented with a clinical case study.

SUMMARY *518*

Pulmonary rehabilitation is a multidisciplinary comprehensive program of care for patients with chronic respiratory disease that is designed to reduce symptoms, optimize physical functioning and social participation, and reduce health care costs.[1] A diversity of health professionals is essential to meet the medical, physical, social, and psychological needs of the patient with pulmonary disease. The team may include a nurse, physician, physical therapist, occupational therapist, nutritionist, pharmacist, respiratory care practitioner, exercise physiologist, psychologist, and, most important, the patient and the patient's family and caregivers.

Years ago, patients with chronic pulmonary disease were given a standard prescription for rest and avoidance of exercise.[2] The stress imposed by exercise was considered deleterious to people with pulmonary disorders. A pivotal study by Pierce et al[3] provided the impetus to change direction in the treatment of pulmonary dysfunction. Exercise training effects of decreased heart rate (HR), respiratory rate, minute ventilation, oxygen consumption, and carbon dioxide production at submaximal exercise levels were documented in their subjects with chronic obstructive pulmonary disease (COPD). Increased maximal aerobic capacity was also documented.[3] Reconditioning of patients with pulmonary disease was found to be possible.

COPD, asthma, and cystic fibrosis are the most common chronic obstructive lung diseases for which pulmonary rehabilitation is rendered. Patients with a restrictive lung disease, such as idiopathic pulmonary fibrosis, have also demonstrated improvement in functional abilities following pulmonary rehabilitation.[4] It is clear that pulmonary rehabilitation is of value for all patients in whom respiratory symptoms have resulted in a decreased functional capacity or a decreased quality of life.[1]

In this chapter, the most common chronic pulmonary diseases that present to pulmonary rehabilitation

programs will be discussed, as well as the physical therapy examination and treatment of patients with chronic pulmonary disease. A brief review of ventilation and respiration is warranted for a better understanding of the disease pathologies and for understanding the rationale of the physical therapy procedures.

RESPIRATORY PHYSIOLOGY

Air is inspired through the nose or mouth, through all of the conducting airways until it reaches the distal respiratory unit, which contains the respiratory bronchiole, alveolar ducts, alveolar sacs, and alveoli (Fig. 12.1). The movement of air through the conducting airways is termed **ventilation.** At full inspiration, the lungs contain their maximum amount of air. This volume of air is called **total lung capacity** (**TLC**), which can be divided into four separate volumes of air: (1) tidal volume, (2) inspiratory reserve volume, (3) expiratory reserve volume, and (4) residual volume. Combinations of two or more of these lung volumes are termed *capacities.* Figure 12.2 illustrates the relationship of lung volumes and capacities.

The amount of air inspired or expired during normal resting ventilation is termed **tidal volume** (**TV or V_t**). As this tidal volume of air enters the respiratory system, it travels through the conducting airways to reach the respiratory units. Tidal volume is about 500 mL/breath for a young, healthy, white male. The amount of inspired air that actually reaches the distal respiratory unit and takes part in gas exchange is about 350 mL of that 500 mL total of the tidal breath. The remaining 150 mL of the inhaled tidal breath remains in the conducting airways and does not take part in gas exchange. When only a tidal breath occupies the lungs, there is "room" for additional air that can be further inhaled. This inspiratory volume in excess of that used in tidal breathing is the **inspiratory reserve volume** (**IRV**). Aptly named, it is the volume of air that can be inspired when needed, but is usually kept in reserve. There is a quantity of air that can potentially be exhaled beyond the end of a tidal exhalation. Although it is usually kept in reserve, the volume of air that can be exhaled in excess of tidal breathing is called the **expiratory reserve volume** (**ERV**). The lungs are never completely emptied of air even after maximally exhaling the expiratory reserve volume. The volume of air remaining within the lungs when ERV has been exhaled is called the **residual volume** (**RV**).

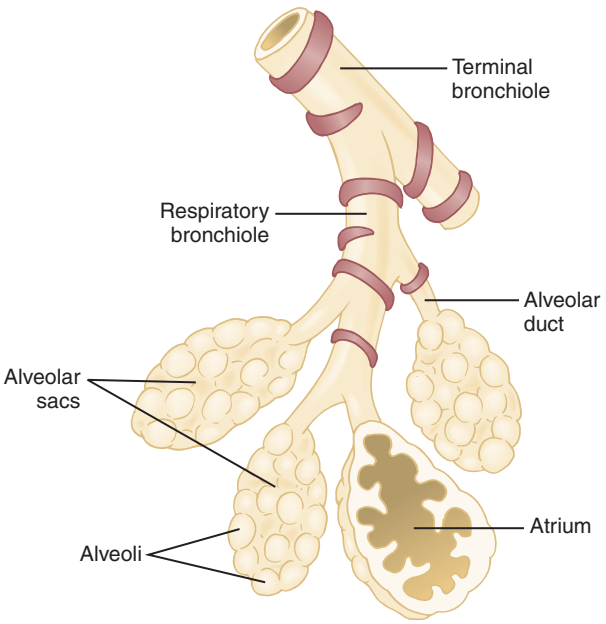

Figure 12.1 Anatomy of the distal conducting airway, the terminal bronchiole and the respiratory unit, the respiratory bronchiole, alveolar ducts, alveolar sacs, and alveoli.

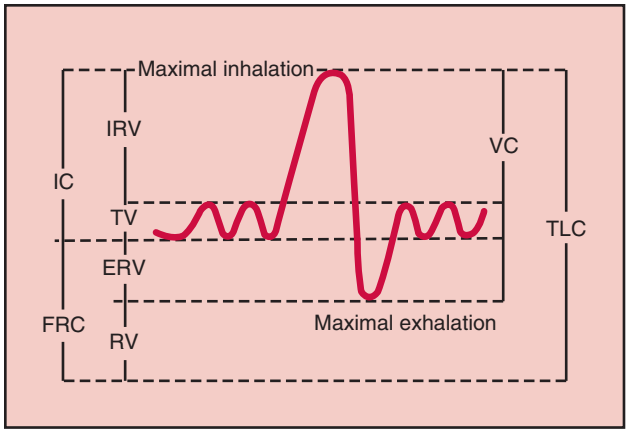

Figure 12.2 Lung volumes and capacities. ERV = expiratory reserve volume; FRC = functional residual capacity; IC = inspiratory capacity; IRV = inspiratory reserve volume; RV = residual volume; TLC = total lung capacity; TV = tidal volume; VC = vital capacity.

The sum of two or more volumes is referred to as a *capacity*. Tidal volume plus the inspiratory reserve volume is known as the **inspiratory capacity** (**IC**). This refers to the volume of air that can be inspired beginning from a tidal exhalation. The combination of residual volume and expiratory reserve volume is the **functional residual capacity** (**FRC**). Functional residual capacity is the volume of air that remains in the lungs at the end of a tidal exhalation. The sum of inspiratory reserve volume, tidal volume, and expiratory reserve volume is called the **vital capacity** (**VC**). It is all of the possible volume of air within the lungs that is under volitional control. The common method of measuring VC is to achieve maximal inspiration, then forcibly exhale as hard and fast as possible into a measuring device until ERV has been exhausted. Because this is a forced expiratory maneuver, it is termed the *forced vital capacity (FVC).* As stated earlier, all volumes together equal total lung capacity:

$$TV + IRV + ERV + RV = TLC.$$

Flow rates measure the volume of air moved in a period of time. Expiratory flow rates, therefore, are

measurements of exhaled gas volume divided by the amount of time required for the volume to be exhaled. Flow rates reflect the ease with which the lungs can be ventilated, the state of the airways, and the elasticity of the lung parenchyma (tissue). An important airflow measurement is the volume of air that can be forcefully exhaled during the first second of a forced vital capacity maneuver. This is called the *forced expiratory volume in 1 second (FEV_1).* This flow rate is thought to reflect the status of the airways of the lungs. In healthy individuals, FEV_1 is 70% or more of the total FVC (FEV_1/FVC > 70%).[5] *Peak expiratory flow rate (PEF)* is the greatest flow rate generated during a maximal forced expiratory maneuver. Individuals with lung disease often measure PEF on a daily basis with a handheld peak flow meter to track their pulmonary status. Daily peak flow rates are compared to the patient's own "best" test value.[6] A drop in a patient's peak flow rate indicates airway narrowing and may indicate the need for a physician visit and/or change in medication regimen.

Inspiratory mechanics can be helpful in understanding a patient's pulmonary disease. *Maximum inspiratory pressure* (PI_{max}) reflects the greatest static inspiratory effort that can be generated from residual volume. It is measured as a pressure in millimeters of mercury or cubic centimeters of water and reflects the strength of the muscles of inspiration. *Maximal sustained inspiratory pressure* (SIP_{max}) is a test of inspiratory muscle endurance. The patient is initially challenged with −6 cm H_2O pressure resistance. Gradually the resistance is increased −2 cm H_2O every 2 minutes until the patient can no longer achieve adequate ventilatory flow levels.[7] The maximal pressure is defined as the highest level that the patient could tolerate during the testing procedure.

Lung volumes, capacities, flow rates, and mechanics depend on the size and configuration of the thorax. Therefore, height, gender, and race influence static and dynamic lung measurements. Any alteration in the properties of the lungs or chest wall due to the aging process or a disease process will also change the lung volumes, capacities, flow rates, and/or mechanics.

Respiration is a term used to describe the gas exchange within the body. This should not be confused with *ventilation,* which describes only the movement of air. External respiration is the exchange of gas that occurs at the alveolar capillary membrane between atmospheric air and the pulmonary capillaries. Internal respiration takes place at the tissue capillary level between the tissues and the surrounding capillaries. The following discussion traces the course of gas exchange, specifically that of oxygen and carbon dioxide, during both external and internal respiration (Fig. 12.3).

For external respiration to take place, there must first be an inhalation of air from the environment, through the conducting airways, and into the respiratory bronchioles and alveoli. Oxygen diffuses through the walls of the respiratory unit, through the interstitial space, and through the pulmonary capillary wall. Most of the oxygen (98.5%) then travels through the blood plasma into red blood cells where it occupies one of the gas-carrying sites of hemoglobin. A small portion of dissolved oxygen (1.5%) is carried in the plasma.

The now oxygenated blood in the pulmonary capillaries travels to the left side of the heart via the pulmonary veins. From there it is pumped into the aorta, and then through a network of connecting arteries, arterioles, and capillaries, until its destination, the tissue, is reached. Internal respiration begins when the arterial blood reaches the tissue level. Oxygen diffuses from the gas-carrying sites of hemoglobin, out of the red blood cell, out of the capillary, through the cell membranes, and into the mitochondria of the working cells.

Carbon dioxide (CO_2), which is produced at the tissue level as a by-product of metabolism, diffuses out of the working cells into the capillaries. Carbon dioxide is transported in the blood through the venous system into the right side of the heart. Once the carbon dioxide–ladened blood makes its way through the right atrium, the right ventricle, the pulmonary artery, and the pulmonary capillaries, it diffuses out through the capillary membrane, through the interstitial space, and into the alveoli, where it is finally exhaled into the atmosphere.

When the cycle of external and internal respiration has occurred, oxygen has been extracted from the environment and provided to the body tissues. Meanwhile, carbon dioxide has been removed from the body tissues and released into the external environment. Of course, this system is dependent on an intact cardiovascular system to pump the blood through the lungs and through the heart, deliver it to the working cells, and then return it back to the lungs, all in a timely fashion.

CHRONIC LUNG DISEASES

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is the most common chronic pulmonary disorder. It is the fourth-leading cause of morbidity and mortality in the United States.[5]

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) is an ongoing collaborative work of the National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO). Initially begun in 2001, GOLD set out to increase worldwide awareness of COPD, to advocate for its prevention as well as to decrease morbidity and mortality from the disease. According to GOLD, COPD is defined as a preventable and treatable disease. The pulmonary component of COPD is characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases. Additional significant extra pulmonary effects, such as a decrease in body mass index (BMI) and exercise

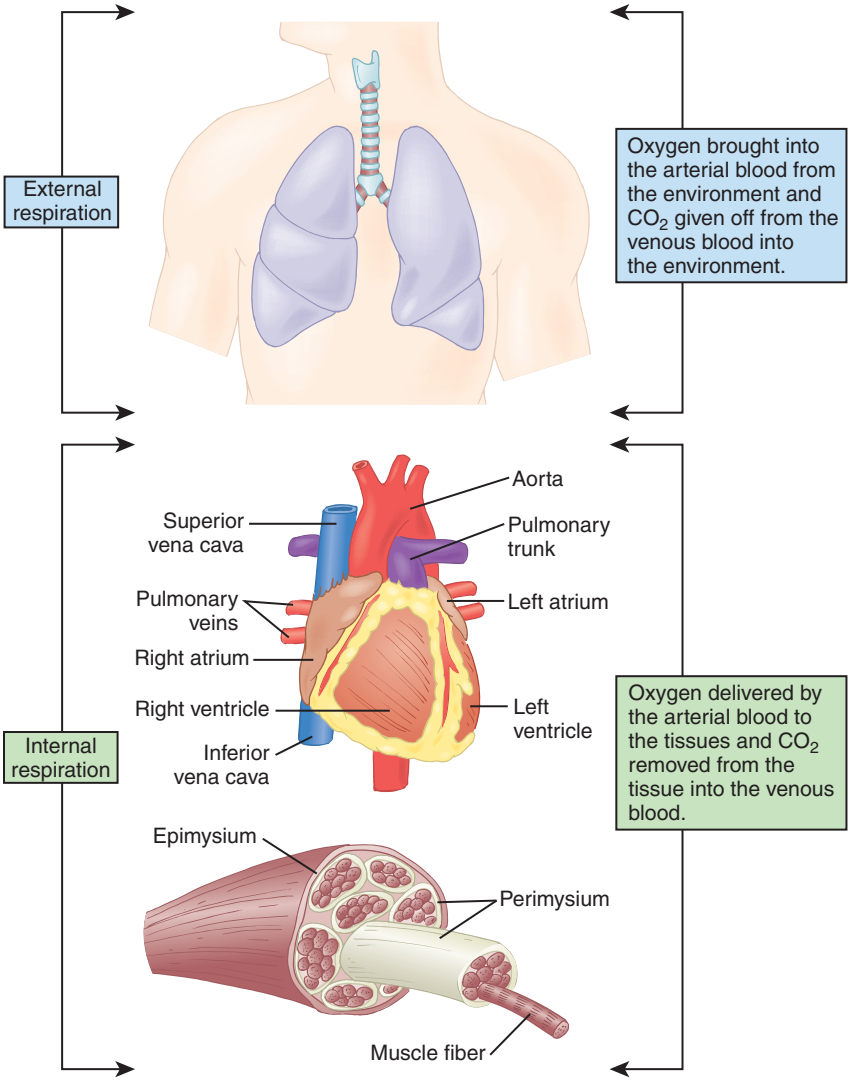

Figure 12.3 The process of external and internal respiration.

tolerance, contribute to the severity of COPD in individual patients.[5] Classification of disease severity is based on both clinical symptoms and measurements of airflow limitation. Table 12.1 shows the GOLD COPD classification of disease severity based on a patient's altered FEV_1 and presenting symptoms.

Risk Factors

Risk factors for the development of COPD include both environmental factors and host factors. Cigarette smoking is the major environmental causal agent in the development of COPD.[5] Smoking history is quantified in units of *pack/years,* the number of packs per day times the number of years smoked. Other environmental factors that contribute to the development of COPD include occupational exposures (e.g., organic and inorganic dusts), indoor pollutants (e.g., secondhand smoke), and outdoor pollutants (e.g., urban pollution).[5]

Host factors that would make a person more susceptible to the development of COPD include hyperreactivity of the airways, overall lung growth (the amount of lung tissue developed during childhood, which is dependent on the person's nutritional status, health status, height, exposure to pollutants, and so forth), and genetics. One genetic cause of COPD is an alpha-1 antitrypsin deficiency.[8] It is perplexing that not all smokers go on to develop clinically significant COPD. The COPDGene® Study is investigating the potential for a genetic influence that would help explain the development of COPD in only a portion of smokers while others, who may exhibit similar airway inflammation from cigarette smoke, do not develop the disease.[9] At this point, it would appear that the development of COPD results from a combination of both host and environmental factors.

Pathophysiology

COPD is a combination of chronic airway inflammation and remodeling (reorganization of tissue during healing) that results in airway narrowing, parenchymal destruction, and pulmonary vascular thickening. Chronic inflammation, characterized by an increase in neutrophils, macrophages, and T lymphocytes, damages the endothelial lining of the airways. Airway inflammation is made

Table 12.1 The Global Initiative for Chronic Obstructive Lung Disease (GOLD) Classification System for Severity of Chronic Obstructive Pulmonary Disease

Stage	Characteristics
I: Mild COPD	• $FEV_1/FVC < 70\%$ • $FEV_1 \geq 80\%$ predicted • With or without symptoms of cough and sputum production
II: Moderate COPD	• $FEV_1/FVC < 70\%$ • $50\% \leq FEV_1 < 80\%$ predicted • Shortness of breath with exertion • With or without symptoms of cough and sputum production
III: Severe COPD	• $FEV_1/FVC < 70\%$ • $30\% \leq FEV_1 < 50\%$ predicted • Greater shortness of breath with exercise, decreased exercise capacity, fatigue and repeated exacerbations of their disease
IV: Very Severe COPD	• $FEV_1/FVC < 70\%$ • $FEV_1 < 30\%$ predicted or $FEV_1 < 50\%$ predicted plus chronic respiratory failure

Classification based on postbronchodilator FEV_1.

FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity; respiratory failure = arterial partial pressure of oxygen (Pa_{O_2}) < 8.0 kPa (60 mm Hg) with or without arterial partial pressure of CO_2 ($PaCo_2$) > 6.7 kPa (50 mm Hg) while breathing air at sea level.

Adapted with permission, NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) workshop summary, Update 2009, page 1.[5]

worse by an imbalance of proteases/antiproteases and oxidants/antioxidants in patients with COPD.[5] Airway damage results in airway repair, leading to airway remodeling. These airway changes appear to be most pronounced in the smaller peripheral airways (bronchioles).[5] The glands and goblet cells within the bronchial walls hypertrophy producing excessive secretions, which either partially or completely obstruct the airways. Decreases in ciliary function and alterations in physiochemical characteristics of bronchial secretions impair airway clearance and contribute to airway obstruction. Damaged and inflamed mucosa shows an increased sensitivity of irritant receptors within the bronchial walls, which in turn cause bronchial hyperreactivity.

During normal inspiration, the lungs and the airways are pulled open, increasing the diameter of the airway lumen. During normal exhalation, as the thorax returns to its resting position, the airways decrease in size. In COPD, during inspiration, the airways are pulled open wide by thoracic expansion, allowing air to enter. During exhalation, the airways, already narrowed by inflammation, remodeling, and excessive secretions, are prematurely closed, trapping air in the distal airways and airspaces. This air trapping causes **hyperinflation**, which is defined as an abnormal increase in the amount of air within the lung tissue at the end of a tidal exhalation (increased FRC).

The most common parenchymal changes found in COPD are dilation and destruction of the airspaces, which is thought to be due to an imbalance of proteases and antiproteases in the lung.[5] This change results in loss of the normal elastic recoil properties of the lung tissue. The pulmonary vasculature is also altered early in the development of COPD. Endothelial changes result in thickening of the vessel walls. In advanced stages of the disease, there is destruction of the pulmonary capillary bed.[5]

Ventilation in the alveoli and **perfusion** in the capillary membrane are no longer matched. This results in **hypoxemia**, a condition in which a decreased amount of oxygen is carried by the arterial blood to the tissues. As the disease progresses and more areas of the lungs become involved, hypoxemia will worsen and **hypercapnea**, a condition in which there is an increased amount of carbon dioxide within the arterial blood, will develop. Increased pulmonary vascular resistance secondary to capillary wall damage and reflex vasoconstriction in the presence of hypoxemia results in right ventricular hypertrophy, termed **cor pulmonale**. **Polycythemia**, an increase in the amount of circulating red blood cells, is another complication of advanced COPD.

Clinical Presentation

Patients with COPD will usually present with a history of cigarette smoking and symptoms of chronic cough, expectoration, and exertional dyspnea. The intensity of each symptom varies from patient to patient. Cough and expectoration appear slowly and insidiously. Dyspnea is first evidenced during exertion. As the disease progresses, symptoms worsen. Dyspnea occurs at progressively lower activity levels. Severely involved patients may feel dyspneic even at rest. On physical examination, the thorax appears enlarged owing to loss of lung elastic recoil and hyperinflation. The anterior-posterior diameter

of the chest increases and a dorsal kyphosis results. These anatomical changes give the patient a barrel-chest appearance (Fig. 12.4).

As the resting position of the thorax is now held in a more inspiratory mode, the available range of thoracic motion is limited, that is, decreased thoracic **excursion**. There are morphologic changes to the ventilatory muscles due to a greater demand, both in frequency and in power needed for this altered thorax. The muscles of ventilation hypertrophy as a result. Figure 12.5 shows many of the accessory muscles of ventilation that may be recruited for breathing. In severe disease, these muscles are recruited even at rest to aid in the work of breathing. The length–tension relationship of muscles of ventilation is altered as the thorax increases in size with chronic hyperinflation. There are changes in the alignment of fibers, especially the fibers of the diaphragm, with hyperinflation. The diaphragm becomes flatter, or less domed. In severe disease, the diaphragm fiber alignment may become more horizontal than vertical, resulting in an inward motion of the lower ribs during a diaphragm muscle contraction of inhalation (Fig. 12.6).

Breath sounds and heart sounds may be distant and difficult to hear. Partially obstructed bronchi and bronchioles may result in an expiratory **wheeze,** a musical, whistling sound. **Crackles,** an intermittent bubbling or popping sound, may also be present from secretions in the airways. Hypertrophy of accessory muscles of ventilation, pursed-lip breathing, **cyanosis**, and digital **clubbing** may all be present in the advanced stages of COPD. (See Examination in section titled Physical Therapy Management for clarification of terms.)

Significant and progressive airway limitation is reflected in altered pulmonary function tests. Lung volumes and capacities, especially RV and FRC, are increased from the normal value due to air trapping. Figure 12.7 shows the changes in lung volumes and capacities that occur in obstructive pulmonary disease.

Expiratory flow rates, especially FEV_1, are decreased. The ratio of FEV_1 to FVC is also decreased (less than 70%).[5] These changes in pulmonary function do not show a major reversibility in response to pharmacological agents.

Arterial blood gas analyses may reflect hypoxemia (decreased oxygen in the arterial blood) in the early stages of COPD. Hypercapnea (increased carbon dioxide in the arterial blood) appears as the disease progresses. With disease progression, chest radiographs show several characteristic findings. These include depressed and flattened hemidiaphragms; alteration in pulmonary vascular markings; hyperinflation of the thorax, evidenced by an increased anterior-posterior diameter of the chest; and an increase in the size of the retrosternal airspace, hyperlucency reflecting a decreased tissue density, elongation of the heart, and right ventricular hypertrophy.

The inflammatory reaction in the airways of patients with COPD can also affect other organ systems.[10] COPD is, therefore, not only a pulmonary disorder, but also has extrapulmonary (i.e., systemic) effects, including changes to skeletal muscle mass and function, cardiovascular disease, osteoporosis, and depression.[11]

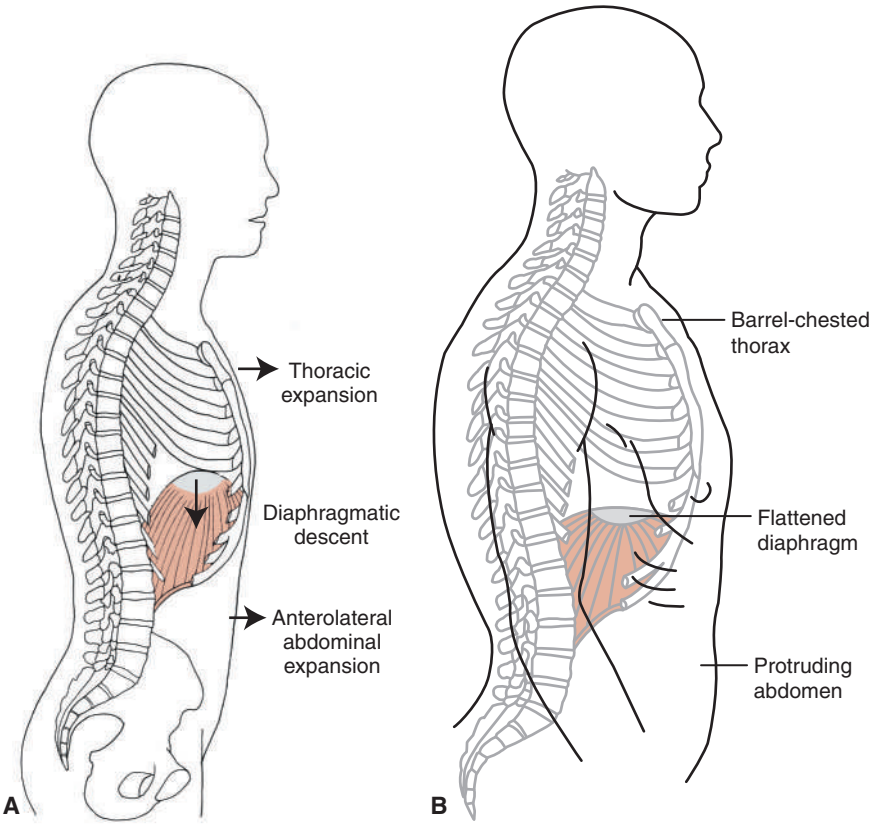

Figure 12.4 **(A)** Normal thoracic configuration. **(B)** Changes in the configuration of the thorax with chronic obstructive pulmonary disease. *(A, From Levangie, P, and Norkin, C. Joint Structure and Function, ed 5, 2011, p 202, with permission. (B, Adapted from Levangie, P, and Norkin, C. Joint Structure and Function, ed 5, 2011, p 209, with permission.)*

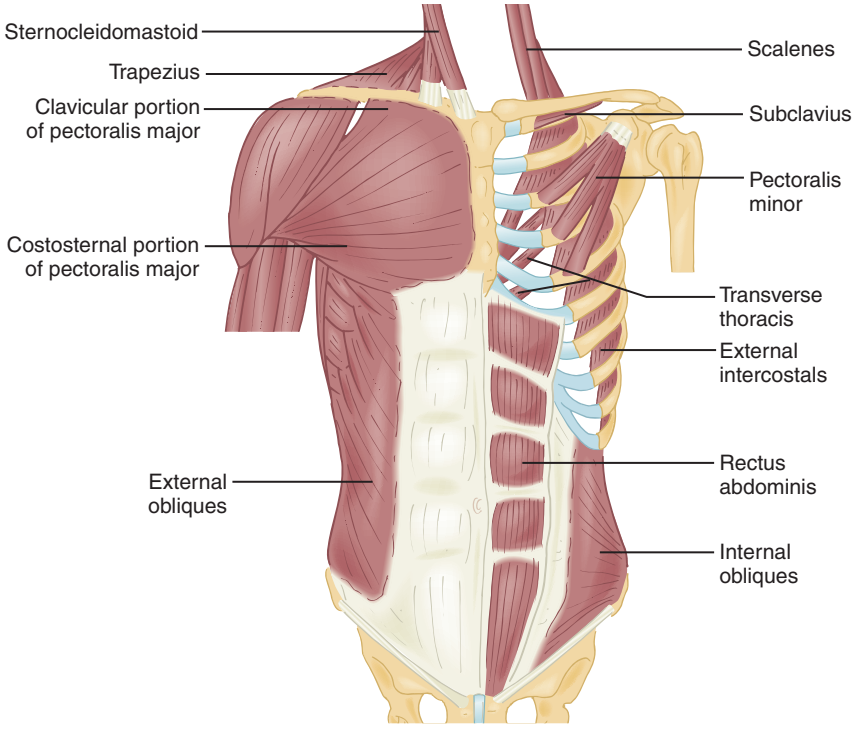

Figure 12.5 Accessory muscles of ventilation are those used during times of increased ventilatory demand. The right side of the figure shows some of the anterior superficial muscles of the thorax that can be accessory muscles of ventilation, and the left side shows the deeper accessory muscles of ventilation.

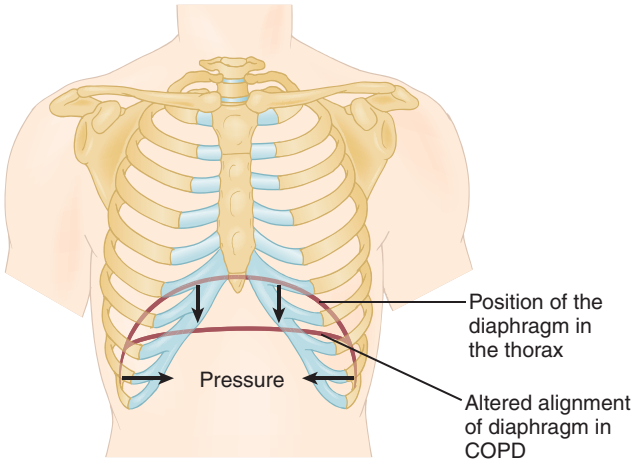
Course and Prognosis

The clinical course of COPD has an insidious onset with a disease progression that can progress over many years. Early identification of those individuals at risk for the development of COPD has been elusive. Although smoking is the most prevalent risk factor for the development of disease, not all smokers develop clinically significant lung disease. Therefore, a smoking history in and of itself is not predictive for the development of COPD. Prognostic indicators for mortality include advanced age, need for supplemental oxygen, exercise capacity, and disease distribution within the thorax.[12] The *BODE* index has been developed as a prognostic indicator for mortality risk in patients COPD. The index uses four domains to calculate mortality risk: body mass index (B), pulmonary obstruction (O), dyspnea (D), and



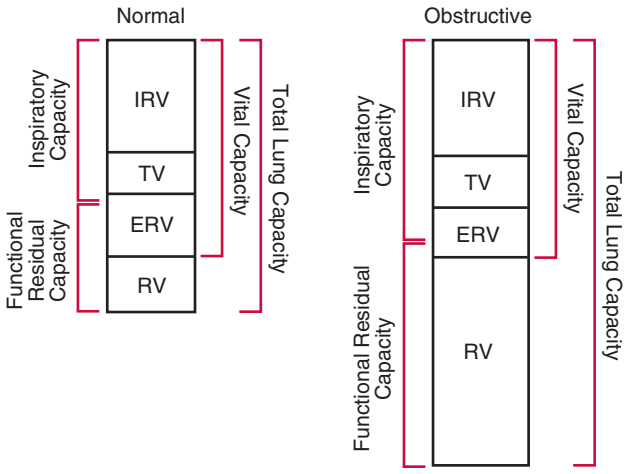


Figure 12.6 Alteration in alignment of fibers of the diaphragm due to hyperinflation. Note that the configuration of fibers is more horizontal than vertical and the normal dome shape is minimized. *(Adapted from Levangie, P, and Norkin, C. Joint Structure and Function, ed 5, 2011, p 202, with permission.)*

ERV: Expiratory reserve volume
IRV: Inspiratory reserve volume
RV: Residual volume
TV: Tidal volume

Figure 12.7 Lung volumes of a healthy pulmonary system compared with the lung volumes found in obstructive disease. *(Adapted from Rothstein, J, Roy, S, and Wolf, S: The Rehabilitation Specialist's Handbook, ed 3. FA Davis, Philadelphia, 2005, p 428, with permission.)*

exercise capacity (E).[13,14] This index can be found in Table 12.2. The higher the score on the BODE, the greater the mortality risk. Leading causes of death in patients with COPD are respiratory failure, lung cancer, and cardiovascular disease.[15]

Asthma

Asthma is a common chronic pulmonary disease, affecting 300 million people worldwide.[16] The disease is characterized by chronic airway inflammation associated with airway hyperresponsiveness (hyperreactivity) resulting in **bronchospasm**. Wheezing, breathlessness, and coughing with sputum production that is at least partially reversible in nature are characteristic symptoms of asthma. Asthma exacerbations may improve spontaneously or with medical intervention and are interspersed with symptom-free intervals.

Diagnosis

The diagnosis of asthma is clinically based on a history of episodic wheezing, shortness of breath (SOB), tightness in the chest, and/or coughing, which may be worse at night in the absence of any other obvious cause. The FEV_1 during exacerbations will be less than 80% of the predicted value. With the use of a rescue drug (used to quickly relieve acute symptoms, e.g., inhaled short-acting beta-2 agonist), an improvement of at least 12% (or 200 mL) in FEV_1 indicates reversibility of the airway limitation consistent with a diagnosis of asthma.[16,17] An improvement of PEF of 60 L/min (or greater than 20%) following the use of a beta-2 agonist would also suggest the diagnosis of asthma.[16]

Table 12.2 The Prognosis of COPD Using the BODE Index[13]

Variable	Points on BODE Index			
	0	*1*	*2*	*3*
FEV_1 (% predicted)	≥65	50-64	36-49	≤35
6-Minute Walk Test (meters)	≥350	250-349	150-249	≤149
MMRC dyspnea scale	0-1	2	3	4
Body mass index	>21	≤21		

BODE = (B) body-mass index; (O) obstruction of airflow severity; (D) dyspnea; and (E) exercise capacity. FEV_1 = forced expiratory volume in 1 second; MMRC dyspnea scale = Modified Medical Research Council dyspnea scale.

Reprinted with permission, Celli, B, et al: N Engl J Med 350(10):1007, 2004.[13]

Etiology

The etiology of asthma is not completely understood. Historically, two types of asthma have been described. Allergic (or extrinsic) asthma has an immunologic (immunoglobulin E [IgE]–mediated) response to certain environmental triggers (dust mites, pollen, mold, animal dander). The resulting eosinophilic inflammatory response (an increased number of eosinophils found in the airway mucosa) produces the common symptoms and pathophysiological findings of asthma. **Atopy**, or allergic sensitivity, is the strongest factor for the development of allergic asthma. Nonallergic (or intrinsic) asthma is a less common form of asthma. There are no clinical findings of atopy in nonallergic asthma; however, an inflammatory response does result from exposure to an irritant such as smoke, fumes, infections, or cold air. Literature in asthma has begun to consider that the two types of asthma are not all that different: one has a known and widespread allergic response (extrinsic) whereas the other has a more local inflammatory response (intrinsic).[18] The Global Initiative for Asthma (GINA) does not differentiate allergic from nonallergic asthma in its guide to management and prevention.[16] Viral infections have been suggested to play a role in both the development and exacerbation of asthma.[19] Symptoms of asthma may begin at any age.

Pathophysiology

The major physiological manifestation of asthma is narrowing of the airways in response to a trigger. The airway narrowing occurs as a result of eosinophilic inflammation of the bronchial mucosa, bronchospasm, and increased bronchial secretions. The narrowed airways increase the resistance to airflow and cause air trapping, leading to hyperinflation. These narrowed airways provide an abnormal distribution of ventilation to the alveoli. Even during periods of remission, some degree of airway inflammation is present (Fig. 12.8).

Clinical Presentation

The clinical symptoms of asthma during an exacerbation may include cough, dyspnea on exertion or at rest, and

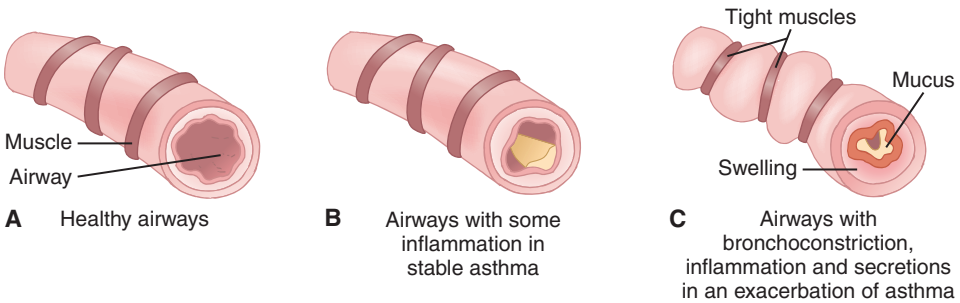

Figure 12.8 **(A)** Airways of a healthy pulmonary system; **(B)** airways showing chronic inflammation of asthma; and **(C)** airways during an asthma exacerbation.

wheezing. The chest is usually held in an expanded position, indicating that hyperinflation of the lungs has occurred. Accessory muscles of ventilation may be used for breathing, even at rest. Intercostal, supraclavicular, and substernal **retractions** (visible inward motion of the soft tissue) may be present on inspiration. While expiratory wheezing is characteristic of asthma, crackles may also be present. With severe airway obstruction, breath sounds may be markedly decreased owing to poor air movement and wheezing may be present not only during exhalation, but may also become present on inspiration.

Chest radiographs taken during an asthmatic exacerbation usually demonstrate hyperinflation, as evidenced by an increase in the anterior-posterior diameter of the chest and hyperlucency of the lung fields. Less commonly, chest radiographs may reveal areas of infiltrate or **atelectasis** from the bronchial obstruction. Chest radiographs may be read as normal between asthmatic exacerbations.

The most consistent change during an exacerbation of asthma is decreased expiratory flow rates, both PEF and FEV_1. RV and FRC are increased because of air trapping at the expense of VC and IRV, which are reduced. The reversibility of these pulmonary function test abnormalities is characteristic of asthma. During remission, the patient with asthma may have normal or near-normal pulmonary function tests.

The most common arterial blood gas finding during an asthmatic exacerbation is mild to moderate hypoxemia. Usually some degree of **hypocapnea** is present secondary to an increased minute ventilation. With severe attacks, hypoxemia will be more pronounced and hypercapnea may occur, indicating that the patient is likely experiencing fatigue and respiratory failure may follow.

Clinical Course

By the time adulthood is reached, many children with asthma no longer have symptoms of the disease.[19-21] When the onset of asthma symptoms begins later in life, the clinical course is usually more progressive, showing changes in pulmonary function tests even during periods of remission. Airway remodeling in response to the chronic airway inflammation is thought to be responsible for the progressive nature of the disease.

Cystic Fibrosis

Cystic fibrosis (CF) is a chronic disease that affects the excretory glands of the body. Secretions made by these glands are thicker, more viscous than usual, and can affect a number of systems of the body: pulmonary, pancreatic, hepatic, sinus, and reproductive. Dysfunction of the pulmonary system is the most common cause of morbidity and mortality in patients with CF. Thickened pulmonary secretions narrow or obstruct airways leading to hyperinflation, infection, and tissue destruction. Other presentations may occur due to the effect of this disease on other organ systems such as failure to thrive, diabetes, sinusitis, biliary disorders, and infertility.

Etiology

CF is a genetic disease transmitted by an autosomal recessive trait (Fig. 12.9). The incidence of disease in children is approximately 1 in 3,700 live births in the United States.[22] Caucasians make up the majority of all cases of CF in the United States. CF is less common in the Hispanic population (white and black) and is rare in the African American and native American populations.[22] The CF gene (cystic fibrosis transmembrane conductance regulator [CFTR]) has been identified on the long arm of chromosome 7. The CFTR functions to transport electrolytes and water in and out of the epithelial cells of many organs in the body, including lungs, pancreas, and digestive and reproductive tracts. Defective transport of sodium, potassium, and water leaves the mucus made by excretory glands thickened and difficult to move, and can often obstruct the lumen of its excretory gland. Over 1,400 mutations of this gene have been described thus far.[23]

Pathophysiology

The chronic pulmonary component of CF is related to the abnormally viscous mucus secreted in the tracheobronchial tree. The altered secretions, resulting in airway

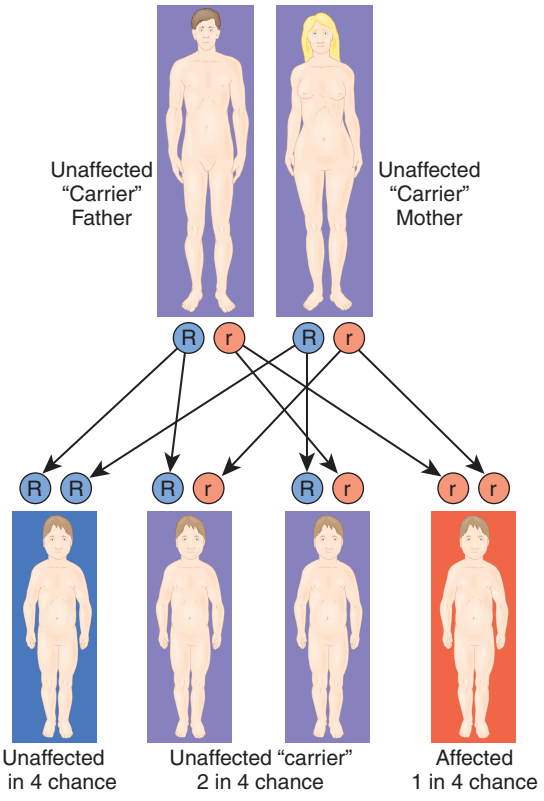

Figure 12.9 Autosomal recessive trait (Mendelian) requires that both parents be carriers of the disease or have the disease in order for their child to have the disease.

obstruction and hyperinflation, impair the function of the mucociliary transport system. Exaggerated and sustained neutrophilic airway inflammation in response to infection is also a feature of this disease.[24] Partial or complete obstruction of the airways reduces ventilation to the alveolar units. Ventilation and perfusion within the lungs are not matched. Fibrotic changes are ultimately found in the lung parenchyma.

Diagnosis

The diagnosis of CF may be suspected in patients who present with a positive family history of the disease, in patients with recurrent respiratory infections from *Staphylococcus aureus* and/or *Pseudomonas aeruginosa,* or with a diagnosis of malnutrition and/or failure to thrive. A chloride concentration of greater than or equal to 60 mEq/L found in the sweat of children is a positive test for the diagnosis of CF. Genotyping for the most common CFTR mutations can also be done, but is usually reserved for patients with borderline sweat chloride test results.

Clinical Presentation

The clinical presentation of CF can be related to any number of involved systems. Failure to thrive due to gastrointestinal dysfunction, diabetes due to pancreatic dysfunction, or frequent respiratory infections and chronic cough from pulmonary dysfunction are all possible presentations of the disease. The severity of the disease, while quite variable, has been linked to the classification of the CFTR mutation.[25]

With pulmonary involvement, a patient presents with thick bronchial secretions that may be difficult to clear. With advancing disease, the chest wall will become barreled with an increased anterior-posterior (AP) diameter and an increased dorsal kyphosis due to loss of elastic recoil of the underlying lungs and hyperinflation. There is a resultant decrease in thoracic excursion. Breath sounds may be decreased with adventitious sounds of crackles and wheezes. Hypertrophy of accessory muscles of ventilation, pursed-lip breathing, cyanosis, and digital clubbing may all be present.

Pulmonary function studies show obstructive impairments including decreased FEV_1, decreased PEF, decreased FVC, increased RV, and increased FRC. The abnormal ventilation–perfusion relationship within the lungs results in hypoxemia and hypercapnea, as shown by arterial blood gas analysis. As the disease progresses, destruction of the alveolar capillary network causes pulmonary hypertension and cor pulmonale. In advanced disease, chest radiographs show diffuse hyperinflation, increased lung marking, and atelectasis.

Course and Prognosis

Seventy percent of new cases of CF are diagnosed when the child is less than 1 year of age, likely due to mandatory infant testing for CF within the United States. Life expectancy continues to increase owing to advances in early diagnosis and improved medical management. Although some patients unfortunately die in early childhood, 45% of all patients diagnosed with CF are currently older than 18 years of age.[23] The predicted mean survival age of patients with CF was 37.4 years in 2008, a remarkable improvement from a mean survival age of 16 years in 1970.[22] Respiratory failure is the most frequent cause of death in patients with CF. Therefore, treatment of the pulmonary dysfunction including removal of the abnormally thick secretions and prompt treatment of pulmonary infections is key to the management of CF. Gastrointestinal dysfunction from CF can be aided by proper diet, vitamin supplements, and replacement of pancreatic enzymes. Habitual exercise has been linked to higher aerobic capacity, increased quality of life, and improved survival.[26] Nutritional status is also a powerful predictor of prognosis.[27]

Restrictive Lung Disease

Restrictive lung diseases are a group of diseases with differing etiologies that result in difficulty expanding the lungs and a reduction in lung volumes. This restriction can arise from (1) diseases of the alveolar parenchyma and/or the pleura; (2) changes in the chest wall; or (3) an alteration in the neuromuscular apparatus of the thorax. For the purpose of this discussion, those diseases most likely to be encountered in a rehabilitation setting—restrictive diseases of the lung parenchyma and pleura—will be presented.

Etiology

This group of disorders has a variety of causes. Numerous agents, such as radiation therapy, inorganic dust, inhalation of noxious gases, oxygen toxicity, and asbestos exposure, can cause damage to the pulmonary parenchyma and pleura and result in restrictive pulmonary disease. The most common restrictive lung disease is idiopathic pulmonary fibrosis (IPF). The etiology of IPF is not known; however, there is an immunological reaction in some cases.

Pathophysiology

The particular changes occurring within the lung parenchyma and pleura depend on the etiological factors of restrictive disease. Parenchymal changes often begin with chronic inflammation and a thickening of the alveoli and interstitium. As the disease progresses, distal airspaces become fibrosed, making them more resistant to expansion (i.e., less distensible). Consequently, lung volumes are reduced. A reduced pulmonary vascular bed eventually leads to hypoxemia and cor pulmonale. Asbestosis (asbestos-induced pulmonary fibrosis) is a type of restrictive lung disease that shows both parenchymal and pleural fibrosis.

Clinical Presentation

Dyspnea with activity and a nonproductive cough are the classic symptoms of parenchymal restrictive lung

diseases. Signs of restrictive lung disease include rapid, shallow breathing; limited chest expansion; inspiratory crackles, especially over the lower lung fields; digital clubbing; and cyanosis.[28]

The plain chest radiograph reveals fine interstitial markings in a **reticular**, or netlike, pattern. Reduction in overall lung volume and radiographic evidence of pleural involvement, when present, can also be seen on plain chest radiographs, although their diagnostic and prognostic abilities are limited. High-resolution computed tomography (HRCT) is a radiologic test for the diagnosis of IPF that typically shows basilar subpleural changes in a reticular pattern along with traction bronchiectasis (misshapen airways due to a pulling by fibrotic tissue on the airway wall) and **honeycombing.**[28,29]

Pulmonary function tests reveal a reduction in VC, FRC, RV, and TLC. Expiratory flow rates may be somewhat normal. The ratio between FVC and FEV_1 may be normal or even increased. Figure 12.10 shows the changes in lung volumes and capacities that occur in restrictive pulmonary parenchymal disease.

Arterial blood gas studies show varying degrees of hypoxemia and hypocapnea. Exercise may significantly lower oxygenation, even for patients with normal oxygenation at rest.

Course and Prognosis

Restrictive pulmonary disease may have a slow onset but is chronic and relentlessly progressive. Survival depends on the type of restrictive disease, the etiological factor, and the treatment. For patients with IPF mean time from onset of symptoms to death is approximately 80 months. From onset of diagnosis to death is about 35 months.[30] Predictors of mortality include age, gender, smoking history, amount of dyspnea, pulmonary function tests, level of oxygenation, and distance walked on a 6-minute walk test.[29,30]

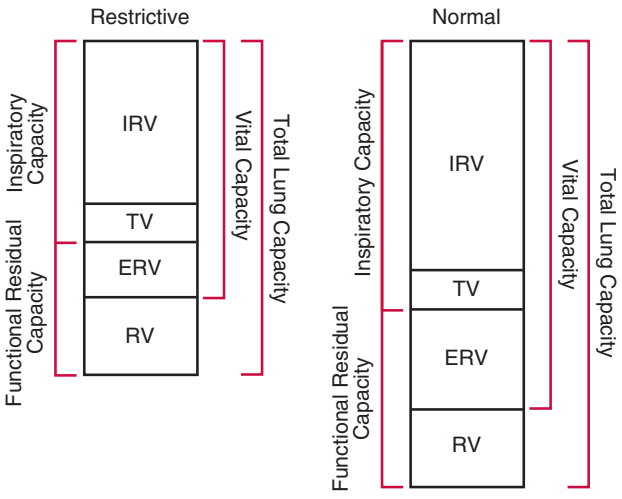

Figure 12.10 Lung volumes of a healthy pulmonary system compared with the lung volumes found in restrictive disease. *(Adapted from Rothstein, J, Roy, S, and Wolf, S: The Rehabilitation Specialist's Handbook. FA Davis, Philadelphia, 2005, p 428, with permission.)*

MEDICAL MANAGEMENT

Medical management of chronic pulmonary disease includes smoking cessation, pharmacological agents, and the use of supplemental oxygen. The following discussion provides an overview of these medical interventions.

Smoking Cessation

Smoking is the major causal agent in the development of COPD, as well as a contributing cause to many other disease processes. Smoking cessation is the most important intervention for improving the outcomes of patients with COPD.[31] The addictive properties of smoking and the withdrawal symptoms of smoking cessation make it difficult for smokers to quit. A majority of smokers who try to quit do so on their own. Unfortunately, 94% of those individuals are not successful on their first attempt.[32] Smokers report an average of six to nine attempts at smoking cessation before they are successful.[32] Using a structured smoking cessation program can increase the success of a person attempting to quit smoking.

There are two general types of smoking cessation programs: behavioral therapy and pharmacological therapy. *Behavioral therapy* includes education on the benefits of being a nonsmoker, counseling, and support through the arduous process of withdrawing from smoking. Acupuncture and hypnosis are considered part of a behavioral therapy approach because the purpose is to change smoking behavior. *Pharmacological therapy* includes the use of nicotine replacement therapy and nonnicotine replacement medications such as bupropion (Zyban) and varenicline (Chantix) to assist in the cessation of smoking. Nicotine replacement therapy, using nicotine gum, lozenges, patches, sprays, or inhalers, decreases the withdrawal symptoms linked to nicotine, such as craving for tobacco products, anger, irritability, anxiety, depression, and concentration problems.[33] Bupropion and varenicline counter the withdrawal symptoms of smoking cessation and increase the likelihood of quitting without the use of systemic nicotine.

Smoking cessation without any support has a success rate of approximately 6%. A 2008 meta-analysis regarding smoking cessation found that the use of behavioral therapy had a 14.6% success rate; pharmacological therapy alone had a 21.7% success rate, and a combination of both behavioral and pharmacological therapy had a 27.6% success rate.[34] Recommendations for smoking cessation need to be tailored to the individual patient, because access to counseling may be difficult to obtain and adverse reactions to some medications may be encountered. The regional offices of the American Lung

Association and the American Cancer Society are good resources for local smoking cessation programs.

Pharmacological Management

Pharmacological agents provide relief from the symptoms of chronic lung disease and improvement in the health and functional status of individuals with lung disease. Each pulmonary diagnosis and the severity of that disease will require a tailored plan of care. It is not unusual for patients to be on a combination of drugs for the management of their pulmonary disease. These drugs can affect exercise performance, HR, and blood pressure (BP), both at rest and with exercise. This discussion will provide information on both maintenance drugs and rescue drugs used in the care of patients with pulmonary disease. Table 12.3 provides foundational information on the pharmacological management of lung disease. Table 12.4 presents the recommended treatments according to the severity of COPD as described by the GOLD standards.[5] Table 12.5 includes recommendations from GINA for pharmacological control of asthma symptoms.[16]

Table 12.3 Drugs Commonly Used in the Medical Management of Patients with Chronic Pulmonary Disease

Category	Drug	Trade Name	Action	Adverse Reactions
Maintenance (taken on a regular basis)	Anticholinergic	Atrovent	Bronchodilation	Throat irritation Drying of tracheal secretions Tachycardia Palpitations
	Long-acting beta-2 agonist	Serevent	Bronchodilation	Tachycardia Palpitations GI distress Nervousness Tremor Headache Dizziness
	Steroids	Flovent Prednisone	Reduces inflammatory response	Increases BP Sodium retention (edema) Muscle wasting Osteoporosis GI irritation Atherosclerosis Hypercholesterolemia Increased susceptibility to infection
	Cromolyn sodium	Intal	Prevents inflammatory response	Throat irritation Cough Bronchospasm
	Leukotriene receptor antagonist	Singulair	Blocks allergic reaction (blocking leukotrienes)	GI distress Sore throat Upper respiratory tract infection Dizziness Headache Nasal congestion
	Methylxanthine	Aminophylline Theophylline	Bronchodilation	Seizures Cardiac arrhythmias GI distress Tremor Headache

Table 12.3 Drugs Commonly Used in the Medical Management of Patients with Chronic Pulmonary Disease—cont'd

Category	Drug	Trade Name	Action	Adverse Reactions
Rescue (used to relieve acute symptoms)	Short-acting beta-2 agonist	Albuterol Ventolin	Bronchodilation	Tachycardia Palpitations GI distress Nervousness Tremor Headache Dizziness

BP = blood pressure; GI = gastrointestinal.

Table 12.4 Suggested Pharmacological Management Based on the Global Initiative for Chronic Obstructive Lung Disease (GOLD) Classification of Lung Severity[5]

	I: Mild	II: Moderate	III: Severe	IV: Very Severe
Characteristics	• $FEV_1/FVC < 70\%$ • $FEV_1 \geq 80\%$	• $FEV_1/FVC < 70\%$ • $50\% \leq FEV_1 < 80\%$	• $FEV_1/FVC < 70\%$ • $30\% \leq FEV_1 < 50\%$	• $FEV_1/FVC < 70\%$ • $FEV_1 < 30\%$ or $FEV_1 < 50\%$
	Reduction of risk factor(s), influenza vaccination *Add* short-acting bronchodilator when needed			
		Add regular treatment with one or more long-acting bronchodilators *Add* rehabilitation		
			Add inhaled glucocorticosteroids if repeated exacerbations	
				Add long-term oxygen if chronic respiratory failure *Consider* surgical treatments

FEV = forced expiratory volume; FVC = forced vital capacity.

Table 12.5 Suggested Pharmacological Management of Patients with Asthma According to the Global Initiative for Asthma (GINA)

Step 1	Step 2	Step 3	Step 4	Step 5
Asthma education Environmental controls Rapid-acting beta-2 agonist, as needed				
	Select one	Select one	Add one or more	Add one or both
	Low-dose inhaled steroid	Low-dose inhaled steroid plus long-acting beta-2 agonist	Medium- to high-dose steroid plus long-acting beta-2 agonist	Oral steroids (lowest dose)
	Or leukotriene modifier	Medium- to high-dose inhaled steroid	Leukotriene modifier	Anti-IgE treatment
		Low-dose inhaled steroid plus leukotriene modifier	Sustained-release theophylline	
		Low-dose inhaled steroid plus sustained-release theophylline		

Step 1 is intended for everyone with a diagnosis of asthma to promote gaining and maintaining control of symptoms. If Step 1 is insufficient in controlling symptoms, the patient moves to the next step(s). *Shaded cells* are the preferred pharmacological options. Adapted from Global Strategy for Asthma Management and Prevention, Update 2008, p 14 (reference 16), with permission.

Maintenance Drugs

Maintenance drugs are used to reduce or minimize pulmonary symptoms throughout the day. These drugs are taken on a regular schedule to keep respiratory symptoms at bay. Steroids, anticholinergics, long-acting beta-2 agonists, cromolyn sodium, and leukotriene antagonists are commonly prescribed maintenance drugs for patients with chronic pulmonary disease. Theophylline, though an effective drug for the treatment of chronic pulmonary diseases, is less frequently prescribed because safer medications are available. Routes of administration of maintenance drugs are usually inhalation or ingestion. When inhalation is effective, it is the advisable route of administration because it limits systemic side effects of the drug.

Inhaled or systemic anti-inflammatories, such as steroids, are the mainstay of medical management of the chronic inflammation of asthma.[35] Inhaled anticholinergics are commonly prescribed for patients with COPD. The action of an anticholinergic is to block the smooth muscle constriction brought on by the parasympathetic nervous system, thus encouraging bronchodilation. Inhaled long-acting beta-2 agonists are used to mimic the sympathetic nervous system encouraging bronchodilation in patients with bronchoconstriction as a chronic symptom of their pulmonary disease. Inhaled cromolyn sodium is used to prevent the inflammatory response within the respiratory system by stabilizing the mast cell within the alveolar units. Used before an exposure of a known trigger for bronchoconstriction, cromolyn sodium can prevent airway narrowing before it can begin. It is therefore helpful in patients with predictable bronchoconstriction, such as exercise-induced bronchospasm. Leukotriene antagonists are systemic drugs that reduce airway inflammation and relax airway smooth muscle. Again, all of these maintenance drugs are used for the long-term management of chronic lung disease. Among the determinants for use and dosage of maintenance drugs are the severity of disease, the patient's symptoms, and response to the medication.

Rescue Drugs

Rescue drugs are used for immediate relief of *breakthrough* symptoms of bronchoconstriction (symptoms that "break through" and become apparent despite careful management). Inhaled short-acting beta-2 agonists are used for this purpose. Patients are advised to use their prescribed inhaled short-acting beta-2 agonist on an as-needed basis, rather than on a regular schedule. If a patient reports an increased frequency in the use of a rescue drug, it is indicative of a flaw in the maintenance drug regimen or a change in the patient's pulmonary status. Short-acting beta-2 agonists can be used before the onset of activity to decrease pulmonary symptoms in cases where exercise is the trigger for bronchospasm.[36]

Although the mechanism of action of each bronchodilator is different, there may be an increase in resting HR and BP with their use. Employing the **heart rate reserve method** (Karvonen's formula) when prescribing exercise intensity acknowledges the elevated resting HR and an appropriate target HR can be calculated. (See Physical Therapy Management section, Exercise Prescription, for further information.) Other common side effects of bronchodilators include nervousness, tremor, anxiety, and nausea. The side effects of systemic steroids, including osteoporosis, myopathies, and muscle wasting, may require modifications to an exercise program.

Antibiotics

Pulmonary infections are frequent in patients with chronic pulmonary diseases. They can be devastating to the patient and cause major setbacks in pulmonary rehabilitation efforts. The early signs of an infection are often noted by changes in the patient's baseline status (i.e., a change in exercise ability, peak flow rates, dyspnea, color or amount of sputum, or an increase in the use of rescue inhalers). Antibiotics are used to interfere with the growth and/or proliferation of bacteria. The action of these drugs is either bacteriostatic or bactericidal. There are many categories of antibiotics (e.g., penicillins, cephalosporins, tetracyclines) that are effective on different infecting organisms. It is important to identify the infecting organism in order to prescribe the appropriate antibiotic. Prophylactic use of antibiotics has not been demonstrated to prevent infections, and the Alliance for the Prudent Use of Antibiotics (APUA) encourages the use of antibiotics for only diagnosed bacterial infections to reduce antibiotic-resistant strains of bacteria.[37]

Supplemental Oxygen

The use of supplemental oxygen has been shown to prolong the survival of patients with COPD whose resting arterial partial pressure of oxygen (P_aO_2) is lower than 60 mm Hg.[38,39] An absolute indication for use of long-term oxygen therapy is a P_aO_2 of 55 mm Hg or less, which correlates with an S_aO_2 of 88% or less.[40] If a patient is limited in the ability to exercise due to dyspnea, supplemental oxygen may be warranted.[38,41] The amount of oxygen used should be titrated individually to maintain an S_aO_2 of at least 90%, if possible.[42] Various supplemental oxygen delivery methods are available; continuous flow, pulsed flow, and reservoir are among the most common.

Surgical Management

There are few surgical options for the patient with pulmonary disease. Lung volume reduction surgery (LVRS) is a surgical technique that removes nonfunctional, overdistended lung tissue, in order to restore more normal biomechanics to the thorax. LVRS may be indicated in patients with heterogeneous areas of relatively nonfunctional emphysema alongside of functional lung tissue. The surgical procedure removes approximately 20%

to 35% of the most diseased lung tissue, relieving the more normal lung tissue of its burden. This surgical procedure reduces RV and FRC (i.e., decreases hyperinflation), allowing for a more normal resting position of the diaphragm, an increased diaphragmatic excursion, and a more normal chest wall motion.[5] Research has shown postoperative results of increased exercise capacity, lung function, quality of life, and gas exchange in patients with moderate *upper lobe* lung disease.[5,43] Patients with severe lung disease distributed to other areas of the lung do not appear to benefit equally from this intervention. Rather, they show only slight improvement in functional abilities and quality of life scores with a high mortality rate.[5,43-46] Many centers that perform LVRS advocate a preoperative pulmonary rehabilitation program. Participants in these preoperative programs demonstrated shorter hospital stays and fewer days on mechanical ventilation.[47]

Lung transplantation for end-stage pulmonary disease has an overall survival rate of 83% at 1 year and approximately 54% at 5 years.[48] The goals of lung transplantation are to restore normal lung function, restore normal exercise capacity, and prolong life.[49] People awaiting a lung transplant include patients with COPD, CF, idiopathic pulmonary fibrosis, and pulmonary hypertension. The number of patients awaiting lung transplantation continues to grow, far exceeding the number of organs available for transplantation, making transplantation a reality for only a small number of individuals.[48]

PHYSICAL THERAPY MANAGEMENT

Chronic pulmonary disease and its associated dysfunction have a slow yet progressive course. The person with pulmonary dysfunction often avoids activities that result in the uncomfortable sensation of dyspnea. A slow but steady decrease in these patients' functional activities follows, resulting in progressive aerobic deconditioning. It is not uncommon for someone with pulmonary disease to have lost many functional abilities before ever seeking medical help. The intended outcome of pulmonary rehabilitation is to interrupt this downward spiraling of physical ability, improve exercise performance, decrease the symptom of dyspnea, and improve quality of life.[50-52]

Goals and Outcomes

The *Guide for Physical Therapist Practice* provides a general framework for physical therapy intervention for patients with impaired ventilation, respiration, and aerobic capacity and endurance associated with ventilatory pump dysfunction (Practice Pattern 6F).[53] The development of specific anticipated goals and expected outcomes for the individual patient with pulmonary dysfunction can be based on the general goals presented in Box 12.1.

Box 12.1 Examples of General Goals and Outcomes for Patients with Chronic Pulmonary Dysfunction

- Patient/client, family, and caregiver understanding of disease process, expectations, goals, and outcomes is enhanced.
- Cardiovascular endurance is increased.
- Strength, power, and endurance of peripheral muscles are increased.
- Performance of physical tasks, both basic activities of daily living and instrumental activities of daily living, is improved.
- Strength, power, and endurance of ventilatory muscles are increased.
- Independence in airway clearance is improved.
- Overall work of breathing is decreased.
- Patient/client decision making ability regarding the use of health care resources is improved.
- Patient/client self-management of symptoms and self-management of pulmonary disease are enhanced.

Examination

The examination of a patient's pulmonary status has several purposes: (1) to evaluate the appropriateness of the patient's participation in a pulmonary rehabilitation program; (2) to determine the therapeutic interventions most appropriate for the participant's plan of care (POC); (3) to monitor the participant's physiological response to exercise; and (4) to appropriately progress the participant's POC over time.

Patient History

A patient interview should begin with the chief complaint and the patient's perception of why pulmonary rehabilitation is being sought. Commonly, the chief complaint is often SOB and/or loss of function. A medical history contains pertinent pulmonary symptoms specific to that patient: cough, sputum production, wheezing, and SOB. Occupational, social, medication, and family histories should also be obtained and documented.

Tests and Measures

Vital Signs

HR, BP, oxygen saturation (S_aO_2), respiratory rate, temperature, and presence of pain (usually associated with SOB) should be examined and documented (see Chapter 2, Examination of Vital Signs). An individual's height should be measured, because there is a direct relationship between height and lung volumes. Weight should be measured on a standard scale and each subsequent measurement should be performed on the same scale.

Observation, Inspection, and Palpation

By observing the neck and shoulders of a patient with pulmonary disease, the use of accessory muscles of ventilation can be observed (see Fig. 12.5). A normal configuration of the thorax reveals a ratio of AP to lateral

diameter of 2:1. Destruction of the lung parenchyma results in an increase in the AP diameter and a reduction of this ratio (up to 1:1) (see Fig. 12.4). During inhalation and exhalation, both sides of the thorax should move symmetrically; asymmetries should be noted and documented.

Cyanosis is a bluish discoloration of the skin that can be observed periorally, periorbitally, and in nail beds; it indicates acute tissue hypoxia. An indicator of more chronic tissue hypoxia is digital clubbing of the fingers and toes. In digital clubbing, there is an increase in the angle created by the distal phalanx and the point where the nail exits from the digit. The tip of the distal phalanx becomes bulbous (Fig. 12.11).

Auscultation of the Lungs

Auscultation involves listening over the chest wall as air enters and exits the lungs. To perform auscultation of the lungs, a stethoscope is placed firmly on the patient's thorax anteriorly, laterally, and posteriorly (Fig. 12.12). The patient is asked to inspire fully through an open mouth, then to exhale quietly. Inhalation and the beginning of exhalation normally produce a soft rustling sound. The end of exhalation is normally silent. This characteristic of a normal breath sound is termed **vesicular**. When a louder, more hollow, and echoing sound occupies a larger portion of the ventilatory cycle, the breath sounds are referred to as **bronchial**. When the breath sounds are very quiet and barely audible, they are termed **decreased**. These three terms—*vesicular, bronchial,* and *decreased*—allow the listener to describe the intensity of the breath sound.[54]

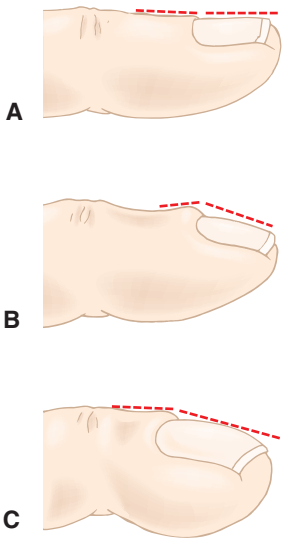

Figure 12.11 Digital clubbing is a sign of chronic tissue hypoxia. **(a)** Normal. **(b)** Early clubbing with increased angle present between nail and proximal skin. **(c)** Advanced clubbing; tip of distal phalanx becomes bulbous.

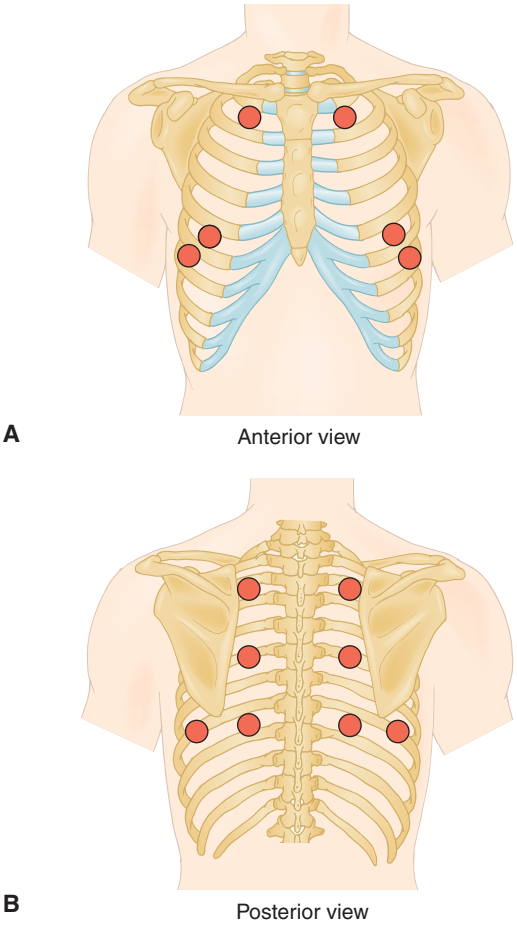

Figure 12.12 Auscultation of the lungs. A global assessment of lung sounds requires that the therapist listen through a stethoscope, which is placed anteriorly, posteriorly, and laterally on the upper, middle, and lower thorax.

In addition to the description of the intensity of the breath sound, there may be additional sounds and vibrations heard during auscultation. These are called **adventitious** breath sounds. These sounds are superimposed on the already-described intensity of the breath sound. According to the American College of Chest Physicians and the American Thoracic Society, there are two types of adventitious sounds: crackles and wheezes.[55] Crackles, historically termed *rales* and *rhonchi,* sound like the rustling of cellophane and have a multitude of potential causes (tissue fibrosis, secretions in the airways, and so forth) while wheezes have been described as high-pitched, coarse, whistling sounds. A decrease in the size of the lumen of the airway will create a wheezing sound, much as stretching the neck of an inflated balloon narrows the passageway through which air must escape and produces a whistling sound.

Measurement of Dyspnea and Quality of Life

Quantifying dyspnea at the beginning and the end of a rehabilitation program and during periods of exacerbation can be accomplished using the *Baseline Dyspnea*

Index (BDI) (Table 12.6).[56,57] Quality-of-life (QOL) measures specific to chronic pulmonary dysfunction such as the *Chronic Respiratory Questionnaire* or the *St. George's Respiratory Questionnaire* may be helpful in determining the patient's baseline health-related quality of life. The Chronic Respiratory Questionnaire has a subscore for rating dyspnea and the St. George's Respiratory Questionnaire has a subscore for symptoms. Both of these QOL measure as well as the BDI may be helpful in demonstrating improvement made with physical therapy intervention.[58,59]

Measurement of Function

Examining a patient's functional abilities at baseline using the 6-Minute Walk Test (6-MWT) or the 10-Meter Shuttle Walk Test (10-MSWT) should be used as an outcome measure to document physical improvements following physical therapy intervention.

Table 12.6 Baseline Dyspnea Index

Functional Impairment		Magnitude of Effort	
_____ Grade 4:	*No Impairment.* Able to carry out usual activities and occupation without shortness of breath.	_____ Grade 4:	*Extraordinary.* Becomes short of breath only with the greatest imaginable effort. No shortness of breath with ordinary effort.
_____ Grade 3:	*Slight Impairment.* Distinct impairment in at least one activity but no activities completely abandoned. Reduction in activity at work *or* in usual activities that seems slight or not clearly caused by shortness of breath.	_____ Grade 3:	*Major.* Becomes short of breath with effort distinctly submaximal. Tasks performed without pause unless the task requires extraordinary effort that may be performed with pauses.
_____ Grade 2:	*Moderate Impairment.* Patient has changed jobs *and/or* has abandoned at least one usual activity due to shortness of breath.	_____ Grade 2:	*Moderate.* Becomes short of breath with moderate effort. Tasks performed with occasional pauses and require more time to complete than the average person.
_____ Grade 1:	*Severe Impairment.* Patient unable to work *or* has given up most or all customary activities due to shortness of breath.	_____ Grade 1:	*Light.* Becomes short of breath with little effort. Tasks performed with little effort or more difficult tasks with frequent pauses and requiring 50%–100% longer to complete than the average person might require.
_____ Grade 0:	*Very Severe Impairment.* Unable to work *and* has given up most or all customary activities due to shortness of breath.	_____ Grade 0:	*No Effort.* Becomes short of breath at rest, while sitting, or lying down.
_____ W:	*Amount Uncertain.* Patient is impaired owing to shortness of breath, but amount cannot be specified. Details are not sufficient to allow impairment to be categorized.	_____ W:	*Amount Uncertain.* Patient has limited exertional capacity due to shortness of breath, but amount cannot be specified. Details are not sufficient to allow impairment to be categorized.
_____ X:	*Unknown.* Information unavailable regarding impairment.	_____ X:	*Unknown.* Information unavailable regarding limitation of effort.
_____ Y:	*Impaired for Reasons Other than Shortness of Breath.* For example, musculoskeletal problem or chest pain.	_____ Y:	*Impaired for Reasons Other than Shortness of Breath.* For example, musculoskeletal problem or chest pain.
Magnitude of Task			
_____ Grade 4:	*Extraordinary.* Becomes short of breath only with extraordinary activity, such as carrying very heavy loads on the level, lighter loads uphill, or running. No shortness of breath with ordinary tasks.

Table 12.6 Baseline Dyspnea Index—cont'd

Functional Impairment		Magnitude of Effort
_____ Grade 3:	*Major*. Becomes short of breath only with such major activities as walking up a steep hill, climbing more than three flights of stairs, or carrying a moderate load on the level.	
_____ Grade 2:	*Moderate*. Becomes short of breath with moderate or average tasks, such as walking up a gradual hill, climbing less than three flights of stairs, or carrying a light load on the level.	
_____ Grade 1:	*Light*. Becomes short of breath with light activities, such as walking on the level, washing, standing, or shopping.	
_____ Grade 0:	*No Task*. Becomes short of breath at rest, while sitting, or lying down.	
_____ W:	*Amount Uncertain*. Patient has limited exertional capacity due to shortness of breath, but amount cannot be specified. Details are not sufficient to allow impairment to be categorized.	
_____ X:	*Unknown*. Information unavailable regarding limitation of magnitude of task.	
_____ Y:	*Impaired for Reasons Other than Shortness of Breath*. For example, musculoskeletal problem or chest pain.

Measurement of Strength

Patients with pulmonary disease may show peripheral and ventilatory muscle weakness due to deconditioning, malnutrition, steroid use, and systemic effects of the disease process.[10,11,60] Muscle weakness can contribute to exercise limitations and an inability to perform activities of daily living (ADL). Therefore, measurement of muscle strength (e.g., manual muscle tests) and inspiratory pressures (e.g., PI_{max}) should be performed to determine the need for strength training during rehabilitation.

Laboratory Tests

Various laboratory studies may be performed to examine patients with pulmonary disease. These include radiology, pulmonary function tests (PFTs) including flow rates, **exercise tolerance tests** (ETTs), functional performance measures, arterial blood gas (ABG) analysis, S_aO_2 measurements, and electrocardiograms (ECGs).

Exercise Testing in Patients with Pulmonary Disease

A determination of functional capacity is part of the examination of a patient with pulmonary disease. An ETT can provide the objective information to (1) document a patient's symptomatology and physical impairment; (2) prescribe safe exercise; (3) document changes in oxygenation during exercise and determine the need for supplemental oxygen; and (4) identify any changes in pulmonary function during exercise performance. If the ETT is repeated following physical therapy intervention, it can provide important outcome data.

A number of testing methods are available to determine the maximal oxygen consumption and functional abilities of patients with pulmonary disease. An ETT protocol, usually utilizing a treadmill or cycle ergometer, gradually increases exercise intensity to stress the patient with pulmonary dysfunction to the point of limitation. Vital signs are monitored throughout the test. The ECG, continuously displayed during exercise, records the exercise HR and electrical activity of the cardiac conduction system. BP measurements recorded at 1- to 3-minute intervals during exercise and during recovery from the test provide information on the hemodynamic status of the patient. ABGs measured during exercise provide the best method for determining arterial oxygenation and the adequacy of alveolar ventilation, though the invasive nature of this test limits its use. Arterial S_aO_2 monitoring provides less information, but the noninvasive nature of the test makes its use more widespread. Oxygen consumption, VO_2, is a helpful

measure that can be collected during an ETT, but requires equipment not always found in an exercise testing laboratory. A number of ETT protocols are outlined in Table 12.7.[61-66] (Refer to the section on exercise testing in Chapter 13, Heart Disease, for more information on exercise protocols.) The symptom-limited ETT requires the patient to continue the exercise protocol until symptoms dictate cessation of exercise. Criteria for stopping a pulmonary exercise test are presented in Box 12.2.

The 10-MSWT is a functional performance measure that uses a recorded audio signal to dictate incrementally increasing walking speeds on a level 10-meter course. Two destination points are placed 10 meters apart. The person is asked to reach each destination point by the time the increasingly frequent audio signal sounds. The results of the 10-MSWT have a positive correlation with $VO_{2\ max}$ (maximal oxygen consumption).[67,68]

The 6-MWT is also a functional performance measure that asks a patient to walk as far as possible in 6 minutes. The patient is allowed to stop and rest during the administration of the test as total distance walked is the recorded result of the test. The 6-MWT has been shown to be a good predictor of functional abilities.[69,70] Both the 10-MSWT and the 6-MWT are easy to administer, and the ready availability of the required equipment makes them useful outcome measurements to demonstrate changes in a patient's abilities following physical therapy intervention.

Exercise test data provide information that can be used to determine disability, predict mortality, assess the ability to perform ADL, quantify health-related quality of life, determine the need for oxygen therapy, demonstrate the effectiveness of medication changes, and prescribe exercise.[13,68-72] PFTs performed before and after an exercise test document the effects of exercise on lung function. A reduction of greater than or equal to 10% in FEV_1 is an indication that exercise provoked airway hyperresponsiveness.[73] Finally, a prescription for exercise that will safely promote improved cardiopulmonary fitness can be developed based on the ETT.

Box 12.2 Graded Exercise Test Termination Criteria

1. Maximal shortness of breath
2. A fall in P_aO_2 of greater than 20 mm Hg or a P_aO_2 less than 55 mm Hg
3. A rise in P_aCO_2 of greater than 10 mm Hg or greater than 65 mm Hg
4. Cardiac ischemia or arrhythmias
5. Symptoms of fatigue
6. Increase in diastolic blood pressure readings of 20 mm Hg, systolic hypertension greater than 250 mm Hg, decrease in blood pressure with increasing workloads
7. Leg pain
8. Total fatigue
9. Signs of insufficient cardiac output
10. Reaching a ventilatory maximum

Exercise Prescription

Exercise prescription incorporates four variables that together allow the therapist to develop a patient-specific exercise formula designed to produce an increase in functional capacity. These variables are *mode*, *intensity*, *duration*, and *frequency*.

Mode

Any type of sustained **aerobic exercise** can be used for pulmonary rehabilitation. Lower extremity (LE) activities, including walking, jogging, and cycling, are often used

Table 12.7 Exercise Testing Protocols Used for the Patient with Pulmonary Disease

Test	Author(s)	Protocol
Cycle tests	Jones[62]	Begin at 100 kpm, increase 100 kpm every minute
	Berman and Sutton[63]	Begin at 100 kpm, increase 100 kpm every minute, or 50 kpm if FEV_1 is <1 L/sec
Treadmill tests	Bruce et al[64]	Begin at 1.7 mph, 10% treadmill grade; increase both speed and grade every 3 minutes
	Naughton et al[65]	Begin at 1.2 mph 0% grade; increase speed and 3% grade every 2 minutes
	Balke and Ware[66]	Begin at constant speed of 3.3 mph, increase grade 3.5% every minutes
10-Meter Shuttle Test	Revill et al[67]	Walking between two markers, 10 m apart, at increasing walking velocities, which are synchronized to an auditory signal or metronome
Walk Test (6- or 12-minute)	American Thoracic Society[69]	Ambulate (walk) as far as possible in the allotted time

to improve exercise tolerance because these modes of exercise more easily translate into functional abilities. Upper extremity (UE) aerobic exercise (e.g., arm ergometry, free weights) can also be included. The combination of UE and LE training in a rehabilitation program results in improved functional status compared to either exercise alone.[74] Many programs utilize a circuit approach (combining a variety of resistive and aerobic exercises) to train different muscle groups and maintain the participant's interest.

Intensity

Three parameters can be used to prescribe exercise intensity: oxygen consumption, HR, and rating of perceived exertion (RPE) or rating of perceived dyspnea (RPD). Below is a discussion of each means of prescribing exercise intensity.

Exercise Intensity as a Percent of VO_{2max}

An ETT may report functional capacity in terms of maximal VO_2. Exercise intensity can be prescribed using a moderate intensity, 40% to 60% of the maximum VO_2 achieved on an ETT, or moderate to vigorous intensity, greater than 60% of the maximum VO_2 achieved on an ETT.[75] Patients with mild to moderate pulmonary disease may be able to exercise for a period of time at these intensities in order to produce a training effect. However, patients with severe pulmonary disease may not tolerate long periods of activity at high intensities (greater than 60% of their maximum). Lowering the exercise intensity may not be the answer for patients with severe pulmonary disease as using a lower exercise intensity has resulted in a lesser to no training effect.[76,77] Rather, exercise will be tolerated and a training effect achieved when short bursts of activity using a high percentage of a participant's peak workload are interspersed with low-intensity exercise or rest periods.[75-84] Current research on interval training versus continuous exercise training is presented in Box 12.3 Evidence Summary. There is a dose relationship between exercise intensity and training outcomes, meaning the higher the exercise intensity, the greater the training.[50]

Exercise Intensity as a Percent of Heart Rate Reserve

While using a percentage of VO_2 may be the most accurate method of prescribing exercise from a graded exercise test, it does not give the clinician a means to monitor exercise intensity during actual performance of

Box 12.3 Evidence Summary Exercise Training Intensity: Interval versus Continuous Exercise

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Beauchamp et al[80] (2010)	8 randomized clinical trials using 388 patients	Systematic review		No difference was found between interval training and continuous training in their effect on exercise capacity or health-related QOL measures in patients with COPD.	
Nasis et al[81] (2009)	42 patients with COPD (FEV_1 42% predicted)	Randomized clinical trial (RCT) of 2 treatment groups: 1. Interval training group using 126% of peak workload from cycle ergometer test 2. Continuous training group using 76% of peak workload from cycle ergometer test	Both groups: 3 sessions per week for 10 weeks. Interval training group used 30 sec of training with 30 sec of rest for 45 min on cycle ergometer. Continuous session was 30 min on cycle ergometer.	BODE index scores (by reducing dyspnea scores and increasing the 6-MWT distance) were significantly improved in both groups. There was no significant difference between the groups on these measures.	If interval training is as good as continuous exercise in lowering the BODE index, which is a prognostic indicator, then both training strategies would be beneficial to patients with COPD.

Box 12.3 Evidence Summary Exercise Training Intensity: Interval versus Continuous Exercise—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Arnardottir et al[82] (2007)	60 patients with COPD (FEV_1 of 32%–35% predicted)	RCT of 2 treatment groups: 1. Interval training group using alternating 80% and 30%–40% of peak workload from cycle ergometer test 2. Continuous training group using 65% of peak workload from cycle ergometer test	Both groups: 2 sessions of 39 min of exercise twice weekly for 16 weeks. Interval training group alternated between 3 min of high-intensity training with 3 min of low-intensity training for 39 minutes. Continuous training group performed 39 min of continuous exercise on cycle ergometer.	Peak work and VO_2 peak were significantly increased in each group. Functional capacity, dyspnea ratings, and health-related QOL measures were significantly improved in each group. There was no difference in the improvement between groups.	If interval training is as effective as continuous exercise, then interval training is beneficial for those patients who cannot sustain long periods of activity.
Varga et al[83] (2007)	71 patients with COPD (FEV_1 of 55% of predicted)	Pre-test, post-test clinical trial of 3 treatment groups. 1. Interval training group using alternating 90% and 50% of peak workload using cycle ergometer 2. Continuous training group using 80% of peak workload using cycle ergometer 3. Self-paced group used the maximum load tolerated using either a cycle ergometer, level walking, or stair climbing	All groups: 45 min per session, 3 times per week for 8 weeks. Interval training group: 2 min of high-intensity training alternating with 1 min of low-intensity training for 30 min with 7.5 min warm-up and 7.5 min cool-down. Continuous training group: 45 min on cycle ergometer. Self-paced group: exercised starting with 30 min and increasing for 45 min duration by the study's end.	All three interventions were equally effective in improving the scores on an activity questionnaire. The supervised groups (interval and continuous) groups had a significantly higher peak work rate compared to the self-paced group. Peak VO_2 and lactic acidosis thresholds were improved in all groups without statistical significance between groups.	Participants were assigned to the self-paced group if they lived too far from the research center. Remaining patients were then randomized into the interval training group or the continuous training group. Therefore, this is not a true randomized clinical trial.

Continued

Box 12.3 Evidence Summary Exercise Training Intensity: Interval versus Continuous Exercise—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Puhan et al[84] (2006)	87 patients with COPD, FEV_1 of 34% of predicted	RCT of 2 treatment groups: 1. Interval training group using alternating 50% and 10% of peak workload using steep ramped cycle ergometer 2. Continuous training group using 70% of peak workload using incremental cycle ergometer	Both groups participated in 12 to 15 sessions of exercise lasting 20 min each over 3 weeks of an inpatient pulmonary rehabilitation program. Interval training: alternating between 20 sec of high-intensity and 40 sec of low-intensity training for 20 minutes. Continuous training: 20 min of continuous cycling.	Both groups showed a greater than minimally important change in the CRQ scores. Both groups showed statistically significant increases in the 6-MWT (42 m improvement in the interval exercise group after training and 37 m improvement in the continuous exercise group after training).	Changes in the 6-MWT, although statistically significant, did not approach the clinically significant difference of 54 m. Patients assigned to the interval training group had better adherence than those in the continuous training group. Therefore, it might be worth considering using interval training to improve exercise adherence.

BODE = prognostic tool that incorporates (B) body-mass index; (O) obstruction of airflow severity; (D) dyspnea; and (E) exercise capacity. COPD = chronic obstructive pulmonary disease; CRQ = Chronic Respiratory Questionnaire; FEV_1 = forced expiratory volume in 1 second; 6-MWT = 6-Minute Walk Test; QOL = quality of life; VO_2 = volume of oxygen consumed.

the exercise. There is a relationship between increasing workloads, increasing VO_2, and increasing HR, making exercising HR a practical choice for measuring and monitoring exercise intensity.[85] The **target heart rate range** (**THRR**) defines a wide, safe, and effective range of exercise intensity that can be performed during the treatment session. The **target heart rate** (**THR**) for a specific patient defines a more narrow HR (within the prescribed THRR) that will be most appropriate to ensure aerobic training and patient adherence.

A common method to determine a patient's THRR and the THR is using the heart rate reserve (HRR) method or Karvonen's formula.[75] The HRR is the difference between the resting HR (HR_{rest}) in the seated position and the maximal HR (HR_{max}) achieved on an ETT. To calculate the THRR, percentages (40% and 85%) of the HRR are added to the resting HR. Karvonen's formula for determining the upper and lower limits of the THRR is:

$$\text{Lower limit of THRR} = [(HR_{max} - HR_{rest}) \times 0.40] + HR_{rest}$$

$$\text{Upper limit of THRR} = [(HR_{max} - HR_{rest}) \times 0.85] + HR_{rest}$$

For example, a person achieves a maximal HR of 165 beats per minute (beats/min) on an ETT. The person's resting HR was 85 beats/min. The HRR is calculated to be 165 (85 = 80 beats/min; 40% of 80 beats/min (32) + resting HR (85) = 117 beats/min; 85% of 80 beats/min (68) + resting HR (85) = 153 beats/min. Thus, for this person, a THRR of 117 to 153 beats/min has been calculated from the exercise test data.

Determination of the appropriate THR is based on a complete patient's history as well as data from all tests and measurements. Patients with mild to moderate pulmonary disease may not have a pulmonary limitation to their ability to perform exercise; therefore, a maximal cardiovascular exercise test is likely to have been performed. If the patient has no other concomitant diseases, has no musculoskeletal or neurological constraints, and is committed to exercise, the higher end of the THRR could be used. For example, if the THRR was determined to be 117 to 153, the THR for this person could be at the high end or 141 to 153. If, on the other hand, the patient had other co-morbidities, such as musculoskeletal, neurological, or renal issues, and has no exercise experience, then the middle (129 to 141) or even lower (117 to 129) end of the THRR might be used.

Patients with severe pulmonary impairment will likely approach their ventilatory maximum before their cardiovascular maximum is reached; that is, their peak exercise HR may be lower than their cardiovascular HR maximum owing to pulmonary constraints. For these patients, exercise intensities that approach their maximum ventilatory symptoms can be used. This may translate into the upper end of the THRR as calculated by Karvonen's formula or even higher.[61,79] According to the *Guidelines for Pulmonary Rehabilitation* from the American College of Chest Physicians (ACCP) and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR), an exercise intensity that uses a high percentage of the patient's peak exercise capacity is well tolerated and physiological training effects have been documented.[79] However, they caution that lower intensity exercise may be associated with better adherence.[79] It should be emphasized that exercise intensity, when prescribed by HR, should have an upper and a lower HR limit, not a single number.

Exercise Intensity by Rating of Perceived Exertion or Rating of Perceived Dyspnea

With severe pulmonary disease, dyspnea is often reported as the limiting factor in the patient's ability to perform exercise. Using HR to prescribe exercise, as described in the previous section, does not always directly address the cause of physical limitation in patients with low ventilatory reserve. Borg's RPE is often used as a means of prescribing exercise intensity for patients with cardiovascular and pulmonary diseases.[75,86] Using the RPE scale allows the patient to self-regulate exercise intensity based on his or her perception of exertion (Table 12.8). RPE has been correlated with VO_2, making it a useful means of prescribing and monitoring exercise intensity. Perceived exertion ratings of 3, 4, and 5 were correlated with 60%, 72%, and 78% of VO_{2max}, respectively.[80] A variation of the RPE scale uses *rating of perceived dyspnea* (RPD) as a gauge for exercise intensity[87,88] (Table 12.9). Perceived dyspnea ratings between 3 (moderate SOB) and 6 (between severe and very severe SOB) define the range within which patients with pulmonary dysfunction generally exercise. A rating of up to 3 corresponds approximately to 50% of VO_{2max}. A rating of about 6 (between 4 and 8) corresponds to approximately 80% of VO_{2max}[89] (see also Chapter 13, Heart Disease, for additional information).

Clinicians often prefer to prescribe exercise by utilizing a combination of parameters (e.g., THR and RPE and RPD).

Duration

Exercising within prescribed exercise intensity for at least 20 to 30 minutes is recommended.[75] The duration of the training session varies according to patient tolerance, with some participants not being able to

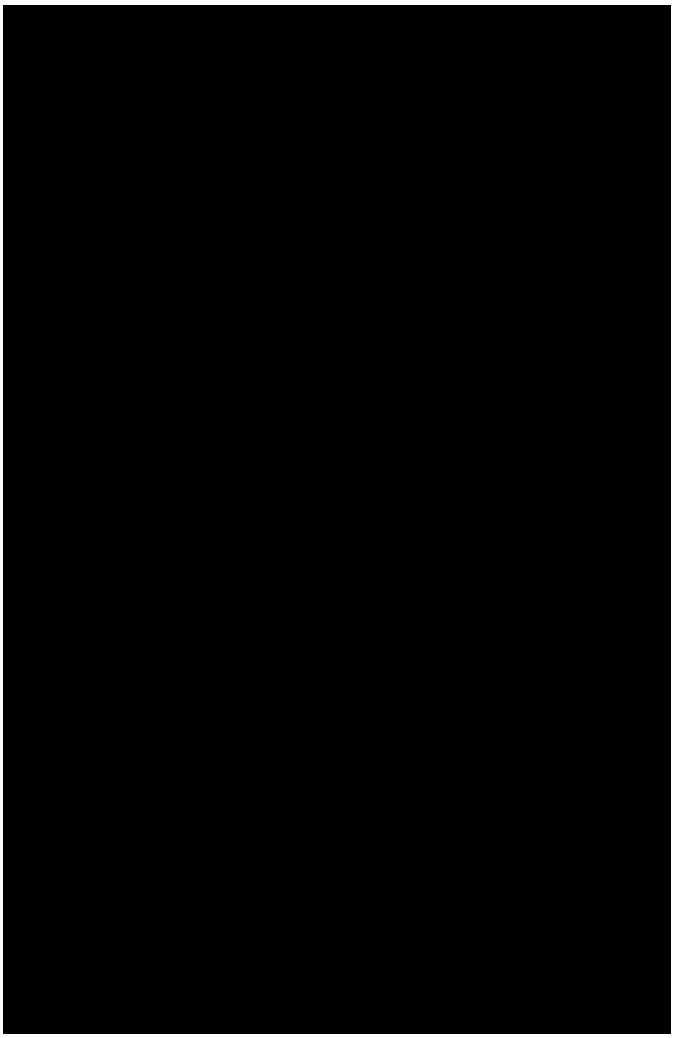

Table 12.9 Rating of Perceived Shortness of Breath

Scale	Perceived Shortness of Breath
0	Nothing at all

9	Very, very severe (almost maximal)
10	Maximal

maintain continuous exercise for 20 to 30 minutes. Frequent rest periods can be interspersed with exercise to accomplish a total of 20 to 30 minutes of discontinuous exercise.

Frequency

The frequency of exercise refers to the number of sessions performed on a weekly basis during the exercise-training period. The frequency of exercise is often dependent on the intensity that can be achieved and the duration that can be maintained. If 20 to 30 minutes of continuous aerobic exercise can be accomplished within the THR, then three to five evenly spaced workouts per week are recommended. More frequent exercise sessions are recommended for patients with lower functional abilities. One to two daily sessions are advisable for patients with very low functional work capacities.

Pulmonary Rehabilitation

Aerobic Training

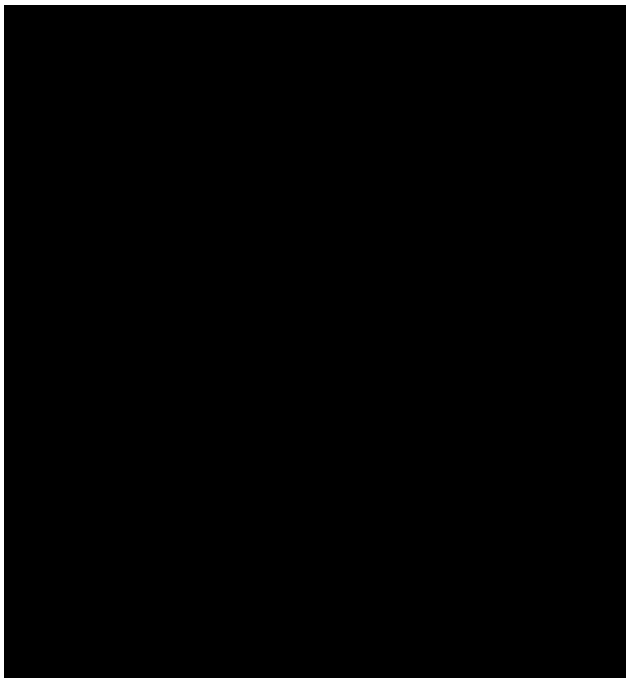
The aerobic exercise training portion of a pulmonary rehabilitation session includes the following components: check-in, warm-up, aerobic exercise, and cool-down. The check-in period is a time to obtain baseline data, including resting HR, respiratory rate, BP, oxygen saturation, auscultation of the lungs, and weight. It is also the time to discuss medication schedules, any problems the patient may have encountered since last visit, and any changes that need to be addressed by a member of the pulmonary rehabilitation team, such as a change in flow rates, cough, or sputum production. If the patient were found to have a significant decrease in FEV_1 on the ETT, a maintenance drug would typically be prescribed to reduce or minimize pulmonary symptoms. PFTs with a handheld device may be performed pre and post exercise to assess the impact of the maintenance medication. The potential need for use of a beta-2 adrenergic inhaler before exercise should be determined. If a patient is found to have a significant decrease in oxygenation with exercise, supplemental oxygen should be readied before initiation of physical activity.

The warm-up component is a time to slowly increase the HR and BP to ready the cardiovascular system for aerobic exercise. For those patients with mild to moderate lung disease who had a cardiovascular end point to their exercise test, the warm-up is usually accomplished by performing the same mode of exercise that will be used in the aerobic portion of the program but at a lower intensity, with an emphasis on controlled breathing. For example, cycling with no resistance could be used as a warm-up activity for a biking program. The warm-up for patients performing continuous exercise lasts between 5 and 10 minutes. For patients with severe lung disease who are prescribed short bursts of high-intensity exercise, there is little opportunity for a warm-up. In these situations, the program should be designed so that each exercise bout of the circuit gradually builds on the previous exercise to ramp up activity.

The aerobic portion of the exercise session consists of a mode or modes of aerobic activity at the appropriate intensity to maintain the THR of the exercise prescription for the advised duration. This portion of the program lasts for at least 20 minutes of either continuous or discontinuous activity. Participant monitoring can be accomplished using RPE and RPD scales, and measures of HR, respiratory rate, and S_aO_2 (oximetry).

The aerobic training period should be followed immediately by a cool-down period consisting of a slow decline in exercise intensity as the patient nears completion of the circuit. This may consist of 5 to 10 minutes of low-level aerobic activities that slowly return the cardiovascular system to near pre-exercise levels or ramping down of the intensity of short bouts of exercise. Again, there is an emphasis on controlled breathing.

Finally, stretching exercises are performed to maintain joint and muscle integrity and to help prevent injury. Stretching exercises should be performed during exhalation to prevent a **Valsalva** maneuver, which would worsen a participant's pulmonary capabilities. Patients often use accessory muscles of ventilation during the exercise program; therefore, the muscles of the neck and UEs should be incorporated into the stretching program.



General Strength Training

Extremity Training

While cardiopulmonary endurance training through aerobic exercise is the mainstay of pulmonary rehabilitation, generalized strength training has been found to counter the systemic effects of COPD that result in peripheral and ventilatory muscle weakness. Strength of both UEs and LEs has been shown to increase with appropriate training. Strength training can use similar modes of exercise as the endurance training with a change to higher resistance and lower repetitions (i.e., increase the grade of treadmill, increase resistance on stationary cycle or arm ergometer), or weight training of the targeted muscle groups can be prescribed. Participants should be encouraged to refrain from using the Valsalva maneuver during training because this may impair ventilatory exchange and affect exercise performance.

Ventilatory muscle training

Patients with COPD may have weak inspiratory muscles that translate into breathlessness and exercise limitations.[79] Ventilatory muscle training devices provide resistance to the inspiratory phase, the expiratory phase, or both phases of ventilation in order to increase the strength and endurance of the muscles of ventilation. Figure 12.13 shows one type of ventilatory muscle training device (Philips Healthcare, Andover, MA). Many research studies have demonstrated the ability to increase ventilatory muscle strength and endurance using these loading devices, especially in the presence of known

respiratory muscle weakness.[90-94] Ventilatory muscle trainers have also been studied for their ability to alter the perception of dyspnea. A number of researchers have demonstrated a decrease in the severity of dyspnea with ventilatory muscle training during the performance of ADL and during exercise.[92,95,97,98] Current research on the benefits of ventilatory muscle training can be found in Box 12.4 Evidence Summary.

Whether training the muscles of ventilation alone translates directly into a clinically significant functional improvement is still not clear. Statistically significant changes in 6-MWT and 10-MSWT data have been demonstrated with ventilatory muscle training.[92,93,95,98] However, these changes do not always translate into a clinically significant improvement. For example, a change of greater than 54 meters needs to be realized on a 6-MWT in order to be clinically significant.[69] Although Hill et al[98] found a statistically significant increase in distance on the 6-MWT in those patients in the ventilatory muscle treatment group, the increase

			resistances (see design).	Significant improvement in CRQ scores (QOL). No significant change in $VO_{2\ max}$, $VE_{\ max}$, or W_{max} was found in either group after training. No significant change in rate of perceived exertion was found in either group after training.	inhalation and exhalation time via visual feedback.
Weiner et al[93] (2003)	32 patients with COPD, FEV_1 < 50% predicted	Randomized control trial using 3 treatment groups + 1 control group: 1. SIMT group: high-load IMT and low-load EMT 2. SEMT group: high-load EMT and low-load IMT 3. SEMT and SIMT group: high-load IMT and EMT 4. Control group: low-load IMT and EMT	1 hr/day (30 min of IMT and 30 min of EMT), 6 days/wk for 3 months. High load was ramped up to 60% of max by the end of first month. Low load was 7 cm H_2O pressure.	Groups that trained inspiratory muscles showed a significant increase in PI_{max}. Groups that trained expiratory muscles showed a significant increase in PE_{max}. Significant increase in 6-MWT in treatment groups. Significant change in dyspnea scores in only the SIMT and SEMT + SIMT group. Significant change in perception of dyspnea in only the SIMT and SEMT + SIMT group.	Small sample size of only 8 participants per group. Increases in 6-MWT were statistically significant but the SEMT and the SEMT + SIMT did not reach clinical significance for improvement in that test (>54 m).
Beckerman et al[95] (2005)	42 patients with COPD, FEV_1 < 50% predicted	Randomized control trial using 2 groups: 1. Treatment: began IMT with 15% of PI_{max} load, increasing to 60% by 4 weeks, and increased to maintain 60% of new weekly PI_{max}	Both groups trained for 15 min, 2 times/day, 6 days a week for 12 months. Training for the first month was onsite in the rehabilitation center, the next 11 months was at home with daily phone calls and	6-MWT—significant increase in the treatment group beginning at 3 months with small gains following during next 9 months. No change in the control group. Inspiratory muscle strength: statistically significant in-	Daily contact for 1 year by a health care professional is unreasonable; therefore the ability to replicate this study is questioned. 11 out of 42 participants did not complete the program (6 were deaths).

Box 12.4 Evidence Summary Ventilatory Muscle Training—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
		2. Control: trained with S-IMT at a low load known to not improve inspiratory muscle strength	weekly home visits. Assessments were at 3, 6, 9, and 12 months.	crease in PI_{max} in the treatment group (not in the control group) starting at 3 months and continuing throughout the course of study. Dyspnea: treatment group showed a significant decrease in dyspnea beginning at 6 months compared to the control group. HRQOL as measured by SGRQ improved significantly over the control group beginning at 6 months.	There was a decrease in hospital length of stays among the treatment group; the number of exacerbations requiring hospitalization was similar between groups.
Weiner and Weiner[96] (2006)	28 patients with COPD (FEV_1 of 36%–39% predicted) and documented inspiratory muscle weakness	Randomized control trial using 2 groups: 1. Treatment: began IMT with 15% of PI_{max} load, increasing to 60% by 4 weeks, and increased to maintain 60% of new weekly PI_{max} 2. Control: IMT at a steady load of 7 cm H_2O	Training was 6 days per week, 1 hr/day for 8 weeks for each group.	Statistically significant increase in the PI_{max} in the training group (46.1 to 58.7 cm H_2O), no change in the control group.	The increase in PI_{max} was also correlated to an increase in peak inspiratory flow rates. These higher flow rates would improve the drug deposition to the lungs when using a dry powder inhaler.
Magadle et al[97] (2007)	34 patients with COPD (FEV_1 45%–46% predicted) currently enrolled in a 12-week pulmonary rehabilitation program of GER	Randomized control trial using 2 groups of IMT or S-IMT in addition to continued GER for another 6 months: 1. Treatment group began IMT training with 15% of PI_{max} load increasing to 60%	Pulmonary rehabilitation program was 1.5 hr/day, 3 times per week for the first 12 weeks. Second 6 months included 1 hr/day, 3 days/ week of GER for both groups. IMT was performed daily, 6×/wk for the next 8 weeks.	Following the first 12 weeks of GER, there was significant increase in 6-MWT for all participants. There was no significant improvement in perceived dyspnea or SGRQ scores . After the addition of IMT and S-IMT to GER, there was	The addition of the IMT caused changes in QOL measures and dyspnea ratings that were not found in pulmonary rehabilitation programs of GER alone. As patient's chief complaint is often dyspnea or loss of

		by 4 weeks, and increased to maintain 60% of new weekly PI_{max} 2. Control group used S-IMT, the same device as the treatment group but set at a fixed, sufficiently low load that would not provide a training effect	It is difficult to distinguish between how the treatment and control groups were handled.	no further improvement in the 6-MWT in either group. The treatment group showed a significant increase in PI_{max}, and significant improvement in perceived dyspnea and in the SGRQ when compared to the control group.	function, this article is compelling in its recommendation to add IMT to an already existing pulmonary rehabilitation program.
Hill et al[98] (2006)	35 subjects with COPD (FEV_1 of 37.4% predicted)	Randomized control trial using 2 groups: 1. Treatment (H-IMT) used the maximum load tolerable for 2 min followed by 1 min rest, repeated 7 times 2. Control: S-IMT used a constant load of 10% of baseline PI_{max} throughout training	Sessions were 21 min, 3×/wk for 8 weeks for both groups.	Inspiratory muscle strength significantly increased by 29% in the H-IMT, whereas the S-IMT group increased by 8%. Inspiratory muscle endurance increased by 56% in the H-IMT group whereas the S-IMT group remained unchanged. 6-MWT increased by 27 m in the H-IMT group, with no change in the S-IMT group. QOL measures in the dyspnea and mastery domains increased in both groups. The H-IMT group also showed improvements in the domains of fatigue and emotional functioning.	Although the results show an increase of 27 m in the 6-MWT, an increase of 54 m is necessary in order to be clinically significant. Therefore, although there is a significant change in the 6-MWT, this will not necessarily relate to clinical improvement.

6-MWT = 6-Minute Walk Test; CRQ = Chronic Respiratory Questionnaire; EMT = expiratory muscle training; GER = general exercise reconditioning; GXT = Graded Exercise Test; H-IMT = high-intensity inspiratory muscle training; HRQOL = health-related quality of life; IMT = inspiratory muscle training; MIP = maximal inspiratory pressure; MVV = maximal voluntary ventilation; PE_{max} = maximal expiratory pressure; PI_{max} = maximal inspiratory pressure; QOL = quality of life; SEMT = specific expiratory muscle training; SF12 = Short Form 12; SGRQ = St. George's Respiratory Questionnaire; S-IMT = sham inspiratory muscle training; SIMT = specific inspiratory muscle training; SIP_{max} = maximal sustained inspiratory pressure; SWT: 10-Meter Shuttle Walk Test; VE_{max} = maximum minute ventilation; $VO_{2\,max}$ = maximal oxygen uptake; W_{max} = maximum workload.

was less than 54 meters, meaning that the increase may not be of clinical value. Following a meta-analysis, Lotters et al[90] indicate that the ability to affect functional improvement by the use of ventilatory muscle training is yet to be determined. In patients with severe pulmonary disease and documented ventilatory muscle weakness, training improved their ventilatory muscle strength and endurance and decreased dyspnea.[79,94] However, in patients with mild to moderate pulmonary disease, training did not significantly improve ventilatory muscle function. The use of a specific ventilatory muscle training device should be made individually, based on the type of disease, the severity of disease, the presence of inspiratory muscle weakness, and the motivation of the participant.[79]

Exercise Progression

A patient's age, functional ability, symptoms, and severity of disease should be considered before any change in the exercise prescription. Exercise progression is appropriate when the individual perceives the exercise session to be easier (lower RPE or target dyspnea) or when the same exercise workload is performed with a lower HR, that is, as the individual physiologically adapts to exercise.

Exercise progression should first be directed toward increasing the number of continuous minutes of exercise and decreasing the amount of time spent in low-intensity exercise or rest periods. When 20 minutes of continuous activity can be accomplished, an increase in exercise duration or intensity can be proposed. Frequency should be adjusted as necessary, based on duration and intensity.

Program Duration

Improved exercise tolerance can occur in multiple settings: an inpatient rehabilitation hospital program, an outpatient pulmonary rehabilitation program, or a home-based program.[1] Because of the limited length of stay for many inpatient rehabilitation hospital admissions, most increases in functional capacity occur in an outpatient or home pulmonary rehabilitation program. Generally, conditioning exercises are conducted up to three times per week over a course of 6 to 12 weeks.[79] At the end of the rehabilitation program, QOL measurements and dyspnea measurements should be readministered to assess the benefits of pulmonary rehabilitation for each participant. A follow-up 6-MWT or a 10-MSWT should be repeated at the end of the program to assess the change in aerobic conditioning of each participant. Exercise abilities gained in a pulmonary rehabilitation program have been found to gradually decline over 12 to 18 months following completion of the program. Pulmonary rehabilitation programs that last longer than 12 weeks have shown greater sustained benefits than shorter programs.[79]

An unfortunate reality is that patients with pulmonary dysfunction often have decreased exercise ability following an exacerbation of their disease. It is currently not clear that repeated bouts of pulmonary rehabilitation are beneficial to patients with pulmonary disease.[99] Continued support in the form of self-help groups and community exercise groups is essential to maintaining the new level of physical activity obtained with pulmonary rehabilitation.[1]

Home Exercise Programs

A home exercise program (HEP) begins while the participant is enrolled in a pulmonary rehabilitation program. When deemed appropriate (based on exercise response and laboratory data), the participant can be assigned home exercise activities. The patient uses an exercise log to record parameters such as exercise HRs, RPEs, exercise workloads, and any questions that may arise about the HEP (Fig. 12.14). At regular intervals, the therapist analyzes the data and adjusts the HEP as necessary. Progression to an independent HEP is an important rehabilitation goal to promote a participant's lifelong commitment to exercise.

Multispecialty Team

Although aerobic exercise training is integral to pulmonary rehabilitation, patients require additional services and information to optimize their exercise capability and to improve quality of life. The following sections address other elements of a pulmonary rehabilitation program: patient education, secretion removal techniques, and **activity pacing**. Smoking cessation should also be considered as a component of pulmonary rehabilitation. (See the section on smoking cessation in the medical management section of this chapter.)

Patient Education

The concept of self-management is promoted in the individual and group educational sessions of a pulmonary rehabilitation program.[79] Participants are given individual, one-on-one time to identify their own needs and address issues that are particular to themselves. Benefits from group discussions include support from peers regarding the patient's feelings or needs, learning from others' experiences and questions, and the socialization only a group can provide. Key components of a patient's education program are presented in Box 12.5.

Education makes it possible for patients to assume the responsibility for their own wellness. A patient will carry out the required activities to produce the desired outcome only if the patient knows what to do, knows how to do it, and also wants to do it. This theory of self-efficacy for the patient with pulmonary disease begins with a daily routine that includes self-assessment, adherence to a medication schedule, performance of airway clearance techniques, ADL with pacing, and an appropriate HEP.

Self-assessment is used to recognize the first sign of an exacerbation of the disease: increased dyspnea, decreased

exercise tolerance; change in pulmonary flow rates, sputum color or consistency; pedal edema; or any other significant change from baseline. An exacerbation protocol is individually devised that includes a set of standard instructions consistent with the participant's disease and abilities. These instructions may include the use of airway clearance techniques, pacing techniques, or a change in the exercise prescription, as well as contact with the primary care physician for a review of symptoms and pharmacological management.

Managing lung disease can be taught through educational programs that address the needs of individuals with pulmonary disorders. Compared to general education alone, education as part of an individualized comprehensive pulmonary rehabilitation program produced significantly improved exercise abilities, decreased dyspnea, and greater self-efficacy.[100] Once the patient has progressed through pulmonary rehabilitation, access to new information and continued support

is possible through community support groups (e.g., the *Better Breathing Club*, sponsored by the American Lung Association).

Secretion Removal Techniques

Secretion retention can interfere with ventilation and the diffusion of oxygen and carbon dioxide in some patients with pulmonary disease. Patients with secretion retention may improve their exercise performance if proper secretion removal techniques have been performed before the physical activity. The preferred practice pattern from the *Guide to Physical Therapist Practice* for these individuals would be 6C-1: Impaired ventilation, respiration, and aerobic capacity associated with airway clearance dysfunction.[53] An individualized program of secretion removal techniques directed to the areas of involvement can optimize ventilation and therefore gas exchange capabilities. Secretion removal techniques include dependent programs that rely on a caregiver (postural drainage, percussion, and shaking) or independent programs, such as the active cycle of breathing technique (ACBT); positive expiratory pressure (PEP), such as the TheraPEP® PEP Therapy System (Smiths Medical, Dublin, OH); airway oscillation devices, such as the Flutter® (Cardinal Health, Dublin, OH) or the Acapella® (Smiths Medical, Dublin, OH); or high-frequency chest compression (HFCC) devices such as The Vest® System (Hill-Rom, St. Paul, MN).

Manual Secretion Removal Techniques

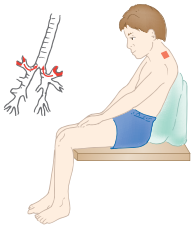
Postural Drainage

Positioning a patient so that the bronchus of the involved lung segment is perpendicular to the ground is the basis for **postural drainage**. Using gravity, these positions assist the mucociliary transport system in removing excessive secretions from the tracheobronchial tree. Standard postural drainage positions are presented in Fig. 12.15. Although these postural drainage positions are optimal for gravity drainage of specific lung segments, such positioning may not be realistic for some patients. Modification of these standard positions may prevent any untoward effects yet still enhance secretion removal. Box 12.6 lists precautions that should be considered before instituting postural drainage with patients with signs and symptoms of increased daily pulmonary secretions. These are not absolute contraindications, but relative precautions. The list is not meant to be inclusive; however, it does provide a range of considerations that should be addressed before instituting postural drainage.

Percussion

Percussion is a force rhythmically applied with the therapist's cupped hands to the patient's chest wall. The percussion technique is applied to a specific area on the thorax that corresponds to an underlying involved lung segment. The technique is typically administered for 3 to 5 minutes over each involved lung segment. Percussion is thought to release the pulmonary secretions from the wall of the airways and into the lumen of the airway. By coupling percussion with the appropriate postural drainage position for a specific lung segment, the probability of secretion removal is enhanced. Because percussion is a force directed to the thorax, there are conditions that would necessitate caution with this technique, such as a fractured rib, a flail chest, osteoporosis, elevated coagulation studies, or a decreased platelet count. These examples are by no means inclusive, but they provide some patient presentations that might require modification (a gentler force applied to the thorax) or elimination of the percussion technique.

Shaking



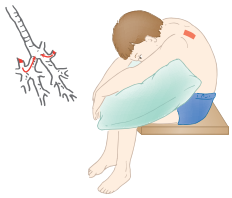
Following a deep inhalation, a bouncing maneuver is applied with the therapist's open hands to the rib cage throughout the expiratory phase of breathing. This **shaking** is applied to a specific area on the thorax that corresponds to the underlying involved lung segment. Five to seven deep breaths with shaking on exhalation are appropriate to hasten the removal of secretions via the mucociliary transport system. Shaking is commonly used following percussion in the appropriate postural drainage position. Because this technique consists of a force applied to the thorax, the same circulatory and musculoskeletal considerations are needed as in the application of percussion.

Airway Clearance

Once the secretions have been mobilized with postural drainage, percussion, and shaking, the task of removing the secretions from the airways is undertaken using an airway clearance technique. Coughing is the most common and easiest means of clearing the airway. However, it should be noted that high intrathoracic pressures, such as those generated during coughing, could force the closing of small airways in some patients with obstructive pulmonary diseases. By trapping air behind the closed airway, the forced expulsion of air during a cough becomes ineffective in clearing secretions. Huffing is an alternative method of airway clearance that is useful for patients with obstructive pulmonary disease. A huff uses many of the same steps of coughing, without creating the high intrathoracic pressures. The patient is asked to take a deep breath and then rapidly contract the abdominal muscles while forcefully saying "HA HA HA." This allows a forced expiration through a stabilized open airway and makes secretion removal more effective.[101]

Active Cycle of Breathing Techniques

ACBT is an independent breathing exercise program the patient can perform to clear secretions from the airways that includes (1) a breathing control phase; (2) thoracic expansion exercises; and (3) a forced expiratory technique. ACBT begins with a few minutes of the breathing

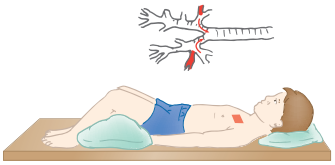


UPPER LOBES Apical Segments

Bed or drainage table flat.

Patient leans back on pillow at 30° angle against therapist.

Therapist claps with markedly cupped hand over area between clavicle and top of scapula on each side.

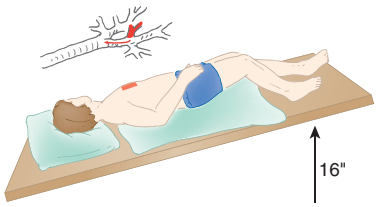


UPPER LOBES Posterior Segments

Bed or drainage table flat.

Patient leans over folded pillow at 30° angle.

Therapist stands behind and claps over upper back on both sides.

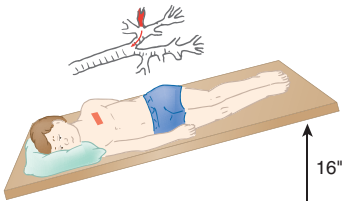


UPPER LOBES Anterior Segments

Bed or drainage table flat.

Patient lies on back with pillow under knees.

Therapist claps between clavicle and nipple on each side.

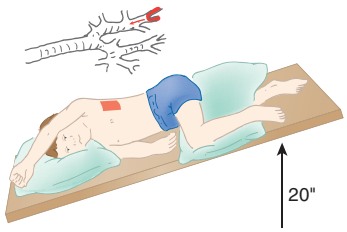


RIGHT MIDDLE LOBE

Foot of table or bed elevated 16 inches.

Patient lies head down on left side and rotates 1/4 turn backward. Pillow may be placed behind from shoulder to hip. Knees should be flexed.

Therapist claps over right nipple area. In females with breast development or tenderness use cupped hand with heel of hand under armpit and fingers extending forward beneath the breast.

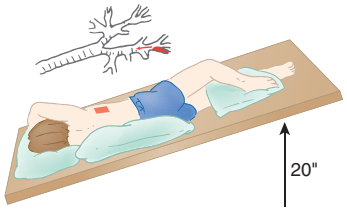


LEFT UPPER LOBE Singular Segments

Foot of table or bed elevated 16 inches.

Patient lies head down on right side and rotates 1/4 turn backward. Pillow may be placed behind from shoulder to hip. Knees should be flexed.

Therapist claps with moderately cupped hand over left nipple area. In females with breast development or tenderness use cupped hand with heel of hand under armpit and fingers extending forward beneath the breast.

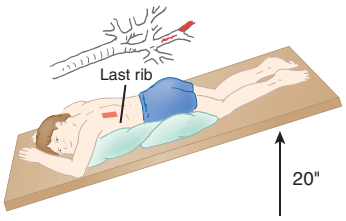


LOWER LOBES Anterior Basal Segments

Foot of table or bed elevated 20 inches.

Patient lies on side, head down, pillow under knees.

Therapist claps with slightly cupped hand over lower ribs. (Position shown is for drainage of left anterior basal segment. To drain the right anterior basal segment, patient should be on the left side in same posture).

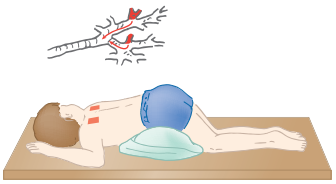


LOWER LOBES Lateral Basal Segments

Foot of table or bed elevated 20 inches.

Patient lies on abdomen, head down, then rotates 1/4 turn upward. Upper leg is flexed over pillow for support.

Therapist claps over uppermost portion of lower ribs. (Position shown is for drainage of right lateral basal segment. To drain the left lateral basal segment, patient should lie on the right side in the same posture).



LOWER LOBES Posterior Basal Segments

Foot of table or bed elevated 20 inches.

Patient lies on abdomen, head down, with pillow under hips.

Therapist claps over lower ribs close to spine on each side.

LOWER LOBES Superior Segments

Bed of table flat.

Patient lies on abdomen with two pillows under hips.

Therapist claps over middle of back at tip of scapula on either side of spine.

Figure 12.15 Positions used for postural drainage. *(From Rothstein, J, Roy, S, and Wolf, S: The Rehabilitation Specialist's Handbook, ed 3. FA Davis, Philadelphia, 2005, p 444, with permission.)*

control phase, defined as relaxed, diaphragmatic, tidal volume breathing. Three to four thoracic expansion exercises, defined as deep inhalations with a 3-second hold followed by a passive exhalation, are performed next. A return to the breathing control phase follows. Depending on the patient's needs, this breathing control phase can last for seconds to minutes. If the patient feels that there are secretions ready to be moved upward, then the forced expiratory technique completes the cycle. If secretions are not ready to be moved, the patient returns to thoracic expansion exercises followed by another period of breathing control for rest and for the patient to assess the status of secretions is their airways. The forced expiratory technique, defined as one or two huffs from tidal volume down to low lung volumes, is used to move secretions higher into the larger airways. The forced expiratory technique is followed by a rest period of breathing control. Using ACBT, secretions are "milked" from smaller to larger airways. Once the secretions have moved into the larger airways, huffs from mid or high lung volumes remove the secretions from the airways. This independent technique has been demonstrated to

Box 12.6 Precautions for Postural Drainage

Precautions for the use of the supine, head lower than feet (Trendelenburg) position:

- Circulatory: Congestive heart failure, hypertension
- Pulmonary: Pulmonary edema, shortness of breath made worse with lowered head position
- Abdominal: Obesity, abdominal distention, hiatal hernia, nausea, recent food consumption, or any patient-specific precautions

Precautions for the use of the side-lying position:

- Vascular: Axillofemoral bypass graft
- Musculoskeletal: Arthritis, recent rib fracture, shoulder bursitis, tendonitis, or any patient-specific precautions

be as effective as postural drainage, percussion, and shaking.[102] Figure 12.16 emphasizes that the patient begins at breathing control and always returns to breathing control for rest and the patient's own assessment of his or her status before moving to either thoracic expansion with breath hold or the forced expiratory technique.

Oral Airway Oscillation Devices

Airway oscillation devices, such as the Flutter® or the Acapella® (Fig. 12.17), alter the exhaled airflow throughout the airways. The patient inhales a normal size breath. During active exhalation through the device, the exhaled air causes an intermittent backward air pressure that jars the airways. The usual procedure is to exhale 10 or so breaths through the device, followed by two large exhaled volumes through the device and finally a huff or cough to clear mobilized secretions. This routine is repeated until secretions are cleared from the lungs. An airway oscillation device has been shown to help in the removal of secretions from airways.[103,104]

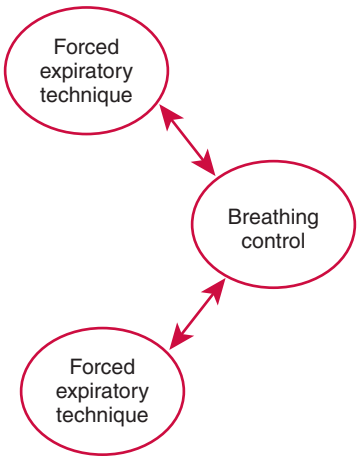


Figure 12.16 Active cycle of breathing begins with breathing control. All choices are made from the breathing control phase. After each choice is made, thoracic expansion or forced expiratory technique, the patient returns to breathing control to rest and make the next choice.

Figure 12.17 The Acapella® device used for an independent program of secretion removal. *(Courtesy of Smith Medical, Dublin OH, 43017.)*

Positive Expiratory Pressure

PEP devices include a valve to regulate expiratory resistance (Fig. 12.18). Inhalation of a normal size breath through the mask or mouthpiece is unresisted. Active exhalation is against a positive expiratory pressure, measuring 10 to 20 cm H_2O. A treatment session lasts approximately 10 to 20 minutes with frequent pauses to remove the mask so that the patient can huff to clear secretions. The session is completed when all secretions have been cleared from the airways. PEP has been shown to be as effective as postural drainage, percussion, and shaking.[105,106]

High-Frequency Chest Compression Devices

HFCC devices use an inflatable vest with air channels that is worn over the patient's thorax (Fig. 12.19). The vest is attached to an air compressor that rapidly delivers small air volumes in and out of the vest. The inflation of the vest causes compression to the chest wall and the deflation allows the chest wall to recoil back to its resting position. The patient assumes a comfortable seated position for treatments lasting between 20 and 30 minutes. Secretions may be huffed clear any time throughout the

Figure 12.18 The PEP system for an independent program of secretion removal. *(Courtesy of Smith Medical, Dublin OH, 43017.)*

treatment. High-frequency chest wall compression has been shown to be as effective as other secretion removal techniques.[107]

Breathing Exercises

Pursed-lip breathing involves an unresisted inspiration followed by an active oral exhalation through a narrowed (or pursed) mouth opening. When pursed-lip breathing is used by patients with COPD, it may delay or prevent airway collapse, allowing for better gas exchange.[108,109] Most patients demonstrate this strategy during periods of dyspnea and rarely need to be taught the technique.

Although diaphragmatic breathing has been taught to patients with chronic pulmonary dysfunction for years, there is little evidence to support its use to improve pulmonary mechanics.[109] Some patients require the use of accessory muscles with exercise, with exacerbation of their disease, or with periods of dyspnea. Strengthening accessory muscles of ventilation may be a more effective treatment program than encouraging the use of an ineffective diaphragm with little ability to generate muscle force and/or limited muscle excursion. In patients with very flat diaphragms, focusing on diaphragmatic breathing may even be detrimental.

Activity Pacing

Activity pacing refers to the performance of any activity within the limits or boundaries of that patient's breathing capacity. For example, an activity that usually causes dyspnea needs to be broken down into component parts such that each component can be performed at a rate that does not exceed breathing abilities. By breaking activities down into component parts and interspersing rest periods between each component, the total activity can be completed without dyspnea or undo fatigue. For example, patients often find that climbing stairs causes a great deal of dyspnea and discomfort. Rather than climbing the entire flight of stairs (usually done too fast and with a breath hold), the patient might be instructed as follows: *"Take a deep breath. Now, on exhalation, walk up one (or two or three) stair(s). Now recover. Take in another good breath and walk up the next one (or two or three) stair(s) and recover. Repeat this technique until the flight of stairs is completed."* The patient is able to reach the top of the stairs without becoming dyspneic and without undue fatigue. Pacing can and should be part of every activity that would otherwise cause dyspnea. Pacing should be used when performing ADL, ambulation, stair climbing, and other daily tasks. Pacing is not a technique to be used during the aerobic portion of a pulmonary rehabilitation program. During exercise, some shortness of breath is expected to occur.

SUMMARY

Pulmonary rehabilitation programs are a well-established treatment for patients with chronic pulmonary disease. Components of these programs typically include exercise training, strength training, education, secretion removal instruction, and psychosocial support. Outcomes of pulmonary rehabilitation may include increased aerobic capacity, increased skeletal muscle strength, reduced dyspnea both during exercise and ADL, and an increase in the perception of health-related quality of life. Gains made in pulmonary rehabilitation programs can make the difference between a lifestyle of dependence and one of independence. Physical therapists have the important role of evaluating patients, determining their potential, and, through exercise prescription and exercise programs, ensuring that rehabilitation goals and outcomes are realized.

Questions for Review

1. How does the clinical presentation of obstructive lung disease differ from the clinical presentation of restrictive lung disease?
2. Explain how altered airway structure leads to airflow limitation.
3. (a) What would be the expected breath sounds of a patient with COPD (describe intensity and adventitious sounds)? (b) What would be the expected breath sounds of a patient with asthma during an exacerbation (describe intensity and adventitious sounds)?
4. Identify the tests and measures required to determine the extent of pulmonary disease.

5. What are the pulmonary end points to a symptom-limited graded exercise test?
6. How does exercise prescription differ for a patient with mild pulmonary disease as compared to the patient with severe pulmonary disease?
7. (a) How do you know when to progress a patient's exercise program? (b) What is the nature of that progression? (c) Do you need a new ETT to progress a patient's exercise workload?
8. How would you respond to a patient's comment that it would take longer to climb stairs with pacing than without?
9. Design a secretion removal treatment plan for a patient with CF that can be carried out independently before coming to pulmonary rehabilitation.
10. What evidence is presented in the current literature regarding the benefits of pulmonary rehabilitation?

CASE STUDY: PATIENT WITH COPD

A 67-year-old white female was admitted to the hospital with a diagnosis of acute bacterial pneumonia. She was treated with mechanical ventilation for 5 days, steroids, antibiotics, and bronchodilators. After the acute care hospital stay of 7 days, the patient was transferred to an inpatient rehabilitation facility for 7 days. She is now referred to outpatient pulmonary rehabilitation.

PAST MEDICAL HISTORY

COPD, pneumonia four times over the past 2 years, s/p lumpectomy of right breast 8 years ago, smoking history of 45 pack/years; quit on day of admission to hospital for acute bacterial pneumonia.

MEDICATIONS

2 L/min of pulsed oxygen, Atrovent (maintenance, anticholinergic) 4 puffs qid, albuterol (rescue, beta-2 adrenergic) 2 puffs PRN, prednisone (maintenance, anti-inflammatory) 5 mg/day.

OCCUPATION

Secretary, works 32 hours/week. Presently on medical leave.

SOCIAL AND ENVIRONMENTAL

Lives with husband in own home. Three steps to enter home, 12 stairs within the home.

OBJECTIVE FINDINGS

Interview

Mental status: awake, alert, talks in three- to four-word sentences. Adequate historian. Chief complaint: shortness of breath limiting function. Patient is able to walk 150 ft before needing to rest to catch her breath. No complaints of increased secretions. Baseline dyspnea index: functional impairment, grade 1; magnitude of task, grade 1; magnitude of effort, grade 1 (see Table 12.6). Patient reports an RPE of 6 (the Borg 0–10 Scale) with one flight of stairs. Patient is dependent in shopping, house cleaning, and laundry. St. George's Respiratory Questionnaire was administered with a score of 54. Patient's desired functional outcome is to be oxygen free and able to care for grandchildren without shortness of breath.

Vital Signs

HR 72, BP 96/74, S_aO_2 at rest 86% on room air, 98% on 2 L/min pulsed O_2 on 1 pulse/breath, respiratory rate 32, temperature 98.5°F.

Observation, Inspection, Palpation

Thin, frail-looking female wearing nasal cannula; kyphosis noted. Patient uses posture of forward sitting with arms supported on chair arms to enhance ventilatory accessory muscle use. Increased AP diameter of thorax, accessory muscle use at rest; labored, symmetrical breathing pattern with pursed-lip breathing. No venous distention, no edema, no cyanosis, minimal clubbing evident.

Auscultation

Decreased breath sounds throughout both lung fields, especially at bases. End expiratory wheezes at left lateral base.

Strength

Bilateral LE manual muscle testing: hip flexion 3+/5, knee extension 3+/5, plantarflexion 3+/5, dorsiflexion, 4/5. Bilateral shoulder elevation, abduction, elbow flexion, wrist flexion and extension, 3+/5. Patient unable to lie prone or supine for further testing secondary to orthopnea. Alternative positions were used to assess the strength of other muscles: all other muscle groups able to move against gravity and able to accept moderate resistance. Maximal inspiratory effort (PI_{max}) 52 mm Hg; SIP_{max} 26 mm Hg.

Exercise Test Data

Patient performed a 7-minute, staged (3 min/stage) treadmill exercise test using a modified protocol. Treadmill speed was held constant at 2 mph, grade increased from 0% (stage 1) to 2% (stage 2) to 3% (stage 3). ECG was within normal limits. HR_{rest} was 84 beats/min, HR_{peak} 121 beats/min. On 2 L pulsed O_2, S_aO_2 resting 98%, 93% at max exercise, 90% during the first minute of cool-down, returned to baseline within 4 minutes of recovery. Rate of perceived exertion at peak exercise was 7 (1–10 scale). Rate of perceived dyspnea at peak exercise was a 9. Exercise was terminated due to patient complaint of shortness of breath. Single-breath TV measurement just before ending test was .99 liters with a respiratory rate of 36 breaths/min. There was no change in pulmonary function tests after exercise. 6-Minute Walk Test: 200 m on 2 liters pulsed O_2.

Laboratory Test Data (after bronchodilator)

Pulmonary Function Test	Results
FEV_1	1.107 L/sec (45% of predicted)
FVC	1.78 L (64% of predicted)
FEV_1/FVC	62%
MIP	36 mm Hg (60% of predicted)

GUIDING QUESTIONS

1. In what stage of GOLD does this patient present?
2. Did the pulmonary system or cardiovascular system stop her exercise test?
3. Identify this patient's impairments, functional limitations, and disability restrictions. Identify general anticipated treatment goals and expected outcomes for a 3-month (12-week) pulmonary rehabilitation program. Identify outcome measures that will be used to assess the effectiveness of a pulmonary rehabilitation program.
4. Formulate a physical therapy plan of care for week 1. Patient will be seen 3 times/week for this first week of therapy. Briefly describe exercise progression for the first month of the program.

Chapter 13

LEARNING OBJECTIVES

1. Describe the etiology, pathophysiology, symptomatology, and sequelae of coronary heart disease.
2. Describe the etiology, pathophysiology, symptomatology, and sequelae of congestive heart failure.
3. Identify and describe the examination procedures used to evaluate patients with heart disease and establish a diagnosis and plan of care.
4. Describe the role of the physical therapist in assisting the patient in recovery from heart disease in terms of interventions, patient-related instruction, coordination, communication, and documentation.
5. Identify and describe strategies of intervention during various phases of cardiac rehabilitation.
6. Analyze and interpret patient data, formulate realistic anticipated goals and expected outcomes, and develop a plan of care when presented with a clinical case study.

SUMMARY *571*

INTRODUCTION AND EPIDEMIOLOGY OF HEART DISEASE

Cardiovascular disease (CVD) is a term referring to the pathological process of atherosclerosis affecting the entire arterial circulation. **Coronary artery disease** (CAD), also called **coronary heart disease** (CHD), refers to the pathological process of atherosclerosis, specifically affecting the coronary arteries. CAD includes the diagnoses of angina pectoris, **myocardial infarction** (MI), silent myocardial ischemia, and sudden cardiac death.

The pathophysiological conditions that underlie CVD are atherosclerosis, altered myocardial muscle mechanics, valvular dysfunction, **arrhythmias**, and **hypertension** (HTN). **Atherosclerosis** is a disease in which lipid-laden plaque (lesions) is formed within the intimal layer of the blood vessel wall of moderate and large size arteries; over time the plaque may extend into the lumen causing a decreased lumenal diameter. Atherosclerosis is also a primary contributor to cerebrovascular disease (cerebrovascular accident [CVA]) and peripheral vascular disease (PVD).

Alteration in myocardial muscle mechanics involving the systolic and/or diastolic properties of the myocardium

results in an impairment of left ventricular (LV) function. **Heart failure** is a clinical diagnosis caused by impaired LV functioning and is referred to as **congestive heart failure** (CHF) when it is accompanied by signs and symptoms of edema (i.e., congestion). There are many causes of heart failure, including myocardial scarring and remodeling as a result of an MI, cardiomyopathy (involving an enlarged, thickened, and/or hardened heart muscle) from various causes, or impaired valvular function, especially within the mitral and aortic valves.

Arrhythmias are caused by a disturbance in the electrical activity of the heart, resulting in impaired electrical impulse formation or conduction. Arrhythmias may present as benign or malignant (i.e., life threatening). Examples of malignant arrhythmias are sustained ventricular tachycardia (V-tach) and ventricular fibrillation (V-fib). An example of a common benign arrhythmia in the elderly is atrial fibrillation (A-fib) with a controlled ventricular response involving a ventricular rate between 60 and 100 beats per minute (bpm).

HTN is the most prevalent CVD in the United States and one of the most powerful contributors to cardiovascular morbidity and mortality. HTN occurs when the systolic blood pressure is consistently greater than 140 mm Hg or the DBP is equal to or greater than 90 mm Hg.

CVD remains the leading cause of death and disability in the United States. According to the American Heart Association's Heart Disease and Stroke Statistics 2011 Update, an estimated 82,600,000 American adults (more than 1 in 3) have one or more types of CVD.[1] Currently, HTN occurs in 76,400,000 individuals, CHD affects 16,300,000, and heart failure is seen in 5,700,000 patients.[1] The average annual rates of first cardiovascular events rise from 3 per 1,000 men at age 35 to 44 years to 74 per 1,000 at age 85 to 94. For women, comparable rates occur 10 years later in life with a narrowing gap with advancing age.[1] On average, 2,200 Americans die of CVD each day with an average of 1 death every 39 seconds.[2] In every year since 1900 except 1918, CVD accounted for more deaths than any other major cause in the United States.[3]

It is also important to note that the United States is in the midst of a demographic shift with a remarkable increase in the diversity of the American population. By 2050, there will be a decrease in the white non-Hispanic population to 52.5% from 75.7% in 1990.[4] The Hispanic population will increase to 22.5%, a change in African Americans to 15.7%, and Asian and Pacific Islanders will account for 10.3% of the population.[4] These statistics will have a major impact on the epidemiology, pathophysiology, and treatment of CVD in the forthcoming years. Thus, within the United States and worldwide, we are faced with major challenges as CVD dominates as a major cause of death and disease. This chapter provides a review of normal anatomy and physiology of the cardiovascular system and its relevance to physical therapist practice followed by a discussion of various pathologies and pertinent physical therapy implications.

CARDIAC ANATOMY AND PHYSIOLOGY

Surface Anatomy

The heart lies within the left thoracic cavity. The base of the heart is located superiorly, approximately between the second and third rib; the apex is located inferiorly, approximately at the level of the fifth rib (Fig. 13.1). In this position, the heart is rotated in the sagittal plane so that the right ventricle (RV) is positioned anterior to the left ventricle (LV) and tipped anteriorly, bringing the apex closer to the chest wall. In the posterior–anterior view of a chest x-ray, the RV occupies a significant portion of the frontal plane. The right atrium (RA) is generally located in the area of the second intercostal spaces and the *angle of Louis.* When one palpates the sternum, the angle of Louis is the "bump" that demarcates the manubrium from the body of the sternum. The second

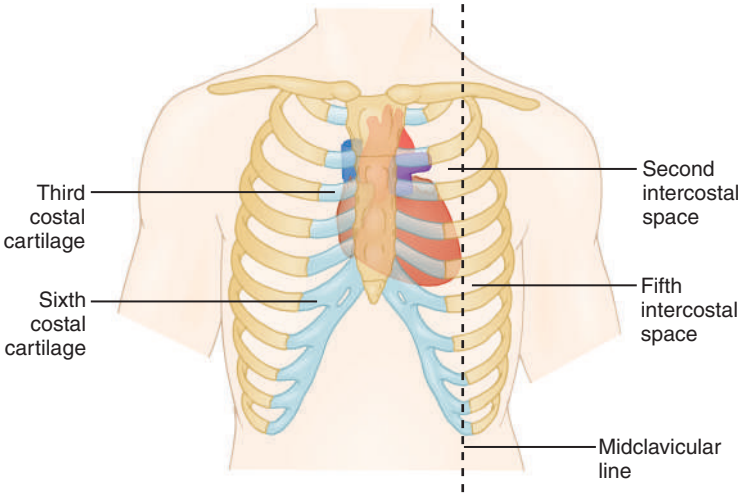

Figure 13.1 Surface anatomy of the heart.

intercostal spaces are lateral and slightly below the angle of Louis. The second intercostal spaces are an important auscultatory landmark; the right space is known as the *aortic area*, the left as the *pulmonic area*. The apex of the normal heart is in the fifth intercostal space at the midclavicular line. In a healthy heart, this area, known as the *point of maximal impulse (PMI),* is where the contraction of the LV is most pronounced.

Heart Tissue

The heart wall is made up of three tissue layers (Fig. 13.2). The outermost layer of the heart is a double-walled sac termed the *pericardium*. The two layers of the pericardium include an outer tough fibrous layer of dense irregular connective tissue termed the *parietal pericardium* and an inner thin *visceral pericardium.*[5] Between these two layers is a closed space filled with pericardial fluid, which serves as a lubricant allowing the two surfaces to slide past one another. Clinically, patients may develop an infection with resultant inflammation of the pericardium termed *pericarditis*. The clinical signs that accompany this pathology and used to differentially diagnose pericarditis include a *pericardial friction rub* (an audible grating sound suggesting irritation of the pericardium) that can be auscultated with each heartbeat accompanied by constant chest pain.[6] In some patients excessive fluid accumulation within the closed pericardial space may lead to a secondary condition known as *cardiac tamponade*. Tamponade involves compression of the heart caused by fluid buildup in the space between the myocardium and pericardium. In this state, patients will demonstrate compromised cardiac function and contractility due to the excess fluid within the closed space pushing against the heart.[7,8]

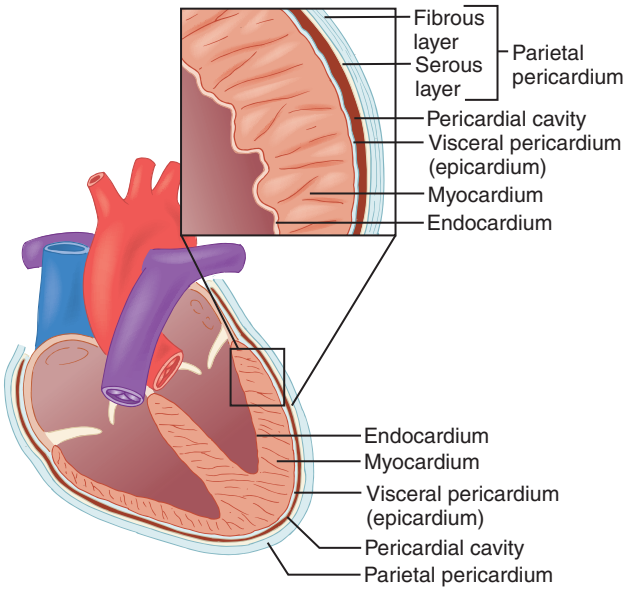

Figure 13.2 Layers of the heart.

The muscular middle layer of the heart is termed the *myocardium*. It is the layer that facilitates the pumping action of the heart to move blood to the entire body. Alterations in the muscular wall of the heart are termed **cardiomyopathies**. There are three common classifications of cardiomyopathies: *dilated, hypertrophic,* and *restrictive*.[9] Dilated cardiomyopathy is evidenced by ventricular dilation and altered cardiac muscle contractile function. CAD is the prime cause of *dilated cardiomyopathy,* causing mitochondrial dysfunction and resultant myocardial damage. Myocarditis (inflammation of the heart muscle) and alcohol abuse are additional causes of dilated cardiomyopathy. *Hypertrophic cardiomyopathy* presents as diastolic dysfunction with an increased ventricular mass. Chronic HTN and aortic stenosis are examples of hypertrophic cardiomyopathy. *Restrictive cardiomyopathy* also presents as diastolic dysfunction owing to the presence of excessively rigid ventricular walls, resulting in a decrease in compliance. The connective tissue changes of the heart associated with diabetes are an example of a restrictive cardiomyopathy. Damage to myocardial cells from cardiomyopathies and various other etiologies lead to cardiac muscle dysfunction and resultant heart failure, which will be comprehensively discussed later in this chapter.

The innermost layer of the heart is termed the *endocardium*. The tissue of the endocardium forms the inner lining of the chambers of the heart and is continuous with the tissue of the valves and the endothelium of the blood vessel. Because the endocardium and valves share similar tissue, patients with infections of the endocardium are at risk for developing valvular dysfunction. Endocardial infections can spread into valvular tissue developing vegetations (a mixture of bacteria and blood clots) on the valve.[9] In patients with newly developed vegetations, bronchopulmonary hygiene procedures including percussions and vibrations are contraindicated because they may dislodge, move as emboli, and cause an embolic stroke.[9]

Coronary Arteries

The coronary arteries originate in the sinus of Valsalva located in the wall of the aorta near the aortic valve.[5] The right coronary originates from the area near the right aortic leaflet, the left coronary from the area near the left aortic leaflet. When the aortic valve is open during systole, the origins of the coronary arteries are located behind the aortic leaflets within the wall; when the aortic valve is closed during diastole, the openings of the coronaries are clearly exposed, allowing them to be easily perfused.[5] The coronary arteries therefore receive the majority of their blood flow during diastole, unlike the other arteries of the body that are perfused during systole. The left coronary artery begins as the left main (LM) and then branches into the left anterior descending (LAD) and the circumflex (CX) (Fig. 13.3). The LAD may have further divisions, known as diagonal branches,

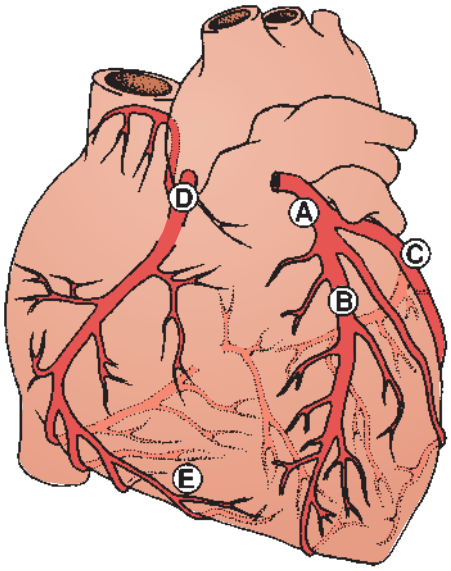

Figure 13.3 Coronary circulation. **(A)** left main (LM); **(B)** left anterior descending (LAD); **(C)** left circumflex (CX); **(D)** right coronary (RCA); **(E)** posterior descending (PDA). The branches of the LAD are known as diagonals; the branches of the CX are known as marginals.

that come off of the primary LAD. The LAD and its diagonal branches primarily supply the anterior and apical surfaces of the LV, as well as portions of the interventricular septum. The circumflex may also have branches, known as marginal branches. The circumflex and its marginal branches supply the lateral and part of the inferior surfaces of the LV and portions of the left atrium (LA). The right coronary artery (RCA) supplies the RA, most of the RV, part of the inferior wall of the LV, portions of the interventricular septum, and the conduction system. The posterior descending artery (PDA) is most commonly a branch of the RCA and perfuses the posterior heart. If the RCA does not perfuse the posterior heart, the CX will supply this area. When the PDA comes from the RCA, the anatomy is referred to as being right dominant; if the PDA comes from the circumflex, the anatomy is referred to as being left dominant. For physical therapists, there is no clinical importance to whether the anatomy of the myocardium is either left or right dominant.

The inner diameter (i.e., the opening) of the arteries through which the blood flows is the *lumen*. The size of the lumen is critical for adequate blood flow. A significant narrowing of the lumen, such as that which occurs with a fixed atherosclerotic lesion of CAD, will decrease the available blood supply to the myocardium. Lumen size may also be altered by the smooth muscle within the walls of the arteries, because smooth muscle regulates vasomotor tone of the coronary arteries. Vasodilation will increase lumen diameter as a result of relaxation of smooth muscle, and vasoconstriction will decrease lumenal diameter as a result of smooth muscle contraction. The responsiveness of arterial smooth muscle is also influenced by the integrity of the endothelium, the lining of the coronary artery that is in direct contact with the lumen. The endothelium has a number of normal functions and "plays the central role in controlling the biology of the vessel wall."[10, p. 1,265] Some of these important functions are anti-inflammatory actions, antithrombotic activity, and its influence on vasodilation. Endothelial cells release *endothelial-derived relaxing factor (EDRF),* which facilitates vascular smooth muscle relaxation. Nitric oxide (NO) is the most prevalent EDRF. An injury to endothelium can result in impaired NO release and a decrease in vasodilation.[11] NO release is influenced by many factors, including acetylcholine, norepinephrine, serotonin, adenosine diphosphate, bradykinin, and histamine.[11]

The etiology of the clinical condition known as coronary spasm, in which smooth muscle contraction within the walls of the artery results in narrowing of the coronary artery, is not clearly understood. Coronary spasm occurs in arteries that have endothelial injury (e.g., atherosclerosis), as well as in those arteries that appear to be normal but exhibit hyperreactivity to a variety of vasoconstrictor stimuli, such as serotonin and ergonovine, and loss of EDRF.[12]

Heart Valves

Four heart valves ensure one-way blood flow through the heart. Two atrioventricular valves are located between the atria and ventricle. The atrioventricular valve, positioned between the RA and RV, is termed the *tricuspid valve*; the left atrioventricular valve is the *mitral valve* (also known as the bicuspid valve), located between the left atrium and ventricle. The *semilunar valves* lie between the ventricles and arteries and are named based on their corresponding vessels (i.e., *pulmonic valve* on the right in association with the pulmonary artery, and aortic valve on the left relating to the aorta).

Flaps of tissue called *leaflets or cusps* guard the heart valve openings. The right atrioventricular valve has three cusps and is therefore termed *tricuspid,* whereas the left atrioventricular valve has only two cusps and hence is termed *bicuspid.* These leaflets are attached to the papillary muscles of the myocardium by chordae tendineae. The primary function of the atrioventricular valves is to prevent backflow of blood into the atria during ventricular contraction or systole, while the semilunar valves prevent backflow of blood from the aorta and pulmonary artery into the ventricles during diastole. Opening and closing of each valve depends on pressure gradient changes within the heart created during each cardiac cycle.

Cardiac Cycle

The cardiac cycle consists of two interrelated phases: *systole*, the contraction phase, and *diastole*, the filling phase. During diastole, the ventricles fill with blood from the atria via open atrioventricular valves. The

atrioventricular valves lie between the atria and the ventricles and include the tricuspid valve on the right and mitral valve on the left. The first two-thirds of ventricular filling is passive; during the last one-third the atria contract and push the blood into the ventricles. This contraction is known as the *atrial kick*. After the atrial kick, diastole ends and the atrioventricular valves close. Systole begins with both the atrioventricular and semilunar valves closed. An initial *isovolumetric contraction,* similar to an isometric contraction of striated muscle, increases the pressure within the ventricles, and the semilunar valve opens. The LV then undergoes a concentric contraction, causing a volume to be ejected, termed the *stroke volume* (SV). After the SV is ejected, the aortic valve closes and systole is complete. The cardiac cycle is defined by the presence of normal heart sounds, S_1 and S_2. Heart sounds are associated with valvular closings; S_1 is associated with atrioventricular valve closure, and S_2 is associated with semilunar valve closure. Systole occurs between S_1 and S_2, and diastole occurs between S_2 and S_1 (Fig. 13.4).

Blood Flow and Hemodynamic Values

Blood enters the heart via the superior and inferior vena cava into the RA. Blood moves forward from the RA through the tricuspid valve to the RV, and through the pulmonic valve to the pulmonary artery (PA) and pulmonary capillaries. The capillaries perfuse the alveoli, and the alveolar capillary membrane is the site of gas exchange. Newly oxygenated blood within the pulmonary veins (PVs) travels to the left atrium (LA) and passes through the mitral valve into the LV. Blood within the LV travels down to the apex, where it is squeezed in a wringing motion during systole and moved from the apex to the LV outflow tract and finally out through the aortic valve to the aorta.

Blood volume in any chamber or vessel generates a pressure. The normal pressure recordings for the cardiovascular system are presented in Table 13.1. Owing to the relationship between blood volumes and pressures, a direct measure of blood volumes within the heart is accomplished by invasive monitoring of the intravascular

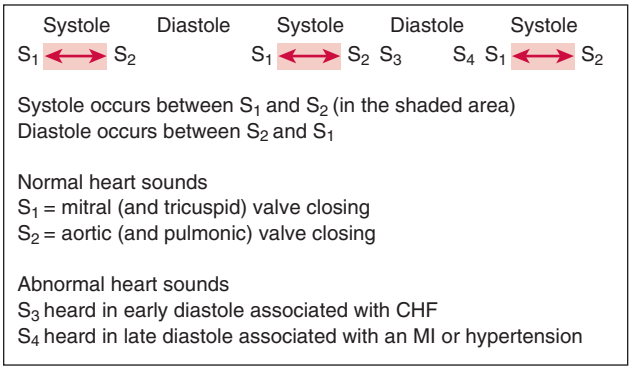

Figure 13.4 Heart sounds of the cardiac cycle.

Table 13.1 Hemodynamic Variables

Right-Sided Heart Catheterization	Normal Ranges
Central venous pressure (CVP)	0–8 mm Hg
Right atrial (mean)	0–8 mm Hg
Pulmonary artery (PA)	Systolic 20–25 mm Hg Diastolic 6–12 mm Hg Mean 9–19 mm Hg
Pulmonary capillary wedge pressure (PCWP)	6–12 mm Hg
Left-Sided Heart Catheterization	**Normal Ranges**
Left ventricular end-diastolic pressure	5–12 mm Hg
Left ventricular peak systolic pressure	90–140 mm Hg
Systemic arterial pressure	Systolic 110–120 mm Hg Diastolic 70–80 mm Hg Mean 82–102 mm Hg
Cardiac output (CO)	4–5 L/min
Cardiac index (CO ÷ body surface area)	2.5–3.5 L/min
Stroke volume	55–100 mL/beat
Systemic vascular resistance	800–1200 dynes/sec/cm^{-5}

Adapted from Braunwald, E, Zipes, D, and Libby, R (eds): Heart Disease: A Textbook of Cardiovascular Medicine, ed 6. Saunders, Philadelphia 1997, p 188; and Parrillo, JE: Current Therapy in Critical Care Medicine. BC Decker Inc., 1987, p 36.

or chamber pressures. In a *right-sided heart catheterization,* an invasive catheter known as a Swan-Ganz catheter or PA catheter, with pressure-sensitive recording ability, is inserted into the internal jugular or subclavian vein and progressed antegrade through the right side of the heart. Common measurements taken with a right-sided heart catheterization are RA pressure, PA pressure, and *pulmonary capillary wedge pressure (PCWP).* The PCWP is an indirect measure of the *left ventricular end-diastolic pressure (LVEDP)*, one of the most sensitive measures of LV function. An advantage of right-sided heart catheterization is the ability to monitor filling pressures not only on the right side, but also left-side heart pressures, by estimation, without the need for the more difficult and risky LV catheterization. Invasive monitoring through left-sided heart catheterization is accomplished by placing a catheter into the femoral or radial artery and advancing it retrograde to the flow of blood through the aorta, across the aortic valve, and into the LV where LVEDP can be directly monitored. The LV catheter lies within a high-pressure system (the left side of the heart and the

aorta), and therefore can stay in place for only a short period of time (e.g., 1 hour) because of the difficulties associated with cannulation (catheter insertion) of a high-pressure system. In contrast, the right-sided heart catheter, which lies within a relatively low-pressure system (the right side of the heart), provides continuous monitoring of pressures and can be kept in place for several days.

Neurohormonal Influences on the Cardiovascular System

The autonomic nervous system (ANS) influences the heart and blood vessels through direct neural and indirect neurohormonal mechanisms. The heart has dual direct innervation from the sympathetic and parasympathetic nervous systems.[13] The sympathetic receptors of the heart are primarily beta-adrenergic receptors[14] and are located on the sinus node and within the myocardium. Stimulation of the receptors by the neurotransmitter norepinephrine (noradrenaline) increases the overall activity of the heart by increasing the heart rate (HR) (*chronotropy*) and force of contraction (*inotropy*), and also results in coronary artery dilation.[13] Sympathetic stimulation of the alpha-adrenergic receptors on peripheral blood vessels causes vasoconstriction and an increase in *peripheral vascular resistance (PVR).*

The sympathetic nervous system may also stimulate the adrenal cortex to secrete the catecholamine epinephrine. This blood-borne hormone has sympathetic effects that at times may even be more long lasting and potent than direct sympathetic activation. Epinephrine is released as part of the normal exercise response, especially when exercise is continued beyond a few minutes. The increase in HR and contractility noted with exercise is in part due to this hormonal influence. Many cardiovascular drugs either enhance or suppress sympathetic functioning. Those that mimic the action of the sympathetic nervous system are known as *sympathomimetics;* those that suppress sympathetic functioning are known as *sympatholytics.* Frequently used sympathomimetics are dopamine, epinephrine, and atropine, which are commonly used in critical care settings. Dopamine and epinephrine increase cardiac output (CO), and atropine increases HR in the presence of critical *bradycardia.* Frequently used sympatholytics are the category of drugs known as beta-blockers (beta-adrenergic antagonists) that suppress beta-adrenergic activity. They are commonly used as part of an antiischemic drug regimen and for the medical management of HTN.

The normal parasympathetic influence via the vagus nerve has a primary impact on the resting heart, influencing resting HR substantially more than the sympathetic nervous system. Parasympathetic stimulation results in a depression of HR, decreased force of atrial contraction, and decreased speed of conduction through the atrioventricular (AV) node. Vagal fiber innervation to ventricular myocardium is relatively small; therefore the effect on LV function is minimal.[14] During exercise, the effects of the sympathetic nervous system and catecholamine release significantly override any effect from the parasympathetic system. The impact of direct parasympathetic influence on peripheral blood vessels is limited to a vasodilatory effect on the bowel, bladder, and genitals.[14]

The catecholamine role in myocardial functioning during exercise is especially crucial for the patient who has lost direct sympathetic activation to the heart. For a patient who has undergone a heart transplant, the heart is essentially denervated; the sympathetic and parasympathetic fibers to the heart are excised. Sympathetic influence on the denervated heart is therefore solely dependent on catecholamine stimulation of the beta-adrenergic myocardial receptors to increase HR and contractility. Clinically, the patient with a denervated heart following transplantation will present with elevated resting HRs to achieve normal cardiac output, delayed elevation in HRs with exercise due to circulating catecholamines, decreased maximum HR responses, and slower decreases in HR values during the recovery phase of exercise.[15]

Cardiac Output

The goal of the heart is to provide adequate CO to generate aerobic energy to meet the metabolic demands of the body. Because the energy demands of the body are constantly changing, the heart's CO must also be able to adapt to the changing systemic energy demands, as well as to its own myocardial oxygen needs. CO is defined as the amount of blood that leaves the ventricles per minute, expressed in L/min. Normal CO at rest is approximately 4 to 6 L/min. It is influenced by HR (expressed as beats per minute [bpm]) and stroke volume (expressed as milliliters per minute [mL/min]).

Stroke volume (SV) is the volume of blood ejected with each myocardial contraction and is influenced by three factors: (1) *preload,* the amount of blood in the ventricle at the end of diastole (also known as *left ventricular-end diastolic volume [LVEDV]*); (2) *contractility,* the ability of the ventricle to contract; and (3) *afterload,* the force the LV must generate during systole to overcome aortic pressure and open the aortic valve.[8] Afterload may also be described as the "load . . . against which the LV contracts during left ventricular ejection."[16]

Throughout the cardiac cycle, diastole and systole place different demands on the ventricles. During diastole, the ventricles must be compliant, able to stretch to accommodate the blood entering the ventricles (preload). During systole, the ventricles must be able to contract adequately to eject the SV. The principle of Starling's length–tension relationship is applicable to the myocardium and the relationship between the properties of diastole and systole. During diastole as muscle length increases (e.g., the ventricular chamber

size increases) the ability of the myocardium to develop force is increased, up to a point. Beyond a certain length, however, force development is impaired owing to the inadequate alignment of the actin and myosin filaments (Fig. 13.5).

In general, SV will increase with an increase in preload or contractility and will decrease with an increase in afterload. Normally about 55% to 75% of the preload is ejected as the SV. The *ejection fraction* (EF) demonstrates this relationship between SV and LVEDV such that EF = SV ÷ LVEDV. This value represents the ratio of the volume of blood ejected by the LV per contraction relative to the volume of blood received by the LV following diastole. Normal EF is approximately 55% to 75% (67% ± 8%) and is widely used clinically as an index of contractility.[17]

Clinically, especially in critical care settings, the concept of **cardiac index (CI)** is often preferred to CO. CI expresses the CO in relationship to the body surface area (BSA) expressed in meters such that CI = CO/BSA. Normal CO range at rest is 4 to 5 L/min; normal CI range is 2.5 to 3.5 L/min/m^2. CI provides a more complete determination of the adequacy of an individual's CO than CO alone. For example, in comparing a 6-ft tall individual and a 5-ft tall individual each with a CO of 3 L/min, the 5-ft tall person will have a higher CI and therefore better tissue perfusion because there is less BSA requiring the 3 L of CO. Determination of BSA and CI is often done using nomograms (two-dimensional diagrams) based on the Geigy scientific tables.[18]

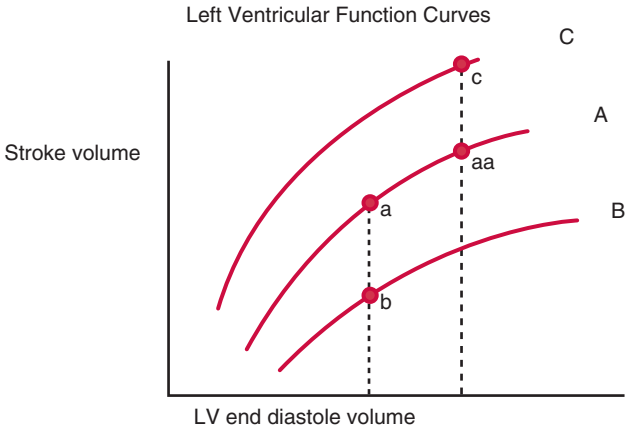

Figure 13.5 Left ventricular (LV) function curves. **(A)** With normal LV function, as the left ventricular volume increases, stroke volume will also increase. **(B)** With LV function impairment, the curve will shift to the right, and for any given length, stroke volume is decreased compared to normal (point *b* has a deceased SV compared to point *a*). **(C)** When normal LV function experiences an increase in sympathetic activity, the curve will shift to the left and SV will increase (note that point *c* is greater than point *aa*).

Electrical Conduction of the Heart

It is important to note that mechanical contraction of the ventricles only occurs with appropriate electrical conduction through the heart. Effective contraction depends on an intact electrical conduction system that results in depolarization of the myocardium and timely repolarization. In *normal sinus rhythm (NSR)* the impulse begins in the sinus node and travels through the atria, the A–V node, bundle of His, Purkinje fibers, septum, and ventricles.

Electrical conduction can be viewed via the electrocardiogram (ECG) complex (Fig. 13.6). Each component of the complex reflects a certain phase of conduction pathway.[19]

- The P wave depicts sinus node and atrial depolarization.
- The PR segment demonstrates conduction through AV node.
- The QRS complex denotes electrical flow through the ventricles causing ventricular depolarization.
- The ST segment describes the initiation of ventricular repolarization.
- The T wave illustrates the completion of ventricular repolarization.

Each ECG complex represents one cardiac cycle or one heartbeat. In a series of ECG complexes representing sinus rhythm, each QRS complex should be preceded by a P wave and the QRS complexes should be equally spaced apart, indicating a regular rhythm. ECG interpretation enables the clinician to differentially diagnose the cause of reduced CO that may occur from a true mechanical problem versus that occurring from an electrical problem disrupting mechanical activity of the heart.

Myocardial Oxygen Supply and Demand

Myocardial oxygen supply and myocardial oxygen demand must be in balance. *Myocardial oxygen supply* depends on the delivery of oxygenated blood through the coronary arteries, the oxygen-carrying capacity of arterial blood, and the ability of the myocardial cells to extract oxygen from the arterial blood. *Myocardial oxygen demand* (MVO_2), the energy cost to the myocardium, is dependent on many factors. Clinically, MVO_2 is calculated as the product of HR and systolic blood pressure (SBP), known as the *rate pressure product (RPP)* or double product.[9] Any activity that increases HR and/or BP will increase MVO_2. Therefore, any increase in systemic oxygen demand (e.g., exercise) will increase the energy cost of the heart and increase MVO_2.

The myocardium is routinely very efficient at extracting oxygen from its blood supply. Therefore, during times of increased energy demand, very little increase in extraction can occur. The primary mechanism for increasing myocardial oxygen supply during times of increased demand is by increased *coronary blood flow*

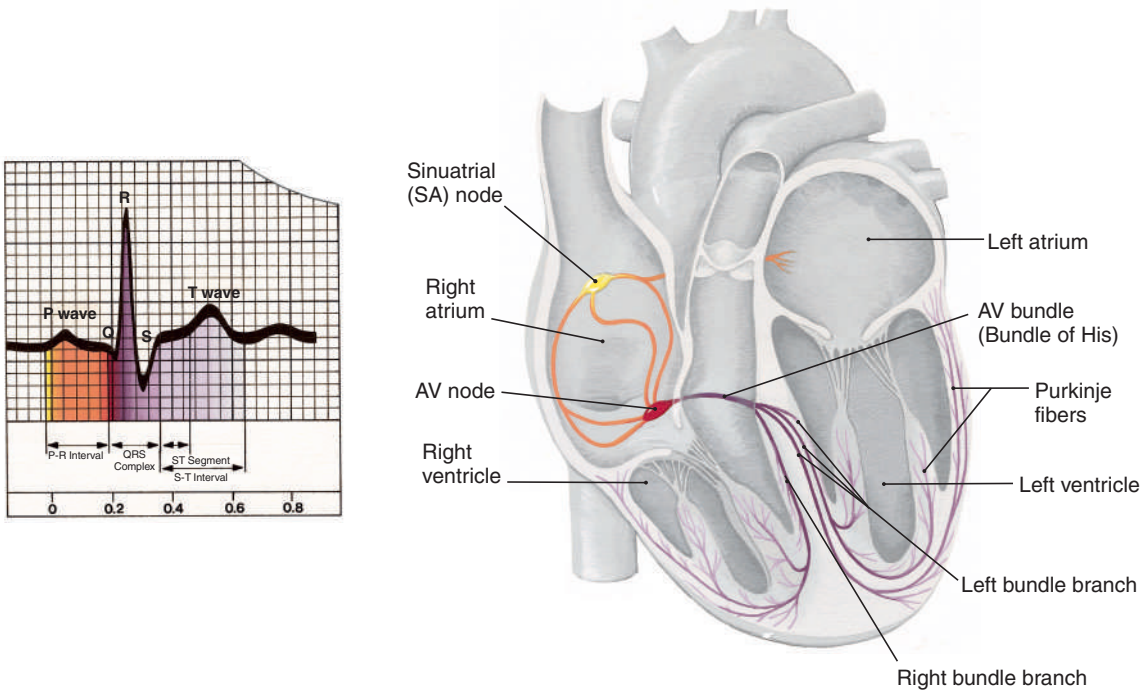

Figure 13.6 Schematic representation of the heart and normal cardiac electrical activity. The ECG is the body surface manifestation of the depolarization and repolarization waves of the heart. The P wave is generated by atrial depolarization, the QRS by ventricular muscle depolarization, and the T wave by ventricular repolarization. The PR interval is a measure of conduction time from atrium to ventricle, and the QRS duration indicates the time required for all of the ventricular cells to be activated. The QT interval reflects the duration of the ventricular action potential. *(Adapted from Taber's Cyclopedic Medical Dictionary, ed 21. FA Davis, Philadelphia, PA, 2005, p 1,022, with permission.)*

(CBF).[11] In general, there is a linear relationship between CBF and MVO_2. During exercise, CBF may increase five times above resting level in response to the increased demand. Unlike skeletal muscle, which has the capability of both aerobic and anaerobic metabolism, the heart muscle (myocardium) is essentially dependent on aerobic metabolism and has very limited anaerobic capacity.

Laboratory Values

When managing patients with heart disease, certain laboratory values are particularly important. Table 13.2 provides reference values for various laboratory tests. The hemoglobin and hematocrit levels depict the oxygen-carrying capacity within the system. Each gram of hemoglobin carries approximately 1.34 mL of oxygen within arterial blood. A normal hemoglobin level is approximately 12 to 14 g/100 mL of blood in adult males and 14 to 16 g/100 mL of blood in adult women. For example, for a hemoglobin level of 15 g/100 mL of blood, the oxygen-carrying capacity is approximately 20 mL O_2/100 mL of blood (15 × 1.34 = 20). Now, if we consider a patient with a hemoglobin level reduced to 7.5 g/100 mL of blood, the oxygen-carrying capacity is reduced by half and is approximately 10 mL of O_2/100 mL of blood. With reduced oxygen-carrying capacity, the heart must work harder to compensate for low oxygen levels to provide sufficient oxygen to the peripheral tissue. During heart failure, increased workload placed on a failing heart will exacerbate the failure. A general rule of thumb is to use caution and lower the intensity when exercising patients with hemoglobin levels less than 8 g/100 mL of blood.

Table 13.2 Laboratory Tests and Reference Values

Test	Reference Value
Sodium	135–145 mEq/L
Potassium	3.5–5.0 mEq/L
Chloride	95–105 mEq/L
Calcium	9–11 mg/dL
BUN	10–20
Creatinine	0.5–1.2 mg/dL
Glucose	70–110 mg/dL
Carbon dioxide	20–29 mEq/L
Magnesium	1.5–2.5 mEq/L
Hgb (g/dL)	Adult female: 12–16 Adult male: 13–18
HCT (%)	Adult female: 36-46 Adult male: 37–49

Electrolyte levels are also important to consider before treating patients with heart disease. Appropriate levels of potassium, calcium, and magnesium allow for normal electrical conduction through the heart. *Hypokalemia*, low potassium (usually less than 3.5 mEq/L), produces arrhythmias with flattened T waves and depressed ST segments, as well as bilateral lower extremity muscle cramping. *Hypocalcemia* (low blood serum calcium levels) and *hypomagnesemia* (low magnesium in blood) have the potential of increasing ventricular ectopy within the heart. In addition, calcium enhances contractile function of muscle cells. Patients with hypocalcemia have reduced cardiac contractility whereas those with hypocalcaemia present with erratic heart beats.

Renal function tests are done to determine kidney function and examine *blood urea nitrogen* (BUN) and *creatinine* levels. These levels are especially important to review in patients with heart failure and patients prescribed with diuretics. Finally, a large number of patients with heart disease also have diabetes and therefore it is important to review blood glucose levels before exercise.

CARDIOVASCULAR RESPONSES TO AEROBIC EXERCISE

Normal Responses

An increase in oxygen uptake occurs with an increase in external workload. There is a direct, almost linear relationship between HR and external workload (Fig. 13.7). Therefore, if the physical therapy intervention requires an increase in systemic oxygen consumption expressed as either an increase in MET levels, kcal, L/O_2, or ml of O_2 per kg of body weight per minute, then HR should also increase. Although some cardiac medications, particularly the beta-blockers, which suppress the sympathetic nervous system's effect on the heart, will limit the actual amount of increase, HR should rise nonetheless. Failure of the HR to increase with increasing workloads (chronotropic incompetence) should be immediately evaluated. Other physiological parameters should be quickly examined, such as BP, respiratory rate, skin color, and temperature, as well as the patient's level of cognition and perceived exertion. An adverse response in any of these parameters is an indication of the patient's inability to hemodynamically respond to the given amount of work.

Blood pressure (BP) should be taken before and immediately after exercise with the patient in the same position (i.e., supine, sitting, standing) and from the same arm each time. Ideally, BP should be taken during exercise to determine the actual hemodynamic response to the increased workload. However, depending on the type of exercise modality, this may be technically difficult. In these cases HR and BP must be taken immediately after exercise. As with HR, a linear increase in systolic pressure is expected with increasing levels of work (see Fig. 13.7). Hellerstein et al[20] reported that for each 10% increment of maximal HR, systolic BP increased 12 to 15 mm Hg. Naughton and Haider[21] interpreted an increase in systolic BP in excess of 12 mm Hg/MET as a hypertensive exercise response and an increase below 5 mm Hg as a hypotensive exercise response. Diastolic pressure exhibits limited changes with exercise; it may not change, or may either increase or decrease by 10 mm Hg.

In addition, as systemic oxygen requirements increase, the depth and rate of respirations will normally increase from rest. Therefore, tidal volume depicting the depth of respiration and respiration rate indicating the number of breaths per minute will change to meet the metabolic needs of the tissue.

Abnormal Responses

Signs and symptoms of exercise intolerance are presented in Box 13.1. If a patient experiences any of these symptoms, the activity should be stopped and the patient stabilized. It is also important to inform patients that some responses may be delayed for as long as several hours after exercise (e.g. prolonged fatigue, insomnia, sudden weight gain due to fluid retention). Observation of the patient throughout the physical therapy intervention provides a mechanism for ongoing examination. The therapist must be alert to subtle changes in the patient's facial expression, skin color, tone of voice, or thought processing because these may indicate activity intolerance and may require immediate patient examination and modification of the intervention. In addition to the patient's subjective complaint of fatigue or discomfort, there are other responses that warrant termination of an exercise session.[15] These abnormal responses are included in Box 13.1.

CARDIAC PATHOLOGIES AND PHYSICAL THERAPY IMPLICATIONS

The pathophysiological conditions that underlie heart disease are HTN, atherosclerosis within the coronary arteries, altered myocardial muscle mechanics, valvular dysfunction, and arrhythmias. The clinical presentations of CVD are diverse and depend on the source of the impairment: perfusion of coronary arteries, contractility of LV myocardium, or alteration of electrical activity. Common signs and symptoms associated with heart disease are chest pressure, dyspnea, fatigue, syncope, and palpitations. However, although these clinical manifestations are strongly associated with heart disease, they are not exclusive for heart disease. Therefore, taking a thorough patient history and performing an appropriate examination and evaluation are crucial to establishing the physical therapy diagnosis, anticipated goals, expected outcomes, and plan of care (POC).

An important consideration is that there is no direct objective measurement of activity limitations based solely on the cardiac diagnosis and pathology. Individuals with seemingly similar cardiac pathology may experience different activity limitations. Activity limitations

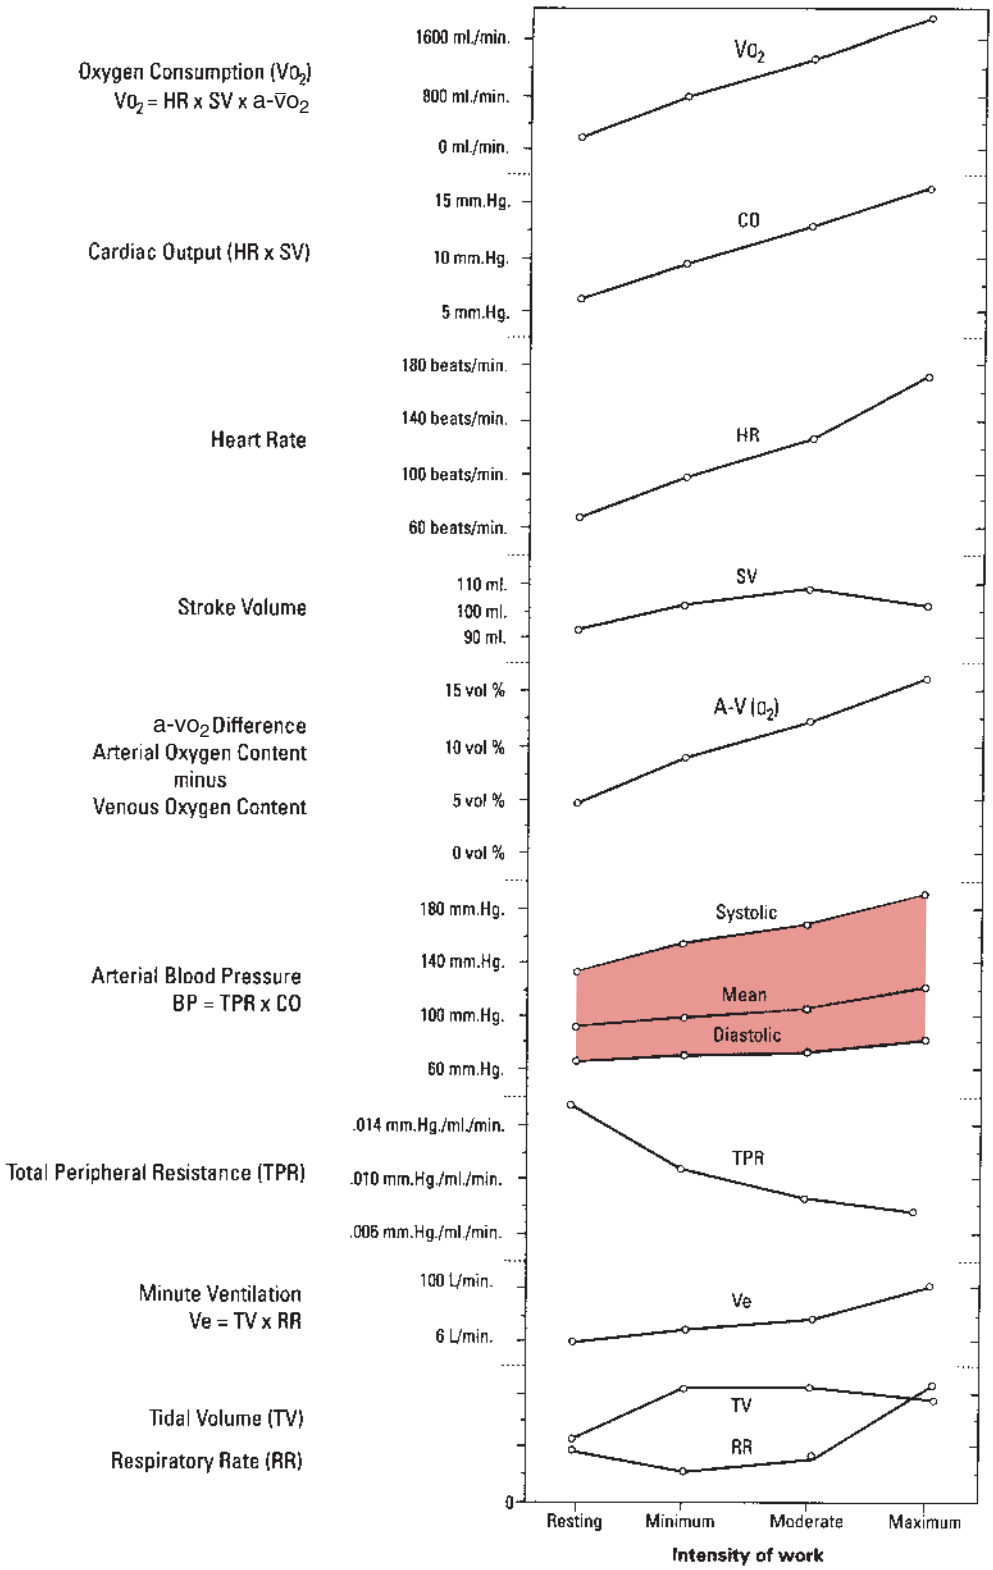

Figure 13.7 Cardiopulmonary response to acute aerobic exercise. *(Adapted from Berne, RM, and Levy, MN: Cardiovascular Physiology, ed 5. CV Mosby, St. Louis, 1986, p 237; Zadai, CC: Clinics in Physical Therapy, Pulmonary Management in Physical Therapy. Box 13.1 Indications of Exercise Intolerance That Warrant Modification or Termination of an Exercise Session

Signs and Symptoms

- Moderately severe or increasing angina
- Marked dyspnea
- Dizziness, light-headedness, or ataxia
- Cyanosis or pallor
- Excessive fatigue
- Leg cramps or claudication

Other Abnormal Responses

- Failure of the systolic pressure to rise as exercise continues
- A hypertensive BP response, including a systolic pressure of greater than 200 mm Hg and/or a diastolic pressure greater than 110 mm Hg
- A progressive fall in systolic pressure of 10–15 mm Hg
- A significant change in cardiac rhythm detected either by palpation or by ECG monitoring (e.g., arrhythmias, ST-T wave changes).

Adapted from ACSM's Guidelines for Exercise Testing and Prescription, ed 8. Lippincott Williams & Wilkins, Philadelphia, 2010.

experienced by the patient with CAD or heart failure may vary widely and are influenced by many factors other than the amount of intact, perfused myocardium or LV function. In response to cardiac impairments, neurohormonal and cardiovascular compensatory mechanisms are activated that allow cardiac functioning to continue for a period of time before the patient becomes symptomatic or there is a significant change in function. Activity limitations are therefore influenced by the amount of compensation as well as the pharmacological management. The following section will delineate the major pathologies affecting heart function, medical management of these conditions, and pertinent implications for physical therapist practice.

Hypertension

HTN is "the most prevalent cardiovascular disease in the United States and one of the most powerful contributors to cardiovascular morbidity and mortality."[22] It is estimated that 76 million Americans have HTN.[1] In addition, the prevalence of HTN in blacks in the United States is highest in the world with prevalence increasing from 35.8% to 41.4% from 1994 to 2002.[23]

HTN is defined as a persistent elevation of the systolic arterial blood pressure above 140 mm Hg or diastolic blood pressure above 90 mm Hg. In some patients, the blood pressure is not consistently elevated and fluctuates between hypertensive and normal values. This is termed *labile HTN* and is diagnosed following the evaluation of elevated blood pressure values over a prolonged period of time.

The Joint National Committee (JNC VII) that evaluates and makes recommendations for HTN management defines the following stages of HTN: prehypertension, stage 1, stage 2, and stage 3 (Table 13.3).[24] Hypertensive individuals may have elevations in both systolic and diastolic values; however, in the elderly, isolated systolic hypertension (ISH) is commonly noted with elevations in the systolic blood pressure above 140 mm Hg with diastolic blood pressures in the normal range.[24]

Broadly, HTN may be divided into two major categories: *primary (or essential)* HTN and *secondary (or nonessential)* HTN. *Primary or essential HTN* is diagnosed when there is no known cause for the elevation in BP values and exists in approximately 90% to 95% of all patients with HTN. Genetic factors, environmental influences (including dietary sodium intake), stress, obesity, alcohol consumption, and other risk factors (including age, lack of exercise, and glucose intolerance) have implications on the occurrence of essential HTN. Regardless of the underlying cause, HTN results secondary to failure of control mechanisms responsible for lowering BP. *Secondary or nonessential HTN* occurs in approximately 5% to 10% of the hypertensive population and is caused by an identifiable medical problem such as renal, endocrine, vascular, or neurological complications.

Uncontrolled elevated BP levels produce a variety of additional complications, including heart failure, renal failure, dissecting aneurysms, PVD, retinopathy, and stroke. These negative consequences are directly related to the level of BP. Prior research indicates that higher systolic blood pressure at any given level of diastolic blood pressure increases morbidity in both genders.[25]

Medical Management of Hypertension

Pharmacological intervention is the most common form of medical management of HTN. Six classes of medications currently exist: beta-adrenergic blockers,

Table 13.3 Stages of Hypertension as Defined by JNC VII [24]

Hypertension is defined by either systolic or diastolic elevation. A BP of 110/90 is Stage 1 diastolic hypertension; a BP of 160/60 is Stage 3 systolic hypertension.

Stages of Hypertension	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)
Prehypertension	120–130	80–89
Stage 1	130–140	90–100
Stage 2	140–160	100–110
Stage 3	>160	>110

Normal: 119/79 or below.

alpha-adrenergic blockers, angiotensin-converting enzyme (ACE) inhibitors, diuretics, vasodilators, and calcium channel blockers.[9] In addition to pharmacology, it is important for clinicians to recommend lifestyle modifications, including weight reduction, sodium restriction, moderation of alcohol intake, and regular aerobic exercise, for patients diagnosed with HTN. The benefits of these lifestyle changes include lowering the dosage of medications and reduced occurrence of adverse side effects.

Implications for the Therapist

HTN is generally asymptomatic until complications develop in various organs throughout the body. It has therefore been called the "silent killer." When HTN affects heart function, the individual develops hypertensive heart disease and presents with exertional dyspnea, fatigue, impaired exercise tolerance, tachycardia, chest discomfort, and possible signs of heart failure. The *Guide to Physical Therapist Practice* indicates that BP monitoring is crucial for all adults over age 35 and in younger patients who are obese or have a history of glucose intolerance, diabetes, or renal dysfunction.[26] In addition, clinical monitoring of BP values must be done both at rest and during exercise. According to the American College of Sports Medicine, if resting BP is elevated (above 200 mm Hg systolic or above 100 mm Hg diastolic), physician clearance must be obtained before exercising the patient.[15] Also, if SBP rises to more than 250 mm Hg or if DBP exceeds 115 mm Hg, exercise must be terminated.[15]

Acute Coronary Syndrome

Acute coronary syndrome (ACS) is the new terminology for ischemic heart disease or CAD. It involves a spectrum of entities ranging from the least involved condition on the spectrum (unstable angina) to the worst involved condition (sudden cardiac death). Additional entities on the spectrum include non-Q myocardial infarction (NQMI) or non–ST-elevation myocardial infarction (NSTEMI) and Q myocardial infarction (QMI), also referred to as ST-segment elevation myocardial infarction (STEMI). The hallmark sign for any patient presenting with any condition on the spectrum is ischemic chest pain because of a dyssynchrony between the myocardial oxygen supply and demand.

The primary impairment in acute coronary syndrome is an imbalance of myocardial oxygen supply to meet the myocardial oxygen demand (MVO_2). The decrease in supply results from a narrowing of the lumen of the coronary artery, usually due to a fixed atherosclerotic lesion. Atherosclerosis is a disease in which lipid-laden plaque (lesions) is formed within the intimal layer of the blood vessel wall of moderate and large size arteries; over time the plaque may extend into the lumen causing a decreased lumenal diameter. The lesion results from an initial endothelial injury that causes changes within the intima of the blood vessel and progresses to lumenal narrowing. The cause of the initial injury is not well understood, but risk factors have been identified that are associated with an increased risk for the formation of an atherosclerotic lesion. The earliest identified risk factors by epidemiological studies such as the classic *Framingham Heart Study* included smoking, high cholesterol, HTN, diabetes, emotional stress, and family history.[27-29] Obesity, sedentary lifestyle, and elevated blood homocysteine and fibrinogen levels have also been identified as possible contributors.[30]

Clinical Manifestations

Occlusions may occur in coronary arteries and not produce symptoms. In general, symptoms of CAD are not experienced until the lumen is at least 70% occluded. There are, therefore, many patients who are unaware of their subacute occlusions. It is imperative that an individual's risk factors are known and interventions and monitoring adjusted accordingly.

The clinical conditions resulting from atherosclerosis of the coronary arteries are due to inadequate myocardial oxygen supply to meet the MVO_2. The three common clinical presentations of ACS are angina, injury, and infarction.

Angina

Angina, or cardiac-related chest pain, is due to ischemia. Ischemia is characterized by reduced blood flow to the myocardium. Ischemia is a temporary condition due to the imbalance between the myocardial oxygen supply and demand. On restoring the balance between oxygen supply and demand, ischemia will be reversed and the angina will disappear.

There are three major types of angina: unstable, stable, and variant angina. *Unstable angina,* sometimes referred to as preinfarction angina or crescendo angina, typically occurs at rest without any obvious precipitating factors or with minimal exertion. It is chest pain that increases in severity, frequency, and duration and is refractory to treatment. Unstable angina usually warrants immediate medical intervention, because the patient is at impending risk for further complications such as an MI or a lethal arrhythmia (V-tach or V-fib).

The term *stable angina* is used when angina occurs during exercise or activity. Chest pain is experienced at a certain intensity of exercise when the myocardial oxygen demand exceeds the blood supply to the myocardium and is alleviated by decreasing the MVO_2. As mentioned earlier, the MVO_2 is calculated as the product of HR and SBP, known as the rate pressure product (RPP). When patients experience episodes of stable angina, exercise must be terminated and HR and BP need to be taken to determine the RPP ($RPP = HR \times SBP$). In addition to terminating exercise and resting, MVO_2 can also be reduced through the use

of nitroglycerin (NTG). In stable angina, the patient often describes the sensation as an intensity less than 5/10, which improves to 0/10 when the oxygen supply is able to balance the demand. It is important to remember that any report of angina requires intervention; the clinician cannot ignore the symptoms even when the patient describes the sensation as light (1 to 2/10).

The third type of angina is *variant* or *Prinzmetal angina* and is caused by a vasospasm of coronary arteries in the absence of occlusive disease. Patients with this type of angina respond to NTG for short-term management of their chest pain. However, the preferred long-term pharmacological choice is a calcium channel blocker to reduce the influx of calcium into the smooth muscle cells of the coronary arteries and reduce vasospasm.

Injury and Infarction

Injury represents the presence of a new acute MI.[31] The term *injury* is used because the myocardial tissue is being acutely injured during a sudden heart attack. Acute injury to the myocardial tissue then progresses to irreversible, dead infarcted tissue. The tissue, once dead, is irreversible and dead forever. Thus the term *injury* illustrates the presence of a new MI, whereas the term *infarction* depicts an old heart attack with dead tissue that cannot be reversed.

Individual myocardial cells may differ in their tolerance for ischemia; however, irreversible changes start to appear 20 minutes to 2 hours from the onset of myocardial ischemia.[32] The actual process of injury and infarction evolves over a period of hours. Angina commonly precedes an MI, but the intensity of the symptoms is dramatically increased. Patients frequently describe their discomfort as 10 out of 10 on a pain scale during an acute MI. Infarction is irreversible. Whereas ischemia is due to a partial blockage of the coronary artery, an infarction results from complete occlusion of the vessel. This occlusion commonly results from a rupture of a vulnerable plaque with resultant formation of a thrombus. The type of plaque, more so than the size, will influence the risk of rupture. Lipid-rich and soft plaques are more vulnerable to rupture than collagen-rich and hard plaques. Angiographically large plaque lesions are not necessarily more susceptible to rupture than smaller lesions. Because atherosclerosis begins within the walls of the artery, many vulnerable plaques are invisible via angiogram or appear smaller than their actual size. Although not as common as plaque rupture, coronary occlusion can occur as a result of coronary spasm, coronary emboli, congenital anomalies, and a wide variety of inflammatory diseases.[33] The actual cause of plaque rupture is not clearly understood; however, as a result of the rupture, a thrombus is formed. There may be several mechanisms for thrombosis formation, such as mechanical obstruction of the lumen, release of tissue thromboplastin and the initiation of the clotting cascade, and platelet plug formation from the contact of platelets and exposed collagen.[34] Only lesions that occlude the lumen by 70% or more can cause ischemia, but smaller lesions can and do cause MIs. It is important to remember that the size of the initial lesions does not determine whether or not an MI can occur; a small plaque lesion of 30% as well as a larger lesion of 80% may rupture and subsequently form a thrombus that occludes the remainder of the lumen. The majority of MIs occur as a result of initial plaque lesions that occlude less than 60% of the lumen and are not hemodynamically significant to cause ischemia.[35] The effects on the ventricle as a result of the infarction often extend beyond the acute infarction period; these long-term effects occur primarily in ventricles that have sustained a moderate to large MI. As the ventricle heals, a process of *remodeling* occurs as a result of the presence of the infarcted tissue and subsequent dilation. Over time, this reengineering process produces an alteration in ventricular size, shape, and function. Thus, the resultant ventricle often operates at an increased myocardial energy cost due to its inefficient muscle mechanics. Often pictured as three concentric circles (although not absolutely histologically correct), the area of infarction would be at the center of the circle surrounded first by an area of injury and then an outside area of ischemia (Fig. 13.8).

Although most MIs heal initially without incident, complications may occur. The major complications following an MI are recurrence of ischemia, LV failure, and ventricular arrhythmias. Therefore, when a patient is said to have had a *complicated MI*, it is indicative that ischemia, LV failure, or significant ventricular arrhythmias have developed in the acute post-MI period. Ischemia after MI is particularly important because it indicates that there may be vulnerable myocardium with a reduced oxygen supply that may go on to infarct

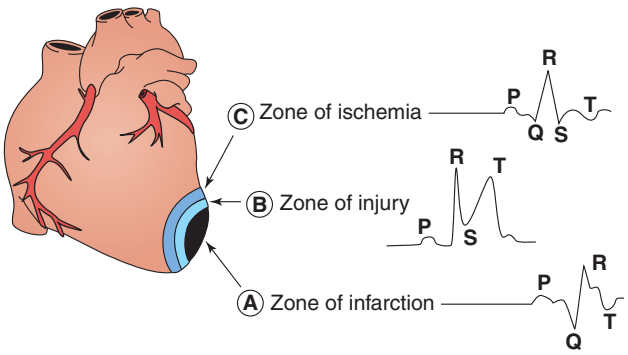

Figure 13.8 ECG following an MI. **(A)** *Zone of infarction*: when infarction occurs through the full thickness of the myocardium (transmural) an abnormal Q wave usually appears. **(B)** *Zone of injury*: ST elevation occurs in the area of injury. **(C)** *Zone of ischemia*: ST depression and/or T-wave inversion occurs in an area of decreased perfusion (ischemia).

and thereby potentially enlarge the MI. The ultimate complication would be **cardiogenic shock** with inadequate CO and insufficient arterial BP to perfuse the major organs as a result of severe LV failure. This may necessitate extraordinary medical interventions such as the *intra-aortic balloon pump (IABP).* The IABP facilitates CO, decreases MVO_2, and increases coronary artery perfusion. The IABP is a balloon catheter placed within the aorta that inflates during diastole, thereby increasing coronary artery perfusion, and deflates during systole, thereby decreasing afterload. The IABP may be used in other conditions besides post-MI cardiogenic instability, for example, patients with hemodynamic decompensation who are awaiting heart transplantation, patients with unstable angina and malignant arrhythmias (such as V-tach or V-fib), or post–cardiac surgical patients with severe hemodynamic instability.[16]

Evaluation of Acute Coronary Syndrome (the Evaluation Triad)

In addition to the history taking and review of systems, the evaluation of patients with ACS places emphasis on three major components: evaluating patient complaints, ECG changes, and cardiac enzyme levels (Fig. 13.9). Below is a review of each component.

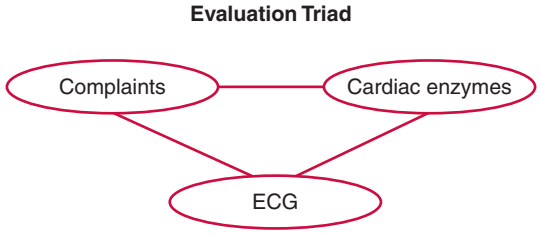

Figure 13.9 Evaluation triad for patients with acute coronary syndrome.

Patient Complaints

Chest pain from ischemic origin is diffuse and retrosternal. The patient usually reports an intense pressure like "an elephant sitting on the chest." It may radiate to anywhere in the upper extremities and thorax, most specifically to the left arm and left jaw. Figure 13.10 delineates common areas for referred patterns of chest pain. The hallmark approach to differentially diagnosing ischemic chest pain from nonischemic chest pain is to observe for accompanying signs and symptoms of compromised cardiac output. These signs include dizziness, lightheadedness, weakness, diaphoresis (sweating), fatigue, and weakness. Thus, cardiac chest pain during ischemia or an infraction will be accompanied by signs of compromised CO, but chest pain from other etiologies, including pulmonary chest pain, pleural pain, or musculoskeletal pain will not.

ECG Changes

MIs are identified by 12-lead ECG findings. The ECG (also referred to as EKG) is used to examine HR, rhythm, conduction delays, and coronary perfusion. Two of the most common types of ECG are the single-lead and the 12-lead ECG (Fig. 13.11). In the single-lead ECG, only one area of the heart (e.g., anterior, lateral, or inferior) may be viewed at a time. This area may be changed, however, by altering the location of the electrodes. In the 12-lead ECG, 12 areas may be viewed.

The single-lead ECG is sensitive to rate and rhythm changes and is commonly used for monitoring patients during ambulation and activity. Continuous monitoring is accomplished either via telemetry (radio transmission), allowing the patient freedom to move around when wearing this portable device, or by hardwire, where the patient is attached to the monitor by a cable approximately 15 ft long, therefore limiting mobility. A variation of the single-lead ECG is the 3-lead ECG,

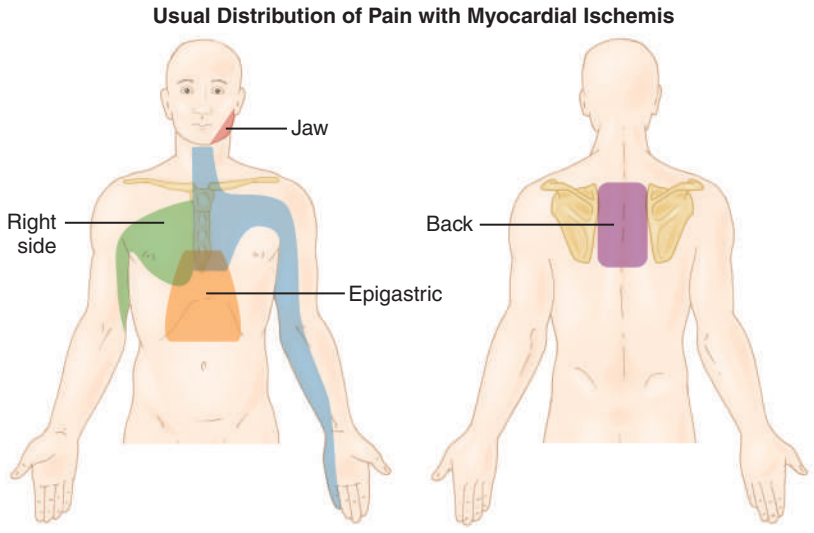

Figure 13.10 Referral pattern for chest pain.

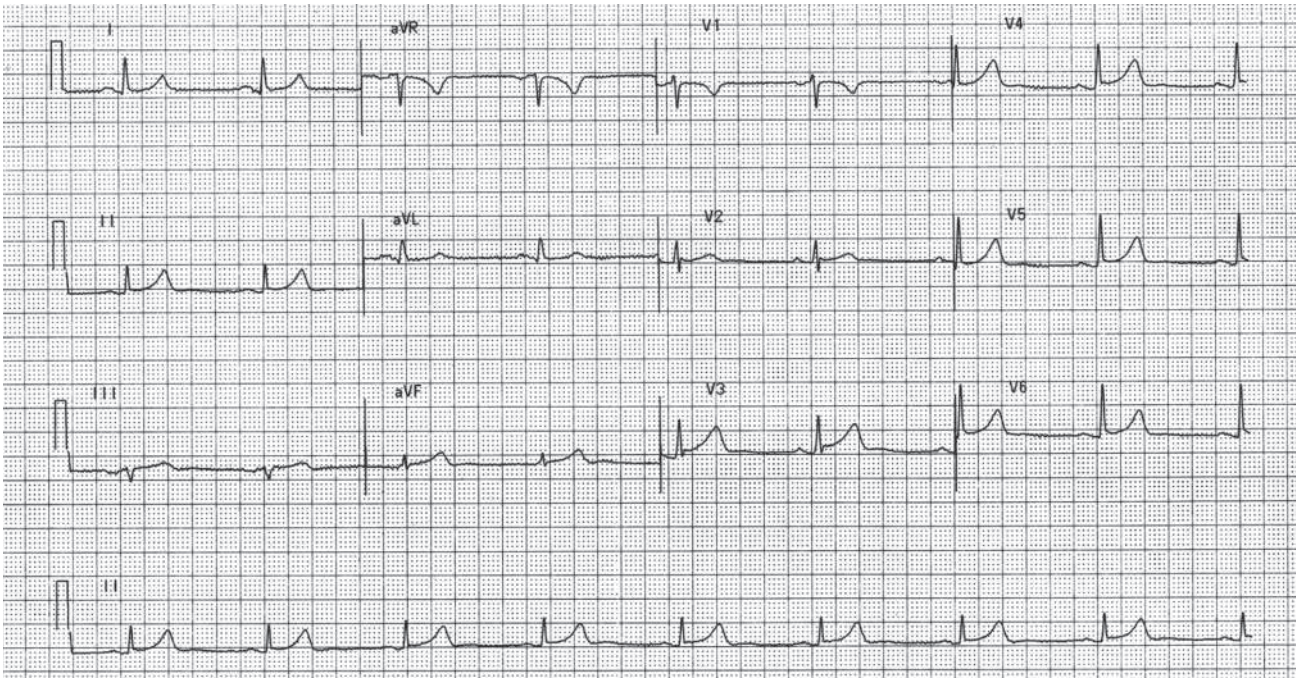

Figure 13.11 Normal 12-lead ECG from 50-year-old woman; slight ST elevation is insignificant. Twelve leads are presented; at the bottom of the page is a rhythm strip from lead II. Heart rate from the rhythm strip is approximately 52 (there are 5.8 large boxes between complex 3 and 4; therefore 300/5.8 = 52).

which is usually hardwire and is used for monitoring in an inpatient setting. It can be worn continuously throughout an entire treatment session or throughout the entire hospitalization. Unlike the single-lead or 3-lead system, the 12-lead ECG does not provide continuous monitoring, except during an **exercise tolerance test** (**ETT**). Two common uses for the 12-lead ECG are the resting ECG taken with the patient quietly supine and the ETT. Twelve-lead ECGs are invaluable in identifying perfusion impairments in the coronary arteries and in assisting with arrhythmia detection. During the ETT, the ECG is continuously monitored to determine the presence of ischemia or arrhythmias with each increase in workload. The 12-lead ECG is sensitive to changes in perfusion as well as rate, rhythm, and conduction. Each coronary artery is represented by a cluster of leads that, although not absolutely correlated with each individual's anatomy, gives a general schema for myocardial perfusion.

During the examination of a 12-lead ECG, the ST segment is clinically useful in identifying the presence of impaired coronary perfusion, either ischemia or injury. The *J point,* the point where the S wave turns into the ST segment, is the point of reference for interpreting the ST segment. If ischemia is present, the ST segment will be depressed (one or two small boxes) at two small boxes beyond the J point, and the T wave may also be inverted (flipped). Ischemic changes will be present only while the ischemia is present; when the ischemia has resolved, the ECG will return to normal. Conversely, a large acute MI, with subsequent injury to the myocardial tissue, will produce ST-segment elevations on the 12-lead ECG. Large ST elevation myocardial infarction (STEMI) will produce pathological Q waves hours to days following the acute process. Therefore a QMI represents a large MI (formerly known as a *transmural MI* because it was believed to involve the full thickness of the ventricular wall). Conversely, an acute MI may be relatively smaller and not cause acute injury to the myocardial tissue. In this case, ST segments are not seen on the ECG and the MI is termed an NSTEMI or an NQMI. An NQMI was formerly known as a *nontransmural* or *subendocardial MI* because it usually involved the endocardium. An MI that initially presents as an STEMI may be an indication for emergent thrombolytic therapy or revascularization.[16]

Anatomical classifications for MIs are based on the surfaces of the LV and not the anatomical heart. An anterior MI involves the anterior surface of the LV, an inferior MI involves the inferior surface of the LV (the diaphragmatic region), a lateral MI involves the lateral surface of the LV (also may be referred to the free wall of the LV for the lateral wall is not adjacent to another structure), a septal MI involves the septum, and a posterior MI involves the LV posterior wall. MIs to different aspects of the ventricle result from compromised levels of blood flow within specific vessels. The RCA supplies blood to the inferior and posterior aspects of the LV and therefore is responsible for producing an inferior- or

posterior-wall MI. The anterior and septal aspects of the LV are perfused by the LAD and therefore LAD occlusions are likely to produce anterior or septal MIs. The CX artery supplies blood to the lateral wall of the LV and thereby produces a lateral infarction when it is occluded. The involvement of specific vessels can be determined by a 12-lead ECG. RCA involvement is most likely depicted on leads II, III, and aVF (augmented unipolar limb lead). LAD pathology will be illustrated in chest leads V1, V2, V3, and V4, whereas CX pathology will most likely be demonstrated in leads I, aVL, V5, and V6 (Fig. 13.12).

Enzyme Levels

Blood work also helps determine the presence of an MI. Creatine kinase MB subunit (CK-MB), an isoenzyme, is released into blood and elevates with intracellular myocardial damage. Creatine kinase (CK) is found in many tissues besides the myocardium, especially striated muscle, brain, and liver. Injury to these areas will elevate total CK.

I Lateral Circ	aVR	V1 Septal LAD	V4 Anterior LAD
II Inferior RCA	aVL Lateral Circ	V2 Septal LAD	V5 Lateral Circ
III Inferior RCA	aVF Inferior RCA	V3 Anterior LAD	V6 Lateral Circ

Figure 13.12 Anatomic pathology and ECG interpretation. Leads I, aVL, V5, and V6 depict problems in the lateral aspect of the left ventricle due to occlusion of blood flow within the circumflex artery. Leads II, III, and aVF depict problems in the inferior aspect of the left ventricle due to occlusion of blood flow within the right coronary artery. Leads V1 to V4 depict problems in the anterior aspect of the left ventricle due to occlusion of blood flow within the left anterior descending artery.

To differentiate the type of tissue injured, use of CK-MB will isolate the source to the myocardium. Troponin levels should not be elevated in the setting of striated muscle trauma. Other markers that may be used to diagnose an acute MI are the proteins troponin I, troponin T, and myoglobin. Total CK-MB, troponin I, and troponin T have a high sensitivity for the diagnosis of an MI.[10,11] CK-MB and myoglobin may be the most sensitive biomarkers for patients presenting for emergent medical intervention within 6 to 10 hours of the onset of an MI.[10] For patients presenting after 10 hours, troponin biomarkers are preferred over CK-MB because of their increased sensitivity.[11] Table 13.4 provides a summary of enzyme levels that are elevated with a myocardial infarction.

Medical Management of Acute Coronary Syndrome

Once the diagnosis of an MI has been reached (i.e., the patient is "ruled in" for an MI), the goal of medical management is to keep the patient hemodynamically stable and optimize the wound healing of the myocardium. Revascularization procedures and pharmacological interventions are addressed in the following sections.

Revascularization Procedures

Percutaneous Transluminal Coronary Angioplasty

Percutaneous transluminal coronary angioplasty (PTCA) uses a balloon and collapsed stents (stainless steel "cage-like" tube with multiple slots) on the tip of a catheter inserted into the radial or femoral artery and advanced retrograde along the aorta to the openings of the coronary arteries. The catheter is inserted into the coronary artery until the site of the lesion is reached. The balloon is then inflated and the stent expands, compressing the plaque against the interior artery walls, thereby increasing the lumenal area. The balloon is deflated and removed and the stent holds the lumen open. The stent is commonly coated with a drug (e.g., paclitaxel [Abraxane]). Drug-coated stents (collectively referred to as *drug-eluting stents*) are used to prevent endothelial cell proliferation, which may occur in response to endothelial

Table 13.4 Cardiac Enzymes Associated with Myocardial Injury and Infarction

Enzyme	Normal Level	Minor Cardiac Dysfunction	Major Cardiac Dysfunction	Peak Levels
Creatine kinase - myocardial band CK-MB	0%–3%	5%	10%	14–36 hours
Lactic dehydrogenase LDH	100–225 mU/mL or 127 IU	300–750 mU/mL	≥1000 mU/mL	
Troponin	0–0.2 µg/mL	5 µg/mL	≥10 µg/mL	24–36 hours
Myoglobin	<100 ng/mL	200 ng/mL	≥500 ng/mL	

trauma and the presence of a foreign object placed within the coronary artery and result in restenosis (recurrence of stenosis).

Clinical Implications for the Therapist

The surgical and catheterization reports identify which vessels were revascularized and which vessels have less than 70% lesions and were therefore not revascularized. Because a vessel is not currently a candidate for revascularization does not guarantee that it will not be problematic at a later date, either by rupturing or continuing to demonstrate progressive atherosclerosis. It would be short sighted to assume that a patient who has had a revascularization procedure cannot become ischemic.

There are at present no strict guidelines for when a patient may resume aerobic training following an angioplasty. Conventional wisdom, however, favors waiting approximately 2 weeks to allow the inflammatory process resulting from the intervention an appropriate time to subside. The new exercise prescription should be based on the results of the post-angioplasty ETT, not the pre-angioplasty ETT, which was more than likely positive. Patients may continue to ambulate at a low intensity and comfortable pace during the first 1 to 2 weeks following the PTCA, but should avoid the moderate to higher intensities associated with aerobic training.

Coronary Artery Bypass Graft

Coronary artery bypass graft (CABG) uses a donor vessel to bypass the lesion (narrowed lumen) and establish an alternate improved blood supply. The donor vessel may be the radial artery of the nondominant upper extremity (UE), the saphenous vein, or the internal mammary artery. The patient's harvested saphenous vein or radial artery must be completely detached from both its proximal and distal insertions; the graph is sutured proximally into the aorta and distally into the involved artery beyond the occlusion. When the internal mammary artery is used, it maintains its native proximal attachment while the distal segment is reattached below (bypass) the area of occlusion. Bypass surgery techniques are constantly evolving; traditionally, the full sternum was cut and retracted, but newer minimally invasive techniques termed *minimally invasive direct coronary artery bypass* (MIDCAB) have emerged that involve less sternal cutting, and some techniques involve no sternal cutting at all, but access the heart via the intercostal space.

Most CABG procedures involve placing the patient on an artificial heart–lung machine (bypass pump), which maintains the oxygenation and circulation of the blood while the heart is stopped during the surgical procedure. As a result of the bypass pump, patients may have additional fluid weight gain following surgery, may feel fatigued, and some patients may have transient A-fib and cognitive changes. Newer techniques have facilitated the use of *off-pump procedures* to limit the time on the bypass pump. Thus the surgeon operates on a beating heart for the entire or part of the procedure to limit time on the heart–lung machine and reduce the negative sequelae that result from excessive pump time.

Clinical Implications for the Therapist

For patients who have had bypass surgery (e.g., CABG), recovery is somewhat slower than that for PTCA owing to the complexity of the surgical procedure and the incisional healing. Prolonged time in the crucifix position during surgery may predispose individuals to developing an ulnar nerve palsy after surgery. Examination of sensation and manual muscle testing is indicated to rule out the potential for brachial plexus injuries.

The number and location of incisions depend on the surgeon's technique (i.e., either a full sternal cut, partial sternal cut, or intercostal approach). The donor graph site may require additional incisions: a leg incision if saphenous vein is used, a nondominant arm incision if radial artery is used, or no additional incision if grafted with the internal mammary artery. Physical therapy intervention will address any soft tissue impairments associated with the incision to maintain appropriate tissue extensibility and range of motion (ROM), with awareness that patients often indicate soreness and/or discomfort around the donor site. If a sternal wound is present, appropriate posture, scapula retraction, and functional shoulder movements should be encouraged. Proprioceptive neuromuscular facilitation (PNF) UE diagonal patterns often work well, as do the traditional cardinal plane ROM exercises. Patients should be reminded that only a few repetitions at a time throughout the day are better tolerated than more intensive repetitions 1 to 2 times per day; the latter regimen often results in incisional soreness. Some surgeons choose to limit UE ROM exercises during the 4 to 6 weeks following surgery while the sternum is healing; however, it is unclear as to the rationale for the limitation.

Sternal precautions are commonly applied to reduce dehiscence of the incision. Cited risk factors for dehiscence include diabetes, pendulous breasts, obesity, and COPD.[36] Interestingly, there is no direct evidence that links the use of arm movements or activity to an increased risk of sternal complications after surgery.[36] Prior research has indicated that patients with chronic sternal instability demonstrate greatest sternal separation when pushing up from a chair with sit-to-stand transfers and least sternal separation when elevating both arm overhead.[37] In addition, in normal health individuals, the greatest amount of sternal skin movement was seen with sit-to-stand and supine–to–long sitting transfers and the least movement was noted when raising a unilateral weighted UE (less than 8 lb) above shoulder height.[38] Patients with chronic sternal instability tend to experience pain that is greater when raising a unilateral loaded UE compared to raising bilateral loaded UEs.[39]

Sternal precautions vary greatly by physician, institution, and type of surgery performed. Instructions may

include limiting lifting of objects between 5 and 10 pounds for up to 8 weeks after surgery. It is important to develop a professional collegial relationship with the surgical team to discuss surgical techniques and mobility concerns to ensure the best outcome for the patient.

To avoid sternal discomfort, all patients will benefit from splinting the incision with a hand or pillow when laughing, coughing, or sneezing. Patients will also appreciate information regarding energy conservation and rest periods. Even though the heart function is perhaps the best it has been in quite some time, the effects of major surgery on energy level and mobility must be emphasized. The impact of fatigue on the patient's sense of well-being may be profound, and it is important that patients understand the need for rest as well as ambulation. Early ambulation and mobility beginning the first day after surgery will assist in the patient's physical and emotional recovery.

During the initial weeks following cardiac surgery, the early in-hospital limitations following cardiac surgery have perhaps more to do with the surgical procedure and altered mobility and less to do with the heart itself, which is theoretically healthier than it was before surgery. Postoperative fatigue may be due to a combination of factors, including anesthesia, blood loss, initial weight gain due to cardiopulmonary bypass machine, common arrhythmias such as A-fib, and the energy cost of healing. As with the post-MI recovery period, when the patient returns home following surgery it is a good idea to break the day into many subunits including rest, leisure activity, and perhaps visiting with friends by phone or in person. Developing a schedule but keeping it flexible helps the patient exert some control over the day and energy level.

The patient is encouraged to gradually increase walking, with a goal of 30 minutes of ambulation 1 to 2 times per day at 4 to 6 weeks after surgery. If the patient is walking in the neighborhood, suggest that the initial walks be back and forth in front of the house rather than around the block. In this way, if the patient overestimates his or her energy level, the close proximity of home will provide a welcomed rest and prevent overexertion. Many patients ambitiously begin their walk only to find themselves suddenly fatigued and further from home than they would like. Continuing exercises for posture, UE and trunk mobility, and sternal protection are also important components of the home exercise program (HEP).

Once a patient's incisions have healed (approximately 6 weeks) and his or her blood counts including hematocrit and hemoglobin are in acceptable ranges, cardiac rehabilitation may begin. The patient may have a maximal ETT and begin aerobic and strength training.

Pharmacological Management

Cardiovascular pharmacological agents are critical in the medical management of patients with CAD. There are a variety of drugs designed to reestablish the balance of myocardial supply and demand, with new drugs being added all the time. The major anti-ischemic categories are beta-blockers, calcium channel blockers, and nitrates. *Beta-blockers* decrease beta-sympathetic activity on the heart, resulting in a decrease in HR and contractility and therefore energy demand. *Calcium channel blockers* reduce BP and therefore decrease the work of the heart. Calcium channel blockers are also somewhat unique in preventing coronary smooth muscle spasm and thereby may increase myocardial blood supply. *Nitrates,* one of the oldest categories of drugs, are potent vasodilators that decrease preload and afterload, and therefore decrease myocardial work, as well as dilate coronary arteries. *Afterload reducers,* particularly those that affect the renin–angiotensin–aldosterone system such as *angiotensin-converting enzyme (ACE) inhibitors* and *angiotensin receptor blockers (ARBs),* are frequently used to normalize BP and reduce workload on the heart. The effect of some of the more widely used cardiac drugs on HR, BP, and ECG findings are presented in Table 13.5.

Heart Failure

Heart failure is a syndrome characterized by impaired cardiac pump function, resulting in inadequate systemic perfusion and an inability to meet the body's metabolic demands. Being a syndrome, patients in heart failure present with an array of signs and symptoms. This section presents the epidemiology, causes and types of heart failure, pathophysiological and clinical presentation of heart failure, and medical management and evaluation for this patient population. A discussion of physical therapy interventions for managing patients with heart failure will be delineated later in this chapter.

Epidemiology of Heart Failure

With the marked improvement in anti-ischemic medications, increased knowledge and management of CAD risk factors, availability of sophisticated monitoring, and revascularization techniques, more patients are living longer with coronary disease than similar patients 20 or 30 years ago. New technology and medications continually improve the understanding and management of CAD; however, an undesired effect of long-term CAD may be the increased prevalence of heart failure, also known as **congestive heart failure (CHF)**. Technology and other advances in medicine are reducing mortality with a concomitant increase in morbidity. Therefore, patients with heart failure are less likely to die and more likely to live longer with the worldwide prevalence and incidence of heart failure approaching epidemic proportions. In the United States, heart failure affects 5.7 million individuals with approximately 670,000 incident cases of heart failure diagnosed annually.[40] Estimates of the prevalence of heart failure in the general European population are similar to the Unites States and range from 0.4% to 2%.[41] In North America and Europe the lifetime risk of developing heart failure in both sexes at age 40 is approximately 1 in 5. In addition, 6% to 10% of people older than 65 have heart failure, indicating an exponential rise in the prevalence of

Table 13.5 Effects of Medications on Heart Rate, Blood Pressure, ECG, and Exercise Capacity

Medications	Heart Rate	Blood Pressure	ECG	Exercise Capacity
I. Beta-blockers (including carvedilol and labetalol)	↓* (R and E)	↓ (R and E)	↓ HR* (R) ↓ ischemia† (E)	↑ in patients with angina; ↓ or ↔ in patients without angina
II. Nitrates	↑ (R) ↑ or ↔ (E)	↓ (R) ↓ or ↔ (E)	↑ HR (R) ↑ or ↔ HR (E) ↓ ischemia† (E)	↑ in patients with angina; ↔ in patients without angina; or ↔ in patients with congestive heart failure (CHF)
III. Calcium channel blockers			↑ or ↔ HR (R and E) ↓ ischemia (E)	↑ in patients with angina; ↔ in patients without angina
Amlodipine Isradipine Nicardipine Nifedipine Nimodipine	↓ or ↔ (R and E)	↓ (R and E)		
Diltiazem Verapamil	↓ (R and E)		↓ HR (R and E) ↓ ischemia† (E)	
IV. Digitalis	↓ in patients w/atrial fibrillation and possibly CHF Not significantly altered in patients w/sinus rhythm	↔ (R and E)	May produce nonspecific ST-T wave changes (R) May produce ST segment depression (E)	Improved only in patients with atrial fibrillation or in patients with CHF
V. Diuretics	↔ (R and E)	↔ or ↓ (R and E)	↔ or PVCs (R) May cause PVCs and "false-positive" test results if hypokalemia occurs May cause PVCs if hypomagnesemia occurs (E)	↔ except possibly in patients with CHF
VI. Vasodilators,				
ACE inhibitors and angiotensin II blockers	↑ or ↔ (R and E) ↔ (R and E)	↓ (R and E) ↓ (R and E)	↑ or ↔ HR (R and E) ↔ (R and E)	↔ except ↑ or ↔ in patients with CHF ↔ except ↑ or ↔ in patients with CHF
Alpha-adrenergic blockers	↔ (R and E)	↓ (R and E)	↔ (R and E)	↔
Antiadrenegic agents without selective blockade	↓ or ↔ (R and E)	↓ (R and E)	↓ or ↔ HR (R and E)	↔
VII. Nicotine	↑ or ↔ (R and E)	↑ (R and E)	↑ or ↔ HR May provoke ischemia, arrhythmias (R and E)	↔ except ↓ or ↔ in patients with angina

Key: ↑ = increase; ↔ = no effect; ↓ = decrease; E = exercise; R = rest.

*Beta-blockers with intrinsic sympathomimetic action (ISA) lower resting HR only slightly.

†May prevent or delay myocardial ischemia.

heart failure with increasing age.[42] In looking at gender differences, although the relative incidence of heart failure is lower in women compared to men, women constitute half of all cases with heart failure because of their longer life expectancy.[43] Heart failure has surpassed MI as the leading cause of cardiac deaths in the United States and is the most frequent cardiac diagnosis for hospital admissions and readmissions.

Causes of Heart Failure

The most common cause of heart failure is cardiac muscle dysfunction. *Cardiac muscle dysfunction* is a general term describing altered systolic and/or diastolic activity of the myocardium that usually develops as a result of an underlying abnormality within the cardiac structure or function.[9] Several reasons exist for the development of cardiac muscle dysfunction. Box 13.2 presents potential precursors and risk factors for the development of cardiac muscle dysfunction.

Types of Heart Failure

Heart failure may be categorized based on a structural perspective and a functional perspective. From a structural perspective, heart failure is described as being *left-sided heart failure* or *right-sided heart failure*.[44] **Left-sided heart failure** occurs with LV insult. Pathology of the LV reduces the CO leading to a backup of fluid into the LA and lungs. The increased fluid in the lungs produces the two hallmark pulmonary signs of left-sided heart failure: shortness of breath (SOB) and cough. Primary **right-sided heart failure** occurs from direct insult to the RV caused by conditions that increase PA pressure. Increased pressure within the PA subsequently increases the afterload, thereby placing greater demands on the RV and causing it to go into failure. With RV failure, blood is not effectively ejected from the RV and backs up into the RA and venous vasculature, producing two hallmark peripheral signs: jugular venous distention and peripheral edema. Often, left-sided heart failure may be severe as seen in patients experiencing a heart failure exacerbation. With severe LV pathology, fluid from the LV backs up into the lungs, increasing PA pressure and causing fluid to back up into the right side of the heart and the systemic venous vasculature. This is termed **biventricular failure**. Therefore, patients with biventricular failure will present with both pulmonary and systemic signs of heart failure. Table 13.6 provides hemodynamic pressures noted with left, right, and biventricular failure.

Box 13.2 Causes of Cardiac Muscle Dysfunction

Precursors	Description
Hypertension	Increased peripheral arterial pressure contributes to increased afterload and pathological hypertrophy of the left ventricle.
Coronary artery disease	Acute injury to myocardial tissue damages ventricular contractility causing systolic dysfunction. Scar formation seen in infracted tissue alters relaxation and may lead to diastolic dysfunction.
Cardiac dysrhythmias	Normal electrical conduction through the heart allows for normal mechanical contraction of the ventricles. Altered electrical conduction alters the mechanical activity of the ventricles exacerbating heart failure.
Valve abnormalities	Cardiac valve pathology (stenosis or regurgitation) causes structural changes to the chamber behind the valve resulting in cardiac muscle dysfunction and failure.
Pericardial pathology	Pericarditis (fluid in the pericardial space) with resultant cardiac tamponade compresses the ventricles leading to cardiac muscle dysfunction and heart failure.
Cardiomyopathies	Damage to the myocardial cells from various pathological processes alters the systolic and/or diastolic function of the ventricles.

Table 13.6 Example of Hemodynamic Pressures Associated with Heart Failure

An increase in PAP and/or PCWP is associated with LV failure; an increase in CVP is associated with RV failure; and an increase in CVP, PAP, and PCWP is associated with biventricular failure.

Pressure (Norms)	LV Failure	RV Failure	Biventricular Failure
CVP (0–8 mm Hg)	6 mm Hg	12 mm Hg	12 mm Hg
PAP (9–19) mm Hg	22 mm Hg	16 mm Hg	22 mm Hg
PCWP (6–12) mm Hg	18 mm Hg	10 mm Hg	18 mm Hg

CVP = central venous pressure; LV = left ventricle; PAP = pulmonary artery pressure; PCWP = pulmonary capillary wedge pressure; RV = right ventricle;

From a functional perspective, heart failure is described as systolic or diastolic dysfunction.[44,45] *Systolic dysfunction* is characterized by compromised contractile function of the ventricles causing reductions in the SV, CO, and EF. Patients with systolic dysfunction will usually present with compromised ejection fractions (EFs) less than 40%. *Diastolic dysfunction* is characterized by compromised diastolic function of the ventricles. With this condition, the ventricles cannot relax and fill appropriately during the relaxation (diastolic) phase of the cardiac cycle. The impaired ability to fill the ventricles with blood reduces the volume of blood ejected with each contraction (the SV) and the overall volume of blood ejected per minute (the CO). EF is unaltered and remains normal between 55% and 75%. No reduction in the ratio is noted because there is no change in the contractile ability of the ventricles. However, there is a low volume of blood being ejected with each contraction as less blood entered into the ventricle before the contraction phase.

Pathophysiology of Heart Failure

Heart failure involves a complex series of events involving pathophysiological and compensatory factors in response to cardiac muscle dysfunction.[46-51] When the myocardium is dysfunctional, compensatory mechanisms are activated with the goal of maintaining adequate cardiac output. Neurohormonal mechanisms including activation of the sympathetic nervous system are triggered to increase HR and maintain CO at rest. Thus patients experiencing an acute bout of heart failure are very likely to be tachycardic at rest.

When patients are in heart failure and the ventricle is ejecting low blood volumes, blood begins to accumulate within the ventricles, causing congestion. This congestion increases the LVEDV and contributes to an elevation in LV pressure. The increased pressure is transmitted retrograde toward the LA and the pulmonary veins. This increase in hydrostatic pressure in the pulmonary veins causes fluid to move from the veins into the interstitial space of the lung, resulting in **pulmonary edema**.[45]

It is also important to consider kidney function for patients with heart failure. Low blood volume pumped out of the heart causes less blood to perfuse the kidney and is likely to put the kidney in failure. Patients experiencing an acute heart failure exacerbation often go into renal failure. It is therefore crucial for therapists to monitor BUN and plasma creatinine levels. An increase in urea production, elevated BUN and creatinine levels, and decreased urine output indicate renal dysfunction.[45]

From a musculoskeletal standpoint, patients with heart failure often present with skeletal muscle wasting, myopathies, and osteoporosis. These negative sequelae are associated with inactivity and prolonged bedrest. Several studies have investigated the effects of CHF on skeletal muscle abnormalities and found reductions in the size and number of Type I and Type II muscle fibers.[52-54] It is therefore imperative that the physical therapy POC place emphasis on interventions to improve overall endurance and functional mobility in this patient population.

Clinical Manifestations of Heart Failure

The clinical presentation of the patient with CHF depends not only on the amount of LV failure, but also on the status of compensatory mechanisms and the impact of drug therapy. Over time, the energy cost of the compensatory mechanisms proves to be too much for the impaired myocardium. The patient then begins to present with signs and symptoms of CHF, and now moves from being asymptomatic to symptomatic. Although the terminology may be somewhat confusing, it is important to note that when a patient is referred to as being in *compensated heart failure,* the patient's congestive symptoms can be relieved by medical intervention. A patient who is *noncompensated* is showing signs and symptoms of congestion and requires medical and pharmacological readjustment.

Common signs and symptoms of CHF include fatigue, dyspnea, edema (pulmonary and peripheral), fluid weight gain, presence of an S_3 heart sound, and renal dysfunction. Pulmonary edema may be evident by chest x-ray and auscultation of adventitious sounds. Peripheral edema may be evident in gravity-dependent LEs by the presence of indentations in the skin when pressure is applied, that is, **pitting edema**. Pitting edema associated with CHF is usually bilateral and may extend from the foot to the pretibial area.[55,56] Documentation should include a numerical grade based on the duration of indentation after fingertip pressure. See Chapter 14, Vascular, Lymphatic, and Integumentary Disorders, for pitting edema grading scale. Weight gain and peripheral edema are among the signs of systemic volume overload.

On auscultation of the heart and lungs characteristic sounds are heard with CHF. The usual abnormal heart sound associated with CHF is the presence of an S_3 heart sound. This is a low-frequency heart sound heard in early diastole and occurs due to poor ventricular compliance and subsequent turbulence of blood within the ventricle.[7] Heart murmurs (extra heart sounds), especially those of mitral regurgitation, may also be present owing to the effect of the enlarged LV pulling on the mitral valve. Lung auscultation for patients with heart failure reveals the presence of crackles or rales. These are crackling/bubbling sounds suggesting fluid in the lung. The sounds are usually heard during inspiration and represent the movement of fluid in the alveoli and subsequent opening of the alveoli that were previously closed because of the excess fluid.[44]

Dyspnea is one of the most common symptoms experienced with left-sided CHF. The SOB is associated with pulmonary edema. When fluid accumulates in the lungs, gas exchange is altered at the alveolar capillary interface. Gas exchange (respiration) will occur at the alveolar capillary interface only when ventilation within the alveoli is matched with perfusion within the pulmonary capillary

(V/Q matching). Excessive amounts of fluid within the pulmonary parenchyma cause a ventilation/perfusion mismatch, thereby reducing the amount of oxygen delivered to blood and causing dyspnea.

Two other symptoms reported by patients in CHF are paroxysmal nocturnal dyspnea and orthopnea. **Paroxysmal nocturnal dyspnea (PND)** is characterized by sudden episodes of SOB occurring in the night. **Orthopnea** is increased SOB in the recumbent position. The severity of orthopnea is often crudely documented by observing the number of pillows a patient needs to keep the upper body in an upright or semirecumbent position. Therefore, a patient with three- or four-pillow orthopnea suggests a greater severity of heart failure when compared to a patient with one-pillow orthopnea. Physiologically, as patients assume a recumbent position from an upright position, with their legs elevated to the same horizontal level as their trunk, fluid moves back to the heart causing an increase in preload. A failing heart cannot keep up with the additional preload and excess fluid returning to the heart and therefore causes a backup into the lungs producing increased symptoms of SOB.

Increased arterial resistance is also seen in patients with CHF and results in an increase in afterload and therefore in MVO_2. The increased resistance may result from a combination of factors, including (1) increased sympathetic adrenergic stimulation; (2) decreased vasodilation of vascular smooth muscle as a result of a decrease in the availability of the endothelium-derived relaxant factor, nitric oxide; (3) an increase in the endothelial-derived smooth muscle vasoconstrictor, endothelin-1; (4) an increase in vascular stiffness as a result of salt and water retention; and (5) the presence of the powerful peripheral vasoconstrictors angiotensin II and vasopressin.[57]

One of the common complaints of patients with CHF is early onset of muscle fatigue. The cause of the muscle fatigue may be multifactorial, including a decrease in peripheral blood flow, changes within the peripheral vascular beds, peripheral vasoconstriction, atrophy of muscle fibers, and increased utilization of anaerobic metabolism for energy production.[58,59] The contribution of intracellular mechanisms to muscle fatigue has been studied. Examples of these intracellular mechanisms include an alteration in the control of calcium release and reuptake[60] and myocyte apoptosis.[61] In addition to peripheral muscle functioning in patients with heart failure, exercise studies have also investigated various other factors, including oxygen uptake kinetics, neurohormonal parameters, and endothelial function, that may influence the exercise response.[62-64] Although there are many potential reasons for the fatigue associated with CHF (especially Class III and IV), a recently identified contributor is obstructive sleep apnea. Sleep apnea may be treated in this patient population with the use of continuous positive airway pressure worn while sleeping.[65,66]

Patients with heart failure will present with decreased exercise tolerance owing to a culmination of the pathophysiological and compensatory events associated with heart failure. It is difficult for patients to exercise when they have gained weight, have SOB, and have a rapid HR. There are a variety of methods to measure exercise tolerance in patients with heart failure. Physicians utilize the New York Heart Association (NYHA) and Functional Classification Scale (Table 13.7). Classification is based on the development of symptoms and the amount of energy required to provoke them. Patients in Class I have mild heart failure and relatively better exercise

Table 13.7 Functional Classifications of Patients with Diseases of the Heart

Functional	Continuous–Intermittent Permissible Workloads	Maximum
Class I	4.0–6.0 cal/min Patients with cardiac disease but without resulting limitations of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.	6.5 METs
Class II	3.0–4.0 cal/min Patients with cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.	4.5 METs
Class III	2.0–3.0 cal/min Patients with cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.	3.0 METs
Class IV	1.0–2.0 cal/min Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	1.5 METs

tolerance compared to patients in Class IV with severe CHF and poor exercise tolerance.

Medical Examination and Evaluation of Heart Failure

Medical interventions include a variety of tests to identify the etiology and evaluate the severity of heart failure. Following an examination of signs and symptoms of heart failure in a given patient, several key tests are typically performed. These include a chest x-ray, laboratory tests, echocardiography, and nuclear imaging studies.

Radiological Findings in CHF

Three hallmark characteristics of the chest x-ray help confirm the diagnosis of CHF[9] (Fig. 13.13):

1. An enlarged cardiac silhouette: The enlargement of the heart in patients with CHF occurs secondary to congestion of fluid in the lungs and possible pathological hypertrophy of the ventricles.
2. Opacities (white areas) in the lung field with interstitial and parenchymal edema. This occurs when excessive fluid collects in the lung when LV end-diastolic pressures exceed 25 mm Hg.[44]
3. Blunting of the costophrenic angle. The lower ribs meeting the diaphragm creates this sharp image observed on the chest x-ray. In patients with CHF, fluid settles to the lower, dependent aspect of the lung, producing an opaque appearance, and blunts the costophrenic angle.

Laboratory Findings in CHF

Natriuretic peptides including atrial natriuretic peptide (ANP) and B-type or brain natriuretic peptide (BNP) are released from atrial and ventricular myocytes in response to volume overload within the respective chambers.[67] ANP and BNP are cardiac neurohormones that target the kidney when released to increase diuresis and decrease the overall volume of fluid within the vasculature and chambers of the heart.[44] Circulating levels of BNP are elevated in plasma in patients with heart failure. There is no level of BNP that perfectly separates patients with and without heart failure. Normal levels of BNP are less than 100 pg/mL. Values above 500 are generally considered to be positive for heart failure. The BNP level provides an indication of the extent of heart failure where higher BNP levels without renal failure indicate worsening failure of the ventricles. Therefore a patient with a BNP of 1,000 pg/mL has more significant heart failure than a patient with a BNP of 500 pg/mL. BNP has been found to be a statistically significant ($p < 0.05$) prognostic indicator of heart failure,[68-69] and studies have discovered moderate to strong (from $r = -0.38$ to -0.64) correlations between BNP and peak oxygen uptake (VO_{2max}).[68,69]

Figure 13.13 Radiographic examination to confirm CHF.

Echocardiogram and Nuclear Imaging

With ultrasound technology, the echocardiogram is used to examine wall motion integrity, valvular status, wall thickness, chamber size, and LV function. The EF may also be calculated using the data obtained from the echocardiogram. An echocardiogram may accompany a stress test and is known as a *stress echo.* The purpose of a stress echo is to compare LV function and wall motion between rest and exercise when an increased VO_2 results in an increased MVO_2. A positive stress echo indicates a worsening of LV function as activity increases; a negative stress echo indicates that the LV has adequately adapted to the increase in energy demand. Nuclear imaging (e.g., thallium sestamibi) compares coronary perfusion between rest and exercise. If there is no decrease in perfusion with increasing workloads, the test is negative; if there is a decrease, the test is considered positive.

Pharmacological Management of CHF

With the advent of new medications such as combined alpha- and beta-blockers, ACE inhibitors, and vasodilators, the symptoms of volume overload are more effectively managed.[70,71] The principles of drug management with CHF are twofold: (1) to increase the contractility or pumping ability of the heart to relieve congestion and (2) to decrease the workload on the heart by reducing either the total volume of fluid in the system (the preload) or the vascular resistance (the afterload). Drugs that increase contractility are known as *positive inotropes;* the common oral drug in this category is digoxin. Diuretics decrease preload, thereby decreasing LVEDV. Patients are often on a sliding scale dosage of diuretics depending on the amount of fluid weight gain; they are instructed to weigh themselves daily and adjust diuretics accordingly. Afterload reducers, particularly those that block the effects of the renin–angiotensin system (e.g., ACE inhibitors or ARBs), are often a critical component of drug management in this population. By blocking salt and water retention through aldosterone suppression, preload is decreased; by blocking vasoconstriction through angiotensin II suppression, afterload is reduced.

The increase in sympathetic activity that accompanies heart failure causes an increase in MVO_2 (from beta-receptor stimulation), peripheral vasoconstriction, and resultant reduction in peripheral blood flow (from alpha-receptor stimulation). Drugs that combine both beta-receptor blockade and alpha-receptor blockade minimize these affects. Beta-blockade will result in a decrease in MVO_2 and alpha-blockade will result in decreased afterload due to suppression of peripheral vasoconstriction.

Mechanical and Surgical Support

For the symptomatic patient in NYHA Class III/IV, there are dramatic surgical options that may improve function, such as heart transplant, left ventricular assist devices (LVADs), myoplasty, and biventricular pacing. It is beyond the scope of this chapter to discuss in detail the complexity of each of these procedures. Heart transplantation involves replacing the patient's heart with a donor heart. The donor heart will be denervated; therefore, it will not have any direct sympathetic or parasympathetic connection and will be dependent on the intrinsic pacemaker of the SA node and hormonal stimulation to increase HR. The patient with a heart transplant requires careful pharmacological management. Immune-suppressing drugs are used to prevent the body from rejecting the organ, as well as for careful control of infection.

The LVAD is a temporary pump inserted into the patient to perform the work of the LV or to augment the function of the failing heart. The patient is connected to an external energy source but also has the option of wearing a battery pack that allows freedom of movement for hours, in which the patient can go shopping, go to the movies, and so forth. It is important for the therapist to consider the effects of a 6-lb mass (created by the external energy source) resting below the diaphragm that is likely to alter ventilator performance. Finally, gentle progression of exercise intensity must be utilized. Therapists must be vigilant to check for flow limitations (10 to 12 L/min) or changes in cardiovascular function that may occur secondary to use of a mechanically driven pump.

Myoplasty is a surgical procedure in which an enlarged LV undergoes a size reduction by removing dilated, scarred myocardium that is ineffective in contributing to contractility.

A new class of pacemaker, the biventricular pacer, includes an intraventricular conduction delay (e.g., left bundle branch block on the ECG) for patients with severe CHF. This pacer coordinates the contraction of the right and left ventricles and in doing so provides a more effective LV contraction and increased CO.[73]

Valvular Heart Disease

Broadly, three major disorders encompass valvular dysfunction of one or more of the four heart valves.[74] These are stenosis, prolapse, and regurgitation.

1. *Stenosis* involves narrowing of a heart valve limiting the flow of blood through the valve. As the pathological condition progresses, the chamber behind the valve pathologically hypertrophies to pump against the obstruction.
2. *Prolapse* involves enlarged valve cusps that become floppy and bulge backward. When the cusps and support mechanisms of the valve are destroyed, the valve droops down. As the disease progresses, prolapse may progress to regurgitation.[75]
3. *Regurgitation* refers to the forward and backward movement of blood resulting from incomplete valve closure. During certain phases of the cardiac cycle valves must close appropriately to prevent blood from flowing in a retrograde fashion. In a regurgitant valve, the valve does not close properly leading to regurgitation of blood into the chamber behind the pathological valve.

Valve replacements are often used for treating valvular disease. Patients with stenosis or regurgitation of the aortic or mitral valves are prime candidates for valve replacement surgeries. A median sternotomy is the route to access the heart. Two major types of valves are used for valve replacement procedures: (1) mechanical valves and (2) biological valves derived from cadavers, porcine tissue, or bovine tissue.[74,76] Mechanical valves are preferred in patients younger than 65 because of their durability and long life. However, the major disadvantage is that they tend to be thrombogenic. Patients who receive a mechanical valve must be on lifelong anticoagulation therapy. For this reason, patients who have a history of a prior bleed, wish to become pregnant, or have poor medication adherence may not be candidates for a mechanical valve. For these patients, biological valves may be more appropriate. The postoperative care for patients with a valve replacement is similar to that for patients who have had a CABG. In addition, neurological monitoring must be continuous postoperatively owing to the potential for an embolic stroke that may occur during or after the procedure.

Electrical Conduction Abnormalities

Arrhythmias are any alteration in the electric conduction of the heart from the normal beat. They are caused by a disturbance in the electrical activity of the heart, resulting in impaired electrical impulse formation or conduction.[76] Arrhythmias may present as benign or malignant (i.e., life threatening). Examples of malignant arrhythmias are sustained ventricular tachycardia (V-tach) and ventricular fibrillation (V-fib). An example of a common benign arrhythmia in the elderly population would be atrial fibrillation (A-fib) with a controlled ventricular response. This section will review a few conduction abnormalities and relevant implications for the physical therapist.

Ectopic Beats

A beat that originates from a site other than the sinus node is known as an *ectopic beat*. The common ectopic

beats are atrial *(premature atrial contractions [PACs])* and ventricular *(premature ventricular contractions [PVCs]).* PVCs may occur either by themselves or in groups such as couplets (two PVCs) or triplets (three PVCs), or alternating with sinus beats such as bigeminy (every other beat a PVC) or trigeminy (every third beat a PVC).[77,78]

A PAC is an ectopic beat that originates in the atria and may present as an irregular rhythm (Fig. 13.14B). It may be difficult to distinguish a PAC from a premature junctional contraction (PJC), an ectopic beat that originates within the area around the A-V node. Usually, PACs or PJCs will not compromise CO, and physical therapy intervention may be appropriate if accompanied by adequate hemodynamic responses.

The presence of ectopic beats results in an irregular rhythm. Usually, ectopic beats are transient, and their severity depends on their impact on CO. It is certainly common to have a few PVCs even in a normal heart. Many people may have ectopic beats during times of stress or with stimulants such as nicotine and caffeine. Even though this may be a common response in a normal heart, it is important to educate patients with myocardial impairments who may have ectopic beats or irregular rhythms to avoid these aggravators. An increase in ectopy is undesired. It is unwise for any patient with cardiac disease to engage in exercise following recent cigarette smoking. Although the specific time frame that a patient may be at risk for increased ectopy is not clearly known, a good rule of thumb may be abstinence of smoking for at last 2 hours either before or after exercise. Patient education on wellness strategies and smoking cessation is always useful for any patient identified as a smoker.

Supraventricular Ectopy

Supraventricular ectopy involves the rapid firing of an ectopic focus that originates in any location above the ventricles (atrial or junctional area). Examples of supraventricular ectopy include (1) paroxysmal atrial tachycardia and (2) supraventricular tachycardia. A sudden run of PACs occurring at a fast rate (100 to 200 bpm) is known as *paroxysmal atrial tachycardia (PAT).* A run of either PACs or PJCs at a rate of 150 to 250 bpm is known as supraventricular tachycardia (SV-tach) (Fig. 13.14C). Patients with SV-tach usually respond to a carotid massage where stimulation of the baroreceptors within the carotid bodies of the carotid artery produce a parasympathetic response. Other treatment interventions to reduce heart rate for patients with SV-tach include coughing and breath-holding techniques achieved through the Valsalva maneuver.

Ventricular Ectopy

PVCs are ectopic beats that originate in the ventricle and may present as irregular rhythms. Two hallmark characteristics identify PVCs on the ECG: (1) A P wave is absent as the impulse originates in the ventricle and (2) a wide and bizarre QRS complex signifying abnormal electrical conduction through the ventricle (Fig. 13.14D). Single PVCs will not compromise CO if less than 7 per minute. Therefore, physical activity may be appropriate if accompanied by an adequate hemodynamic response. If the PVCs increase with activity, the activity should be stopped and the patient examined for possible signs of compromised cardiac output. PVCs may come from the same irritable site and are termed *unifocal PVCs*. If they originate from different ectopic sites within the ventricle they are known as *multifocal PVCs* (Fig. 13.15A). Multifocal PVCs suggest a more irritable ventricle and are therefore more serious than unifocal PVCs. It is appropriate for the therapist to have the patient medically evaluated before beginning or continuing an activity. Finally, a rare type of PVC known as an *R-on-T PVC* occurs when PVC fires *very prematurely*, on the T wave of the preceding cardiac cycle (Fig. 13.15B). These patients must be monitored closely because they are at an increased risk for developing a life-threatening dysrhythmia such as ventricular tachycardia.[77]

In ventricular bigeminy (Fig. 13.14E), every other beat is a PVC; in trigeminy, every third beat is a PVC (Fig. 13.14F).[77] These rhythms occur transiently or episodically, and many patients have frequent bursts of these rhythms. If ectopy increases with activity, the activity should be immediately stopped. When two PVCs occur together, it is known as a couplet (Fig. 13.14G); when three PVCs occur together, it is known as a triplet. Couplets and triplets are important in that they suggest a high level of ventricular irritability. Altered LV function and ischemia are two of the more common causes for ventricular ectopy; therefore, medical management is directed toward improved LV function and perfusion whenever possible, as well as arrhythmia control. Physical therapy intervention is conservative at best and depends on the hemodynamic stability of the patient.

Ventricular Tachycardia

A run of four or more PVCs in a row is known as V-tach (Fig. 13.14H). V-tach may be either sustained or nonsustained. *Sustained V-tach,* by definition, occurs at an HR of at least 100 bpm and lasts for at least 30 seconds.[79] The patient may or may not have a palpable pulse and, if present, the pulse will be weak. Because of the severe decrease in CO and rapid hemodynamic deterioration associated with this rhythm, the presence of sustained V-tach is considered an emergency situation. Medical intervention must be initiated as soon as possible. No physical therapy intervention is appropriate, except assisting the patient in stabilization, initiating cardiopulmonary resuscitation (CPR) when indicated, and activating the advanced cardiac life support (ACLS) system. V-tach may deteriorate quickly into V-fib.

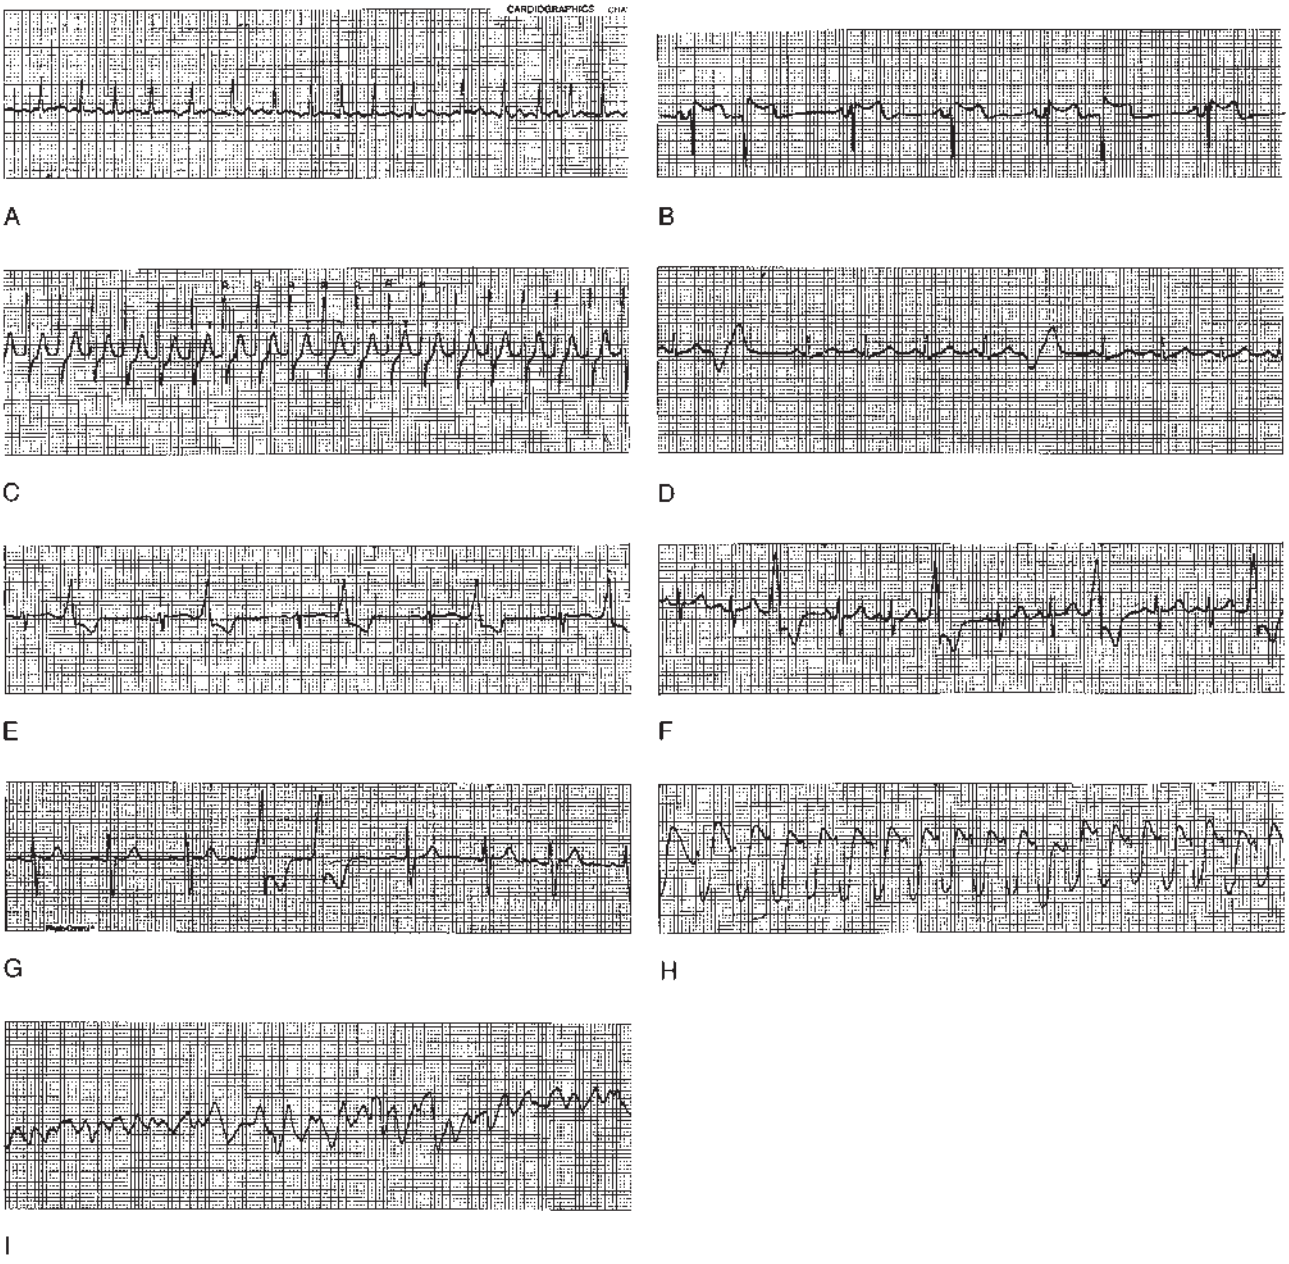

Figure 13.14 Examples of ectopy and arrhythmias. **(A)** Atrial fibrillation. **(B)** Atrial premature beat, also known as premature atrial contraction (PAC) (note third complex). **(C)** Supraventricular tachycardia (SVT). **(D)** Premature ventricular contraction (PVC) (note third complex). **(E)** Bigeminy (note second, fourth, and sixth complexes are PVCs). **(F)** Trigeminy (note second, fifth, and eighth complexes are PVCs). **(G)** Couplets (note fourth and fifth complexes are PVCs). **(H)** Ventricular tachycardia (V-tach). **(I)** Ventricular fibrillation (V-fib) (V-tach deteriorates into V-fib). *(From Brown, K, and Jacobson, S: Mastering Dysrhythmias: A Problem-Solving Guide. FA Davis, Philadelphia, 1988, p 30, with permission.)*

Nonsustained V-tach occurs either in groups of three to five PVCs known as *salvos,* or a run of six or more PVCs lasting for up to 30 seconds.[79] Nonsustained V-tach is considered a high-risk indicator for potentially lethal arrhythmias. Because the rhythm is nonsustained, the decrease in CO may not be sufficient to cause symptoms. However, until the etiology of the arrhythmia is identified and the rhythm controlled, physical therapy intervention is generally inappropriate.

Ventricular Fibrillation

V-fib is characterized by quivering of the ventricles resulting from inadequate electrical stimulation. The ECG demonstrates a sustained run of different-looking PVCs coming from different ectopic foci (Fig. 13.14I). When

the ventricles do not contract but rather quiver, there is ineffective CO. The patient will arrest and expire if this rhythm is not altered immediately. The treatment of choice is activation of ACLS, including electrical defibrillation and medication. Patients who survive fibrillation through defibrillation become candidates for an indwelling defibrillator placement known as an *automatic implantable cardiac defibrillator* (AICD).

Automatic Implantable Cardiac Defibrillator

The AICD is implanted in patients who have life-threatening ventricular arrhythmias (V-tach, V-fib). The AICD is programmed to deliver an electrical shock if it detects an HR higher than its programmed HR limit. Therefore, it is important for the physical therapist to know this limit and avoid an exercise intensity that may inadvertently activate the device.[80] In addition to knowing the HR settings for the patient with an AICD, there are other considerations. ST-segment changes on the ECG may be common and are not specific for ischemia; therefore, other diagnostic studies must be done. In addition, UE aerobic or strengthening exercises should be avoided initially after placement of the pacer to avoid inadvertently dislodging the device or the lead wires.[80] Checking with the physician when these exercises may be included is prudent. There may be a danger for patients with AICDs or pacemakers from electromagnetic signals such as anti-theft devices, either causing the AICD to discharge or causing pacers to slow down or speed up. It may be no problem for patients to walk through these devices but lingering within a few feet could be dangerous.[81]

Atrial Fibrillation

A-fib is characterized by quivering of the atria due to inadequate electrical stimulation. A varied number of non–sinus originating P waves (known as fibrillatory waves) exist for each QRS complex (Fig. 13.14A). The ventricular rhythm is said to be "irregularly irregular" because there is no regularity to the irregularity of the ventricular rhythm. It is important to note that effective contraction of the atria accounts for approximately 15% to 20% of CO—the *atrial kick*.[9,74] In patients with abnormal electrical conduction causing a quivering of the atria (A-fib), the mechanical contractile ability of the atria is reduced, resulting in a low atrial kick and compromised CO.[9,74]

Patients may exhibit A-fib continuously as their baseline rhythm or go in and out of this rhythm at rest or with activity. Physical therapy intervention may be appropriate for patients in A-fib who have a good ventricular rate at rest, with appropriate hemodynamic and HR increase with exercise. In patients with A-fib and rapid ventricular rates (greater than 100 bpm) at rest, exercise intensity must be lowered and hemodynamic responses monitored carefully. This is because a rapid ventricular rate in addition to the loss of atrial kick further compromises the CO and results in altered hemodynamic responses. A good rule of thumb is to avoid physical activity and seek medical consultation if the patient's resting HR is greater than 115 bpm, if the patient appears uncomfortable, or if there is an inadequate hemodynamic response. Because this rhythm is irregular, it is important to monitor the HR for a full minute rather than 15 to 30 seconds to obtain an accurate pulse rate.

Conduction Delays and Blocks

Changes in the length of the PR interval, the width of the QRS complex, and the length of the QT interval are some of the ECG measurements indicative of conduction abnormalities.

Conduction delays through the A-V node are classified as first-, second-, or third-degree heart blocks. *First-degree heart block* occurs when the conduction time through the A-V node is prolonged; therefore, the ECG will have an increased length of the PR interval (Fig. 13.15C). There are two categories of *second-degree heart block:* Mobitz type I and Mobitz type II; each is hallmarked by the presence of dropped beats. Mobitz I, also known as *Wenckebach,* presents with a gradual increase in PR interval length in the preceding beats and then an eventual dropped beat (Fig. 13.15D); Mobitz II has normal PR intervals in all the beats preceding the dropped beat (Fig. 13.15E). In *third-degree heart block,* a mismatch of atrial and ventricular conduction exists, so there is no consistency between the atrial contraction and the ventricular contraction (i.e., no relationship between P waves and QRS complex on the ECG) (Fig. 13.15F). Patients in first-degree block have no limitations to exercise. Whether or not exercise is permitted with second- and third-degree blocks depends on the etiology and subsequent hemodynamic responses. Medical clearance is warranted before beginning any exercise.

Conduction delays through the bundle of His are known as either right bundle branch block (RBBB) or left bundle branch block (LBBB). Bundle branch blocks are not true arrhythmias because there is no change in the actual rhythm, just in the timing of conduction through the bundle of His. The heart is still depolarized from the same pacemaker; only the route of activation is changed. Bundle branch blocks present on the ECG as a distortion of the QRS complex with an increased duration (i.e., widening) (Fig. 13.15G). The presence of an LBBB on the ECG is usually permanent and indicates a pathological condition. RBBB may occur from a variety of reasons; it may be a permanent change due to underlying disease, or it may be benign. RBBB can also occur transiently. LBBB usually indicates the presence of more significant disease than RBBB.

The presence of a new bundle branch block should be medically evaluated before beginning or progressing an exercise program. Following medical clearance, there

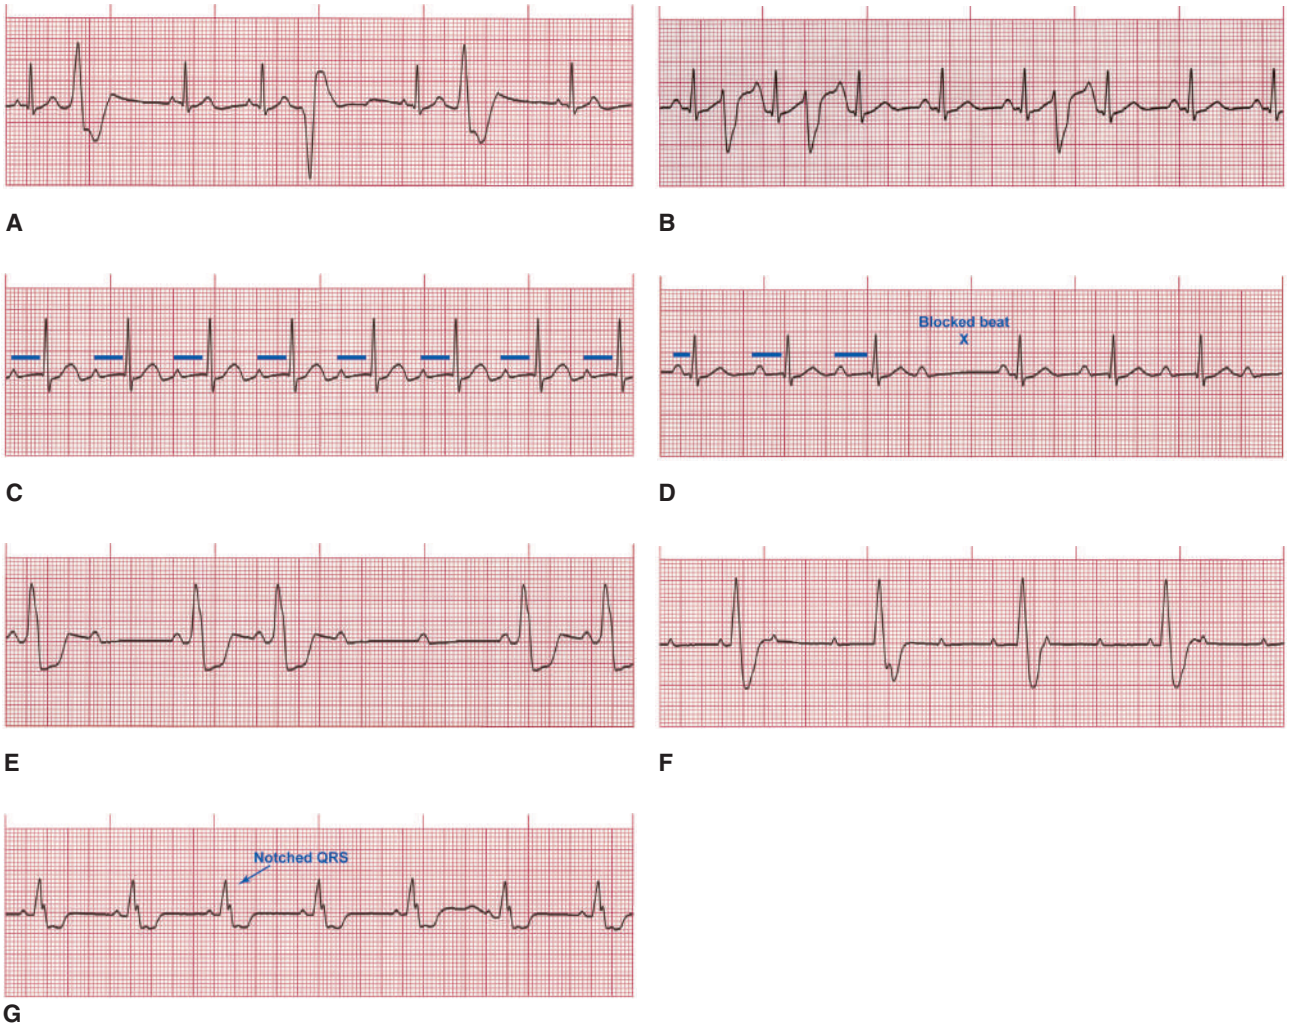

Figure 13.15 **(A)** Multifocal or multiform PVCs; **(B)** R-on-T PVC; **(C)** first-degree AV block; **(D)** Wenckebach rhythm; **(E)** second-degree type II; **(F)** third-degree AV block; **(G)** bundle branch block. *(From Jones, S: ECG Success: Exercises in ECG Interpretation. FA Davis, Philadelphia, 2008.)*

is usually no contraindication to exercise in either the RBBB or LBBB population. Because of the alteration of the QRS complex and as a result the ST segment, the sensitivity of the ECG in detecting ischemia via ST depression is lost in the patient with LBBB.

Pacemakers

The use of pacemakers has increased considerably, with the most common indications for placement of a permanent pacemaker being (1) an HR that is too slow (symptomatic bradycardia); (2) an HR that fails to increase appropriately with exercise (chronotropic incompetence); or (3) an electric pathway that it blocked resulting in atrioventricular delays or bundle branch blocks.[82]

A pacemaker is a device that is placed subdermally near the heart and consists of an implantable pulse generator and lead wires that connect the pacemaker to the myocardium. The pulse generator contains a long-life battery and circuitry for timing, sensing, and output functions. The life of the battery usually dictates the life of the pacemaker and varies depending on the type of battery and the extent to which the pacemaker is being used. In some cases, the patient is dependent on the pacemaker for every cardiac contraction and is likely to utilize the life of the battery in a shorter period of time.[83] The average pacemaker battery life is between 5 and 10 years. Replacement of pacemaker batteries is done after serial assessments have confirmed a reduction in battery life. Battery life may be consumed more rapidly when the patient is more reliant on the pacemaker for maintaining an appropriate HR.

Patients are reliant on pacemakers at different levels. Some patients have normal electric conduction at most times and do not need to be reliant on the pacemaker at all times. Other patients have altered electrical conduction through the heart and may be very reliant on the pacemaker to keep them alive. Therefore, it is important

for therapists to determine how reliant the patient may be on his or her pacemaker. When pacemakers trigger a pace due to altered electrical conduction through the heart, the ECG reveals a pacer spike. Thus, if the patient has a pacemaker and no pacer spikes are evident on the ECG, the therapist can infer that the heart is conducting normally, and the pacemaker is there for emergency needs only. Conversely, if the ECG demonstrates a pacer spike in every cardiac cycle, the therapist must understand that this patient is 100% reliant on the pacemaker and thus ensure that the pacemaker is adequately rate responsive during activity.

The basic functions of the pacemaker lead wires are to provide the pacemaker with information on intrinsic myocardial activity and pace the myocardium when intrinsic activity fails. There are four primary functions of pacemakers: (1) the ability to sense intrinsic cardiac function, (2) the ability to stimulate cardiac depolarization in response to failed intrinsic activity, (3) the ability to respond to increased metabolic demand by providing rate-responsive pacing, and (4) the ability provide diagnostic information stored within the pacemaker.[84]

Pacemakers have rate and rhythm sensitivity as well as the ability to override certain arrhythmias. Pacemakers may also be combined with AICD capabilities. Pacemakers are coded by either a three- or five-category system according to which chamber (atria or ventricle) is sensed, what chamber is paced (atria or ventricle), and whether the electrical stimulus will trigger a response or be inhibited[85] (Table 13.8). Because pacemakers may fail to work properly, ECG monitoring is helpful to determine if the pacer is working properly.

As stated previously, patients with Class III CHF and LBBB may be candidates for a specialized pacemaker known as a biventricular pacemaker, the purpose of which is to synchronize LV contractility to provide a more effective CO. The biventricular pacer does not influence HR or heart rhythm.[86]

Heart Transplant

Patients who have undergone a heart transplant may present with the following: (1) calf cramps (occurring in approximately 15% of patients) owing to the immunosuppressive drug cyclosporine; (2) decreased LE strength; (3) obesity owing to long-term corticosteroid use; (4) increased risk of fracture owing to osteoporosis associated with long-term, high-dose corticosteroids; and (5) an increased probability of developing atherosclerosis in the coronary arteries of the donor heart after the first postsurgical year.[87] Because the heart is denervated, HR alone provides a limited measure of exercise intensity. Therefore, BP and perceived exertion should be included in the routine data collection.

CARDIOVASCULAR EXAMINATION

Owing to the increasing incidence and prevalence of heart disease on our society, many patients referred to physical therapy will have cardiovascular dysfunction or may be at risk for developing CVD. The history taking, review of systems, and data from specific tests and measures will guide and inform development of the physical therapy diagnosis, anticipated goals and expected outcomes, prognosis, and POC. This section addresses tests and measures specific to the cardiovascular system.

Medical Record Review

The medical record of a patient with a history of cardiovascular impairments may at times be overwhelming. The patient interview is typically helpful if clarification of the medical record is needed. Depending on the type of setting (inpatient, outpatient, acute rehabilitation, home care), the specific contents of the medical record may vary. Important items to note within the medical record include the following:

1. Medical problems, past medical history, physician's examination
2. Medications, including type, dosage, and schedule

Table 13.8 Pacemaker Classification System

Chamber Paced	Chamber Sensed	Response	Rate Responsive Pacing
O = none	O = none	O = none	R = rate responsive
A = atria	A = atria	I = inhibit	
V = ventricle	V = ventricle	T = trigger	
D = dual chamber	D = dual chamber	D = capacity to both inhibit and trigger	

Pacemakers are commonly identified by a three-letter code as displayed in the first three columns. Pacemakers may also have the capacity to respond to physiological stimuli to increase rate (column 4) and to override atrial tachycardia. A fifth column, for antitachycardiac function, is rarely used due to the increased sophistication of the newer implantable defibrillators/pacemakers, which renders this function unnecessary. Example: VVI pacer will provide an electrical impulse to the ventricle if it senses that there is no ventricular activity within an appropriate time frame. If there is intrinsic ventricular electrical activity, the pacemaker will be inhibited.

3. Laboratory tests
   - Blood tests for specific cardiac enzymes that may indicate an MI has occurred, such as a positive CK-MB or troponin level
   - Electrolytes, including potassium, and magnesium and calcium if ventricular arrhythmias are present
   - Complete blood count (CBC), which may indicate the presence of anemia via the hemoglobin and hematocrit values
   - Status of the kidney (BUN and creatinine) and liver function (liver function tests)
   - Presence of CAD risk factors, such as elevated lipid values (e.g., total cholesterol, low-density lipoproteins [LDLs], triglyceride), and elevated blood sugars (glucose)
   - Arterial blood gases (ABGs)
4. Results of any diagnostic studies or interventions: chest x-ray, ECGs, ETT, cardiac catheterization, surgical reports, hemodynamic monitors (e.g., pressure readings from central line and/or arterial line)
5. Nursing and other health care provider notes

The medical record contains information regarding what has happened to the patient, as well as the status of the patient within the last 24 hours or since the last health care provider intervention. Flow charts, which record vital signs, temperature, oxygenation requirements, and volume status over time, provide up-to-date patient data, especially when working with the more medically challenged patient.

Patient Interview

The formal patient interview should follow the medical record review. A determination of overall cognition (e.g., orientation, memory, learning needs, comprehension) should be made. Information regarding the patient's lifestyle, previous level of functioning, recreational interests, work requirements, and goals is important in establishing the intervention. Data should also be obtained about the patient's response to health and illness, coping status, support systems, and knowledge of heart disease. It is important to note that not all the information from the interview needs to be obtained on the first session. During subsequent sessions, the patient may begin to feel better and less anxious and may therefore be able to communicate more easily. Patient education can often be woven into the interview process, either subtly or overtly. The patient should describe, in his or her own words, the quality and location of the symptom for which medical attention is being sought. It is common for physical therapists to ask a patient about pain; for patients with cardiac disease, one should be cautious about assuming that the patient's symptom is pain. Many patients will not use pain as their qualifier, but instead describe their symptoms as pressure, heaviness, SOB (dyspnea), aching, heartburn, or general malaise, to identify a few. Knowing the symptom presentation for each individual will make patient education and activity progression easier. It is also important to identify any consistent precipitating factors and alleviators, as well as duration and frequency of symptoms.

The interview also helps to establish rapport and trust between therapist and patient, creating an environment for mutual goal setting. This in turn facilitates patient adherence to the rehabilitation program. Patients who are recovering from an MI or from surgery need to have an understanding of time frames for healing and convalescence. Education for family members and significant others is also crucial for patient adherence and understanding.

Physical Examination

The physical therapist carefully monitors vital signs (see Chapter 2, Examination of Vital Signs) at rest and with activity, auscultates the heart and lungs, and performs a general observation of the patient's appearance. An overview of the pertinent components is presented.

Heart Rate and Rhythm

In taking an initial HR, either by palpation or auscultation, it is important to count for a full minute. When examining the patient's response to an activity and no arrhythmia is present, an immediate postexercise HR can be taken for 10 to 15 seconds. Always note if the rhythm is regular or irregular and report it as such. Unless there is ECG monitoring, it is impossible to identify a specific rhythm by palpation or auscultation alone. Note that there is a normal respiratory variation in HR; inspiration results in an increase in HR, exhalation in a slowing down of HR.

HR can also be determined from an ECG strip. The ECG graph paper consists of a series of small boxes (represented by light black lines) and large boxes (represented by heavy black lines). Each large box is made up of five small boxes. The horizontal axis represents time; when the ECG paper is moving at the usual speed of 25 mm/sec, five large boxes constitutes one second. Knowing that time is on the x-axis, there are many ways to calculate HR from the ECG graph paper. An easy way to calculate a minute rate is to count the number of complexes in 6 seconds (i.e., 30 large boxes) and multiply by 10. Often the ECG paper will have 3-second intervals premarked. An alternative approach is to identify an R wave from one ECG complex that is close to or on a heavy black line (i.e., a large box), and then assign each of the following heavy black lines (large boxes) a number in the following order: 300, 150, 100, 75, 60, 50, 40. The heavy line closest to the next R wave will provide an approximation of HR (Fig. 13.16). Finally, dividing 300 by the number of large boxes between two R waves will also indicate the HR. If the rate is regular, any of the preceding strategies will work. If the rate is irregular,

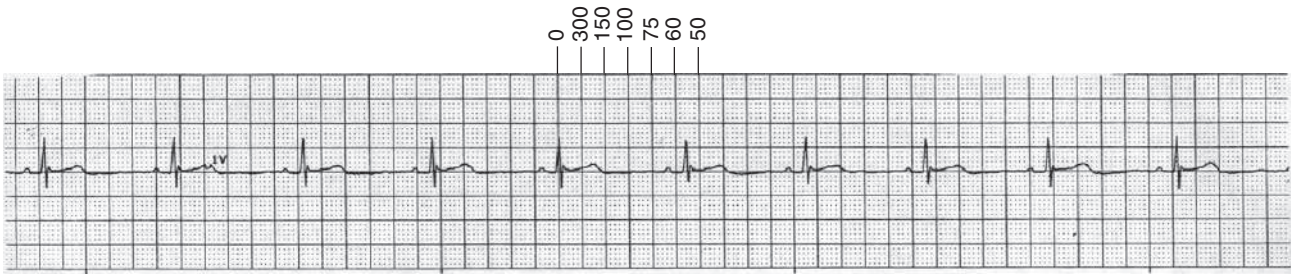

Figure 13.16 Calculation of a heart rate from a rhythm strip. Begin with the fifth complex (which falls on a large black line) and count each large black line to the right of this complex in the order of 300, 150, 100, 75, 60, 50. The sixth complex falls between two large lines (i.e., 50 and 60). There are five small lines between each large line. Between 50 and 60 there are 10 beats, therefore each small line in this case would be two beats. The heart rate would be 60 – 4 = 56. An alternate method would be to count the number of complexes in a 6-second strip and multiply by 10.

however, the complexes will need to be counted over a long time frame, and a minimum of a 6-second strip should be used.

Respiratory Rate, Rhythm, and Dyspnea

As with the heart, both rate and rhythm of respirations should be noted, as well as the breathing pattern and use of accessory muscles. Patients with cardiac impairments frequently complain of dyspnea. Patients with LV dysfunction from CAD, CHF, cardiomyopathies, valvular dysfunction, hypertensive heart disease, pericarditis with tamponade, and arrhythmias may all present with dyspnea. Sometimes, dyspnea begins with activity and is termed *dyspnea on exertion (DOE)* and progresses to occurring at rest. It is important to document and understand the amount and types of activity that provoke DOE. Dyspnea associated with a cardiovascular etiology is usually accompanied by signs and symptoms of compromised CO, including lightheadedness, dizziness, fatigue/weakness, and hypotension; symptoms may worsen in the supine position (orthopnea).[88] Some patients may experience dyspnea as their anginal equivalent; that is, they do not have the typical chest discomfort often associated with ischemia but instead experience SOB. For these patients, treatment should be immediate and follow the guidelines for ischemia. A commonly used tool to objectively identify subjective feelings of dyspnea is the Dyspnea Scale (Box 13.3).

Angina

The classical presentation of angina is substernal chest pressure accompanied by the *Levine sign* (the patient clenching his or her fist over the sternum). The Levine sign has a high diagnostic accuracy for ischemia.[89] For some patients, angina does not present in the classic way but rather may present as a pain or heaviness in the shoulder, jaw, arm, elbow, or upper back between scapulae. Angina may radiate from the chest to the arm or up to the throat, or it may present as indigestion or even SOB. The patient is often asked to rank his or her discomfort on the Angina Scale (Box 13.4).

Blood Pressure

Arterial BP is a product of CO and total peripheral resistance (TPR) where BP = CO × TPR. An increase in either of these factors will increase BP, and a decrease in either may decrease BP. Clinically, therefore, aerobic exercise of increasing intensity increases CO and concomitantly increases BP. Conversely, a drop in BP during aerobic exercise indicates a drop in CO, or signifies the inability of the heart to meet the metabolic needs of the peripheral tissue.[90] This drop in BP is usually accompanied by signs of compromised CO, including fatigue, weakness, tiredness, dizziness, and so forth, that occur during the activity. Therefore, BP values of a patient with heart disease who demonstrates signs of compromised CO during ambulation should be closely monitored to

Box 13.3 Dyspnea Scale

0 = No dyspnea
1 = Mild, noticeable
2 = Mild, some difficulty
3 = Moderate difficulty, but can continue
4 = Severe difficulty, cannot continue

Box 13.4 Angina Scale

0 = No angina
1 = Light, barely noticeable
2 = Moderate, bothersome
3 = Severe, very uncomfortable: preinfarction pain
4 = Most pain ever experienced: infarction pain

determine if CO is being maintained. Lower exercise BP values when compared to resting values denote that CO is not being met during exercise.

Accurate measurement of BP is a vital process within the examination process. Using inappropriate cuff sizes when measuring BP is the most frequent error in BP measurement.[91] Proper cuffs must have a bladder length of 80% and a width of 40% of arm circumference. In addition, maintaining the arm at the level of the heart promotes accurate measurement of BP to negate the effects of hydrostatic pressure. For every 2.5 cm above or below the level of the heart, BP readings can change by 1 to 2 mm Hg. An arm maintained above the level of the heart lowers BP readings and if placed at a level below the heart falsely increases BP measurements.[91] For more information on measurement of BP, see Chapter 2, Examination of Vital Signs.

Observation and Inspection

The patient's skin color should be inspected. **Cyanosis**, a bluish color of the skin, nail beds, and possibly lips and tongue, may be present when arterial oxygen saturation is 85% or less.[74] **Pallor**, the absence of a pink, rosy color, may indicate a decrease in CO. **Diaphoresis** (excess sweating, cool clammy skin) should also be noted because it may indicate excessive effort or inadequate cardiovascular response. Cold fingertips may be due to compensatory vasoconstriction in response to a decreased CO or from the suppressed beta-sympathetic response of some beta-blockers.

The extremities are inspected for the presence of edema; patients with LV failure may have an increase in peripheral edema owing to the increase in hydrostatic intravascular pressure associated with increased pressure from the LV transmitted retrograde through the heart to the venous system. Bilateral peripheral edema may be a result of CHF. Edema of one leg, however, is usually associated with local factors within the same leg such as varicose veins, lymphedema, or thrombophlebitis.[90] The patient with chronic CHF who has a weight gain owing to sodium and water retention may notice edema of the ankles and lower legs during the day (due to an increase in hydrostatic pressure) that diminishes during the night.

Heart Auscultation

Invaluable information as to the status of the heart is obtained from **auscultation** (listening) of the heart and lungs. Normal heart sounds are identified as S_1 (lub), which occurs at the time of the closure of the mitral (and tricuspid) valve and marks the beginning of systole and S_2 (dub), which occurs at the time of aortic (and pulmonic) valve closure and marks the end of systole. Figure 13.17 depicts locations on the chest for appropriate auscultation of each valve. The aortic valve is best auscultated at the second intercostal space, right sternal border. The pulmonic valve is heard at the second intercostal space, left sternal border. The tricuspid valve

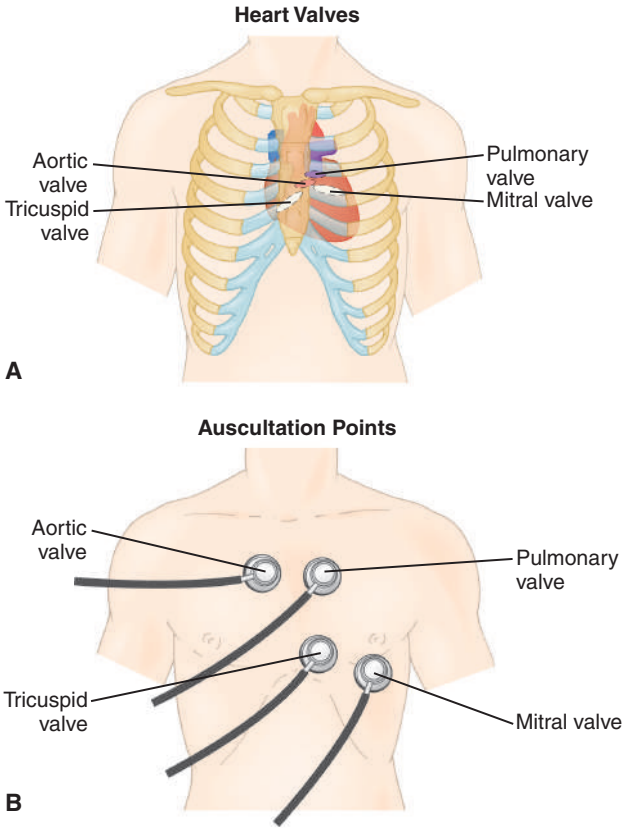

Figure 13.17 Anterior view of the chest wall of a man showing skeletal structures, heart, location of the heart-valves, and auscultation points.

is auscultated at the fourth intercostal space, left sternal border, and the mitral valve is best heard at the fifth intercostal space, along the midclavicular line.

Murmurs are abnormal heart sounds commonly the result of valvular disorders due to the changes in blood flow around and through the altered valve. A *systolic murmur* will present as audible turbulence between S_1 and S_2, and a *diastolic murmur* as turbulence between S_2 and S_1. A *stenotic* valve has impaired opening, and a regurgitant valve has impaired closing. A valve may be both stenotic and regurgitant.

Other abnormal sounds are S_3 and S_4. S_3, also known as a *ventricular gallop,* occurs after S_2 and is clinically associated with LV failure. S_4, also known as an *atrial gallop,* occurs before S_1 and is clinically associated with an MI or chronic HTN.

Another type of auscultatory finding is the *pericardial friction rub.* These friction sounds are high pitched with a leathery and scratchy quality, although they may vary in intensity from hour-to-hour or day-to-day, or may even transiently disappear.[92] The pericardial rub has been described as similar to the squeaking sound of rubbed leather.[93] This rub results from an inflammation of the pericardial sac, either with or without excessive fluid. Pericardial disease may result from many causes

such as trauma, infections, tumors, collagen diseases, anticoagulants, and MI. Post-MI pericarditis is known as *Dressler's syndrome.*[94] An example of documentation for heart sounds would be *Cor: RRR Ø m, g, r,* which would be interpreted as *Heart: regular rate and rhythm without murmurs, gallops, or rubs*.

Auscultation of the heart borders is also done to examine size. The location of the apex and point of maximal impulse (PMI) is noted. The PMI is usually present at the fifth intercostal space along the midclavicular line. If the LV has increased in size, as frequently occurs with patients in LV failure, the PMI will be displaced laterally toward the axilla.

Lung Auscultation

Auscultating the lungs is an important component of the cardiac physical examination. Normal lung tissue produces vesicular (soft, low-pitched) sounds in the peripheral aspect of the lungs and bronchial breath (loud, high-pitched) sounds centrally along the manubrium of the sternum.[7] Vesicular sounds are longer and louder with inspiration, whereas bronchial breath sounds are longer and louder with expiration. Figure 13.18 demonstrates appropriate sites for the auscultation of lung fields.

Patients with LV failure often have the adventitious sounds of *crackles.* Crackles may also appear as a result of atelectasis; in that case, deep breathing with an inspiratory hold and coughing may correct this impairment. A patient with decreased breath sounds or consolidations may have a decrease in the oxygen content of his or her blood; a decrease in oxygenation may result in an increase in myocardial work and aggravate a preexisting cardiac impairment.

Jugular Venous Distention

Patients with CHF with backup of fluid into the venous vasculature should be examined for the presence of jugular venous distention. To examine for this sign, the patient is placed at a 45-degree semirecumbent position.[74] The

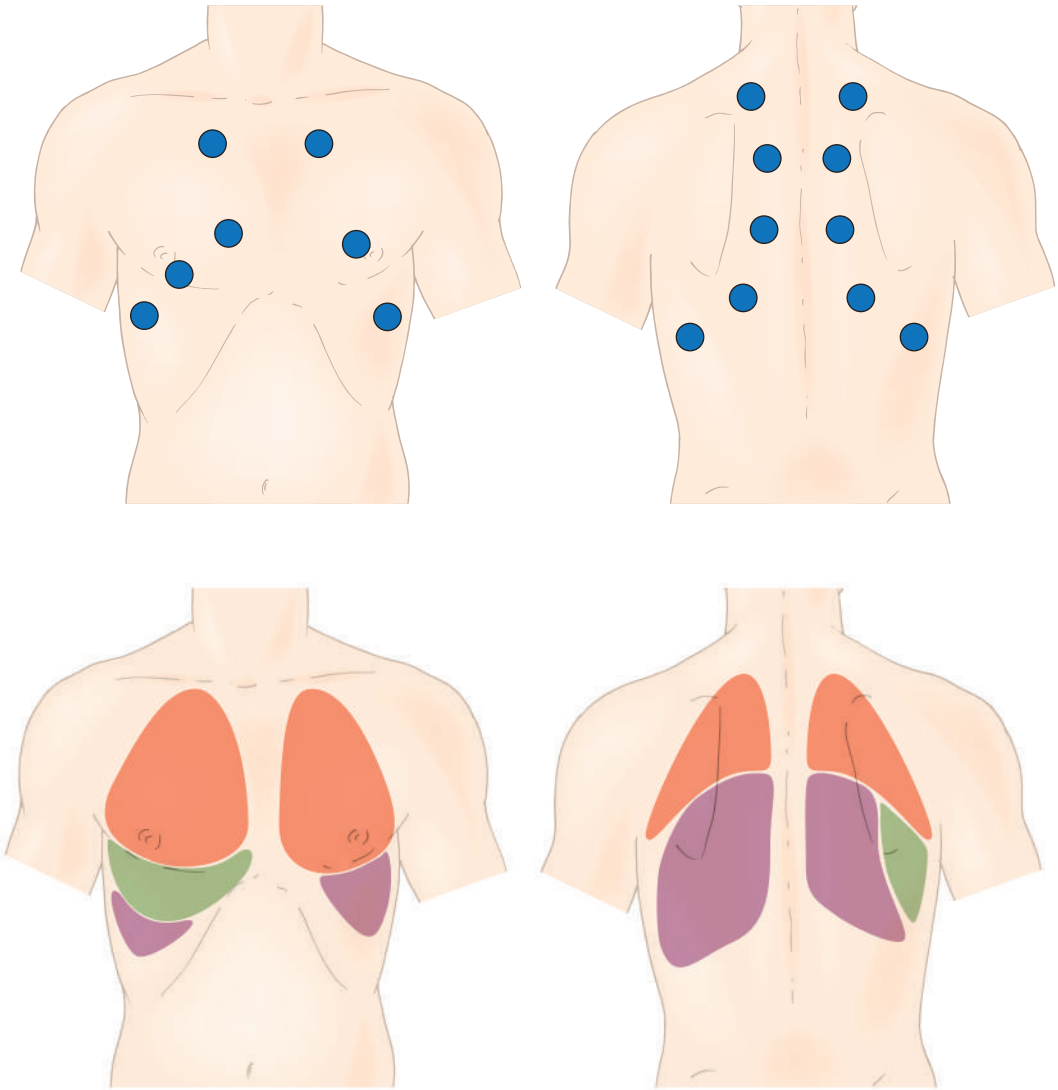

Figure 13.18 Auscultation of lungs.

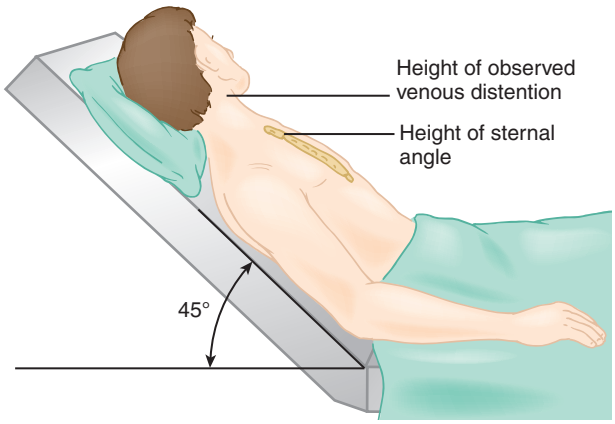
patient's head is turned away from the side to be evaluated and the clinician observes for a distention or pulsations of the jugular vein 3 to 5 cm above the sternum.[44] The highest point of visible pulsation is determined and the vertical distance between this level and the level of the sternal angle of Louis is recorded (Fig. 13.19).

Pitting Edema

In patients with congestive heart failure, low SV causes a reduced blood volume perfused to the periphery. This stimulates the pressoreceptors as they sense a decrease in volume. These pressoreceptors subsequently relay a message to the kidney to retain fluid. This retention of fluid increases the hydrostatic pressure within the peripheral vasculature, thereby pushing fluid into the interstitial space resulting in peripheral edema and weight gain. Edema can be assessed through girth measurements or by using the pitting edema scale. See Chapter 14, Vascular, Lymphatic, and Integumentary Disorders, for the pitting edema grading scale. The severity of peripheral edema is categorized into four stages based on the time taken for the skin to rebound to its original contour after pitting. It is also important to note that edema can accumulate in the abdominal area (ascites) or sacral areas of the body.

Exercise Tolerance Tests

To examine the ability of the cardiovascular system to accommodate to increasing metabolic demand, an ETT, stress test, or graded exercise test is performed. The patient exercises through stages of increasing workloads, expressed in units of oxygen. Oxygen cost may be expressed in L/min, mL O_2/kg/min, kcal, or **metabolic equivalents (METs);** the MET represents the basic systemic oxygen requirement at rest, roughly 3.5 mL O_2/kg/min. The clinical usefulness of METs is that an activity can be expressed in comparison to resting energy cost. For example, the first stage of the Bruce protocol requires roughly 5 METs of energy (i.e., it requires five times the energy expended at rest). The most common modalities used in exercise testing of patients with cardiac impairments are the treadmill, bicycle, and arm ergometer (Fig. 13.20). In the earlier years of exercise testing for examination of CAD, the step test was routinely used; however, it has for the most part been replaced by the other modalities. The step test is useful for fitness screening in the relatively healthy population and in exercise training for both the cardiac and noncardiac populations.



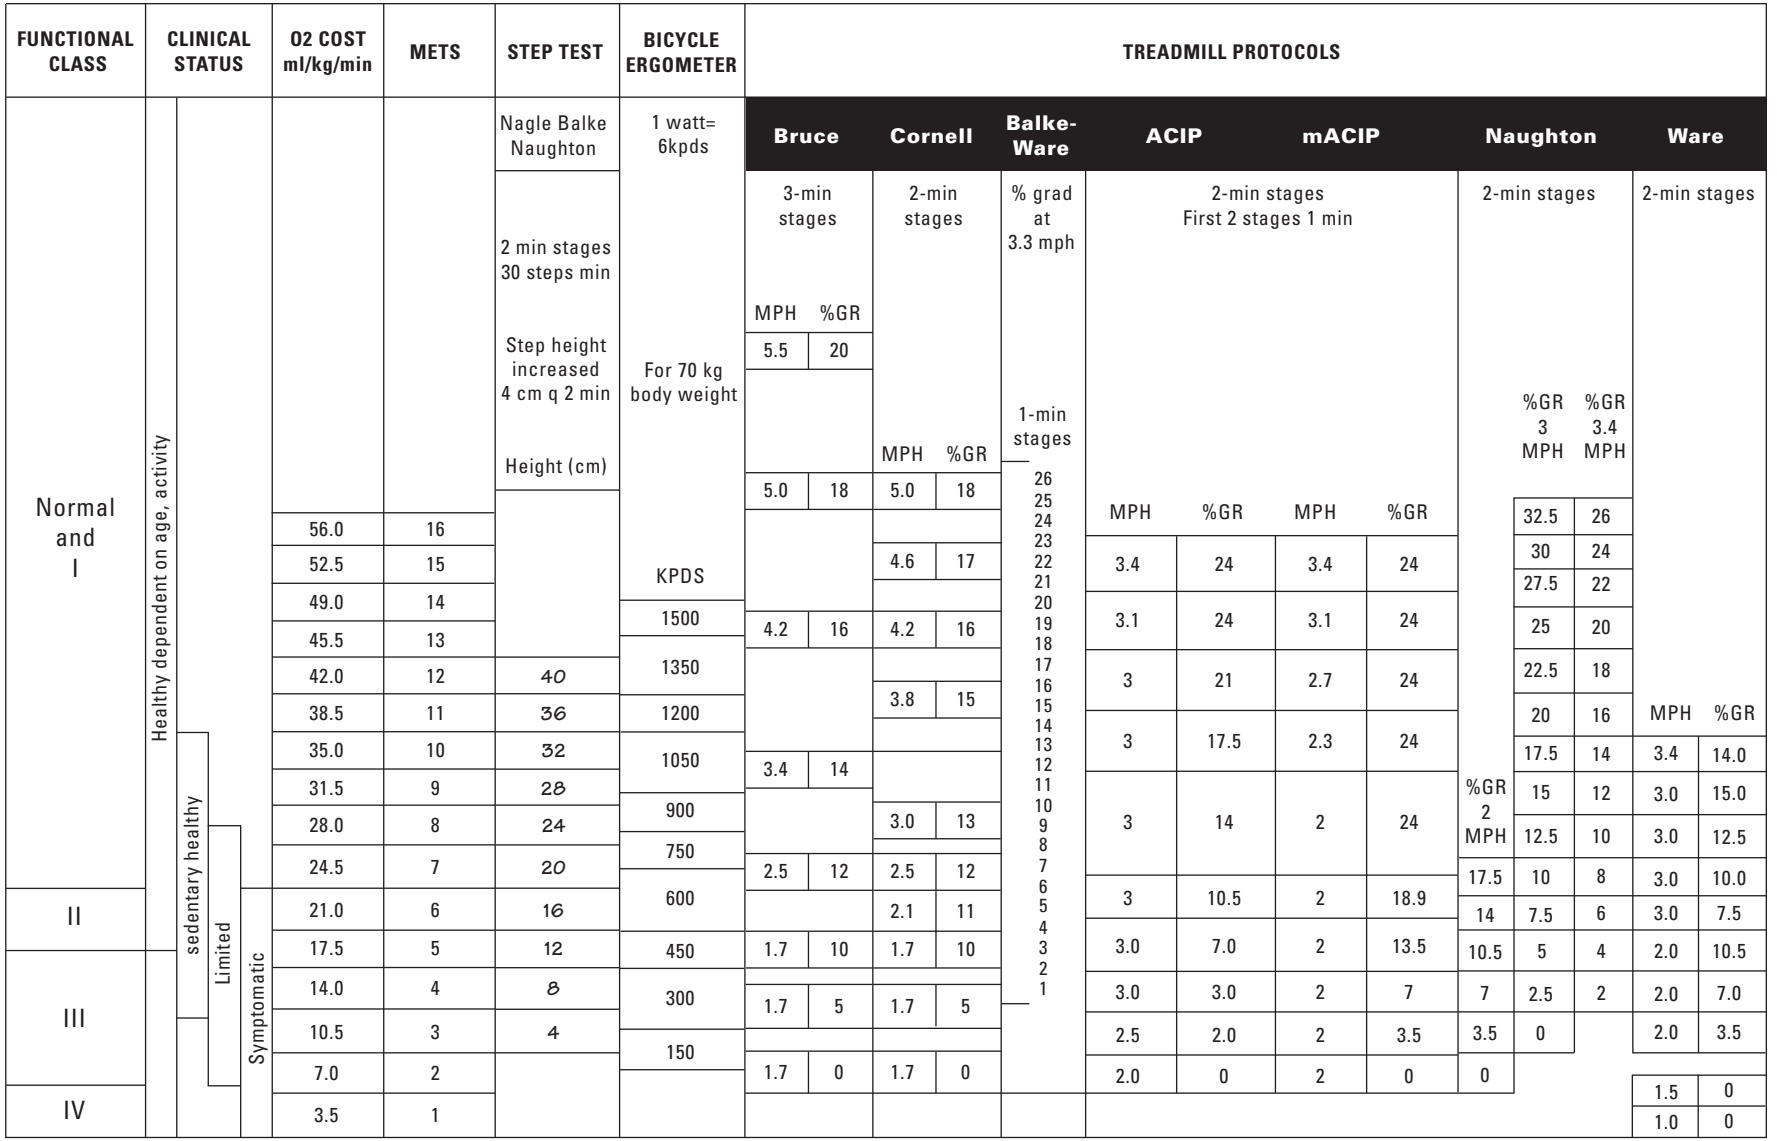


Figure 13.19 Examination of jugular venous distention.

Knowledge of systemic energy requirements is important in prescribing exercise and activity guidelines, as well as in exercise testing for patients with cardiac impairments. Many charts are available that express systemic energy requirements using a variety of oxygen equivalents (Table 13.9).

The two major goals of exercise testing are to detect the presence of ischemia and to determine the functional aerobic capacity of the individual. The patient is monitored with a 12-lead ECG throughout the test and recovery; information regarding perfusion, rhythm, or conduction changes is therefore immediately available. In addition to the ECG, other diagnostic tools may be used, most commonly the echocardiogram and nuclear imaging. The stress echo examines wall motion abnormalities that may or may not be present at rest, but may become more pronounced with increasing workloads. Nuclear imaging (e.g., thallium sestamibi) compares coronary perfusion between rest and exercise. If there is no decrease in perfusion with increasing workloads, the test is negative; if there is a decrease, the test is considered positive.

Stress tests are interpreted as either positive (+) or negative (–). A *positive ETT* indicates that there is a point at which the myocardial oxygen supply is inadequate to meet the myocardial oxygen demand, and the test is therefore positive for ischemia. A *negative ETT* indicates that at every tested physiological workload there is a balanced oxygen supply and demand. Patients are often confused regarding this grading system. It is helpful to reassure them that in this case, a negative test is in fact good. Stress tests are not unlike other diagnostic tools; however, they are not 100% specific and sensitive in identifying the presence of ischemia. A *false-negative ETT* is one that is interpreted as negative but the patient in fact has ischemia. Conversely, a *false-positive ETT* is one that is interpreted as positive but the patient does not have ischemia.

When a patient is unable to perform an exercise test because of limitations such as musculoskeletal or neurological impairments, a pharmacological stress test such as a *persantine thallium* test is often recommended. Persantine, when given intravenously, decreases coronary vascular resistance by causing arterioles to vasodilate, and therefore increases the blood flow through the capillary beds. If an artery is atherosclerotic, its arteriole may have gradually dilated over time in an attempt to increase capillary blood flow by means of pressure autoregulation. Therefore, when persantine is given, the diseased arteries may have a limitation in the amount of further arteriolar

Figure 13.20 Estimated oxygen requirements for step, bicycle, and treadmill. The standard Bruce protocol begins at 1.7 mph and 10 percent grade (roughly 5 METs). Oxygen requirements increase with progressive increases in workload for all modalities. *(Adapted from Fletcher et al,[112] p. 156.)*

Table 13.9 Metabolic Equivalent (MET) Chart

Intensity (70-kg Person)	Endurance Promoting	Occupational	Recreational
1½–2 METs 4–7 mL/kg/min 2–2½ kcal/min	Too low in energy level	Desk work, driving auto, electric calculating machine operation, light housework, polishing furniture, washing clothes	Standing, strolling (1 mph), flying, motorcycling, playing cards, sewing, knitting
2–3 METs 7–11 mL/kg/min 2½–4 kcal/min	Too low in energy level unless capacity is very low	Auto repair, radio and television repair, janitorial work, bartending, riding lawn mower, light wood-working	Level walking (2 mph), level bicycling (5 mph), billiards, bowling, skeet shooting, shuffleboard, powerboat driving, golfing with power cart, canoeing, horseback riding at a walk
3–4 METs 11–14 mL/kg/min 4–5 kcal/min	Yes, if continuous and if target heart rate is reached	Brick laying, plastering, wheelbarrow (100-lb load), machine assembly, welding (moderate load), cleaning windows, mopping floors, vacuuming, pushing light power mower	Walking (3 mph), bicycling (6 mph), horseshoe pitching, volleyball (6-person, noncompetitive), golfing (pulling bag cart), archery, sailing (handling small boat), fly fishing (standing in waders), horseback riding (trotting), badminton (social doubles)
4–5 METs 14–18 mL/kg/min	Recreational activities promote endurance; occupational activities must be continuous, lasting longer than 2 min	Painting, masonry, paperhanging, light carpentry, scrubbing floors, raking leaves, hoeing	Walking (3½ mph), bicycling (8 mph), table tennis, golfing (carrying clubs), dancing (foxtrot), badminton (singles), tennis (doubles), many calisthenics, ballet
5–6 METs 18–21 mL/kg/min	Yes	Digging garden, shoveling light earth	Walking (4 mph), bicycling (10 mph), canoeing (4 mph), horseback riding (posting to trotting), stream fishing (walking in light current in waders), ice or roller skating (9 mph)
6–7 METs 21–25 mL/kg/min 7–8 kcal/min	Yes	Shoveling 10 times/min (4½ kg or 10 lb), splitting wood, snow shoveling, hand lawn mowing	Walking (5 mph), bicycling (11 mph), competitive badminton, tennis (singles), folk and square dancing, light downhill skiing, ski touring (21/2 mph), water skiing, swimming (20 yards/min)
7–8 METs 25–28 mL/kg/min 8–10 kcal/min	Yes	Digging ditches, carrying 36 kg or 80 lb, sawing hardwood	Jogging (5 mph), bicycling (12 mph), horseback riding (gallop), vigorous downhill skiing, basketball, mountain climbing, ice hockey, canoeing (5 mph), touch football, paddleball
8–9 METs 28–32 mL/kg/min 10–11 kcal/min	Yes	Shoveling 10 times/min (5½ kg or 14 lb)	Running (5½ mph), bicycling (13 mph), ski touring (4 mph), squash (social), handball (social), fencing, basketball (vigorous), swimming (30 yards/min), rope skipping
10+ METs 32+ mL/kg/min 11+ kcal/min	Yes	Shoveling 10 times/min (7½ kg or 16 lb)	Running (6 mph = 10 METs, 7 mph = 11½ METs, 8 mph = 13½ METs, 9 mph = 15 METs, 10 mph = 17 METs), ski touring (5+ mph), handball (competitive), squash (competitive), swimming (greater than 40 yards/min)

dilation that can occur. In comparison to the nondiseased arteries, there will be a relative decrease in blood flow through the capillary beds of the diseased arteries. Imaging studies will thus detect a relative decrease in blood flow to the area of the myocardium that is perfused by the diseased artery compared to that perfused by a nondiseased artery. Adenosine, which is a coronary and peripheral vasodilator (as well as an antiarrhythmic), has similar effects as persantine and may be used instead.[95]

Assessment of Aerobic Capacity and Endurance

The best indicator of an individual's aerobic capacity is through examination of the peak oxygen uptake or VO_2 maximum and anaerobic threshold. However, to obtain these numbers, sophisticated and expensive equipment such as a metabolic cart is required. Most physical therapists do not have access to this equipment to determine these numbers. Therefore, the physical therapist can continually monitor the patient's responses during exercise to better understand the individual's tolerance and level of endurance. HR, BP, pulse oximetry, and respiratory rate and rhythm at every given level of intensity will provide clinicians with a good picture of the patient's aerobic capacity and endurance.

Another useful test to determine an individual's functional status, exercise tolerance and oxygen consumption is the *6-Minute Walk Test (6-MWT).* Patients are asked to walk as far as they can in 6 minutes, taking as many rests as needed during this time.[96-98] The 6-MWT, although considered submaximal, closely approximates the maximal exercise of persons with CHF and can be correlated to peak oxygen consumption.[98,99] In addition to prediction of the peak oxygen uptake, a distance of 300 m is an important indicator of short-term and long-term survival in patients with CHF. Coats[100] found that patients unable to ambulate greater than 300 m during the 6-MWT had poorer short-term survival, and Bittner et al[101] reported that patients who were unable to ambulate distances over 300 m had poorer long-term survival.

PHYSICAL THERAPY INTERVENTION FOR PATIENTS WITH HEART DISEASE

Intervention for Patients with Coronary Artery Disease

According to the APTA *Guide to Physical Therapist Practice,* the preferred practice pattern for management of patients with CVD is Pattern 6-D. The development of specific anticipated goals and expected outcomes for the individual with CAD is based on the general goals of physical therapy intervention presented in Box 13.5.

Physical therapists treat not only patients who have a primary diagnosis of heart disease, but also, and perhaps more commonly, patients with multiple medical diagnoses, only one of which is cardiac. Physical therapy intervention during the traditional acute cardiac rehabilitation phase involves following the patient while recovering from his or her cardiac event, such as an MI, providing hemodynamic monitoring of progressive activity, discharge guidelines, education, and information regarding outpatient referral. It may include outpatient management as well, ideally in a multidisciplinary setting including nursing and nutrition. Patients with cardiac histories commonly have physical therapy needs at other points throughout their lives. For example, the patient with a previous MI might require ambulation training as a result of a fractured hip, an outpatient knee rehabilitation program following a skiing injury, tennis elbow intervention, prosthetic ambulation training, or intervention following a CVA. If the physical therapist understands the pathophysiology of the cardiac condition and the energy demands being placed on the patient, the therapist will be able to adjust the POC accordingly.

It is important to remember that a patient with known CAD may not have symptomatic ischemia, either because the lesions are not of significant size to interfere with blood flow, or the anti-ischemic medications are able to keep the patient's physiological response to activity below his or her ischemic threshold. Following a noncomplicated MI, ischemia should not occur in the area perfused by the involved artery because infarcted tissue cannot become ischemic. However, if there is disease in other arteries, ischemia can occur in any noninfarcted tissue that has a compromised blood supply. A physical therapist working with patients with significant CAD must be aware that their basic cardiac impairment is an imbalance of myocardial oxygen supply and demand, and any increase in systemic oxygen consumption

Box 13.5 Coronary Artery Disease—Anticipated Goals and Expected Outcomes

- Aerobic capacity is increased.
- Ability to perform physical tasks related to self-care, home management, community and work integration or reintegration, and leisure activities is increased.
- Physiological response to increased oxygen demand is improved.
- Strength, power, and endurance are increased.
- Symptoms associated with increased oxygen demand are decreased.
- Ability to recognize a recurrence is increased, and intervention is sought in a timely manner.
- Risk of recurrence is reduced.
- Behaviors that foster healthy habits, wellness, and prevention are acquired.
- Decision making is enhanced regarding health of patient and the use of health care resources by patient/client, family, significant others, and caregivers.

will increase myocardial oxygen consumption. A past medical history of CAD does not mean that the disease occurred in the past and is no longer present; once a person has been diagnosed with CAD, he or she has the potential for atherosclerosis progression at any later point in time. Although the precipitating factors for plaque rupture are not clearly understood, the plaque with increased levels of oxidized LDLs is thought to be unstable with a greater potential for rupture.[102] It is important to note that plaque rupture may occur with lesions of any size, not just those that are greater than 70%.[102] Therefore, it is prudent for the physical therapist to know the status of all the coronary arteries, not just those that were revascularized or have a greater than 70% lesion.

The degree of a patient's risk for increased morbidity and mortality is based on a number of factors. The *American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR)* and the *American College of Physicians* provide a framework for stratifying patients with cardiac impairments (Table 13.10).

Table 13.10 Risk Stratification Criteria for Cardiac Patients by the American College of Physicians (ACP) and American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR)

ACP	AACVPR
Low Risk	
Uncomplicated MI or CABG	Uncomplicated MI, CABG, angioplasty, or atherectomy
Functional capacity ≥8 METs 3 weeks after clinical event	Functional capacity ≥6 METs 3 or more weeks after clinical event
No ischemia, left ventricular dysfunction, or complex arrhythmias	No resting or exercise-induced myocardial ischemia manifested as angina and/or ST-segment displacement No resting or exercise-induced complex arrhythmias
Asymptomatic at rest with exercise capacity adequate for most vocational and recreational activities	No significant left ventricular dysfunction (EF ≥ 50%)
Intermediate (Moderate) Risk	
Functional capacity <8 METs 3 weeks after clinical event	Functional capacity <5–6 METs 3 or more weeks after clinical event
Shock or CHF during recent MI (<6 months) (EF 31%–49%) Inability to self-monitor heart rate	Mild to moderately depressed left ventricular function
Failure to comply with exercise prescription	Failure to comply with exercise prescription
Exercise-induced ST-segment depression <2 mm	Exercise-induced ST-segment depression of 1–2 mm or reversible ischemic defects (echocardiography or nuclear radiography)
High Risk	
Severely depressed LV function (EF <30%)	Severely depressed LV function (EF ≤30%)
Resting complex ventricular arrhythmias (low grade IV or V)	Complex ventricular arrythmias at rest or appearing or increasing with exercise
PVCs appearing or increasing with exercise	
Exertional hypotension (≥15 mm Hg decrease in systolic pressure during exercise)	Decrease in systolic blood pressure of >15 mm Hg during exercise or failure to rise consistent with exercise workloads
Recent MI (<6 months) complicated by serious ventricular arrhythmias	MI complicated by CHF, cardiogenic shock, and/or complex-ventricular arrhythmias
Exercise-induced ST-segment depression >2 mm	Patients with severe CAD and marked (>2 mm) exercise-induced ST-segment depression
Survivor of cardiac arrest	Survivor of cardiac arrest

From American College Sports Medicine: Guidelines for Exercise Testing, ed 5. Williams & Wilkins, Baltimore, 1995, pp 20, 21, with permission.

CABG = coronary artery bypass graft; CHF = congestive heart failure; EF = ejection fraction; LV = left ventricular; MET = metabolic equivalent; PVC = premature ventricular contraction.

Exercise Prescription

The *Clinical Practice Guidelines for Cardiac Rehabilitation* were established after extensive and critical review of published scientific literature.[103] These guidelines support the beneficial effect of exercise training on exercise tolerance for patients with heart disease. The most consistent benefit appeared to occur with exercise training at least three times per week for 12 or more weeks' duration. The duration of aerobic exercise training sessions varied from 20 to 40 minutes at an intensity approximating 70% to 85% of the baseline maximal exercise test HR. Exercise prescriptions are based on frequency, intensity, time (duration), and type (mode), the FITT equation. Activity should be gradually progressive in a logical stepwise fashion of increasing energy costs (i.e., METs, kilocalories) with appropriate HR and BP monitoring.

Although exercise is highly recommended for the patient with heart disease, there are conditions in which exercise is unwise. The AACVPR established guidelines for evaluating a patient's appropriateness for exercise participation. Contraindications for exercise training include unstable angina, symptomatic and uncompensated heart failure, uncontrolled arrhythmias, moderate to severe aortic stenosis, uncontrolled diabetes, resting blood pressure values in excess of 200/110, and uncontrolled resting tachycardia.[104]

The patient should be evaluated once these conditions have been corrected and, when appropriate, begin (or resume) the exercise program. Recognizing that cardiac disease is a dynamic process, and that the patient who was stable and able to participate in physical therapy last week may not be stable this week, is a critical concept. The importance of a patient-specific examination and evaluation before each session will allow the physical therapist to critically plan the appropriate intervention.

Exercise Intensity

Intensity may be prescribed by either HR or by subjective report, a *rating of perceived exertion (RPE)*. Subjective ratings of intensity of exertion have been used to quantify effort during exercise. The original *Rating of Perceived Exertion Scale (The Borg RPE Scale),* developed by Borg, has been used extensively (Table 13.11). It consists of numbers ranging from 6 to 20, which patients use to rate their perceptions of how hard they are working. Descriptive words accompany the numbers, such as hard or very hard. Commonly, patients are asked to limit their exertion to between fairly light and somewhat hard. Borg also developed a category-ratio scale of 0 to 10. Both local symptoms, such as muscle aches, cramps, pain, or fatigue, and central symptoms, such as feelings of fatigue or breathlessness, contribute to the overall feelings of work performance. High correlation of RPE ratings with HR and aerobic power has been found in normal individuals and in patients with cardiac disease.

A common aerobic exercise prescription based on HR is 70% to 85% of HR_{max}. However, the more deconditioned patient may be aerobically trained at as low as 50% to 60% of HR_{max}. Any patient who has documented CAD should have a medically supervised ETT before beginning an aerobic exercise program. Without an ETT, it is impossible to assume what the maximum HR would be for a patient with cardiac disease. The ECG monitoring during the ETT is useful in the detection of exercise-induced ischemia. If no ETT data are available, it is unwise to prescribe an exercise based on HRs. Cautious progression of activity is warranted, along with use of RPE and knowledge of adverse signs and symptoms for exercise intolerance. An easy tool for self-monitoring is for the patient to be able to talk without becoming breathless while exercising. This is termed the *Talk Test* and provides a fair indication that the patient is appropriately exercising below his or her anaerobic threshold, which usually occurs at approximately 55% to 70% of the maximal oxygen uptake.

Exercise Frequency

Exercise is commonly prescribed three to five times per week. The patient should not experience increased fatigue as a result of exercise. If fatigue does occur, the frequency and/or intensity of exercise should be decreased. Patients who choose to exercise daily must watch for signs and

symptoms of fatigue and overexertion, recognizing that fatigue may not just occur during the activity, but be delayed until later in the day or the next day.

Exercise Duration (Time)

The goal of 30 to 40 minutes of aerobic exercise with an additional 5 to 10 minutes of warm-up and an adequate cool-down is appropriate. If this amount of activity is uncomfortable for the patient, whatever amount he or she can do comfortably without adverse symptoms is appropriate. Patients who are deconditioned may require interval work, brief rests every 5 minutes during their early training. Adequate warm-up is crucial for all patients but especially for patients with CAD. By gradually increasing the MVO_2 and allowing the coronary arteries time to vasodilate, a balanced myocardial supply and demand may be possible with subsequent activity.

Mode of Exercise (Type)

The variety of exercise equipment has expanded in the last 20 years. The good news is that the patient has the opportunity to experience a variety of equipment including treadmills, stair climbers, bicycles, rowers, cross-country ski simulators, reclining bicycles, steppers, arm ergometers, and others. Patients frequently ask which is the best equipment; the one that they enjoy and the one that they will use is by far the best for them.

If a patient becomes symptomatic with angina during a physical therapy intervention, the immediate goal is to decrease MVO_2; the activity should be immediately stopped. The patient should sit or, if possible, lie down on a bed or plinth. The physical therapist should take the patient's HR and BP and calculate the rate pressure product (RPP = HR (SBP) as soon as possible to determine the MVO_2 at which the patient became ischemic, termed the *ischemic threshold.* If the patient is in an inpatient facility, help may be sought immediately to ensure that facility guidelines are quickly initiated. Such guidelines may include supplemental oxygen, a 12-lead ECG, administration of NTG, and other anti-ischemic medications. If the patient is in an outpatient setting and has his or her own NTG (which the patient should be carrying at all times), the patient should take it and follow the prescribed guidelines. NTG usually produces a tingling or burning sensation if it is effective. Failure of the NTG to produce these sensations may indicate that the NTG is outdated. Patients are generally instructed to take one NTG pill sublingually (under the tongue), although some patients use an NTG spray. They can then wait 5 minutes and repeat administration if the symptoms are not completely gone. A third NTG may also be taken after waiting another 5 minutes. Patients are frequently told that if the symptoms have not resolved completely after three doses of NTG they should come to the emergency department for further management. If the patient is in an outpatient setting without his or her own NTG and has symptoms that do not resolve after a few minutes of rest, the facility guidelines to activate advanced care for the patient should begin quickly. If the patient's symptoms escalate, even after the first NTG, emergency care needs to be initiated immediately. If the patient is climbing stairs, the patient should stop, take a few easy deep breaths, and then descend when the symptoms have abated and walk slowly to the first available support. However, if the patient's symptoms are quickly accelerating despite stopping the activity and taking deep breaths, the patient should be assisted to a position of comfort and further medical assistance sought immediately. It is important that therapists maintain a calm demeanor, reassuring the patient that the situation can be handled efficiently and easily.

Cardiac Rehabilitation: Myocardial Infarction

Although it is common today to take cardiac rehabilitation for granted, it was not so long ago that treatment for patients with MI included weeks of prolonged bedrest. In the pivotal 1952 study by Levine and Lown,[105] chair rest and low-level activity was found to be more beneficial than the traditional 8 weeks of bedrest. Today, the patient with a noncomplicated MI may be hospitalized for as few as 3 to 5 days.

Cardiac rehabilitation (cardiac rehab) is multidisciplinary and may include the physician, nurse, physical and occupational therapists, exercise physiologist, nutritionist, and social service caseworker. Cardiac rehab begins in the hospital and extends indefinitely into the maintenance phase. The inpatient component is referred to as *Phase I.* Outpatient phases include *Phase II,* the exercise-training period, and *Phase III,* the maintenance period. Phase II is usually described as occurring immediately after discharge, requiring intensive monitoring and supervision including ECG monitoring and intensive risk factor interventions.[106] Aerobic and strength training may begin based on the results of the ETT, which is usually done at approximately 4 weeks. In Phase III, the patient has stabilized and requires ECG monitoring only if signs and symptoms necessitate; endurance training and risk factor modification continue. Ideally, Phase II is initiated within 2 weeks of hospital discharge. It is important to note that these phases are not absolutes and the timelines and activities of these phases may vary according to managed care models, contracts with reimbursement plans, and treatment protocol designs. Owing to insurance coverage, some patients do not enter into a formal cardiac rehab program until after their symptom-limited maximum ETT at 4 to 6 weeks post-MI.

Inpatient/Phase 1

The length of hospital stay for a patient with an MI has changed dramatically in the last decade and is commonly 3 to 5 days for an *uncomplicated MI* (no post-MI angina, malignant arrhythmias, or heart failure), compared to at least three to four times that duration in the early 1980s.

Inpatient cardiac rehab uses a team approach based on activity progression, patient education, and hemodynamic and ECG monitoring, together with medical and pharmacological management. The role of the physical therapist is to monitor activity tolerance, prepare for discharge, educate the patient to recognize adverse symptoms with activity, support risk factor modification techniques, provide emotional support, and collaborate with other team members.

Vital sign monitoring occurs before and after and, if possible, during activity. The intensity of the activity is considered to be low level, and perceived exertion for the patient should be comparable to the "fairly light range" of the Borg RPE Scale (see Table 13.11). For an increase of 1 to 2 METs, an HR increase of 10 to 20 bpm is appropriate, if beta-blockers or other HR suppressers are not used; however, the absence of beta blockade in Phase I is uncommon. If a beta-blocker is used, there is no standardization as to the degree of HR suppression; subjective ratings of perceived exertion and objective observation of patient effort become increasingly important. A patient on beta-blockers who has an HR increase of 20 bpm during low-level inpatient activity would be considered inadequately medicated, unless the activity level was considerably higher than appropriate. A decrease in HR or BP during activity for any patient, regardless of medications, should be evaluated for the presence of an arrhythmia. Following the physical therapy intervention, the patient's tolerance of activity and hemodynamic stability should be documented.

There are a variety of inpatient cardiac rehab programs, frequently progressive based on levels of increasing energy costs (e.g., MET levels). Each facility will establish its own levels and criteria for activity progression and education; an example of an inpatient program is shown in Table 13.12. Following are some general comments and recommendations about the various levels. It is important to note that activity progression occurs along a continuum and is not done in a rigid format. Although a patient must demonstrate the ability to sit at the bedside with appropriate hemodynamic response before ambulating in the hallway, the patient's individual response and medical history will dictate how quickly he or she is able to progress. A patient may progress through more than one level within any treatment session.

Level 1. The patient is in the intensive care unit (ICU) and is stable; generally physical therapy intervention does not begin until after the first 24 hours from admission or until the patient has been stable for 24 hours. Physical therapy intervention should begin after the blood work has indicated the MI is completed. CK and troponin (both I and T) levels are monitored. For both CK and troponin levels, reliable diagnostic sensitivity (greater than 90%) is reached within 12 to 16 hours of the onset of symptoms.[106] CK peak levels occur between 14 and 36 hours, with a return to normal level after 48 to 72 hours; troponin peaks at 24 to 36 hours, with a return to normal levels within 10 to 12 days.[107] Commonly, three sets of CK levels collected 8 hours apart are collected. Because CK is released very quickly into the bloodstream with cellular damage, it is typical for the first and second CK levels to show a progressive increase and the third set to be less than the second (i.e., the CK peak has occurred, and the values are now trending downward). Because CK may be released with cellular damage to areas other than to the myocardium, specific myocardial isoenzymes known as CK-MB are monitored. Appropriate activity for the patient in the ICU during the first 24 hours is to move comfortably within the bed, perform ankle pumps, perform deep-breathing exercises, use the commode (if hemodynamically stable), and perform limited personal care.

Level 2. Once the patient has been hemodynamically stable for 24 hours he or she may progress out of bed (OOB). The therapist should also be alert to signs of orthostatic hypotension when the patient changes position from supine to sitting on the side of the bed. The patient's feet should be supported on a stool to assist venous return if they are not able to touch the floor. The patient walks to a bedside chair. The patient sits in an upright chair for up to 30 minutes a few times a day. There is a real temptation for many health care providers to have the patient "do" something while seated, such as washing, eating, or visiting with family. It is probably wise to just let the patient sit for the first time, without being encumbered with other tasks. The therapist is thus better able to evaluate the patient's response to being upright. If the patient has had a large MI or requires a slow progression to upright posture, the use of a reclining chair is a way to gradually assume the upright position. The patient performs LE exercises such as ankle pumps, knee extensions, or marching in place. Vital signs are monitored for hemodynamic stability and appropriate activity response. Ensuring sufficient healing time, pacing activities, and creating a healthful environment are components of a comprehensive patient education program.

Level 3. Patients are instructed to gradually increase their ambulation. One approach is to educate patients to judge their ambulation in terms of time instead of distance. Time is a more reproducible measurement, whereas distance may be difficult to judge (e.g., "I want you to walk for 2 minutes" vs. "I want you to walk 200 ft"). It also allows for an easier transition to the HEP, which is commonly based on length of time. For documentation purposes, it is most effective to document the distance covered in the time period whenever possible (e.g., "Patient ambulated 500 ft in 6 minutes with

an RPE of 10/20"). Information regarding CAD risk factors allows patients to begin to take responsibility for their choices about activity and lifestyle. However, for some patients this may be too early in their recovery, and they are unable to focus on what is being said. Giving patients written information is a good way to provide education and yet give patients the choice when to read it. Use of the Borg RPE Scale assists the patient in monitoring of activity intensity.

Levels 4 through 6. Patients gradually increase the frequency and time of their walks at a comfortable and leisurely pace. The goal is to progress walks from 2 minutes, to 5 minutes, to 10 minutes with appropriate hemodynamic response. Stairs may be climbed foot over foot with a planned rest halfway or so, or one foot at a time, depending on the status of the patient. Patients are often hesitant to move, especially in stretching their arms overhead; therefore performing a variety of trunk, arm, and standing leg exercises for a few repetitions each often allays the fear and helps the patient feel more comfortable moving.

Patients need to be made aware of the fatigue that often accompanies seemingly innocuous activities (e.g., showering) and plan their rests accordingly. Visitors are often a hidden energy cost; patients are often very excited and reassured to have visitors, but the fatigue that follows is sometimes very disconcerting. Helping the patient understand the concept of energy and the cost of not just physical but emotional and mental activities is invaluable. Comparing energy costs to money may help the patient to pace activity. Patients are told that they have a dollar's worth of energy and everything they do is going to cost them some part of that dollar; however, they can never spend more than 50 or 60 cents at one time. Every time they rest, it is like going to the ATM for a quick refill. In this way, patients become knowledgeable about the expendability of energy and yet are given the responsibility to spend (and save) as they choose.

Documentation

There are many ways to document physical therapy examination and intervention. In this patient population, appropriate documentation would include the following:

1. Objective activity data, including time period and distance ambulated, type of sitting and standing exercises, and stair climbing (number of steps); number and duration of rests.
2. Patient's vital sign response to each activity, including a statement that addresses patient performance with respect to vital signs (e.g., "Patient ambulated 6 minutes covering 500 ft and climbed 10 steps foot over foot using handrail with adaptive VS response without signs or symptoms of hemodynamic compromise").
3. Education provided and response of patient, family, and caregivers.

Home Exercise Program

Two of the more important concepts for a patient to understand at the time of discharge are symptom recognition and appropriate activity guidelines. It is crucial that the patient recognizes cardiac symptoms and understands the action to take if they occur.

Physical therapists establish activity guidelines during the first 4 to 6 weeks after MI while the myocardium is healing. During this healing phase, physical activity involves a gradual increase in ambulation time, with a goal of 20 to 30 minutes of ambulation one to two times per day at 4 to 6 weeks after MI. Patients are encouraged to walk comfortably, dress appropriately, and to try to exercise in ambient temperature at indoor malls if weather is not appropriate (i.e., below 40°F including wind chill factor, over 80°F, or excessive humidity and poor air quality). Some patients are very sensitive to environmental factors and should exercise only in ambient conditions or indoors. For some patients, home exercise equipment is affordable and may be a reasonable alternative to outdoor exercise. For safety reasons, the patient should be monitored on similar equipment before independently beginning to exercise at home. This is not the time for a patient to try a new type of exercise modality but to stay with what is familiar. Walking appears to be the exercise of choice owing to its ease and familiarity.

The patient's days will be a combination of rest and low-level activity including ambulation and LE and UE mobility. The patient should be encouraged to try to change positions or activity every 1 to 2 hours. For example, it is generally not a good idea for the patient to be up all morning and then rest all afternoon. It is invaluable to have patients verbally outline what their days will include once they are discharged. This affords an opportunity to better understand the interests of the patient and make specific suggestions, as well as provide an opportunity to determine the patient's understanding of activity guidelines and energy conservation techniques.

Outpatient Phase II

Patients commonly undergo a symptom-limited maximal stress test (ETT) at 4 to 6 weeks after MI. Based on the results of the tests, either positive (+) for ischemia or negative (–) for ischemia, an exercise prescription is prescribed. For a (–) ETT, a common exercise prescription would be 70% to 85% of the peak achieved on the test (i.e., HR_{max}); however, an equally effective alternative would be 65% to 80% of HR_{max}. Understanding that a negative test does not mean the patient is disease free and that vulnerable plaques may exist, a conservative prescription may be a wiser choice.

Table 13.12 Inpatient Cardiac Rehabilitation Program

CCU–Essentially Bedrest

Level 1
1–1.5 METs
- Evaluation and patient education
- Arms supported for meals and activities of daily living (ADL)
- Bed exercises and dangle with feet supported (if CK levels have peaked and patient has no complications)

Education
- Introduction to inpatient cardiac rehab and role of physical therapy
  - Education
  - Monitored progression of activity
  - Home exercise/activity guidelines/outpatient cardiac rehab

Sitting—Limited Room Ambulation

Level 2
1.5–2 METs
- Sitting 15–30 min, 2–4 times/day
- Leg exercises
- Commode privileges
- Reclining upright chair
- Limited ADL
- Electric razor
- Limited supervised room ambulation for small uncomplicated MI

Education
- Identification of CAD risk factors
- Concept of "healing interval" and need to pace activities

Room—Limited Hall Ambulation

Level 3
2–2.5 METs
- Room or hall ambulation up to 5 min as tolerated 3–4 times/day
- Standing leg exercises optional*
- Sit on side of bed or in bathroom to wash (per discretion nurse/physical therapist [PT])
- Manual shave
- Bathroom privileges
- Independent or assisted ambulation in room or hall as advised by PT

Education
- Size of infarct and how it relates to the need for gradual resumption of activities
- Impact of exercise on reducing the patient's risk factors
- Teach use of Borg's Scale for Rating of Perceived Exertion and appropriate parameters with activity

Progressive Hall Ambulation

Level 4
2.5–3 METs
- Hall ambulation 5–7 min as tolerated 3–4 times/day
- Standing trunk exercises optional*
- Independent or assisted ambulation in hall as advised by PT

Education
- Teach pulse taking and appropriate parameters with activity
- Reinforce benefits of outpatient cardiac rehabilitation

Progressive Hall Ambulation

Level 5
3–4 METs
- Hall ambulation 8–10 min as tolerated
- Arm exercises optional*
- Standing shower
- Independent hall ambulation as advised by PT

Education
- Written home exercise/activity guidelines reviewed
- Patient given written information on outpatient cardiac rehab

Stair Climbing

Level 6
4–5 METs
- Progressive hall ambulation as tolerated
- Full flight of stairs (or as required at home) up and down one step at a time†

Education
- Answer patient's questions
- Check for understanding of activity guidelines

Patient Outcome—No Evidence of Hemodynamic Compromise with Activity Progression (All Levels)

No systolic drop in BP >10 mm Hg or increase >30 mm Hg
No HR increase >12 if beta blocked, or no HR increase >20 if not beta blocked
No complaints of dizziness, lightheadedness, or angina
Perceived exertion <13/20

Hemodynamic Monitoring

Level 1
- HR and BP before and after supine bed exercises
- Orthostatic signs supine and dangling at bedside

Level 2
- Orthostatic signs (supine, sit, and stand) before exercises and transfer
- HR and BP after leg exercises/transfer to chair
- HR and BP after return to bed

Levels 3–6
- HR and BP in sitting and standing prior to activity
- HR and BP immediately following activity
- HR and BP 5 min after activity

From Rehabilitation Services Department, Newton Wellesley Hospital, Newton, MA, with permission.
*Optional exercises are at the discretion of the PT and may be used to establish the patient's CV response in the room, prior to moving on to more challenging hallway ambulation; or in those patients who require general strengthening exercises.
†Stair climbing activities should take place after the ETT if the scheduling of the ETT permits. Otherwise patients may, at the discretion and supervision of the PT, climb stairs on the day prior to the ETT.

If a patient has had a *positive ETT,* the exercise prescription becomes relatively simple: during aerobic training, it is important to keep MVO_2 below the patient's ischemic MVO_2. Remember that a clinical measure of MVO_2 is the product of HR and SBP, known as the rate pressure product (RPP = HR × SBP). The importance of considering the ischemic threshold is the recognition that BP will vary during use of different pieces of exercise equipment owing in part to the differences in muscle recruitment. If there is a difference in BP for a given HR, then there will be a difference in the MVO_2 to the patient. For example, if a patient has an HR of 100 bpm and a BP of 140/80 mm Hg while exercising on the treadmill, and an HR of 100 bpm and a BP of 160/80 mm Hg while exercising on the stationary bicycle, the bicycle is costing the myocardium more energy than the treadmill, even though HR is the same. Depending on the patient's ischemic threshold, it is possible that angina may occur on the bicycle but not on the treadmill. A good safety tip is to not exceed 90% of the ischemic RPP. The remainder of the exercise prescription may follow the common guidelines for aerobic training in regard to frequency, intensity, and duration for patients with cardiac involvement.

Strength Training

The inclusion of strength training in a cardiac rehab program is a relatively recent addition to the traditional cardiac rehabilitation program. Initial concern was that resistance work would inordinately increase MVO_2 and ventricular arrhythmias and therefore be detrimental.[108] A publication by Beniamini et al[109] gives excellent insight into this area. The AACVPR's thorough review of the literature on this topic concluded that "resistance exercise has been shown to be a safe and effective method for improving strength and cardiovascular endurance, modifying risk factors and enhancing self efficacy in low-risk cardiac patients."[106] Resistance training may begin with the use of elastic bands and light hand weights (1 to 3 lb) and progress to a load that allows 12 to 15 repetitions comfortably.[110] *AACVPR guidelines* further state that resistance training should not begin until the patient has been in a cardiac rehab program for at least 3 weeks and is at least 5 weeks post-MI or 8 weeks post-CABG.[110] Some guidelines for resistance training include the following: (1) exercising large muscle groups before small; (2) stressing exhalation with exertion; (3) avoiding a sustained, tight grip; (4) focusing on RPE 11 to 13; (5) using slow, controlled movements; and (6) stopping exercise with any warning of concerning or uncomfortable signs or symptoms.[110] The American Heart Association (AHA), American College of Sports Medicine (ACSM), and AACVPR all advocate the importance of muscular fitness for the patient with cardiac impairment and support the inclusion of resistance training into the patient's exercise program.[106,110-112]

Intervention for Patients with Congestive Heart Failure

The APTA *Guide to Physical Therapist Practice* includes management of patients with CHF under the category of Impaired Aerobic Capacity and Endurance Associated with Cardiovascular Pump Dysfunction or Failure, Pattern 6-D.[26] The development of specific anticipated goals and expected outcomes for the patient with CHF is based on the general goals of physical therapy intervention presented in Box 13.6.

Exercise Prescription

Exercise programs for patients with CHF are relatively recent. Patients whose cardiac status was once thought to be too fragile to participate in organized exercise are now not only participating, but exercise is recommended as an integral component of their medical management.[113-116] Studies have shown that patients with heart failure can exercise safely, and regular exercise may improve functional status, quality of life, and exercise capacity, and decrease symptoms.[117-123]

The safety and importance of strength training and peripheral adaptations have also been studied.[124,125] Using a multidisciplinary approach that includes a thorough physical examination before each exercise session with a review of symptoms and medications, low-level exercise may begin if the patient is hemodynamically stable. CHF is a multisystem disease that affects not just the heart but peripheral muscle and arteries as well. Studies have demonstrated muscle fiber atrophy of skeletal and respiratory muscle, as well as an alteration in arterial vasodilation capacity. Exercise has been shown to limit some of these adverse changes; therefore, an exercise program should consider not only systemic conditioning, but also peripheral endurance training, low-level resistance training, and respiratory muscle training.[126-128] Exercise training can be initiated when

Box 13.6 Congestive Heart Failure—Anticipated Goals and Expected Outcomes

- Physiological response to increased oxygen demand is improved.
- Self-management of symptoms is improved.
- Ability to perform physical tasks is increased.
- Behaviors that foster healthy habits, wellness, and prevention are acquired.
- Disability associated with acute or chronic illness is reduced.
- Risk of secondary impairments is reduced.
- Awareness and use of community resources is improved.
- Performance of and independence in ADL is increased.

ADL = activities of daily living.

the patient is in compensated CHF. Box 13.7 provides the relative criteria for initiation and relative criteria for modification and termination of exercise in patients with heart failure.

Aerobic Exercise

There is no paucity of research indicating that aerobic exercise is beneficial for patients with CHF. Exercise prescription must keep intensity low and gradually increase duration as the patient tolerates. In general, aerobic exercise training may include low-impact exercise with gradual progression of intensity, frequency, and duration. Intensity should be monitored through the use of the dyspnea or perceived exertion scales and should be kept to a rating of fairly light. HR cannot be relied on for evaluating intensity due to the effects of various medications, including beta-blockers. It is also important to note that in the normal heart, an increase in HR is accompanied by an increase in inotropy. In the failing heart, an increase in HR may actually result in a decrease in force; this is known as the *negative treppe effect.*[129]

Monitoring BP response is crucial to determine if CO is being maintained during aerobic exercise. A drop in BP during aerobic exercise signifies the inability of the heart to maintain CO during exercise. For these patients, therapists may chose to reduce the aerobic component and focus more on strength training to achieve peripheral adaptations as opposed to central adaptations. By strength training the peripheral muscles, therapists can increase the number of mitochondria and utilization of blood and oxygen at the level of the muscle, thereby enabling the muscle to make more energy to sustain activity without putting excessive stress on the heart.

Two important studies depict the benefits of exercise training in patients with heart failure. A meta-analysis conducted by van Tol et al[130] in 2006 investigated 35 original randomized crossover trials of patients with systolic heart failure.[130] The average exercise within these studies included aerobic exercise 3 times/week for 60 minutes/session for 12 weeks. The investigators found an increase in 6-minute walk distance with an effect size of 46.2 m, within 15 studies including 599 patients. In 31 studies with approximately 1,240 patients, maximum oxygen uptake was found to increase after exercise with an effect size of 2.06 mL/kg/min. The researchers also found improvements in the resting diastolic BP, resting CO, and resting HR values following exercise. Finally, patients were able to demonstrate an increase in the LVEF and tolerate greater intensity following the 12 weeks of exercise. A systematic review published by Smart and Marwick[131] investigated 81 studies involving 2,387 exercising subjects with 1,197 patients enrolled in controlled studies and included 60,000 patient hours of exercise training. Mean number of subjects was 30 ± 25; mean age was 59 ± 7 years, and mean EF was 27% ± 7%. The investigators reported that studies utilizing aerobic exercise training (n = 40) demonstrated $VO_{2\ max}$ increase of 16.5%. In addition, studies utilizing strength training alone (n = 3) demonstrated $VO_{2\ max}$ increase of 9.3%, and studies that combined aerobic and strength programs (n = 30) demonstrated $VO_{2\ max}$ increase of 15%. Clinically, this could mean that an individual with a $VO_{2\ max}$ of 15 mL/kg/min could increase to 17.4 mL/kg/min, which is an approximately .68 MET increase and could lead to sustained walking on a level surface. Box 13.8 Evidence Summary presents related research investigating the effects of exercise in patients with heart failure.[132-141]

Box 13.7 Criteria for Modification or Termination of Exercise in Patients with Heart Failure

- Marked dyspnea or fatigue
- RR > 40 breaths/min
- Development of S_3 heart sound
- Increase in pulmonary crackles
- Decrease in HR or BP of > 10 bpm or mm Hg respectively during steady state or progressive exercise
- Increase in the CVP by 10 mm of Hg
- Diaphoresis, pallor, or confusion

Criteria for Initiation of Exercise

- Compensated CHF
- Able to speak comfortably without signs of dyspnea with RR < 30 breaths/min
- Less than moderate fatigue
- CI > 2.0 L/min
- CVP < 10 mm Hg
- Crackles in less than one half of the lungs
- Resting heart rate < 120 bpm

Strength Training

Strength training is a crucial component of the exercise plan for patients with heart failure to help improve peripheral muscle strength and endurance. Inclusion of light resistance work has been shown to be safe in this population.[142] Modalities for resistance training may include elastic bands for mild UE and LE resistance work or light weights. A review by Braith and Beck[143] provides clinicians with the benefits of resistance training in helping to improve skeletal muscle morphology and provides clinical guidelines for prescription of resistance exercise. Box 13.9 delineates recommendations for resistance exercise in patients with heart failure.

Ventilatory Muscle Training

Breathing exercises[144,145] and inspiratory muscle training[146,147] have been shown to be beneficial in patients with heart failure. Diaphragmatic breathing may help reduce excessive accessory muscle use and reduce the work of breathing. Pursed-lip breathing has been shown to

Box 13.8 Evidence Summary Studies Investigating the Effects of Exercise on Patients with Congestive Heart Failure

First Author (Reference)	Design	Controls (n)	Exercise	Training Time, Frequency, Duration	Intensity and of Training	Change in Oxygen Consumption
Adamopoulos[132]	Crossover	20	24	30 min, 5 sessions/wk, 12 wk	60%–80% maximum heart rate; aerobic	15%
Barlow[133]	Longitudinal		23	60 min, 3 sessions/wk, 16 wk	50% of 1 repetition max; 90% anaerobic threshold; aerobic + strength	3%
Delagardelle[134]	Longitudinal		20	40 min, 3 sessions/wk, 12 wk	50%–75% max oxygen consumption; 60% of 1 repetition max	0% strength; 8% aerobic
Harris[135]	Longitudinal		24	30 min, 5 sessions/wk, 6 wk	70% maximum heart rate; aerobic	4%
Kemppainen[136]	Controlled nonrandomized	7	9	45 min, 3 sessions/wk, 20 wk	70% max oxygen consumption; aerobic + strength	27%
Stolen[137]	Controlled nonrandomized	11	9	45 min, 3 sessions/wk, 20 wk	50%–70% max oxygen consumption; aerobic + strength	27%
Malfatto[138]	Controlled nonrandomized	15	30	60 min, 5 sessions/wk, 12 wk	40%–50% max oxygen consumption; aerobic	18%
Radzewitz[139]	Longitudinal	88		25 min, 3 sessions/wk, 4 wk	60%–80% max oxygen consumption; aerobic + strength	11%
Santoro[140]	Longitudinal	6		90 min, 3 sessions/wk, 16 wk	50%–60% max oxygen consumption; 50% of 1 repetition max; aerobic + strength	18%
Vibarel[141]	Longitudinal		10	46 min, 3 sessions/wk, 8 wk	70%–80% max oxygen consumption; aerobic	22%

promote the positive end-expiratory pressure not only in patients with COPD but also in patients with CHF.[144] Pursed-lip breathing is also beneficial in helping slow down the respiratory rate in patients with heart failure.[145]

Patients with heart failure are known to have poor ventilatory muscle strength.[148] Strength of the ventilator muscles can be enhanced through use of a device known as a threshold inspiratory muscle trainer. Improvements in the maximal inspiratory pressure are achieved by having the patient breathe with this device, which resists inspiration, thereby strengthening the inspiratory muscles. A general protocol is to use the threshold inspiratory muscle trainer at 20% of the maximal inspiratory pressure, to be used 3 times per day for 5 to 15 minutes at each session.[9]

Activity Pacing and Energy Conservation Techniques

Patients with heart failure require activity pacing and energy conservation techniques to decrease the workload

Box 13.9 Resistance Training Recommendations for Patients with CHF

	NYHA Class I	NYHA Class II–III
Frequency	2–3 days/wk	1–2 days/wk
Duration	15–30 min	12–15 min
Intensity	50%–60%, 1 RM*	40%–50%, 1 RM*
Sets	2–3	1–2
Reps	6–15	4–10

*1 RM = 1 repetition maximum.

on the heart. A few techniques that may be beneficial for patients include the following:

- Recommending frequent rest intervals before they get tired.
- Participate in activities that require greater energy costs at times of the day when they have the most energy.
- Plan ahead to decide activities that possibly may be avoided and delegated to others.
- Alternate easy and difficult tasks with rest intervals.
- Adjust the environment to make tasks easier and sit when feasible while doing strenuous activity.

EDUCATION FOR PATIENTS WITH HEART DISEASE

For patients with heart disease, patient and family education develops along a continuum, depending on the patient's baseline status and readiness to attend to the information. The physical therapist, along with other members of the health care team, must determine the patient's and family's ability to understand and adhere to the information. Appropriate discharge or ongoing outpatient topics to be addressed include the following.

1. *Activity Guidelines*. Patients (and family) need to be able to understand specific activity guidelines, which include planned exercise sessions as well as leisure time and rests.
2. *Self-Monitoring.* Patients may monitor the intensity of their activity in a variety of ways; two of the more common ways are palpating a pulse and RPE. Because many older patients have decreased sensitivity in their palpation skills, the use of RPE may be easier and more reliable. Those patients who are able to take a pulse or choose to invest in an HR monitor may prefer to use those methods. Self-monitoring not only involves HR or RPE, but awareness of other symptoms or signs that may suggest exercise intolerance, such as lightheadedness, mental confusion, dyspnea, and inability to carry on a brief conversation while performing an activity. Patients with CHF commonly use the dyspnea scale and the Borg RPE Scale.
3. *Symptom Recognition and Response.* Being able to recognize their specific cardiac symptoms and to know how to respond is a key component in patient education. Patients should have written information regarding the action they should take when symptoms occur, for example, when to call their physician or go to the hospital. Angina is the most common symptom associated with coronary heart disease, whereas weight gain (2 lb over 1 to 2 days), dyspnea, LE edema, and increased pillows for sleep are common signs and symptoms for CHF.
4. *Nutrition.* Patients commonly meet with a nutritionist to discuss their usual dietary habits and to make recommendations when needed for a more heart-healthy diet. Most commonly, patients with heart disease are instructed to reduce fat intake; patients with CHF are instructed to monitor salt and fluid intake.
5. *Medications*. Patients receive written information regarding the desired action of their medications, potential side effects, dosage, and timing of medications. Patients should also know which nonprescription drugs such as cold, sinus, allergy, or anti-inflammatory medications they should avoid because of possible interactions with prescription drugs. Patients should also be encouraged to disclose all herbal remedies and supplements that they may be taking.
6. *Lifestyle Issues*. Many factors influence whether a patient will return to work after a cardiac event. Many patients with CAD return to work if they were employed before their event; patients with CHF are, in general, an older population when compared to patients with CAD and therefore may have already retired.

   Resumption of sexual activity may be an uncomfortable discussion for some patients. There may be many issues of concern for the patient (e.g., fear, anxiety, performance concerns, lack of libido). Patients and their partners are encouraged to verbalize their concerns to each other and to seek appropriate information from their health care team. Some medications (e.g., beta-blockers) may blunt the sexual response, and it is important that patients communicate this with their physician. Often, another medication or category of medication may be better tolerated. When patients feel ready for sex, their energy level throughout the day is satisfying for them, and they are able to walk outdoors and climb stairs comfortably, they are probably ready for sexual activity. It may be helpful for patients to remember that sexual activity is not unlike other physical activity with respect to energy cost, and therefore planning, pacing, and warm-up are powerful

contributors for a more comfortable outcome. In some cases, the physician may recommend taking prophylactic NTG before sexual activity.

7. See Box 13.10 *Suggested Topics for Patient, Family, and Caregiver Education and Counseling* from the U.S. Department of Health and Human Services Clinical Practice Guidelines for Patients with CHF.[149]

Box 13.10 Suggested Topics for Patient, Family, and Caregiver Education and Counseling

General Counseling

- Explanation of heart failure and the reason for symptoms
- Cause or probable cause of heart failure
- Expected symptoms
- Symptoms of worsening heart failure
- What to do if symptoms worsen
- Self-monitoring with daily weights
- Explanation of treatment/care plan
- Clarification of patient's responsibilities
- Importance of cessation of tobacco use
- Role of family members or other caregivers in the treatment/care plan
- Availability and value of qualified local support group
- Importance of obtaining vaccinations against influenza and pneumococcal disease

Prognosis

- Life expectancy
- Advance directives
- Advice for family members in the event of sudden death

Activity Recommendations

- Recreation, leisure, and work activity
- Exercise
- Sex, sexual difficulties, and coping strategies

Dietary Recommendations

- Sodium restriction
- Avoidance of excessive fluid intake
- Fluid restriction (if required)
- Alcohol restriction

Medications

- Effects of medications on quality of life and survival
- Dosing
- Likely side effects and what to do if they occur
- Coping mechanisms for complicated medical regimens
- Availability of lower-cost medications or financial assistance

Importance of Compliance with the Treatment Care Plan

From Clinical Practice Guidelines, Number 11, Heart Failure: Evaluation and Care of Patients with Left-Ventricular Systolic Dysfunction, AHCPR Publication No. 94-0612, p 42, with permission.

PSYCHOLOGICAL/SOCIAL ISSUES

Cardiac disease may not only create new emotional issues but also enhance some that might have existed before the cardiac event. Reassure patients that many of these issues are normal sequelae of their event. Encourage them to seek guidance and counseling in whatever arena they feel appropriate (e.g., health care, counseling, religion).

Many studies have addressed the relationship of emotional depression following CABG.[150-152] Although depression is reported to exist, there is difficulty in objectively measuring the direct impact of CABG on subsequent depression. Some of the difficulty arises in the use of depression scales (Beck or CES-D), grading criteria, the presurgical emotional status, and gender. Burg et al[150,151] reported two studies in 2003 in which 89 men were followed preoperatively and up to 2 years following surgery. They found that presurgical depression was an independent predictor of postoperative prolonged surgical pain and failure to return to previous activity. In a study by Blumenthal et al,[152] 817 patients were studied preoperatively, up to a mean of 5.2 years postoperatively. They reported that patients with moderate to severe depression at baseline (preoperatively) that persisted postoperatively had an increased death rate compared to the nondepressed patients.[152] Ai et al[153] reported that the presence of preoperative co-morbidities strongly influenced whether depression existed. McKhann et al,[154] in their study of 124 patients, concluded that the majority of patients depressed after surgery were in fact depressed before surgery. Pirraglia et al[155] reported on 237 patients and noted that 43% were classified as depressed preoperatively and only 23% postoperatively. Factors that influenced postsurgical scores were length of ICU stay and the amount of reported social support.[155] The decrease in postoperative depression compared to preoperatively was supported by Lindquist et al[156] in 2003; they studied more than 650 men and women and found less anxiety and depression following surgery than preoperatively. Of interest, they also noted that women's report of quality of life (QOL) was lower than men's up to 1 year following surgery. Westin et al[157] also reported a gender difference in CABG outcomes in regard to depression and QOL measures. In their study of more than 300 patients, women scored lower on the QOL and higher on depression scale than men at 1 month and 1 year following CABG, compared to men.[157] Phillips et al[158] reported women to be at greater risk for both cognitive difficulties and anxiety than men at 1-year postoperative CABG than men. The physical therapist, therefore, needs to be aware that depression may exist following surgery and, as

a member of the health care team, assist in directing appropriate care and support for the patient.

PRIMARY PREVENTION OF CORONARY ARTERY DISEASE

Patients who do not have documented CAD but who have identifiable risk factors should be encouraged to adopt lifestyle behaviors that can modify their risk factors. Health education and primary prevention programs through individualized education and exercise guidelines attempt to modify an individual's risk factors and thereby prevent CAD.

Patients are instructed in appropriate dietary guidelines, including low fat, adequate fiber, minerals and vitamins, and decreased salt, particularly if the patient has high BP. Besides lowering total dietary fat, patients are instructed to decrease their percentage of saturated fats and avoid trans fatty acids. Elevated levels of the amino acid homocysteine appear to increase the risk of arterial endothelial disease. Folic acid, a B vitamin, lowers homocysteine levels. If weight loss is needed, patients are encouraged to see a nutritionist to design a sensible eating plan. Patients are encouraged to gradually increase their endurance activity, such as walking toward a goal of 30 to 40 minutes (not including warm-up and cool-down) four times a week. The *American College of Sports Medicine* and the *American Heart Association* recommend that anyone over age 40 with two or more risk factors should have an ETT before beginning an aerobic or strengthening exercise program. The purpose of the ETT is to identify the presence of any latent ischemia.

If no ischemia is present, a typical aerobic exercise prescription might be as follows:

- Intensity: 70% to 85% of HR_{max} as the aerobic training zone
- Duration: 30 to 40 minutes in the aerobic training zone; appropriate warm-up of 5 to 10 minutes, and cool-down
- Frequency: three to four times per week

Maximum HR may be estimated by subtracting the person's age from 220; this, however, is not an exact science for any individual and cannot be accurate if the person is on any cardiac medications, such as beta-blockers, that may decrease the maximum HR. Supplemental resistance work is also encouraged at moderate intensities, with initial monitoring of HR and BP.

Modification of the other CAD risk factors is also key to the success of any primary prevention intervention. Patients are encouraged to identify risk factors and to seek resources to assist in modifying them. There are many community-based smoking cessation programs or medically supervised programs that a patient might explore. Stress management programs are also varied and can be adapted to the individual's needs. Proper and consistent use of any medications that might be used in controlling risk factors, such as antihypertensives, antihypercholesterolemias, blood glucose–lowering agents (hypoglycemics), and antianxiety agents or antidepressants, is crucial to the success of any program.

HTN, as the most prevalent CVD in the United States, is one of the most powerful contributors to cardiovascular morbidity and mortality. The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends a multifactorial approach and suggests that lifestyle modifications, including weight reduction, physical activity, and moderation of dietary sodium, are recommended as either definitive or adjunctive therapy for HTN.[24]

SUMMARY

Physical activity is important for all individuals and is especially beneficial for those individuals already diagnosed with CAD and CHF. Individuals with heart disease should understand that a consistent exercise program is part of the management for their disease and is as necessary as their medications. Having heart disease means that the person needs to understand the parameters in which he or she may safely participate in activity either recreationally or as a prescribed exercise. The role of the physical therapist is to provide a safe exercise prescription for all patients.

During the time of illness, the effects of decreased activity can be devastating. A paradox exists, however, in that the less activity that is done, the less activity can be done as a result of a decreased work capacity. Therefore, the relative energy cost of all activity increases, and the heart actually works harder for any given task. Not encouraging the patient to resume activity when he or she is medically stable is a disservice. As physical therapists, our role is clear: to understand the pathophysiology of the disease process, to accurately examine the patient, and to establish a safe POC. The ultimate goal is to improve the patient's physiological response to activity and, in doing so, decrease the work of the cardiovascular system.

Questions for Review

1. Discuss key differences between an NSTEMI and an STEMI.
2. Discuss three different types of angina. How would you instruct your patient in symptom recognition? Delineate the physical therapy management if a patient has angina during a treatment session.
3. Discuss sternal precautions that you would instruct your patient to use following a median sternotomy procedure.
4. Discuss differences between compensated and uncompensated CHF.
5. Discuss the physical therapy implications when managing patients with pacemakers.
6. Discuss appropriate goals, education, and treatment interventions for patients with acute coronary syndrome in Phase I cardiac rehabilitation.
7. Discuss appropriate goals and treatment guidelines for patients with CHF.
8. Delineate the adaptation that may be noted following an aerobic training exercise program in patients with heart failure.

CASE STUDY

A 58-year-old man presents to the local emergency department (ER) with chief complaint of SOB and difficulty sleeping last night; patient had to sit up all night to make symptoms even a little better. Patient came to the ER because he was unable to get ready for work owing to increased SOB. Patient reports that he has felt SOB off and on for a couple of months, usually associated with physical activity; symptoms, however, usually resolved with rest. Today's episode was the first related to sleeping.

PAST MEDICAL HISTORY

- Coronary artery disease: anterior MI 4 years ago
- Hypercholesterolemia
- Peripheral vascular disease

MEDICATIONS

- Digoxin, captopril, furosemide (Lasix), diltiazem, simvastatin (Zocor)

FAMILY/SOCIAL

- Patient works full-time as an engineer; travels 3 to 4 days per month.
- Married, lives with his wife in a two-story home on a 2-acre lot; three college-aged children.
- Patient is an avid golfer; enjoys gardening and landscaping.

PHYSICAL EXAMINATION

- Heart sounds: S_1, S_2 normal; S_3 present, no S_4; 2/6 systolic murmur
- Lung sounds: crackles 1/3 way
- Rhythm/rate: irregular, 140 bpm
- Blood pressure: 100/60 mm Hg
- Respiratory rate: 26 breaths/min
- SaO_2:90%
- Jugular venous distention: 5 cm
- Echocardiogram: akinetic apex, akinetic distal septum and anterior wall; dilated atria and LV
- Chest x-ray: unavailable

LABORATORY DATA

- Enzyme pending; CBC WNL except BUN and creatinine slightly elevated.
- BNP: 900 pg/mL.
- Patient remained in the hospital for 2 days while medications were adjusted. During this time patient underwent further testing, including an ETT.

RESULTS OF ETT

- Bruce protocol: 4 minutes; estimated VO_2 max; 20 mL O_2/kg/min (approximately 6 METs); max VS: 130 bpm HR; 120/60 mm Hg BP
- ECG: (–) negative for ischemia, chest pain
- Reason for stopping: absolute exhaustion

- Examination immediately post-ETT: (+) S_3
- Physical and occupational therapy were requested to assist with exercise guidelines and discharge planning

PATIENT'S GOALS

- Return to work.
- Resume hiking.
- Begin to prepare his garden for spring planting within the next 5 weeks.

PHYSICAL THERAPY INTERVENTION

- Exercise tolerance via low-level exercises sitting and standing, as well as 5-minute walk.

Vital Signs

- Sitting (rest): HR 90 bpm; BP 110/60 mm Hg
- Sitting exercises: HR 108 bpm; BP 110/60 mm Hg
- Standing (rest): HR 110 bpm; BP 108/60 mm Hg
- Standing exercise: HR 116 bpm: BP 110/60 mm Hg
- 5-minute walk: 1000 ft; HR 120 bpm; BP 116/60 mm Hg

HOME INSTRUCTIONS

- Meetings planned with patient and his family to discuss discharge guidelines over the next 4 to 8 weeks.

FOLLOW-UP

- Patient returns to his primary care provider 3 months after discharge. Echocardiogram is unchanged with EF 30%. Patient states that he has been following discharge guidelines.

Vital Signs

- HR 100 bpm; BP 116/70 mm Hg (resting).
- Patient states that he feels great and just wants to get on with his life.

GUIDING QUESTIONS

1. What is a reasonable presenting diagnosis? Identify each piece of information (and how you interpreted it) that you used to make this diagnosis.
2. Explain the pathophysiology of the patient's presenting symptoms. Discuss the significance of his HR and heart rhythm in relation to his symptoms.
3. If the patient's symptoms and signs worsened, and he was admitted to the coronary care unit (CCU),
   a. What do you think his Swan-Ganz reading could reasonably look like?
   b. What would you expect these signs/symptoms would be that would bring the patient to the CCU?
   c. What might be a reasonable cause of his signs/symptoms worsening?
   d. What other drugs/interventions might be given in the CCU?
4. What rhythm do you think the patient is in and why? What do you think might be a reason that he is in this rhythm?
5. What do you think the chest x-ray would look like and why?
6. What is your interpretation of the patient's vital sign response to PT intervention? What is your plan for your next session?
7. What exercise prescription would you recommend for the patient at home (modality, intensity, duration, frequency)?

Vascular, Lymphatic, and Integumentary Disorders

Deborah Graffis Kelly, PT, DPT, MSEd

Chapter 14

LEARNING OBJECTIVES

1. Understand basic concepts about the anatomy, physiology, and pathophysiology of the vascular, lymphatic, and integumentary systems.
2. Describe wound physiology as it relates to normal and abnormal wound healing.
3. Recognize the characteristics and risk factors of common disorders of the vascular, lymphatic, and integumentary systems.
4. Identify the components of a comprehensive examination of a patient with a disorder related to the vascular, lymphatic, and/or integumentary systems.
5. Analyze and integrate wound examination data to complete the physical therapy evaluation.
6. Interpret the rationale for skin and wound care treatment with particular attention to moist wound healing, arterial wound hydration, venous wound compression, lymphedema treatment, and foot care for the patient with diabetes.
7. Design an appropriate plan of care for an individual with a vascular, lymphatic, and/or integumentary disorder.
8. Using the case study example, apply clinical decision making skills to design a plan for advanced wound care.

CHAPTER OUTLINE

ANATOMY AND PHYSIOLOGY OF THE VASCULAR, LYMPHATIC, AND INTEGUMENTARY SYSTEMS *577*
- Vascular *578*
- Lymphatic *578*
- Integumentary *579*

WOUND PHYSIOLOGY *579*
- Normal Wound Healing *579*
- Abnormal Wound Healing and the Chronic Wound *583*

VASCULAR, LYMPHATIC, AND INTEGUMENTARY DISORDERS *585*
- Arterial Insufficiency and Ulceration *585*
- Venous Insufficiency and Ulceration *587*
- Lymphedema *588*
- Pressure Ulcers *590*
- Neuropathy *591*

EXAMINATION AND EVALUATION *593*
- Examination *593*
- Evaluation *601*

INTERVENTION *601*
- Coordination, Communication, and Documentation *601*
- Patient/Client-Related Instruction *602*
- Procedural Interventions *602*
- Dressings *614*
- Manual Lymphatic Drainage *618*
- Compression Therapy *618*
- Positioning *623*
- Pressure-Redistributing Devices *623*
- Exercise *624*
- Orthotics *624*
- Scar Management *625*

SUMMARY *626*

Patients and clients with disorders of the vascular, lymphatic, and integumentary systems have complex and often interrelated health problems to be understood before healing can occur. In recent years options for intervention have expanded significantly, providing the physical therapist with challenging and rewarding clinical treatments for clients. This chapter provides foundational material on which to build sound clinical decisions. Though interrelated, the systems discussed have unique characteristics and functions. This chapter facilitates understanding of the separate systems and then illustrates how the systems are intricately and essentially related. The elements of examination and the intervention strategies for all of the disorders are combined to ensure that the overlapping signs, symptoms, impairments, and activity limitations will be addressed and considered in the plan of care (POC). In this text, information about thermal injuries is complementary and supplemental to the information in this chapter (see Chapter 24, Burns).

ANATOMY AND PHYSIOLOGY OF THE VASCULAR, LYMPHATIC, AND INTEGUMENTARY SYSTEMS

In the microscopic world of circulation, blood and lymph vessels permeate most tissues, carrying oxygen

and nutrients while removing carbon dioxide and wastes. Not all vessels involved are the "large tubes" so often associated with the circulatory system. Capillaries are woven throughout most of the tissues of the body, around muscle fibers, through connective tissues, and below the basement membrane of the epithelium.[1] Since arteries and veins are too large and too thick to allow diffusion between the bloodstream and surrounding tissues, a delicate network of blood and lymph capillaries controls all chemical and gaseous exchange between blood, interstitial fluid, and lymph.[1] In the normal system, homeostatic mechanisms adjust blood flow across the capillary walls to meet the needs of peripheral tissues. Every year, new information is uncovered that further elucidates the complexities of the circulatory system and how it interacts with the other systems of the body. It is important to have a clear understanding of the delicate vessels that carry blood to the peripheral tissues and the normal processes that occur there to gain insight into the disorders discussed later in the chapter.

Vascular

Arterial

Arteries carry rich, oxygenated blood away from the heart, branching off into sections with smaller diameters called **arterioles**, leading ultimately to capillaries. Arteries have three-layered walls that give them strength and elasticity. The walls of arteries are generally thicker than those of veins because they have to bear strong blood flow pressures generated by the heart. Arteries are strong and durable, able to keep their cylindrical shape when stretched. The movement of blood through arteries is dependent on heart function. Arteries have the ability to change in diameter when the volume of blood passing through them changes. They can also change in diameter when the sympathetic division of the autonomic nervous system (ANS) is triggered, either contracting (*vasoconstriction*) or relaxing (*vasodilation*). Because they have contractile abilities, arteries do not need valves to effect blood flow. These terms and concepts will be important when the chapter discussion turns to topics such as peripheral vascular disease, capillary blood flow, and wound healing.

Venous

Veins return oxygen-depleted blood from tissues and organs to the heart. At the beginning of the venous system, superficial blood capillaries empty into **venules** that carry blood toward medium-sized veins (about the size of muscular arteries). Superficial veins run above the fascia of the muscles. Deep veins run below the fascia. Perforating veins run between the superficial and the deep, penetrating the fascia to connect the superficial and deep vessels. Veins also have three-layered walls but they do not need to be as muscular or elastic as arteries because the blood pressure in veins is lower than in arteries. Venous walls are so thin that they do not hold their shape well under stress, collapsing or tearing when stretched. As blood moves through the outermost regions of the body (the peripheral vascular system) from the arteries to the veins, blood pressures decrease. The blood pressure in the medium-sized veins is so low that it cannot oppose the force of gravity without structural assistance.[1] In the limbs, medium-sized veins contain *valves* that project from the inner walls of the veins, pointing in the direction of blood flow. Under normal conditions, the valves allow blood to flow in one direction, preventing backflow of blood. When the valves are working normally, any movement that compresses or pulls on a vein will help to push blood toward the heart. Skeletal muscle contraction will squeeze venous blood toward the heart. The act of walking helps to empty veins and move blood out of the lower extremities (LEs). When the walls of veins weaken, or are enlarged, the valves cannot function properly and blood pools in the veins. Eventually the veins become distended, leading to **varicose veins**. If a valve or valves do not close properly, this leads to a condition known as **venous reflux**. These terms and concepts will be important when the chapter discussion leads to topics such as chronic venous disease and LE swelling.

Lymphatic

Although parallel, and working in concert with the venous system, the lymphatic system is separate and unique. Because of its many roles and diffuse locations throughout the body, anatomists place discussion of the lymphatic system with the immune system, the circulatory system, and the integumentary system. The two primary functions of the lymphatic system are to protect the body from infection and disease via the immune response and to facilitate movement of fluid back and forth between the bloodstream and the interstitium, removing excess fluid, blood waste, and protein molecules in the process of fluid exchange. *Lymphatics* are located in all portions of the body except the central nervous system (CNS) and cornea.[2] The lymphatic system includes lymph vessels (superficial, intermediate, and deep, also referred to as lymphatics); lymph fluid; and lymph tissues and organs (lymph nodes, tonsils, spleen, thymus, and the thoracic duct).

Lymph fluid is first absorbed at the capillary level, then channeled through small vessels called *precollectors,* and finally picked up by the larger, valved vessels called *collectors*. The collectors have contractile properties, smooth muscle, and valves. Lymphatics are even thinner and more likely to collapse under pressure than veins.[2-4] Lymph moves throughout the body by a number of mechanisms. Superficially, the process of diffusion and filtration moves lymph fluid. Below the dermis, intrinsic contractions drive lymph propulsion in the deeper collectors. The force to generate a lymph vessel contraction does not come from the heart but from *lymphangions,*

small pump-like segments within the larger lymph vessels. Classic literature reports information about lymph flow.[4-8] Newer literature indicates that scientists continue to explore the intricate world of the lymphatics.[9,10] The human body is wonderfully equipped to provide a variety of stimuli that have an impact on lymphangion contraction:

- Parasympathetic, sympathetic, and sensory *nerve stimulation*
- *Contraction of muscles* adjacent to a vessel
- *Pulsation of arteries* adjacent to a lymph vessel (even pre-capillary arterioles have pulsation)
- Abdominal and thoracic cavity pressure changes that occur during *breathing*
- *Volume changes* within each lymphangion (internal receptors respond to tension and trigger a contraction)
- *Mild mechanical stimulation* of dermal tissue increases the frequency of lymphangion contractions

Excess lymph fluid is transported through the thoracic duct and emptied into the venous angles at the left and right jugular vein trunks. Under normal conditions, lymph flow is not adversely affected by gravity. Under abnormal conditions, the lymphatic system may exhibit excess lymph pooling related to gravity, especially in the LEs.

Integumentary

Also referred to as an organ, the integumentary system is the most often seen and touched by a physical therapist of all the body systems. The integumentary system has a functional relationship to many other body systems. The health of this system is dependent on the normal functions of the arterial, venous, and lymphatic capillaries (dermal circulation). A thorough review of the functions of the skin illustrates the importance of even a small area of damage to this organ. The discussion on skin anatomy, with diagrams, in this textbook will supplement the overview here (see Chapter 24, Burns). The *epidermis* is avascular and water-resistant. It provides protection from infection, abrasion, and chemicals and assists with heat regulation, retention, and dissipation. Melanocytes, present in this layer, determine skin color and provide protection from ultraviolet radiation. The epidermis regenerates rapidly, allowing individuals to heal quickly when conditions are normal. The *dermis* is 20 to 30 times thicker than epidermis. It contains blood vessels and lymphatics, nerves and nerve endings, and sensory neurons that all supply the epidermis. The dermis also contains hair follicles, sweat glands and sebaceous glands, and nails. All of these project through the epidermis to the surface of the skin. These appendages are a deep source of epithelial cells, needed to resurface a wound during healing. The contents of the dermis are surrounded and supported by collagen, elastin, and ground substance that provide structure, strength, flexibility, and elasticity. The *hypodermis* (also referred to as the *subcutaneous* layer) is not part of the integument but is important in stabilizing skin over skeletal muscles and organs. It consists of loose connective tissue and fat cells and provides insulation and protection to underlying structures. The hypodermis plays an important role in the prevention of **pressure ulcers**, especially over the ischial tuberosities and greater trochanters.

When there is an injury to the integument, some or all of the components of the integument are impaired, resulting in many possible sequelae such as decreased lubrication, loss of elasticity, increased scar formation, loss of **tensile strength**, decreased ability to resist infection, and an increase or decrease in sensitivity.

WOUND PHYSIOLOGY

Normal Wound Healing

In the human body, an elegant sequence of events takes place to ensure that when injury occurs, wounds will heal. Within the **endogenous** fluids of the body, every cell and chemical mediator is programmed and ready to act when needed. When conditions are normal, the body is equipped to heal itself.

Phases of Healing

The classic model of overlapping phases of wound healing describes a process that is continuous, its phases not entirely distinct. The model is used in this chapter to draw attention to the normal process and to provide guidelines for what can be expected in normal healing. The number of days to complete each phase will vary based on factors such as age, size of wound, co-morbidities, continued trauma, nutrition, blood flow, medications, stress, and infection. The process of repair is the same for all wounds but the sequence will be much quicker in more shallow wounds with less tissue loss. In all stages of healing, wounded tissues are striving to achieve homeostasis. Italicized words below stress important concepts.

Inflammation (Phase I)

- The *normal* immune system reaction to injury.
- The *central activity* in wound healing.
- Temporary repair initiated by coagulation (clotting factors, platelets) and *short-term decreased* blood flow.
- **Necrosis** occurs after cells have been injured or destroyed.
- The spread of pathogens is slowed: debris and bacteria are attacked by a host of cells. If the wound is acute, some periwound edema, **erythema**, and drainage can be expected.[11] If fluid accumulates at the injury site it is called **pus**.
- Oxygen is delivered via *increased* blood flow to keep the phagocytic cells alive and functioning.
- Permanent repair is facilitated by creating a clean wound, *setting the stage* for the next phase of healing; signals are generated that re-epithelialization can begin.

- Time frame: day of injury to approximately day 10.
- *Rate* of inflammatory process is affected by the size of the wound, blood supply, available nutrients, and the extrinsic environment.
- If this phase is interrupted or delayed, *chronic inflammation can result,* lasting from months to years (see section titled Abnormal Wound Healing and the Chronic Wound).

Proliferation (Phase II)

- *New tissue* fills in the wound as **fibroblasts** secrete collagen.
- Skin integrity is restored by re-epithelialization and/or contraction (see discussion below).
- **Angiogenesis** occurs: new blood vessel growth from endothelial cells, fragile capillary buds grow into the wound bed; new reddish, slightly bumpy tissue is called granulation tissue.
- Epithelial cells differentiate into type I collagen. *Collagen synthesis* occurs but the resulting new scar tissue is fragile and must be protected; trauma during this phase may return the wound to the inflammatory process.
- Time frame: day 3 of injury to approximately day 20.
- *Rate* of proliferation is affected by the size of the wound, blood supply, available nutrients, and the extrinsic environment.
- If this phase is interrupted or delayed, the result may be a chronic wound.

Maturation/remodeling (Phase III)

- Maturation or remodeling of new tissue begins while granulation tissue is forming during the prior (proliferative) phase.
- Epithelial cells continue to differentiate into Type I collagen.
- New skin has *tensile strength* that is 15% of normal. Scar tissue is rebuilding but at best reaches 80% of original tensile strength.
- Underlying granulation tissue is replaced by *less vascular* tissue.
- In deep wounds, dermal appendages are rarely repaired (hair follicles, sebaceous and sweat glands, nerves) but instead are replaced by *fibrous tissue.*
- Over time the scar tissue matures, changing from red to pink to white and from raised and rigid to flat and flexible.
- Time frame: approximately day 9 of injury up to 2 years.
- *Rate* of *maturation/remodeling* is affected by the size of the wound, blood supply, available nutrients, and the extrinsic environment.

The Role of Oxygen in Wound Healing

Oxygen reaches the wound bed through blood flow to the area. The need for oxygen to sustain life is apparent, not only at the systemic level, but also at the cellular level of human physiology. Most cells in the wound environment have an enzyme that converts oxygen to a form that allows the cell to support wound healing.[12] Wound contraction, collagen deposition, angiogenesis, and granulation are examples of wound healing steps supported by oxygen. Wound tissue oxygenation is a sensitive indicator for the risk of post-operative infection.[13] A decrease in oxygen availability in a wound results in increased likelihood of infection. Wound perfusion may be limited for a variety of reasons. The presence of edema and necrotic tissue makes it more difficult for oxygen to reach the wound. Since compression can reduce edema and débridement can reduce the presence of necrotic tissue, these procedural interventions are important components of most wound care. Unless contraindicated owing to arterial disease, compression and débridement will decrease the obstruction to wound oxygenation. Peripheral vasoconstriction can also limit wound perfusion. Problems with vasoconstriction cannot always be improved readily. Interventions that will increase wound perfusion and are appropriate for all individuals include keeping the wound area warm, avoiding smoking, hydrating the individual, and controlling pain and anxiety. Clinical studies have shown that keeping patients warm and giving them supplemental oxygen decreases the rate of infection and shortens hospital stay.[14] Improvement of oxygen levels in wound tissue alone may trigger wound healing. Adequate oxygen levels will also enhance the effectiveness of growth factors and a host of other cells that require oxygenation to maintain their function. The delivery of exogenous oxygen will be discussed later in the chapter under the section on Intervention. The nutritional status of the individual, as discussed below, will also have an impact on oxygenation since hemoglobin, iron, vitamin B_{12}, and folic acid are needed to enable red blood cells to carry oxygen to healing tissues.

The Role of Moisture in Wound Healing

In the past, the goal of wound care was to create and maintain a dry wound, packed with dry dressings, dried by heat lamps, and exposed to the air. Modern wound management is based on the concept of creating and maintaining a *moist wound environment* to facilitate wound healing. More than 50 years ago, research confirmed that a dry wound creates an environment that is hostile to wound healing. A dry wound allows the formation of wound scab and **eschar**, which inhibit migration of epithelial cells, provide food for pathogens, and affect blood flow to the wound bed. A dry wound also allows cooling of the wound surface; without a protective barrier, the surface temperature of the wound is decreased and healing is slowed. Adhesion of gauze or other dry dressings to the wound bed causes trauma to the wound bed and pain to the individual upon removal. Bacteria enter a dry wound more readily because of the lack of a protective barrier. As the wound dries, the rich

endogenous fluids that are lost contain the elements necessary for timely wound healing.

Wound management experts agree that adequate wound hydration is the most important external factor responsible for optimal wound healing.[15-18] Wounds are typically covered with an occlusive or semi-occlusive dressing. This type of dressing is also called a moisture-retentive dressing because the dressing retains fluids on the wound bed. There are many types and styles of dressings that will facilitate a moist environment (see the section on Dressings for further discussion). Maintaining a moist wound with an occlusive dressing should hold an appropriate amount of endogenous fluids on the wound, preserving the cells needed for healing and keeping them in contact with the wound bed. Some chronic wound fluid may contain substances that can delay healing so a balance must be maintained between moisture and exudate removal.[19] Moisture softens wound scab and eschar; under the right conditions, the body's own enzymes will dissolve the eschar in a process called **autolytic débridement**. Occlusive dressings maintain appropriate wound surface temperature to prevent delays in healing and protect the wound surface from trauma and from bacteria and other contaminants. Wound cleansing is facilitated during autolytic débridement and further breakdown of skin in the periwound area is prevented.

Basic principles of moist wound healing include covering the wound with a barrier (occlusive dressing) that preserves adequate wound hydration; limiting fluid loss from the wound surface while the dressing is in place; allowing gaseous exchange; maintaining periwound integrity; controlling heavy **exudate;** and removing the dressing when exudate begins to leak out from edges of dressing.

It has long been believed that occlusive dressings should not be applied over infected wounds because trapped bacteria could fulminate. Studies are now producing evidence that the opposite may be true.[20-22] Because in acute wounds, and some chronic wounds, endogenous fluids have bacteria-fighting chemical elements, evidence of colonized bacteria in the wound does not automatically preclude the use of occlusive dressings. Specially selected dressings such as hydrocolloids are a good choice in this situation.

With the use of a systemic antibiotic and a close watch for signs of change in the patient's symptoms, clinicians may be able to utilize occlusive or moisture-retentive dressings over some types of wounds that are infected. The use of this dressing technique may broaden if the evidence continues to build in strength. Meanwhile, there is ongoing investigation into the contents of chronic wound exudate and its power to break down growth factors and prolong the inflammatory phase of wound healing. Information on this level will guide the use of occlusive dressings in the chronic wound healing environment.[23]

Despite half a century of research to support the concepts of moist wound healing, there are still practitioners who ignore the evidence and utilize outdated methods of wound management. Clinicians must strive to educate patients, families, and all members of the wound care team about appropriate wound care concepts.

The Role of Nutrition in Wound Healing

It is well established that nutritional status can have a significant impact on wound healing. Adequate protein intake is required for collagen synthesis, as well as the formation of new blood vessels and muscle tissue. Literature abounds with information about important nutritional issues such as the role of specific nutrients in wound healing, how poor nutritional status can delay wound healing, the use of special pharmacological interventions, and appropriate routes for nutritional support (enteral versus parenteral).[24-32]

The nutritional status of special populations such as children with special healthcare needs must be addressed by interdisciplinary interaction. Pediatric patients in long-term care, recovering from surgery, or with wounds, burns, or trauma are at risk for pressure ulcers.[33] As with adults, adequate protein intake is essential for healing to occur on time. Another patient population of concern is the elderly, whose tissues are fragile and whose immune systems are easily compromised. Nutrition plays a role in the prevention and management of pressure ulcers in this population as well.[34]

Nutrients that must be present for a wound to heal include iron, vitamin B_{12} and folic acid (essential so that red blood cells can deliver oxygen to tissues), vitamin C and zinc (essential for tissue repair), vitamin A (essential to stimulate collagen cross-linking), and arginine (enhances healing and immune function).[35,36] High protein intake provides the amino acids required to build new tissue. Protein and calorie needs will vary depending on the size of the wound and the medical condition of the patient. What are yet to be established are guidelines about energy levels, or nutrient needs required to heal a wound. In response to the available information and the need for more research, nutrition and metabolic support of acutely and chronically ill patients is emerging as an important branch of medicine.

As a part of the wound care team, a physical therapist will make contributions to the plans for nutritional support of the patient. Clinicians will collect data through chart review, observation, history taking, and the use of dietary examination methods.[37] Because exercise, hydration, and improved appetite often are interrelated, a physical therapist should pay close attention to a patient's activity level, strength, conditioning, and any mobility issues while encouraging fluid and nutrient intake.

Wound Characteristics

The characteristics of wounds may be defined as dry, wet, or granulating. Wounds can also be defined by their etiology, such as diabetic, vascular, or traumatic. Wound

characteristics describe the physical appearance of the wound but often provide the clues to the etiology, phase of healing, and likelihood of closure. Wound characteristics can provide valuable information needed to make sound clinical judgments about treatment. For example, the location of the wound may prompt the clinician to select a particular dressing, change patient positioning, or prescribe orthotic footwear. When wound characteristics are described in documentation, they can indicate progress (or failure to progress) toward closure and healing. Wound characteristics should be identified during the initial examination and then monitored at least weekly during the wound healing phase. Depending on the etiology and chronicity of the wound, some characteristics may not be evident on initial examination but could appear at a later date as complications of the wound healing process. The following are characteristics that should be tracked and documented throughout the phases of wound healing:

- *Location*: where on the body
- *Size*: depth, width, and length
- *Shape*: irregular versus distinct
- *Edges*: condition and shape of wound edges, evidence of premature healing
- *Tunneling, undermining, sinus tracts*: presence and depth
- *Base*: characteristics of the wound base compared to sides and edges
  - Necrosis, eschar, **slough**: amount, color, texture, adherence to wound bed
  - Exudate: amount, color, odor
  - **Granulation tissue**: presence or absence, amount, location
  - Epithelialization: presence or absence, premature or on schedule
  - Exposed structures: color and condition of bone, tendon, ligament
- *Periwound area*: edema, induration, **maceration**
- *Pain*: although not a visible characteristic, it is measurable and significant to the intervention
- *Quantity of bacteria*: amount present in a wound. This is referred to as the **bio-burden**.

The quantitative biopsy is the gold standard for obtaining a wound culture but it is not used universally owing to cost, lack of laboratory facilities, and potential pain for the patient.[12] A swab culture is often used as an alternative but it is limited to detecting surface contamination, not tissue infection. Some literature supports swab culture, when used appropriately, as an adjunct in the management of chronic wounds.[38] Clinical intuition is also important in determining if infection is probable.

The examination will include data about the characteristics that have been gathered using methods such as observation, palpation, measurement, photography, and tracing. A clinician who is new to the wound care team should remember that these are skills that take practice.

Wound Closure

Primary Intention

Healing by primary intention occurs when a surgeon closes a wound by bringing the edges together. Approximating the edges can occur through the use of sutures, staples, glue, skin grafts, or skin flaps. For more information on skin grafting see Chapter 24, Burns. Wounds closed by primary intention still pass through the phases of wound healing but on a smaller scale. The major mechanism for healing wounds by primary intention is connective tissue deposition. A wound closed by primary intention that later opens up again owing to maceration or infection has opened by the process of *dehiscence* (Fig. 14.1). Following dehiscence, a wound is almost always allowed to close by secondary intention.

Secondary Intention

Healing by secondary intention occurs when a wound is left to heal on its own. The mechanisms of healing by secondary intention are contraction, re-epithelialization, or a combination of both. Deeper wounds heal by replacing injured tissue with scar tissue as collagen fills the wound bed.

During the process of contraction, existing tissue migrates, pulling the wound edges toward the center of the wound. This process forms no new tissue. New tissue may be forming in the wound simultaneously but not via contraction. Contraction occurs when growth factors trigger myofibroblasts to pull the wound edges inward. Growth factors and myofibroblasts can be influenced positively or negatively by physiological factors such as

Figure 14.1 Wound dehiscence following appendectomy.

the amount of oxygen and nutrients available, and by mechanical factors such as external compression and the shape of the wound. Even though contraction is a normal occurrence in certain types of wound healing, if it is too rapid, it can cause disfiguring scars and impaired tissue function. Since there is centripetal movement of the entire thickness of the surrounding skin, tissue elongation may not keep up with the pace of contraction, causing significant functional and cosmetic deformity. Clinicians should intervene by applying special types of pressure to the tissues to slow the deforming forces of contraction (scar management discussed later in chapter).

Epithelialization is another response used by the body to close a wound. As noted in the phases of normal wound healing, chemical mediators send signals for re-epithelialization to begin in Phase I (the inflammatory phase). Actual repair begins in Phase II when new tissue is formed to cover the wound. Growth factors stimulate specialized epithelial cells, *keratinocytes,* to begin to migrate from the edges of the wound toward the center. In partial-thickness wounds in which the dermal appendages have not been destroyed, the cells will also migrate from the hair follicles, sebaceous glands, and sweat glands. In smaller, shallower wounds this process may be triggered to begin as early as 12 hours after wounding. In larger wounds, it may be 10 days or longer before the cells begin to migrate. In a chronic wound there are many reasons why this process is not triggered or is interrupted. (See discussion under Abnormal Wound Healing and the Chronic Wound.) When the wound is covered with new skin, re-epithelialization stops by contact inhibition.

When epithelial cells meet at the center of the wound, migration ends and cells will stop dividing. This is referred to as *contact inhibition.* At the time of contact inhibition and/or full re-epithelialization, wound *closure* has occurred. Wound *healing,* however, may continue for several years. A significant amount of intervention is still required to support the wound successfully from "closed" to "healed" status. Factors affecting the rate and type of closure by secondary intention include the following:

- *Wound shape*: linear wounds (surgical) contract most rapidly; circular wounds (pressure ulcers) contract most slowly.[39]
- *Wound depth*: all things equal, the shallower the wound, the quicker the closure.[40-43]
  - *Superficial* (loss of the epidermis): closes by re-epithelialization.
  - *Partial-thickness* (loss of the epidermis and dermis): closes primarily by re-epithelialization with minimal contraction.
  - *Full-thickness* (loss of all layers of the epidermis, dermis, and deeper structures): closes by contraction and scar formation; however, epithelial cells will migrate from the wound edges to assist in wound closure if the environment is homeostatic.
- *Wound location*: areas with least pressure, most perfusion (face) will close more rapidly than areas with most pressure, least perfusion (sacrum, heel).
- *Wound etiology*: least traumatic (surgery) will close more rapidly than most traumatic (pressure ulcer, burn).

As deeper wounds heal, the wound is filled with tissue but the repair process does not replace lost muscle, fat, or dermis with those same types of tissue. The wound is filled with scar tissue made up primarily of collagen. Because the original tissue is not replaced with more of the same, a wound that is closed, and finally healed, does not return to its prewounded state. This concept is particularly important to understanding the position on reverse staging of pressure ulcers as described in the section on Tests and Measurements. It is also important to understand this concept when planning protection, positioning, patient education, footwear, and exercise programs for individuals with all types of wounds whether they are acute, closed, healed, or chronic wounds.

Tertiary Intention

Also called *delayed primary*, this type of closure occurs when a wound is allowed to heal by secondary intention and then is closed by primary intention as the final treatment. The delay in primary closure is usually owing to the presence of infection.

Abnormal Wound Healing and the Chronic Wound

When the sequence of events that leads to normal wound healing does not occur, a chronic wound results. The characteristics and causes of chronic wounds vary owing to the diverse nature of individuals with wounds, their medical histories, and the etiologies of the wounds. Even if the chronic wound moves through the classic phases of wound healing, it does so in an abnormal manner. Vital actions and reactions necessary for wound healing are interrupted, stunted, or absent in the chronic wound.

Although the characteristics of abnormal wound healing may be varied, concepts can be used to illustrate the failure of a wound to pass through phases of wound healing in a timely manner. The following discussion focuses on the results of interruption to the classic phases of wound healing:

- Inflammation (Phase I): if there is inadequate blood flow and oxygen supply to support cellular life and activity, cells may not initiate the repair sequence. Debris and bacteria build up, and pathogens spread more rapidly. Bio-burden is measured as greater than 10^5 organisms/g of tissue, the classic definition of infection.

  - Clinical signs: increase in amount of drainage, change in color or odor, lingering swelling, eschar/necrosis from ischemic conditions, periwound maceration, chronic inflammation, **tunneling**, **undermining**, and infection may develop if the host's immune system is unable to resist the impact of the bacterial load.
- Proliferation (Phase II): if collagen synthesis is delayed in this phase, skin integrity will be poor. If angiogenesis is delayed, there will not be enough myofibroblasts to initiate wound contraction. The need for oxygen and nutrients will be very high and without them, available cells will be unable to reproduce rapidly, resulting in delayed epithelialization.
  - Clinical signs: keratinocytes do not migrate because the wound bed is not moist, healthy, clean, and granulating. Epithelial cells may attempt to migrate from the wound edges but without a wound bed that is ready, they will build up at the wound edge and may migrate over the edge, forming a lip that curls under. Granulation tissue is either absent, pale, or delayed; new tissue is weak and breaks down or bleeds easily; tunneling, eschar, and periwound maceration may be evident. Necrosis, if it has not been removed, will delay angiogenesis. Changes in drainage color, amount, odor, or lingering swelling may signal a return to the inflammation stage.
- Maturation/Remodeling (Phase III): if the synthesis and lysis of collagen is out of balance, weakened tissue will break down too easily or hypertrophic scarring will build up too rapidly.
  - Clinical signs: newly formed skin breaks down with little provocation, and scar tissue builds up within the outline of the original wound (hypertrophic) or beyond the margins of the original wound (keloid).

Infection in Wound Healing

Wound infection is a significant problem for any individual. Bio-burden has a greater impact on wound healing than most underlying medical conditions.[11,44] Infection may turn life threatening if the patient is elderly or critically ill. Regardless of the condition of the individual, wound infection is detrimental to wound closure and healing time. True infection is identified if the presence of bacteria or microorganisms is greater than 10^5 per gram of tissue determined by a quantitative culture. This determination can only be made with a biopsy. Surface swabs that are cultured may or may not be conclusive for actual infection since there are many types of bacteria that exist on the skin all the time.

- Effects of infection
  - Inefficient cellular activity, decreased collagen metabolism, chemical mediators absent or dilute, cells absent or confused by lack of instructions from chemical mediators and presence of other cells; when the bio-burden is greater than 10^5 organisms/g of tissue, epithelialization may not occur[38]
  - Decreased oxygen in the wound bed; insufficient oxygen to support the regeneration of tissue and to assist in the prevention of infection
  - Increased rate of cell necrosis
  - Overall decline of body systems contributes to strain on the specialized cells
  - Risk of wound sepsis, **osteomyelitis, gangrene**
- Signs of potential infection
  - Change in wound drainage (amount, color, odor)
  - Swelling
  - Periwound redness or warmth (less obvious with darker skin)
  - Increase in pain or tenderness
  - Change in the quality of granulation tissue or failure to produce good quality tissue (may be pale, soft, easily broken down)
  - No measurable wound contraction within 2 to 4 weeks
  - Tissue culture/punch biopsy results of greater than 10^5 organisms/g of tissue
  - Fever, nausea, fatigue, loss of appetite

Clinicians should use a structured approach to identify clinical infection. Careful identification of infection may help to avoid the risk of overuse of antibiotics.[45] The punch biopsy is the gold standard for confirming infection, but a physical therapist should watch for the early signs of infection: *warmth, redness, swelling, fever, malaise,* and *loss of appetite*.

Factors Contributing to Abnormal Wound Healing

The factors or triggers that may contribute to abnormal wound healing are varied but can be placed into broad categories for better understanding. Most abnormal wound healing will be influenced by factors from all the categories. Treatment intervention that addresses factors from one category and not the others will be incomplete.

Intrinsic Factors

Intrinsic or internal factors are conditions within the body that may contribute to abnormal healing. These factors relate primarily to the wound and periwound areas, and include hypoxemia owing to inadequate blood flow, oxygen supply and aging skin. As the integument ages, there is a decrease in moisture content leading to an increase in brittle quality and a delay in the renewal time affecting the stratum corneum. **Rete pegs**, undulations between contact layers of the epidermis and dermis, become less functional with increased risk of shearing.

Changes in the dermis include a decrease in elasticity, collagen, and mast cell production, along with a

decrease in the vascularity and number of pain receptors. Available fat in the subcutaneous layer begins to resorb after age 70, leading to a decrease in protection against pressure and shearing. Finally, underlying disease will affect acute and chronic wound healing. The more common conditions known to affect healing are diabetes, cancer, circulatory insufficiencies, human immunodeficiency virus infection, and connective tissue diseases.

Extrinsic Factors

Extrinsic or environmental factors are those influences that come from outside the body. The medical professionals caring for a person with a wound may be able to moderate the impact of extrinsic factors on the wound environment. Factors include the effects of radiation therapy or chemotherapy; incontinence; medication, smoking, recreational drugs, and alcohol (all slow or eliminate cellular reactions needed for healing); dehydration and malnutrition (both slow the delivery of oxygen to wound tissues); bio-burden/infection (healing is slowed by pathogens, necrotic tissue, granulomas); and stress (negative effects of stress can lead to impaired healing).[42,46-51]

Iatrogenic Factors

Iatrogenic refers to any injury or illness that occurs as the result of medical care. Theoretically, these factors are under the control of the medical professionals who care for the patient and are therefore preventable. Factors include, but are not limited to, the following: poor wound management, frequent disruption of the wound through inappropriate cleansing, use of inappropriate dressings and dressing techniques, cytotoxic topical agents that lead to inefficient cellular activity, and lack of moisture resulting in delayed or absent migration of keratinocytes. Frequent dressing changes will slow wound healing by reducing wound temperature. It can take more than 30 minutes for a wound to return to normal temperature after a dressing change. Infection can be an iatrogenic factor when caused by cross-contamination, improper use of gloves and other protective devices, inadequate use of sterile and clean technique, lack of proper hand washing, lack of adherence to **standard precautions**, and inadequate clean or sterile technique. Other iatrogenic factors that contribute to abnormal wound healing include shear injuries (skin tears) that occur during transfers and repositioning and **ischemia** from unrelieved pressure owing to inadequate turning schedules or absent or inadequate *pressure-redistributing devices (PRDs)*.

Complications of Chronicity

A chronic wound creates a complex and serious health problem for an individual (Fig. 14.2). Chronic wounds may lead to complications including any or all of the following: impairments of body function and structures, restrictions in activities and participation, need for assisted living or home care, decreased quality-of-life perceptions, depression, infection, malnutrition and weight loss, protein depletion, tissue **fibrosis**, loss of limb, and death. Every year over 5 million Americans are treated for chronic wounds at a cost of billions of dollars, making this type of wound one of the most costly challenges in health care.[52] A chronic wound fails to heal because of an underlying pathology and will not heal until the cause is corrected or improved. The clinician must determine the factors contributing to abnormal wound healing and then develop an appropriate POC to overcome or address the obstacles.

Figure 14.2 Chronic wound as a result of diabetic neuropathy.

VASCULAR, LYMPHATIC, AND INTEGUMENTARY DISORDERS

Arterial Insufficiency and Ulceration

Arterial insufficiency refers to a lack of adequate blood flow to a region or regions of the body. Many different disorders may arise from arterial insufficiency and can be classified by a variety of descriptors. For the purposes of this chapter, references will be to arterial insufficiency owing to organic disruption of blood flow to the extremities or to **peripheral vascular disease (PVD)**. PVD is a general term used to describe any disorder that interferes with arterial or venous blood flow of the extremities. PVD caused by arterial insufficiency may be related to smoking, cardiac disease, diabetes, hypertension, renal disease, and elevated cholesterol and triglycerides. Obesity and a sedentary lifestyle are related contributors in the cycle of disease and vessel obstruction. When several of these factors are combined, as they often can be, the possibility for health problems is almost 100%. The

damage caused by these factors is reflected in structural changes in the walls of the arteries, causing abnormal blood flow. The following is a brief overview of disorders that occur with abnormal arterial blood flow:

- **Arteriosclerosis:** thickening, hardening, and loss of elasticity of arterial walls.
- **Atherosclerosis:** the most common form of arteriosclerosis, associated with damage to the endothelial lining of the vessels and the formation of lipid deposits, eventually leading to plaque formation.
- **Arteriosclerosis obliterans:** a peripheral manifestation of atherosclerosis characterized by **intermittent claudication**, rest pain, and trophic changes. This is the arterial disease most likely to lead to **ulceration**.[53] Known risk factors for development of the disease are smoking, diabetes mellitus, hypertension, hyperlipidemia, and hyperhomocysteinemia.
- **Thromboangiitis obliterans** (Buerger's disease): inflammation leads to arterial occlusion and tissue ischemia, especially in young men who smoke.
- **Raynaud's disease:** a vasomotor disease of small arteries and arterioles that is most often characterized by pallor and cyanosis of the fingers. In some cases both the hands and feet may be affected. The cause of Raynaud's is unknown but attacks are usually triggered by cold or emotional upset.
- Ulceration: a peripheral sign of a long-standing disease process; by definition, arterial ulcers are associated with arterial insufficiency.

Between 10% and 25% of LE ulcers are caused by arterial disease.[54] The incidence of arterial disease and LE ulceration is significantly lower than that for venous disease and ulceration; however, arterial wounds more frequently lead to loss of limb and death. These important facts signal the significance of taking a thorough history, performing a systems review, and adequate skin inspection during the initial visit with any individual who might have arterial disease.

Clinical Presentation

- Wounds will most frequently be located on the LEs: lateral malleoli, dorsum of feet, toes.
- When wounds are present on an ischemic limb, atherosclerotic occlusion of the peripheral vasculature is almost always present.
- The majority of patients with arterial insufficiency also have diabetes.
- Trophic changes are present and include abnormal nail growth, decreased leg and foot hair, and dry skin.
- Skin is cool on palpation.
- Wounds are painful and patient may also describe pain in the legs and/or feet (see discussion below about intermittent claudication).
- Wound base is usually necrotic and pale, lacking granulation tissue.
- Skin around the wound may be black, mummified (dry gangrene).
- Other signs of arterial insufficiency will be evident: decreased pulses, **pallor** on leg elevation, and **rubor** when dependent.

History

Painful cramping or aching of the LEs during walking is the most common complaint of patients with chronic arterial occlusion of the LEs. The pain is caused by **intermittent claudication** that occurs when exercising muscles are not receiving the blood perfusion needed for normal function. Patients should be examined for other signs of arterial insufficiency if intermittent claudication is occurring. Rest pain that develops at night, awakens the patient, or requires analgesics for relief is considered more severe than claudication. The individual with vascular dysfunction may also be diabetic. Diabetes will contribute to slower healing times and difficulty fighting infection. A wound in a distal, ischemic area is not likely to heal unless the vascular supply is enhanced or restored. Individuals with arterial disease and diabetes are more likely to have hypertension, and may have previous bypass grafts or amputations of the toes, pain on ambulation or rest, pain with elevation, cold hands and feet, and color changes of fingers and toes. Owing to the long latency period between injury to the arterial circulation and clinical appearance of disorders, healthcare providers, families, caregivers, and patients must join forces with education, prevention, and vigilance.

Tests and Measurements

One of the most important tests for individuals with arterial disease is the **Ankle-Brachial Index (ABI)**. The ABI is a test designed to examine the vascular system. Results provide useful information about the potential loss of perfusion in the LEs. Refer to Arterial Perfusion in the section on Tests and Measurements under Examination and Evaluation.

Intervention

If ulceration is present, intervention should enhance chemical and gaseous homeostasis in the wound bed, facilitate superficial blood flow to target tissues, and educate patients about the importance of facilitating blood flow to the extremities. Treatment will include appropriate wound care as well as important adjuncts to wound care. Results of the ABI will guide the therapist and referring practitioner in the appropriate use of compression. In a diagnosis of mixed arterial and venous disease the condition that is more severe should be treated first. If the arterial condition is worse, compression may be inappropriate even when edema is present. A nonhealing wound on an ischemic limb can lead to gangrene, amputation, further amputation, and/or loss of life (Fig. 14.3). In the most severe cases, conditions are inhospitable to wound closure. In this case necrotic tissue should not be débrided, since the dead tissue will not be replaced with new tissue. Conditions for closing and healing the wound are poor. Skin grafts

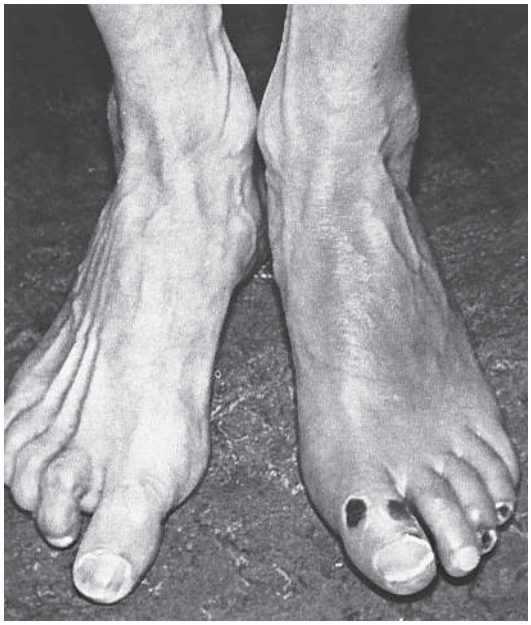

Figure 14.3 Clinical presentation of arterial insufficiency.

do not adhere to the virtually lifeless wound bed. Antibiotics cannot reach the wound systemically and topical agents are too superficial to stop infection. At this point, vascular surgery may be an option for some individuals. A bypass graft is used to restore arterial circulation to the ischemic tissue. For others, living with a chronic nonhealing wound or coming to terms with amputation are the only options. Most experts agree that the single most important intervention in PVD is prevention of smoking. The second most important intervention is exercise for weight control. Exercise will also improve collateral circulation, lipid profiles, and management of hypertension. A physical therapist plays a crucial role in wound care for arterial wounds and should address patient education and exercise in the intervention plan.

Venous Insufficiency and Ulceration

Venous insufficiency refers to inadequate drainage of venous blood from a body part, usually resulting in edema and/or skin abnormalities and ulcerations. **Chronic venous insufficiency (CVI)** refers to venous insufficiency that persists over a long period of time. The majority of individuals with PVD are diagnosed with CVI. CVI is the most common cause of leg ulcers.[55] In current literature, venous insufficiency is synonymous with venous hypertension, defining the beginning of a chain of pathophysiological events that often end in ulceration. Some authors still use the term *venous stasis ulcer* although it has been shown that blood stasis (blood pooling) is not the cause of these wounds.[56] Although it is clear that ulcerations are the result of inadequate venous circulation, the mechanism by which this happens is not clear. Research is currently focused on how skin breakdown is affected by dysfunction of circulating white blood cells (WBCs), endothelial cell dysfunction, **fibrin** deposition, edema, and lymphatic congestion.[57,58]

The incidence of venous ulceration is much higher than that of arterial ulceration (Fig. 14.4). In fact, 80% of all leg ulcers are caused by venous disease.[54] The higher incidence is not clearly understood even though years of clinical and laboratory research have been devoted to understanding venous disease. The path from CVI to ulceration can take many turns. Aging, lack of exercise, obesity, pregnancy, long hours of standing or sitting, and heredity will predispose an individual to venous hypertension and subsequent CVI. Predictors for ulceration include the factors just listed, as well as history of deep vein thrombosis (DVT), number of pregnancies for women, family history of ulceration, and history of vigorous activity in the presence of other risk factors.[59]

Clinical Presentation

- Swelling of unilateral or bilateral LEs relieved in the early stages by elevation
- Complaints of itching, fatigue, aching, heaviness in involved limb(s)
- Skin changes including **hemosiderin staining** and **lipodermatosclerosis**
- *Fibrosis* of the dermis
- Increase in skin temperature of lower legs
- Wounds:
  - Most frequently located on the LEs: proximal to the medial malleolus although can occur anywhere (arterial wounds may also occur at this location).
  - Not significantly painful; usually complaints of minor dull leg pain are relieved with elevation.
  - Granulation tissue is usually present in the wound bed.
  - Tissue is *wet* from a typically large amount of draining *exudate.*
- Signs and symptoms of **lymphedema** may be present (it is common to see the impact of chronic inflammation and fluid overload as triggers for the onset of lymphedema).

Figure 14.4 Venous insufficiency with leg ulcer.

History

Because the incidence of CVI increases with age, clinicians should be suspicious of the disease in older patients. The slow development of venous disease and ulceration usually implies a history of lingering swelling, slow healing, repeated infection, and frequent recurrence of skin breakdown. Once ulceration occurs, venous wounds can exist for years. This progression of symptoms frequently leads to a mechanical overload of the lymphatic system and subsequent development of lymphedema. If the individual is older than age 50, it is likely there are co-morbidities such as diabetes, hypertension, congestive heart failure (CHF), or history of DVT. Owing to the long latency period between injury to the venous circulation and clinical manifestations, health care providers, patients, families, and caregivers must join forces using the tools of education, prevention, and vigilance.

Tests and Measurements

One of the first tasks during the examination process is to address the possibility of an arterial component to the venous pathology. If there is arterial insufficiency, healing will be impaired and compression may be contraindicated.[54,60] Results from the ABI will give preliminary information, but more sophisticated laboratory tests may be indicated to confirm or rule out arterial disease in the individual who also has venous insufficiency. With the exception of mixed arterial and venous disease, the vascular examination results for venous insufficiency will show strong distal pulses and a normal ABI. On palpation, the skin temperature of the lower leg may be elevated. This sign can imply a worsening or impending complication of CVI.[61] The use of instrumentation to measure skin temperature can be invaluable during the examination. Existing edema may decrease with elevation unless it occurs in the advanced stages of disease or in combination with lymphedema. With venous disease, pitting edema may occur in the periwound area, the foot and ankle, or anywhere on the body. Advanced edema and lymphedema are generally unaffected by elevation and require compression as part of treatment.

Intervention

The most important therapeutic measure for prevention and treatment of venous leg ulcers is **compression therapy**. Compression refers primarily to specialized bandaging and specialized garments but can also include intermittent pneumatic compression. All of these treatment interventions will be discussed later in the chapter. Even though edema is a natural characteristic of the first phase of wound healing, excessive edema can delay wound healing by slowing perfusion of tissues and facilitating the growth of bacteria.[15] Along with compression and appropriate wound care, treatment will include exercise to increase mobility, and positioning to support and enhance venous blood flow.[55] Compression therapy is essential for timely healing if arterial disease has been ruled out. As mentioned earlier, in a diagnosis of mixed arterial and venous disease, the more severe pathology is treated first. Significant arterial disease will most likely preclude the use of compression. For the individual with a diagnosis of venous disease or mixed (mild) arterial/venous disease, a combination of therapeutic measures will accelerate results.[62] These include compression bandaging and garments, gait training, *manual lymphatic drainage (MLD)*, and exercise, including range of motion (ROM). A wound care plan should not include whirlpool owing to the risks of dependent positioning, cross-contamination, cytotoxic additives, and unnecessary costs.

Lymphedema

Lymphedema is a chronic disorder characterized by an abnormal accumulation of lymph fluid in the tissues of one or more body regions.[2,63] The accumulation of fluid can be caused by a number of events but is most often owing to a mechanical insufficiency of the lymphatic system. This means that some components of the lymphatic system are not functioning sufficiently to manage the lymph fluid present in the body region. Lymphedema can be classified as primary or secondary lymphedema. **Primary lymphedema** (Fig. 14.5) is caused by a condition that is congenital or hereditary. With primary lymphedema, lymph node or lymph vessel formation is abnormal. The most common abnormality is *hypoplasia,* a condition in which there are fewer lymphatic vessels and they are smaller than normal. One of the more common forms of primary lymphedema appears in **Milroy's disease**. **Secondary lymphedema** (Fig. 14.6) is caused by injury to one or more components of the lymphatic system: some portion of the lymphatic system has been blocked, dissected, fibrosed, or otherwise damaged or altered.

Secondary lymphedema is more prevalent than primary. In developed countries, the most common cause

Figure 14.5 Primary lymphedema of bilateral LEs with one extremity more involved than the other.

Figure 14.6 Secondary lymphedema of unilateral UE.

of secondary lymphedema is surgery and/or radiation therapy as part of breast cancer treatment. The rise in incidence of other types of cancer and the subsequent treatments for those cancers has led to an increase in reports of lymphedema following treatment for cancer of the prostate, bladder, uterus, ovaries, and skin. Cancer is not the only causative factor for lymphedema. It is common for an individual with CVI to develop lymphedema, triggered by long-standing fluid overload in the LEs.[64] Secondary lymphedema can also be triggered by the complications of paralysis, disuse in chronic regional pain syndrome, or trauma to regional lymph nodes following liposuction, pelvic fracture, hernia repair, and other surgical interventions where lymph nodes or lymph vessels are located.[65-67] Lymphedema is a common disease and health care providers can expect an increase in the number of patients rather than a decrease in this condition over the next decade.[68] The collection of data on the incidence of non–cancer-related secondary lymphedema is limited by the lack of specific education related to lymphedema among health care professionals and by a lack of clinical suspicion when examining individuals with a history of swelling. In the tropical and subtropical regions of the world, secondary lymphedema is most often caused by *filariasis.* In filariasis, nematode worm larvae live a full life cycle in the lymphatic vessels, causing inflammation and blocked lymphatic vessels.

Clinical Presentation

- Swelling distal to or adjacent to the area where lymph system function has been impaired
- Swelling usually not relieved by elevation
- Pitting edema in the early stages of disease, nonpitting edema in later stages, as fibrotic changes occur
- Feelings of fatigue, heaviness, pressure, or tightness in the affected region
- Numbness and tingling
- Discomfort varying from mild to intense
- Fibrotic changes of the dermis
- Dermal abnormalities such as **cysts, fistulas, lymphorrhea, papillomas, hyperkeratosis**
- Increased susceptibility to infection, at first local to the affected region but often becoming systemic
- Loss of mobility and ROM
- Impaired wound healing

History

A patient history consistent with lymphatic system damage or deformity will be pivotal in the diagnosis of lymphedema. A patient's history might include cancer, cancer treatment, radiation therapy, lymph node disruption, CVI, trauma, surgery, or (in primary lymphedema) onset of swelling at birth or puberty. There may be a long latency period between injury to the lymphatics and clinical manifestations; thus, health care providers and patients must adhere to prevention guidelines and be suspicious of any signs and symptoms that might suggest lymphedema. The condition can develop within a few weeks of the initial insult to the system or as long as 30 years later.

Tests and Measurements

The diagnosis of lymphedema can be made without the use of special tests for most individuals. A patient history consistent with lymph system damage or deformity, a systems review, differential diagnosis, inspection, and palpation of the integument and girth measurements are adequate for accurate diagnosis in most cases. Unique findings might include the **Stemmer's sign**, skin texture changes, skin folds, fibrosis, increase in girth, **papules**, lymph leakage, and **elephantiasis**. *Severity* is determined by a collection of data including presence of fibrotic tissue changes (brawny or woody [hardened], and/or lobular [rounded projection]); number of episodes of cellulitis; condition of the superficial integument of the lymphedematous limb (papules, leakage, fungus, venous wounds); circumference or volume differences between involved and uninvolved limbs; and quality-of-life issues (sleep, mobility, activities of daily living [ADL], relationships). A noninvasive test called **lymphscintigraphy** is a special test using radioactive tracer and a gamma camera to provide images of the lymphatic system. This test is useful for differential diagnosis and to characterize the severity of lymphedema.[68-70]

Intervention

A physical therapist should be cautious about the application of pressure to an edematous or lymphedematous body part. Although compression is an essential

intervention, pressures that are too high will occlude superficial lymph capillaries and prevent the initial step of fluid absorption needed to control edema and lymphedema.[4]

Current intervention for the patient/client with lymphedema requires attention to detail and a level of expertise not often provided in entry-level professional educational programs. Practitioners are best served by gaining additional education to better prepare them to treat these patients. The current recommended course of care is a two-phase program of **complete decongestive therapy**(CDT).[71-74] Phase I (intensive) includes skin care, MLD, lymphedema bandaging, exercise, and compression garment at the *end* of Phase I. Phase II (self-management) includes skin care, compression garment during the day, exercise, lymphedema bandaging at night, and MLD as needed. A good source of information on training programs or other information on CDT, trained therapists, and patient education related to lymphedema is the National Lymphedema Network (NLN). The NLN can be reached at www.lymphnet.org.

As with many progressive, chronic disorders, the effectiveness of treatment is significantly improved by early intervention. Accurate and early diagnosis occurs when health care professionals are sensitized to the signs and symptoms and carefully evaluate the examination data. In the POC, the number and frequency of treatments should not be determined by lymphedema staging or by circumferential differences between limbs (the severity of the condition is not determined by these data alone). Some individuals with lymphedema may present with more involved signs and symptoms than the measurements imply.

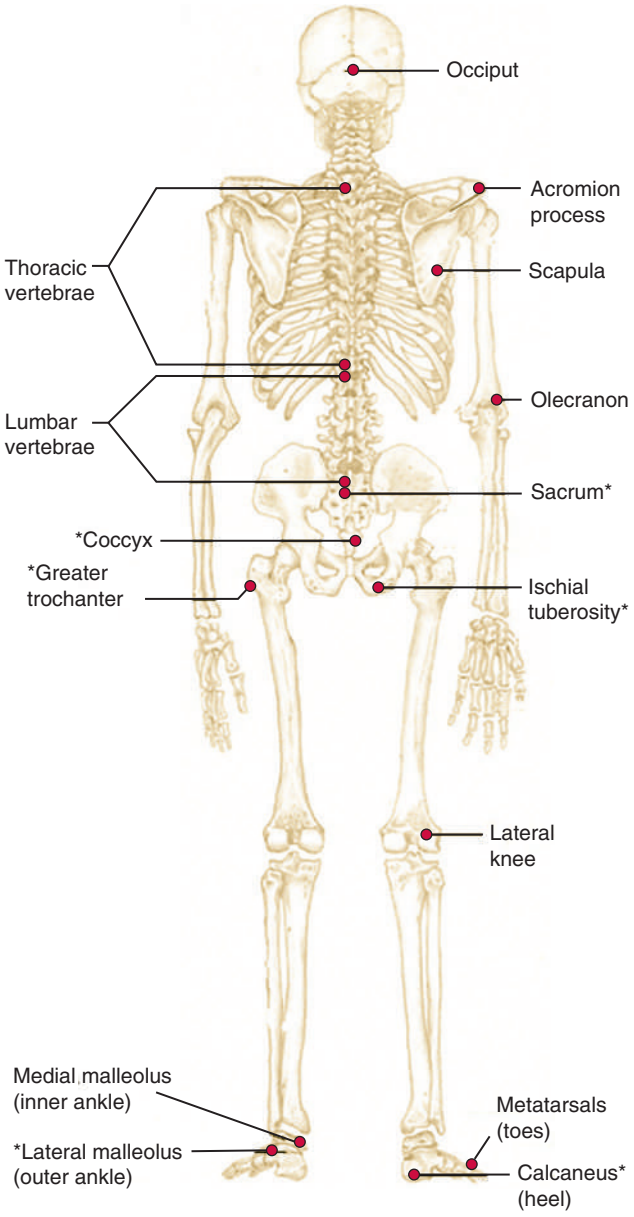
Pressure Ulcers

A *pressure ulcer* is a wound caused by unrelieved pressure to the dermis and underlying vascular structures, usually between bone and support surfaces. When pressure is not relieved in time, the damage is of such magnitude that the tissues cannot repair and recover on their own. As deeper vessels are occluded, decreased blood flow leads to cell death, tissue necrosis, and finally a visible wound. The superficial dermis can tolerate *ischemia* for 2 to 8 hours before breakdown occurs. Deeper muscle, connective, and fat tissues tolerate pressures for 2 hours or less. Thus, there may be significant damage to underlying tissues while the epidermis and dermis remain intact. The clinical implications of this phenomenon are discussed below and in the section on Tests and Measurements. Readers can gain greater understanding about depth of damage to the integument by referring to Chapter 24, Burns, to view cross sections of skin, illustrating which components of the skin are lost at descending levels of damage.

Pressure ulcers occur most frequently among individuals who are immobilized for long periods of time. Although pressure ulcers can occur at any age during prolonged periods of immobility, they are more likely to occur on individuals who are hospitalized, elderly, incontinent, and/or underweight and among individuals of all ages following spinal cord injury (SCI).[45,75-77] Up to 25% of hospital-acquired pressure ulcers may originate during surgery.[78] According to Reed et al,[79] the presence of low albumin levels, confusion, and a *Do Not Resuscitate (DNR)* order are also pressure ulcer risk factors.[79] Pressure ulcers increase the risk of death for elderly individuals whether at home or in a hospital or long-term care setting.[80] In developed countries, the incidence of chronic wounds, including pressure ulcers, is increasing as the population ages.

Clinical Presentation

The severity of pressure ulceration can be estimated by observing clinical signs. A progression from least tissue damage to most severe damage is presented here.[81] More details on the challenges of identifying pressure ulcer depth will be covered later in the chapter.



- The first clinical sign of pressure ulceration is **blanchable** *erythema* along with increased skin temperature. If pressure is relieved, tissues may recover in 24 hours. If pressure is unrelieved, nonblanchable erythema occurs.
- Progression to a superficial abrasion, blister, or shallow crater indicates involvement of the dermis.
- When full-thickness skin loss is apparent, the ulcer appears as a deep crater. Bleeding is minimal, and tissues are **indurated** and warm. Eschar formation marks full-thickness skin loss. Tunneling or undermining is often present (the official staging classification for pressure ulcers will be covered later in this chapter).
- The majority of all pressure ulcers develop over six primary bony areas (Fig. 14.7): sacrum (Fig. 14.8), coccyx, greater trochanter, ischial tuberosity, calcaneus (heel), and lateral malleolus.

History

If an individual has a history of a period of immobility followed by the discovery of a warm, red, spot over a bony prominence, a pressure ulcer can usually be confirmed. If the spot is unnaturally soft to the touch, sometimes referred to as "boggy," this is enough evidence to suspect that damage is deeper than the epidermis.

Tests and Measurements

During examination, along with general wound characteristics, pressure ulcers are classified by grading or staging systems that describe the degree of tissue damage observed. It can also be important to use a tool to measure an individual's risk of developing a pressure ulcer before a pressure ulcer exists. Refer to the section

* Most common sites of pressure ulcers

Figure 14.7 Pressure points of bony prominences.

Figure 14.8 Sacral pressure ulcer. *(From Kloth, LC, and McCulloch, JM, Plate 31, with permission.)*

in this chapter on Integumentary Integrity for more information on risk assessment for pressure ulcers.

Intervention

A physical therapist treats integumentary disorders that involve the epidermis, dermis, hypodermis, or below into exposed bone, tendon, muscle, and organs. For healing to occur, intervention for disorders of the integument must facilitate local and regional homeostasis of the vascular and lymphatic systems. In addition to appropriate wound care, it is imperative that the underlying cause of pressure be addressed. Wounds will not close and remain healed unless the reduction of pressure and prevention of future breakdown are top priorities in the intervention plan. Pressure management is accomplished with the use of pressure-redistributing devices (PRDs), *pressure mapping* to determine pressure loads, *positioning/turning schedules,* and *education* of the patient, family, and caregivers. Other factors that contribute to ulceration or risk of ulceration should be considered and/or addressed. These factors include shear, friction, mobility, sensation, moisture, nutrition, age, and underlying medical condition. With appropriate wound care, control of pressure, and attention to risk factors, a wound should progress through the phases of wound healing, showing signs of improvement in a matter of weeks.[41,82,83]

Neuropathy

Neuropathy can be defined as any disease of nerves and can include peripheral nerves, cranial nerves, and/or autonomic nerves. Neuropathy exists in many disease processes; however, the most common disease process seen with neuropathy is diabetes. For most chronic diseases, including diabetes, the effects of neuropathy are peripheral. Most physical therapists treat patients with peripheral neuropathies caused by diabetes more often than any other cause. The etiology of diabetic neuropathy is not well understood but thought to be related to high levels of glucose in the blood over a long period of time. *Diabetic neuropathy* is a generic term for any diabetes mellitus–related disorder of the peripheral or autonomic nervous systems or the cranial nerves. The majority of symptoms from diabetic neuropathy will be located in the LE with foot insensitivity and subsequent ulceration being the most common (Fig. 14.9).

It is estimated that 15% of individuals with diabetes will develop a foot ulcer sometime in their life, making them almost 40 times more likely to undergo amputation because of a nonhealing wound than the nondiabetic population.[54,84] To complicate matters, many individuals with diabetes have coexisting arterial disease because the conditions are not mutually exclusive. Although the incidence is lower than for venous and arterial wounds in general, the underlying diabetic condition creates a difficult environment in which to close a wound. The incidence of neuropathic LE wounds is likely to grow as the population ages and the incidence

Figure 14.9 Chronic wound as a result of diabetic neuropathy.

of diabetes continues to escalate. According to the U.S. Department of Health and Human Services (HHS), someone in America is diagnosed with diabetes every 25 seconds.[85] Almost half of all adults now are at risk for the disease.[86] Based on information from the Centers for Disease Control and Prevention (CDC), diabetes affects more than 25.8 million people of all ages in the United States. This figure represents 8.3% of the population. About 60% to 70% of people with diabetes have mild to severe forms of neuropathy and more than 60% of the nontraumatic lower-limb amputations that are performed in the United States occur among people with diabetes.[87] A foot ulcer, many of which could have been prevented by appropriate team management, preceded at least half of the amputations. If current trends prevail, the impact of diabetic neuropathy on future wound care needs will continue to expand.

Clinical Presentation

- Ulceration is usually located on the weight-bearing surfaces of the foot
- Usually anesthetic, round, over bony prominences but can be located anywhere
- Sensory neuropathy, if present:
  - Patient unable to sense pain and pressure
  - Risk of skin breakdown without patient awareness
  - Mechanical, repetitive stresses are most common causative factors of wounds
- Motor neuropathy, if present:
  - Loss of intrinsic muscles
  - Hammer-toe, claw-toe deformities adding to risk of breakdown owing to poor weight distribution and rubbing from shoes
  - Foot drop
- Autonomic neuropathy, if present:
  - Decreased or absent sweat and oil production leading to dry, inelastic skin
  - Increased susceptibility to skin breakdown and injury
  - Propensity for heavy callus formation
- Dysvascular symptoms, if present:
  - Usually arterial disorders but can be complicated by reduced cardiac function from autonomic causes
  - Ischemia
  - Impaired healing time (also present owing to diabetes)
  - Impaired transport of oxygen, antibiotics, and nutrients needed for healing

History

A history of diabetes is sufficient to warrant investigation of diabetic neuropathy. If the individual has had diabetes for a number of years or has had trouble regulating insulin levels even for a few years, the presence of diabetic neuropathy is very likely. When ulceration is visible, the history will include specific details about the wound in addition to information about other symptoms.

Tests and Measurements

During the examination, every patient with diabetes should be checked, using monofilaments, for the presence of **protective sensation** in the LEs. This should be part of a systems review for patients with diabetes even when diabetes is not the primary diagnosis. Data on skin temperature of the LEs should also be recorded during the examination. Information about blood glucose levels should be obtained as part of the examination and must be considered for safe development of the POC.

Intervention

Physical therapists are in an ideal position to provide education and comprehensive foot care intervention for the diabetic population. According to the National Diabetes Fact Sheet, comprehensive foot care programs can reduce amputation rates by 45% to 85%.[87] In addition to appropriate wound care and maintenance of acceptable blood glucose levels, intervention must include some method of decreasing weight-bearing stresses. Options for off-loading include crutches or walker, changes in gait patterns, walking casts or splints, and specialized footwear. It would not be unusual to utilize all of the off-loading options over the course of treatment for foot ulceration. Intervention must include a comprehensive program including elements of wound care, foot care, education, PRDs, orthotics, exercise, and modalities. Every effort should be made by clinicians and patients alike to improve or retain skin integrity of the foot. Refer to Appendix 14.A for patient education information on foot care. In addition to other medical complications of diabetes, altered circulation to the foot can complicate symptoms from diabetic neuropathy. Intervention should address the worst problem first but with lower expectations for healing when vascular disorders coexist with neuropathy.

The five most common disorders of the vascular, lymphatic, and integumentary systems have been discussed. Disorders caused by surgery, trauma, malignancy,

hematologic disease, connective tissue disease, and thermal injury *will* affect the systems discussed in this chapter. Owing to space restrictions, however, they will not be discussed at this time. Interested readers should seek one of the texts mentioned in the reference list to supplement information presented here.[1,2,42,56,63] Examination and treatment of other disorders would utilize the same tests and measurements and treatment interventions discussed in this chapter based on the patient's unique characteristics.

EXAMINATION AND EVALUATION

Examination

History

A thorough history will include seeking information on systems beyond the local affected area. As noted in Chapter 1, Clinical Decision Making, physical therapy examinations for all disorders begin with gathering data from the patient, family, and other involved individuals. For the disorders discussed in this chapter, information needed from the history will be similar. Many of the disorders discussed in this chapter have a slow or insidious onset, making history taking challenging but important. See Chapter 1 to review the type of data that may be generated from taking a thorough history.

Systems Review

It might be tempting to skip a systems review before using other tests and measurements in the examination process to save time. This step, however, is of utmost importance as physical therapists move toward greater autonomy. Results may alert the physical therapist to problems that may require referral to another practitioner. A systems review is particularly important here because the disorders discussed in this chapter are the result of dysfunction in other systems of the body. For example, diabetes may lead to wounds of the feet, breast cancer surgery may lead to lymphedema, heart disease may lead to arterial wounds of the legs, and paralysis may lead to pressure ulcers. A comprehensive approach to observing and examining the patient will set the stage for the investigation and data collection that follow.

Tests and Measurements

Owing to the close relationship among disorders of the vascular, lymphatic, and integumentary systems, the importance of differential diagnosis, and the likelihood of a patient or client presenting with more than one disorder, a physical therapist will make use of a wide variety of available tests and measurements during the examination. The tests and measurements discussed in this chapter are described in the order in which they are presented in the *Guide to Physical Therapist Practice*.[88] A review of the test and measurement categories themselves should serve as a reminder of the responsibility of the examining therapist to document thoroughly. For purposes of space, only the most essential categories have been addressed. An annotated version of selected tests and measurements has been included to assist the reader in greater understanding of the tests and the conditions under examination.

Aerobic Capacity/Endurance

Aerobic capacity during functional activities is important to measure since activity will be encouraged as part of long-term management of the disorders in this chapter. In addition to information obtained during the systems review, the gathering of additional data will depend on the individual patient. This might include the use of angina, claudication and dyspnea scales, pulmonary function tests, and electrocardiogram (ECG). A determination of heart rhythm sounds, as well as breath and voice sounds, may also be required.

Anthropometric Characteristics

Height and Weight Data on height and weight are necessary to address and track normal weight values, especially for the patient with a disorder that results in abnormal fluid retention such as diabetes, edema, lymphedema, venous disease, or underlying cardiopulmonary disease.

Volumetric Measurement Volumetrics are performed utilizing special containers that hold water, and a graduated cylinder for water collection (Fig. 14.10). This method is accurate for measuring changes in body dimensions with the most common measurements taken for the hand, full arm, foot, or full lower leg; however, it is time consuming, awkward to administer, and may be inappropriate when open wounds are present owing to cross-contamination risks.

Girth Measurement Girth is recorded using a tape measure to determine circumferential body dimensions (Fig. 14.11). Ideally, a tape measure specially designed to measure girth should be used. Although bony landmarks are sometimes used as reference points in taking girth measurements, the standard among experts who

Figure 14.10 Volumetric examination for edema.

Figure 14.11 Tape measure examination for girth measurement.

treat edema is to use consistent centimeter intervals instead. For example, in measuring the LE, circumferential measurements are taken every centimeter, starting from the floor or weight-bearing surface to the groin. Clinicians choose intervals of 4, 6, or 10 cm. The smaller the interval, the better the representation of body dimensions. Special measuring boards (Fig. 14.12) can be obtained for measuring the LE, or a well-placed clipboard can be used to establish the beginning measurement. A physical therapist should remember that girth measurements by themselves should not be used to determine severity, frequency of visits, or duration of the episode of care. Advanced fibrotic changes can occur to the dermis and underlying connective tissue without a significant increase in the girth of a limb.[2,66]

Figure 14.12 Use of footboard with ruler to establish consistent intervals for measuring lower extremity circumferences.

Additional Tools

Data on anthropometric measurements may be collected using *tonometry* or *bioelectrical impedance*. Although not a standardized procedure, soft-tissue tonometry uses a device that measures tissue tension at the surface of the skin. Less pliable skin creates a higher tension reading, suggesting the presence of fluid and/or tissue fibrosis. Data from tonometry can be useful for subclinical evidence of edema, lymphedema, and fibrotic changes before they are visible or palpable. Bioelectrical impedance analysis provides accurate measurements to help predict the onset of lymphedema, often many months before a clinical diagnosis is possible. The technique involves passing a very small amount of alternating current (AC) through the limb to be tested and measuring the impedance to its flow at various frequencies. This technique is more sensitive than limb volume measurements in detecting changes in the extracellular fluid volume. In studies thus far the false-negative rate has been zero.[89-92]

Staging or Grading of Lymphedema

In an effort to categorize levels of severity, some professionals use staging or grading systems for edema and lymphedema in addition to one or more of the measurement techniques above.[2] Grading or staging of edema and lymphedema is not universally used by health professionals and should be accompanied by objective information in the examination results. One of the more frequently used systems is the *International Society of Lymphology Staging System* as described in Foldi et al[63] and the American Cancer Society:[93]

- Preclinical: patient begins to feel "heaviness" in limb, fibrotic changes and fluid accumulation occur before visible swelling or pitting; even with minimal edema, many patients report a feeling of fullness in the extremity.
- Stage I, reversible lymphedema: accumulation of protein-rich fluid, elevation reduces swelling; pits on pressure.
- Stage II, spontaneously irreversible lymphedema: proteins stimulate fibroblast formation, connective and scar tissues proliferate; minimal pitting even with moderate swelling.
- Stage III, lymphostatic elephantiasis: hardening of dermal tissues, papillomas of the skin, appearance of skin is elephant-like.

Palpation/Pitting Scale

Palpation of soft tissues must be a regular part of vascular, lymphatic, and integumentary examinations. There is no universal pitting scale currently used by healthcare professionals. Some scales are based on how deep an indentation is left after applying fingertip pressure. Other scales are based on how severe the examiner

believes the pitting to be. The following scale, most commonly used by physical therapists and physicians, gives a numerical grade to the pitting based on how long it remains after fingertip pressure is applied:

1+: Indentation is barely detectable.
2+: Slight indentation visible when skin is depressed, returns to normal in 15 seconds.
3+: Deeper indentation occurs when pressed and returns to normal within 30 seconds.
4+: Indentation lasts for more than 30 seconds.

If using a pitting scale during an examination, it is wise to document an explanation of the grades or scoring system used. Pedal edema may be attributed to chronic wounds, inflammation, infection, cellulitis, diabetes, liver disease, renal disease, CVI, lymphedema, phlebolymphedema, CHF, or trauma.

Arousal, Attention, and Cognition

After evaluating screening results during the history and systems review, the physical therapist will decide whether there is a clinical indication for tests and measurements in this category. It is important for the therapist to understand the patient's level of motivation, orientation, attention, and ability to process instructions. Many of the disorders in this chapter, such as diabetic neuropathy, chronic venous insufficiency and lymphedema, require life-long adherence to the self-care component of the treatment in order to retain the gains made during intervention. Most of this information can be obtained through interviews and observations. Additional tools would include cognitive and behavior scales, safety checklists, and learning profiles.

Assistive and Adaptive Devices

It is very likely that patients with vascular, lymphatic, or integumentary disorders will need assistive devices during the intervention and self-care phases of management. Observation, gait analysis, and manual muscle testing are often used to guide this determination.

Circulation

Collecting data about the movement of blood and lymph through the arterial, venous, and lymphatic systems is interrelated with the tests and measurements for integumentary integrity. Tests and measurements for skin changes that may occur with impairment of the circulation are discussed under the section on Integumentary Integrity. The presence or risk of pathology of the circulatory systems can be detected in many cases by skilled observation and palpation (e.g., temperature and pulses).

Temperature

To further examine circulation, skin temperature can be assessed by palpation. Objective data should also be collected and quantified using a **radiometer** or a **thermistor**, because superficial skin temperature changes are often indicative of pathology (Fig. 14.13). A decrease in skin temperature can indicate poor arterial perfusion. An increase can indicate infection or active disease processes such as cellulitis or a **Charcot joint**. An increase in temperature can also indicate a worsening or impending complication of CVI.[61]

Arterial Perfusion

The therapist collects data to determine whether adequate blood flow is reaching distal tissues. If blood flow is adequate, the oxygen supply will be adequate. Some noninvasive tests and measurements are designed to determine *blood flow* and *skin perfusion,* whereas others address *oxygen levels* in the tissues. Pulses should be palpated initially to provide information about possible vascular system involvement. The examination should include palpation of the following arteries: brachial and radial, femoral, popliteal, dorsalis pedis, and posterior tibialis. The following scale, commonly used by physical therapists and physicians, gives a numerical grade to the pulse quality:

0 = *No pulse*
1+ = *Weak* pulse, difficult to palpate
2+ = Palpable but not normal, *diminished*
3+ = *Normal,* easy to palpate
4+ = *Bounding,* very strong, may imply the possibility of an aneurysm or other pathological condition

Auscultation by stethoscope of major pulse points may identify a **bruit**. If turbulent blood flow is heard, the patient may have partial blockage of the artery. Barriers to effective pulse taking include scar tissue, edema, fibrosis, and tissue induration.

Figure 14.13 Skin temperature examination using a skin thermometer.

Doppler ultrasound is considered an essential component of the vascular examination.[53,56,94,95] The examiner uses a handheld probe to direct a sound wave into the vessel to be tested. The sound wave is reflected by red blood cells moving in the vessel. The sound wave signal is changed into audible sound that is transmitted from a small, handheld unit. The ABI is the most frequently performed test using Doppler ultrasound. A blood pressure cuff is inflated to occlude blood flow temporarily and is then deflated as the examiner listens for the return of flow. Blood flow is observed on the upper extremity (UE) at the brachial artery and on the LE at the posterior tibial and the dorsalis pedis arteries (Fig. 14.14). The ABI is a ratio of the LE pressure divided by the UE pressure. Table 14.1 presents the ranges of ABI values and potential vascular indications. Obtaining an ABI will provide useful information about the arterial system since the ABI is an indicator of loss of perfusion in the LE. Results will guide the therapist in decisions about the use of compression and débridement, and will help predict the likelihood of wound closure. When the examiner cannot occlude blood flow with the blood pressure cuff, calculations may show a falsely elevated ABI. Arteriosclerosis or calcified vessels (from diabetes) can make it difficult for the cuff to compress enough to get an accurate ABI. The target arteries would be documented as *noncompressible vessels*. Test options when the vessels are noncompressible include taking toe pressures with a special cuff, proceeding with transcutaneous oxygen testing (see below), or recommending referral for a vascular laboratory workup.

Figure 14.14 ABI test performed using Doppler ultrasound probe. *(From McCulloch and Kloth: Wound Healing: Evidence-Based Management, ed 4. FA Davis, Philadelphia, Figure 7-3, with permission.)*

Table 14.1 Ankle-Brachial Indices with Corresponding Indications

ABI Ranges	Possible Indication
>1.2	Falsely elevated, arterial disease, diabetes
1.19–0.95	Normal
0.94–0.75	Mild arterial disease, + intermittent claudication
0.74–0.50	Moderate arterial disease, + rest pain
<0.50	Severe arterial disease

Trophic Changes

Trophic changes occur in the skin of the LEs when circulation is impaired by poor arterial blood flow. Observation is the most accurate way to note changes. Trophic changes include dry, shiny skin (pale in Caucasians), decreased or absent leg hair, and thick toenails. It should be noted that these signs are also a predictable part of aging but not to the same degree as can be seen with trophic changes. The presence of changes indicates the need for other tests of circulation.

Pain

When related to circulation, a thorough pain history may be all that is necessary to suggest the possibility of arterial disease. Reports of pain indicate the need for further tests and measurements of the vascular system. Pain as the result of intermittent claudication (IC) is described earlier in this chapter. Rest pain that develops at night, awakens the patient, or requires analgesics for relief is considered more severe than IC. Pain can be measured for severity on a Visual Analog Scale (VAS). The degree of impairment from IC is often measured in terms of how far an individual can walk before experiencing acute leg pain or fatigue. IC can be classified objectively with a rating scale to indicate severity based on distance walked before onset of pain. The *Walking Impairment Questionnaire (WIQ)* is a disease-specific questionnaire commonly used to examine claudication. It does not, however, measure the impact of claudication on quality of life (QOL).[96] The most extensively researched disease-specific QOL questionnaire for IC is the *Claudication Scale (CLAU-S)*.[96-98]

Special Tests

There are many other noninvasive and invasive tests used to detect, examine, diagnose, or confirm arterial disease and dysfunction. Appendix 14.B presents a brief description of special tests for arterial and venous function including *rubor of dependency, air plethysmography (APG), transcutaneous oxygen ($TcPO_2$)* measurement, and *skin perfusion pressure (SPP)* measurement. Although some of the tests are useful for predicting healing of ulcers and amputation wounds, they may not be readily reimbursed when performed by a physical therapist.

The APG, $TcPO_2$, and SPP are used primarily for research purposes because they are time consuming to perform.

Venous Patency

Venous disease and dysfunction can be detected with a wide range of tests and measurements. The amount of time available for examination, as well as reimbursement issues, may influence decisions about which tests to use. Refer to Appendix 14.B for a brief description of *Venous Filling Time, Percussion Test,* and the *Trendelenburg Test*. Owing to inconsistencies in interpretation and administration, the *Homans' Test,* or Homans' sign (pain in the calf when the foot is passively dorsiflexed), should not be relied on to detect a DVT. A physician should be contacted and a Doppler study used if an individual exhibits two of the following signs: change in skin temperature, change in skin color (darker), pain in the calf (experienced by approximately half of patients), or swelling.

Lymph Vessel Integrity

Patient history and clinical findings are used most often to make a diagnosis of lymphedema. Most invasive tests have lost popularity because of the risk of triggering the onset of lymphedema or an exacerbation of existing lymphedema owing to the irritation caused by dye and/or needle puncture. When invasive tests are indicated, the most common test procedure is *lymphoscintigraphy.* This test, using dye and a special camera and computer, can visualize many lymphatic system functions.[2,99]

Gait, Locomotion, and Balance

The importance of movement to improve blood and lymphatic flow, and to facilitate the overall return to function for most individuals, will validate the use of tests and measurements to document patient abilities in this area. During the initial examination, gathering data through observation, gait analysis, and postural control tests is usually adequate. The examination results may indicate the need for additional tests such as inventories, or batteries of tests to further document safety (fall risk) or equipment needs. Individuals who are morbidly obese have unique challenges with gait that should be addressed during the examination.

Integumentary Integrity

Collection of data about skin and subcutaneous tissues is interrelated with the tests and measurements for circulation and cutaneous sensation.

Observation and Palpation

Characteristics of the skin are noted almost entirely by observation and palpation. A comparison between involved and normal integument is made with careful attention to color, moisture, texture, firmness, temperature, elasticity, symmetry, and shape. In the presence of a wound, the wound tissue, the periwound area, and the wound exudate should all be observed and data recorded regarding the observations. The location of a wound, presence of edema, and presence of lymphedema can be documented using a *body diagram*.

Trophic Changes

Because they are an important part of many disorders involving the integument, trophic changes are mentioned again under this section. Individuals who are making a quick reference specifically to integumentary integrity in this chapter are reminded to refer to all sections related to trophic changes. As in the section on circulation, observation is an important approach to noting changes.

Fibrosis

The best way to detect fibrotic changes of the skin is through palpation of the affected tissue. The superficial skin and underlying tissue will feel thickened, firm, and unyielding or immobile. Testing for the presence or absence of the *Stemmer's sign* is an objective measurement that can be added to the examination for lymphedema. When the dorsal skin folds of the toes or fingers are resistant to lifting or cannot be lifted at all, the Stemmer's sign is said to be "present." The clinician must be cautious, however, because a negative or "absent" skin fold test does not rule out lymphedema.

Coloration

Skin color will vary based on the underlying disease. Observation is the best way to note comparisons between normal tissues and those under examination. The most abnormal color changes include red, purple, and brown. Color changes may indicate a chronic condition such as hemosiderin staining or an acute situation such as redness associated with DVT. If color changes are intermittent they may signal a disease such as **Raynaud's**.

Temperature

The temperature of the skin is most often examined by palpation but data can be objectively collected and quantified using a radiometer or a thermistor (see Fig. 14.13). Maintenance of normal skin temperatures is essential for good wound healing. Abnormal skin temperatures can signal problems related to the dermis or other structures. A decrease in superficial skin temperature may indicate poor arterial perfusion. An increase may indicate infection or active disease processes.

Wounds

Size and Depth

A number of tools and scales are available for gathering data about wounds, edema, lymphedema, and other aspects of integumentary integrity. Wounds not classified with staging or grading can be described based on the depth of tissue damage. The descriptions used for depth of burn injury, *superficial, partial,* and *full thickness,* can

also be used to describe depth in other types of wounds. Objective measures included in documentation are vital for communication about the patient. A calibrated grid, photographs, tracings, graphs, and specifically designed forms are most commonly used to document wound size and depth.

Drainage

Drainage is measured by observation and is often described in terms of color and thickness. Examination of wound drainage may be very important because it may indicate a normal response to trauma (few days) or a prolonged response to necrotic tissue, a foreign substance in the wound, or infection. The most common language for describing wound drainage is described in Table 14.2.

Staging

Pressure ulcers are typically classified using a *staging* or *grading* system that gives information about the severity of the wound based on depth of tissue destruction. Both the National Pressure Ulcer Advisory Panel (NPUAP) and the Agency for Health Care Research and Quality (AHRQ) support the use of the universal classification system described in Table 14.3.[100,101]

Despite some standardization and acceptance by some government agencies, staging of pressure ulcers is controversial among wound management experts because it is often misused. The misuse most often occurs because the staging system describes only the depth of tissue destruction and not other characteristics of the wound that need to be considered. Treatment plans should not be based solely on the staging system. Staging can be challenging because tissue damage may be deeper than what appears on the surface, wounds cannot be staged when necrotic tissue is present, and darker skin does not always show the reddened alterations indicating Stage I. The NPUAP has redefined the definition of a pressure ulcer and the stages of pressure ulcers to address the challenges of staging. The staging descriptions are intended for use with pressure ulcers and not to describe the severity of other wound types.

Wound Healing Tools

A variety of tools can be utilized to document wound status and wound healing. Since there is no single wound characteristic that can be used alone to monitor healing or predict outcomes, it is best to use a tool that includes multiple characteristics as measures of wound healing. The three tools with the most well-established reliability and validity are the *Sussman Wound Healing Tool (SWHT),*[43] the *Pressure Ulcer Scale for Healing (PUSH),*[43,102] and the *Pressure Sore Status Tool (PSST).*[43] The *Wagner Ulcer Grade Classification* system is a tool designed for examination of the diabetic foot when neuropathy and ischemia are present.[103]

Risk Factor Assessment

Although all individuals may be subjected to the same intensities of pressure for similar amounts of time, they all will not develop pressure ulcers. As a result, factors related to individual risk, susceptibility, or tolerance capacity should be determined. A physical therapist will find that data from a risk assessment can be helpful in planning cost-effective intervention strategies. As discussed earlier in the chapter, there are many factors that put individuals at risk for developing pressure ulcers, such as poor peripheral circulation, diabetes, nutritional status, mobility, and continence issues, to name a few. To objectify and standardize risk assessment, a number of reliable tools have been validated by research:

- *Norton Risk Assessment Scale*: original risk assessment instrument scores individuals on physical condition, mental condition, activity, mobility, and incontinence.[104]
- *Gosnell Scale–Pressure Sore Risk Assessment*: refinement of Norton's scale includes changes to the following scoring categories: nutrition, mental condition, activity, mobility, continence, skin appearance, medication, diet, and fluid balance.[105]
- *Braden Scale for Predicting Pressure Sore Risk*: the six scoring categories of this instrument include sensory perception, moisture, activity, mobility, nutrition, and friction/shear.[106]

Table 14.2 Descriptions of Drainage by Color and Thickness

Drainage Type	Color	Thickness
Transudate	Clear	Thin, watery
Serosanguineous	Clear or tinge of red/brown	Thin, watery
Exudate	Creamy, yellowish	Moderate to very thick, expected with autolytic debridement
Pus	Yellow, brown	Moderate to very thick
Infected pus	Hues of yellow, blue, green	Thick, usually indicates infection (but may be normal as white blood cells macrophage necrotic cells and turn them into slough); drainage can be foul and yet the wound may not be infected

Table 14.3 Pressure Ulcer Staging Criteria Revised by NPUAP

Pressure Ulcer Stage	Definition
Suspected Deep Tissue Injury Further description	Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler as compared to adjacent tissue. Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.
Stage I Further description	Intact skin with nonblanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. The area may be painful, firm, soft, warmer, or cooler as compared to adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones. May indicate "at risk" persons (a heralding sign of risk).
Stage II Further description	Partial-thickness skin loss of dermis presenting as a shallow open ulcer with a red pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled blister. Presents as a shiny or dry shallow ulcer without slough or bruising. (Bruising indicates suspected deep tissue injury.) This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation.
Stage III Further description	Full-thickness tissue loss. Subcutaneous fat may be visible but bone, tendon, and muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling. The depth of a Stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleoli do not have subcutaneous tissue and Stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep Stage III pressure ulcers. Bone/tendon is not visible or directly palpable.
Stage IV Further description	Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunneling. The depth of a Stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleoli do not have subcutaneous tissue and these ulcers can be shallow. Stage IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule) making osteomyelitis possible. Exposed bone/tendon is visible or directly palpable.
Unstageable Further description	Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound. Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as "the body's natural (biological) cover" and should not be removed.

Staging should not be used in reverse order (also called back-staging or down-staging). The staging system is not a measure of healing. A Stage IV ulcer is always a Stage IV. If it is healed, it would be referred to as a healed Stage IV, not a Stage 0.

Muscle Performance

Muscle strength screening during the systems review and specific manual muscle testing during the examination should be included for the individual with a disorder of the vascular, lymphatic, or integumentary system. Functional muscle strength identified during an examination of functional mobility skills and ADL is also important. Lack of strength and immobility go hand in hand, often leading to problems such as pressure ulcers, CVI, increased LE edema and lymphedema, varicosities, and poor control of diabetic sequelae.

Orthotic, Protective, and Supportive Devices

There are many situations in which an individual with disorders from this chapter would need to be assessed for an orthotic, protective, or supportive device. Those individuals already using a device may need a modification. For the individual with impaired sensation of the feet, *extra-depth* shoes may be indicated. Existing shoes should be checked periodically for fit and wear. A referral to another professional for protective footwear may be needed. Supportive devices may allow an individual to increase his or her activity level, offsetting the risks of a sedentary lifestyle. Compression garments and bandaging, considered *supportive devices,* must be checked periodically for fit and function to ensure that they retain their effectiveness. Garments and bandages will be essential intervention choices for most individuals with edema and lymphedema. In the later stages, a patient's need for devices may provide a way to quantify the remediation of impairments or activity limitations imposed by the symptoms of the disorder.

Pain

The presence or absence of pain, its location and intensity, its effect on sleep, and other QOL factors should be measured (see Chapter 25, Chronic Pain). Pain scales, drawings, and maps are effective for documentation. Owing to the high incidence of co-morbidity in patients with disorders of the vascular, lymphatic, and integumentary systems, the measurement of pain may also assist in making a differential diagnosis.

Posture

Indications for examination of posture include pain, heavy or large limbs, scar tissue, poor body image (e.g., following cancer treatment), obesity, and decreased sensation. Data can be obtained with the combined use of a posture grid, tape measure, observation, and palpation. A physical therapist will begin a posture assessment initially by observation the moment the client enters the room, and will continue to assess and observe posture formally and informally during the examination and intervention.

Range of Motion

The need for adequate ROM and the impact of decreased ROM cannot be underestimated. Following ROM screening during the systems review, specific ROM measurements are often indicated, especially with persons for whom movement is an essential part of symptom management. Examples are numerous but include ankle ROM for the person with CVI, shoulder ROM following breast cancer surgery, or knee ROM in the individual with lymphedema of the LE. A universal goniometer and a tape measure are required to obtain objective ROM data.

Self-Care and Home Management

Activity limitations and disability are common with disorders of the vascular, lymphatic, and integumentary systems. Examination, education, and training that allow the patient to safely perform self-care and home management activities are of great importance in planning and implementing the self-management phase. Descriptions and quantifications are needed for documentation and goal setting. Examination tools should include functional measures of both basic activities of daily living (BADL) and instrumental activities of daily living (IADL), as well as fall risk scales (see Chapter 8, Examination of Function).

Sensation

Information from the history and systems review may indicate the need for a detailed examination of sensory function. Therapists should not rely on history alone as an indication for sensory testing, however, because many individuals are unaware of their deficits until tested. Sensory tests are particularly important when symptoms are long-standing, or include complaints of numbness, tingling, or burning. Patients who should routinely be tested are those who may receive LE compression treatments, and all individuals who have a diagnosis of peripheral neuropathy, diabetes, and/or arterial disease. In addition to observation and palpation, initial tests should include testing for protective sensation using filaments such as the *Semmes-Weinstein monofilaments*. The filaments are supplied in varying sizes and are each mounted on a handle. The filament is applied to the skin until it bends. The patient is asked to report, with eyes closed, whether the filament is touching the body part. Each monofilament supplies a specific amount of force when it is placed on the test area and gently bent. The monofilaments are available in a large set but most testing can be accomplished using a few filaments. An individual has *normal sensation* when the 4.17 monofilament (1 *g* of force) can be felt. An individual has *protective sensation* intact when the 5.07 filament (10 *g* of force) can be felt (Fig. 14.15). With loss of protective sensation, the individual cannot sense trauma to the foot, often leading to foot ulceration. For the individual who has lost protective sensation, the use of special protective footwear is indicated. Lack of sensation, especially protective sensation, can be a characteristic of long-standing diabetes. Decreased sensation

Figure 14.15 Semmes-Weinstein monofilament used to assess presence of protective sensation. Bowing of the filament indicates that appropriate pressure has been applied. *(From McCulloch and Kloth: Wound Healing: Evidence-Based Management, ed 4. FA Davis, Philadelphia, Figure 7-6, with permission.)*

may signal a disorder such as **scleroderma**. To test for sharp/dull sensation, vibratory sensation, pressure, and other sensations, tools for gathering data include a pressure scale, tuning fork, and/or aesthesiometer. Additional information can be obtained in this textbook (see Chapter 3, Examination of Sensory Function).

Ventilation and Respiration

Tests and measures should be used to determine if the patient has adequate ventilation and respiration to meet normal oxygen demands. The presence of pathology might be indicated from a predictable source such as breath sounds or the color of nail beds. A less predictable sign, such as swelling around the ankles, could also indicate pathology. Initial data may be gathered by examining arterial blood gases, observing the work of breathing, or utilizing a spirometer. Additional appropriate tests include the airway clearance test and use of a pulse oximeter (see Chapter 12, Chronic Pulmonary Dysfunction).

Evaluation

Diagnosis, Prognosis, and Plan of Care

Once the examination is complete, the physical therapist evaluates the data and determines the diagnosis and prognosis. The physical therapist needs to consider a number of factors including clinical findings, overall physical function and health status, social support, multisystem involvement and co-morbid conditions, and chronicity, severity, and stability of the condition. This information is outlined in the *Guide to Physical Therapist Practice*[88] and presented in this textbook (see Chapter 1, Clinical Decision Making). The next step is the design and implementation of the POC, including procedural interventions.

INTERVENTION

Physical therapist intervention for disorders of the vascular, lymphatic, and/or integumentary systems should include a variety of techniques to address the problems identified during the examination. It is common for patients with disorders in these systems to present with multiple factors contributing to the primary diagnosis. The intervention plan should reflect a holistic view of the patient. For example, an individual with signs and symptoms of venous disease may also present with poor ankle ROM, an LE wound, and lymphedema. The wound must be cleansed and dressed but the limb should also receive compression for optimum healing. Ankle ROM must be improved because ambulation will enhance calf pump function. Another example of the need to view patients holistically would be an individual with signs and symptoms of arterial disease who also presents with decreased LE strength, diabetes, and peripheral neuropathy. Exercise is important for this person, but it must be carefully coordinated to address arterial health, diabetes management, and skin protection.

A natural component of viewing patients holistically is to be able to identify the need for interdisciplinary care. This concept may be more important for individuals with disorders of the vascular, lymphatic, or integumentary systems for the very reasons listed in the previous paragraph: these populations present with complicated, multisystem problems that are often best addressed using a team approach. Integrated care facilitates an exchange of information among all the health professionals that are involved in the care of the patient. This model of care might be delivered by a team of individuals who work together every day or it might be coordinated by a physical therapist who pulls together certain professionals for a particular patient's needs.

Coordination, Communication, and Documentation

In keeping with practice standards, the physical therapist coordinates intervention efforts to ensure the patient receives the highest quality of care. Critical to this goal is open communication among the health care team, patient, family, and caregivers. The team will most likely include a physician, nurse, physical therapist, occupational therapist, dietitian, and social worker. Referrals to other health care professionals (e.g., podiatrist) who can support the patient can also be made. Meticulous documentation will have a significant impact on issues such as continuity of care, receiving adequate number of visits for procedures, and a stronger working relationship with referring practitioners. Photographs, special forms for data collection, and body graphs are very effective tools to enhance communication and documentation. Appendix 14.C provides an example of an examination form that might be used to document

data collected for a patient with a disorder of the vascular, lymphatic, or integumentary system.

Patient/Client-Related Instruction

Disorders of the vascular, lymphatic, and integumentary systems represent major health events for patients and their families and require life-long management strategies. Patients and families often react with anger, despair, or at least confusion when learning about a condition that may be permanent. The value of patient and family education cannot be underestimated. Patient education will be the key to preparing individuals to manage their symptoms, prevent recurrence, and remain vigilant about their condition. Information should be provided that is appropriate to the patient/family/caregiver's educational level with provisions for follow-up and repetition. Motivational strategies are important to ensure adherence to self-management. For many chronic disorders, high-quality patient education has been shown to result in positive changes in health behaviors, QOL perceptions, and adherence to home programs. Instruction for the patient should include resources, education materials, and a home program.

- Resources
  - Community services and support groups related to the patient's diagnosis
  - Counseling services, as needed, especially for assistance with QOL issues
  - Internet sites (Appendix 14.D lists Web-based resources for clinicians, families, and patients with vascular, lymphatic, and integumentary disorders)
  - Family member participation in care
- Education materials
  - Instructional materials, multimedia tools
  - Self-management strategies
  - Available resources include *Wound Care* by Sussman[107] and *Living Well with Lymphedema* by Ehrlich, Vinje-Harrewijn, and McMahon[108]
- Home program
  - Skin and/or wound care; prevention practices; scar management
  - Compression garment or bandage wear and care
  - Exercise
  - Edema control
  - Pressure-redistributing devices
  - Foot care for patients with diabetes (see Appendix 14.A for a foot care guide)

Outpatient or home therapy may be required for some patients. Follow-up visits at regularly scheduled intervals may be the best way to facilitate adherence to the home program and to prevent recurrence or exacerbation of symptoms.

Procedural Interventions

This section has been organized in the order in which a physical therapist would provide patient care. Within each section, information has been organized from most invasive/least selective (nonspecific) to least invasive/most selective (highly specific). In developing the POC, a physical therapist should select interventions that are least invasive/most selective, always trying to create an environment that is conducive to healing. The ultimate goal should be to optimize the body's opportunity to heal. Despite tremendous gains in the management of vascular, lymphatic, and integumentary disorders, there are still an alarming number of practitioners using outdated and often harmful methods to treat these disorders. Overused agents such as povidone-iodine, wet-to-dry dressings, whirlpool, and compression pumps have been replaced for at least a decade with more advanced, biocompatible, and cost-effective methods of treatment. The use of inappropriate agents can delay healing and may cause harm. Supporting literature abounds for the clinician seeking evidence-based practice. Elements of skin and wound care that are often overlooked or underestimated for their impact include PRDs, positioning, exercise, patient education, compression, and orthotics.

The therapist treating a patient with a wound should strive to establish an ideal wound environment. The choices made about intervention should be guided by the goal of achieving this ideal environment, described as moist, free from necrotic tissue, free from exudate, warm, protected from trauma, and protected from infection. Physical therapists may manage wound care in a primary care role, or in consultation with a physician and/or other providers. Interventions involving pharmaceuticals will always require physician consultation for a prescription. "Although practice may change based on new evidence, the search for healing in the most humane way and fastest time possible persists as the goal."[109, p. S1]

Cleansing

Wound cleansing is differentiated from wound débridement, which follows in the next section. The wound cleansing method should be selected based on its ability to support or return a wound bed to homeostasis. Chemical and mechanical trauma should be minimized even in the presence of infection. A decision to cleanse should be made carefully, because many wounds do not need to be cleansed at every dressing change. Often the negative effects to the wound from cleansing outweigh the positives. Not only is there a potential loss of endogenous fluids from the wound surface but also there is significant slowing of cellular activity for up to 3 hours after wound cleansing.[110]

Whirlpool

Since whirlpool can be classified as a means of cleansing and mechanical débridement, it is discussed in both categories of intervention. Despite at least a decade of investigation, with little evidence to support its use, whirlpool is still used for both nonselective mechanical débridement and for wound cleansing. However, many

clinicians involved in wound care have decreased their use of whirlpool significantly in response to the evolution of wound care and subsequent publication of the Agency for Health Care Research and Quality (AHRQ) guidelines. Standards have changed with the increased knowledge of the microenvironment in the wound bed and a greater understanding of the chemical mediators necessary for homeostasis.

The historical rationale for use of whirlpool was based on its use in deodorization, skin and wound cleansing, mechanical nonselective débridement, wound decontamination and infection control, and softening adherent necrotic tissue in preparation for débridement. There is little evidence to support whirlpool as the *optimal* method for achieving these. If using whirlpool for an infected wound, the AHRQ recommends that whirlpool be discontinued when the ulcer is clean. First issued in 1994, the guidelines are considered to still be current.[101] The guidelines include more than 300 references, bibliographic sources, and updates that can be easily obtained.[111]

Evidence-based rationale for a decrease in the use of whirlpool is based on a number of factors. There is risk of contamination from waterborne pathogens and from patient cross-contamination. The dependent position can initiate or increase venous congestion and extremity edema. With whirlpool there is loss of endogenous fluids from the wound bed and heat loss affecting core body temperature and the local wound area. Even mild changes in core body temperature (hypothermia) have negative effects on the cells that are important to wound healing. In addition, mechanical disruption of granulation tissue, epithelial cells, and new skin grafts occurs, primarily from the use of water agitation. Immersion in a whirlpool saturates wound tissue and surrounding skin, creating the potential for maceration, skin breakdown, and temporary inactivation of normal skin defenses. Thus, there is the potential to prolong inflammation and delay wound healing. Whirlpool can also increase heart and respiratory rates. Finally, the use of whirlpool is labor intensive and costly in terms of use of water, utilities, linen, and staff.[3,112-116]

Based on current standards of care and guidance from the literature, it may be possible to justify the use of whirlpool in some situations. Wounds that need intensive cleansing that cannot be accomplished with other methods might benefit from whirlpool. Minimal agitation of water is recommended with only small body areas treated for short amounts of time (5 to 10 minutes) to limit the negative effects of temperature and pressure changes. Unless infection is confirmed with tissue culture, cytotoxic agents in the water should be avoided (e.g., povidone-iodine, chlorine). Wounds that need softening of loosely adherent tissue before sharp, enzymatic, or autolytic débridement might benefit from whirlpool when other tissue-softening methods are not appropriate. (**Note:** there is little to no reimbursement for the use of whirlpool to soften tissue before débridement.) Wounds that would benefit from stimulation of peripheral circulation might benefit from whirlpool. Neutral warmth or normothermia (normal body temperature, 98.6°F [37°C]) is recommended.

Pulsatile Lavage with Suction

Pulsatile lavage with suction (*PLWS,* also referred to as *forceful irrigation*) is a method of wound irrigation combined with suction (Fig. 14.16).[117] Pulsed irrigation and simultaneous suction removes the irrigation fluid, wound exudate, and loose debris. In use for over 20 years, this wound cleansing and débridement method has several advantages over whirlpool cleansing. PLWS uses less water, less staff support, and less treatment time and requires less cleanup time. PLWS can be performed bedside and in the home. (**Note:** family or visitors are not allowed in the room during the procedure owing to aerosolization of microorganisms.)[118] This type of cleansing collects wound exudate and debris efficiently and delivers topical antibiotics, antiseptics, and antibacterial solutions efficiently. PLWS speeds healing by rapid removal of contaminants and treats tunneling wounds and undermining wounds using special cannula tips. Risk of periwound maceration and cross-contamination is eliminated with use of disposable equipment.

Although the advantages are clear, there are disadvantages to using PLWS. These include risk of overuse, especially with clean, granulating wounds, and risk of trauma to newly formed tissue from plastic tips, pulsed irrigant, and/or suction. Treatment may be painful to the patient. PLWS use should be limited to experienced therapists who are well versed in anatomy, especially when irrigating tracts, areas of undermining, or exposed bone, tendon, blood vessels, cavity linings, grafts, or flaps. All staff involved in treatment must wear disposable personal protective equipment (PPE).

Figure 14.16 Physical therapist's fingers mold PLWS shield to sacral wound surface. *(From Kloth, LC, and McCulloch, JM, p 221, with permission.)*

Compared to other irrigation options, disposable, single-use equipment contributes to landfill burden. There is considerable cost when labor, PPE, and equipment are calculated.

Nonforceful Irrigation

As soon as possible, wound cleansing should be accomplished with minimal pressure or force on the wound bed by nonforceful irrigation. This can be accomplished by pouring a solution over a wound, or using a bulb syringe or other device designed to deliver an irrigant to the wound (Fig. 14.17). There are several products that package saline specifically for wound cleansing: Blairex® Wound Wash Saline, manufactured by Blairex Laboratories, Inc., Columbus, IN 47202; and Saljet®, single-dose sterile saline manufactured by Winchester Laboratories, LLC, St. Charles, IL 60174. Several manufacturers produce a spray container that delivers saline or a surfactant at very gentle pressures (Fig. 14.18). Infected wounds can also be effectively cleaned with nonforceful irrigation. Wounds with necrotic tissue or debris, however, may respond best to a few sessions of a more forceful type of cleansing. For wounds that are clean, with new tissue growth, cleansing should be done only to remove excess endogenous fluids or residue left by dressing products.

Commercial Skin and Wound Cleansers

There are many skin and wound cleansers designed as topical solutions and marketed to treat acute and chronic wounds. For many years solutions have been used indiscriminately without consideration or measurement of the potential side effects on the new cells trying to proliferate in the wound bed. These topical cleansers may have some antimicrobial effects but most have significant antimitotic (inhibiting mitosis) effects as well.[119] This means that cleansers may adversely affect important cells such as fibroblasts and epidermal keratinocytes during tissue repair. The cells most affected are the all-important cells that fill and cover a wound. Information on the toxicity of the most common cleansers has been created to assist health care providers in selecting or rejecting the use of cleansers.[119] It is no surprise that acetic acid is extremely cytotoxic to the cells in a wound but of greater concern is the fact that ordinary bath soaps, even moisturizing body washes, are very cytotoxic. A physical therapist utilizing commercial cleansers or ordinary soap must consider the rationale behind the use of each topical agent applied to the wound and weigh the cost to the wound: some contribute to wound healing whereas others contribute to aspects other than wound healing.

Figure 14.17 Wound cleansing with nonforceful irrigation.

Figure 14.18 Wound cleansing with a spray cleanser.

Débridement

Débridement is defined as the removal of foreign material and dead or damaged tissue. Removal of devitalized or infected tissue is an important intervention to prevent or control bacterial growth, encourage normal cellular activity in the wound bed, and enhance the rate of tissue repair. *Nonselective débridement* removes all tissue both necrotic and living. Methods in this category may be quick but are often painful and frequently cause damage to nearby healthy tissue. *Selective débridement* removes necrotic tissue in a controlled method. Selective methods are more comfortable and gentle to the wound bed but may remove tissue more slowly.

The importance of physical therapist proficiency in sharp débridement is reflected in the Physical Therapist Licensure Examination Content Outline (the content outline can be accessed at www.fsbpt.org/download/CandidateHandbook20110114.pdf), the Commission on

Accreditation in Physical Therapy Education (CAPTE) evaluative criteria (the Accreditation Handbook can be accessed at www.capteonline.org/AccreditationHandbook) and the *Guide to Physical Therapist Practice*.[88] In response, most professional-level programs include instruction in sharp débridement within the curriculum. In the majority of states, débridement is included in the scope of practice for physical therapists. Physical therapists should consult their state's practice act to ensure that débridement is within their scope of practice in that state before providing this intervention.

When choosing a method of débridement, clinicians must consider not only the wound status but also the physiological, emotional, and financial status of the patient. Modern wound management experts avoid débridement techniques that cause the wound to bleed owing to the highly damaging effects to the wound tissues.

Nonselective Débridement

Wet-to-Dry Dressings A wet-to-dry (WTD) dressing consists of wet gauze applied to the wound bed and allowed to dry on the wound. Removal of the dry dressing débrides the wound, pulling away any cellular material that has adhered to the gauze. This method of débridement removes necrotic tissue, as well as rich endogenous fluids, fibrin, and other cells critical to wound healing. It is also frequently uncomfortable for the patient, often causing bleeding and trauma to the wound bed. There is literature to describe the use of WTD dressings for débridement, but the efficacy of the procedure has not been demonstrated.[120,121] Wound management experts have agreed for over two decades with a multidisciplinary panel: "One of the most routinely and inappropriately used forms of non-selective mechanical débridement is the wet-to-dry dressing."[122, p. 28] Once believed to be less costly than other dressing options, it has been shown that WTD gauze dressings are actually more costly than advanced dressings. Evidence for the many negative aspects of WTD dressings is summarized in Box 14.1 Evidence Summary.

Since WTD dressings can be classified as a tool for mechanical débridement and/or a primary wound dressing, the procedure has been discussed here and in the section on dressings.

Surgical Débridement Surgical débridement provides rapid results when treating life-threatening necrosis, large wounds, tunneling wounds, and necrotic or infected bone. Wide excision, removing viable and nonviable tissue, is usually done in the operating room with anesthesia. Laser débridement, another form of surgical débridement, may be appropriate when an individual is not a candidate for operating room procedures. Surgical débridement is not within the scope of practice of a physical therapist.

Pulsatile Lavage with Suction PLWS will provide nonselective débridement while cleansing a wound. Refer to the detailed discussion of PLWS in the previous section on Cleansing.

Box 14.1 Evidence Summary Outcome Studies Using Wet-to-Dry (WTD) Dressings as Part of Wound Care

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Ovington[123] (2001)	N/A	Prospective cohort study	N/A	WTD dressings have been standard procedure for wound care although research indicates gauze dressings are not optimal for the patient, the clinician, or the healthcare system.	Gauze dressings do not support optimal healing and are more labor intensive than advanced dressings. This article provides clinicians with the rationale and evidence to collaborate with physicians in choosing cost-effective products to achieve positive patient outcomes.
Shinohara et al[124] (2008)	134 patients with surgical incisions	RCT	7 days postoperative (post-op)	Occlusive hydrocolloid dressings were less expensive to use than gauze dressings. Rate of post-op wound infection was no different between the two.	Post-op dressings still commonly consist of gauze. Evidence continues to show that gauze dressings are not cost-effective. Concerns about infection under occlusive dressings appear to be unfounded.

Box 14.1 Evidence Summary Outcome Studies Using Wet-to-Dry (WTD) Dressings as Part of Wound Care—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Singh et al[125] (2004)	N/A	Meta-analysis	N/A	72% more chronic wounds healed completely with an occlusive dressing than with conventional gauze dressing.	The results are clinically and statistically significant.
Vermeulen et al[126] (2004)	N/A	Systematic review: All RCTs evaluating the effectiveness of dressings and topical agents for surgical wounds healing by secondary intention.	N/A	The use of gauze dressings is associated with an increase in pain, number of dressing changes, and cost, with a decrease in patient satisfaction.	The authors conclude that the use of gauze for the local treatment of surgical wounds healing by secondary intention should be considered carefully. In this category of dressings for surgical wounds healing by secondary intention, most studies are underpowered with little replication. There is a need for further research to validate empirical and anecdotal reports from the field.
Cowan and Stechmiller[121] (2009)	202 subjects with open wounds healing by secondary intention	Descriptive study. A retrospective chart review was performed.	N/A	WTD dressings accounted for 42% of wound care orders. 69% of wounds treated with WTD were surgical. Mechanical débridement was not clinically indicated in more than 78% of wounds treated with WTD dressings.	WTD dressings were inappropriately ordered in 78% of the cases in this review. These findings suggest that WTD dressings are prescribed inappropriately in situations where there is little evidence to support their use.
Bergstrom et al[127] (2005)	882 residents of long-term care facilities, age 18 and older with at least one PrU	Retrospective cohort study with convenience sampling	12 weeks	Multiple regression models, one for each PrU stage grouping were completed. The area of PrUs was reduced more with moist than with dry dressings for all stages.	The treatment factor most significantly associated with healing in this study was the use of moist dressings, which was a stronger factor in healing than dry dressings or no dressings.

Box 14.1 Evidence Summary Outcome Studies Using Wet-to-Dry (WTD) Dressings as Part of Wound Care—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Jones and Fennie[128] (2007)	114 adults in 3 areas of the country, in hospitals, clinics, nursing homes, and home care; 50 years or older with at least one Stage II to IV PrU	Multisite, retrospective chart review using a structured data abstraction form and protocol	N/A	Bivariate analysis showed there were several variables that were significantly associated with healing. Logistic regression models identified the most significant predictors of healing. Among the list was the use of moisture management dressings. Gauze dressings were associated with nonhealing after 6 months of treatment.	Evidence does exist to support the use of dressings that maintain a moist environment at the wound/dressing interface.
Lawrence[129] (1994) and Lawrence et al[130] (1992)	Simulated infected wounds in the first study and 7 subjects with burn wounds in the second study, 14 dressing changes IC: colonized burn wounds	Cohort design	Two dressing changes per wound	Removing dry or damp gauze from a wound released significant numbers of organisms into the air. Significantly fewer organisms were released when removing an occlusive dressing. Significant numbers of bacteria were still in the air as long as 30 minutes after removal of gauze dressings.	Although these studies are older, they are classic and have not been repeated in the literature. Wounds are often undressed in open areas, sometimes with other patients nearby. Some health care practitioners do not wear masks when undressing a wound. There is an appreciable cross-contamination hazard from removing dry or damp gauze dressings without protection to all individuals in the room.
Kohr[131] (2001)	1 subject IC: wound that had failed to heal	Case study: moist wound environment applied to wound that had failed to heal with WTD dressing for 21 days	10 days	Switch from WTD to moist-wound-healing (MWH) dressing: 10 days to significant wound healing.	The temperature in the wound was optimized, autolytic débridement promoted. Cost comparison issues between WTD and MWH also well illustrated in the article.

Continued

Box 14.1 Evidence Summary Outcome Studies Using Wet-to-Dry (WTD) Dressings as Part of Wound Care—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Payne et al[132] (2009)	36 patients with Stage II pressure ulcers at 5 centers in the United States	Prospective RCT; participants were randomized to treatment with a foam dressing or a saline-soaked gauze dressing	4 weeks	Total cost over the study period was lower by $466 per patient in the foam group. Cost spent on dressings per day, cost per ulcer healed, and costs per ulcer-free day were all lower in the foam group over the saline gauze group.	Patients in the foam group had less frequent dressing changes. On the evidence of this study, foam dressings are a more cost-effective treatment than saline-soaked gauze in this group of patients with Stage II pressure ulcers.
Capasso and Munro[133] (2003)	50 adult patients with wounds, IC: 25 WTD dressings, 25 amorphous hydrogel dressings	Nonexperimental, retrospective chart review	4 biweekly data collection points	The overall cost of wound care was significantly higher for patients in the normal saline group, with a higher number and cost of home nursing visits.	Demonstrating the value and cost-effectiveness of hydrogel dressings should enhance therapeutic decision making and guide treatment decisions.

IC = inclusion criteria; MWH = moist-wound-healing; N/A = not applicable; PrU = pressure ulcer; RCT = randomized clinical trial; RCTs = randomized clinical trials; WTD = wet-to-dry.

Whirlpool Whirlpool can be used for mechanical débridement through its feature of water agitation. It can also be used to soften necrotic tissue in preparation for sharp, enzymatic, or autolytic débridement. There are, however, often better methods of preparing tissue for débridement than whirlpool. See discussion in the previous section on Cleansing.

Selective Débridement

Sharp *Sharp débridement* is defined as the removal of dead or necrotic tissue or foreign material from and around a wound using sterile instruments such as a scalpel, scissors, and/or forceps (Fig. 14.19). Considered the *gold standard* of methods for removal of necrotic tissue, sharp débridement is a minor, tissue-sparing procedure that is performed bedside or in a procedure room. In the vast majority of U. S. states, it is within the scope of practice for a physical therapist to perform sharp débridement. It is incumbent on the therapist to be aware of his or her state practice act regarding regulations. The American Physical Therapy Association (APTA) position statement indicates that sharp débridement should be performed exclusively by physical therapists, not other personnel. For a full copy of this statement, go to www.apta.org/uploadedFiles/APTAorg/About_Us/Policies/HOD/Practice/ProceduralInterventions.pdf. Additional information can be found in the *Guide to Physical*

Figure 14.19 Use of scalpel and forceps for sharp débridement.

Therapist Practice.[88] To maintain current standards, a physical therapist should not débride except in the presence of necrotic tissue.

Even though sharp débridement is effective for all types of necrotic tissue, there are situations where this form of débridement is not appropriate. It is contraindicated for vascular wounds with limited blood flow where eschar may be serving as a cap or cover for a chronic open wound. Without adequate perfusion in this scenario, there is little hope of wound closure. Sharp débridement is not appropriate for wounds with tunneling (when the wound bed cannot be seen) or areas affected by dry gangrene. Patients with low platelet counts, on anticoagulants, or with other conditions that inhibit clotting are not suitable candidates. It is also contraindicated for pressure ulcers on the heels covered with dry eschar. (*Note:* Some experts maintain that in this scenario, eschar provides protection as long as there is no infection present; others maintain that eschar must be removed because it inhibits epithelial cell growth.)

Chemical or Enzymatic **Enzymatic débridement** is a type of selective débridement that includes the application of a topical agent containing enzymes that act by dissolving necrotic tissue. There are several types and brands of enzymatic agents, each designed to affect a certain type of necrotic tissue. Advantages for this type of treatment are that débridement is selective, patient discomfort is minimal, and application procedures are simple. Disadvantages include the potential development of dermatitis of the intact periwound skin, frequent dressing changes disrupting the wound bed, and the need to crosshatch existing eschar with a scalpel so that the enzyme can penetrate the wound. Enzymatic débridement agents do not have an impact on pathogen levels in the wound bed and should not be considered antimicrobial. Some enzymatic débridement preparations contain the protein papain. Topical drug products containing papain were taken off the market in the United States in November 2008 because they have not been approved by the Food and Drug Administration (FDA); for more information on this issue go to www.fda.gov/papain. When utilizing other types of enzymatic agents still on the market, a referral for treatment and a prescription for the enzymatic agent are currently required in most regions of North America.

Biosurgery Biosurgery as a form of selective débridement is also referred to as *maggot débridement therapy (MDT),* or maggot or larval therapy (Fig 14.20). Although it has been in use in the Western world for over 150 years, its popularity declined with the advent of antibiotics. Biosurgery is now generating new interest owing to the rise of multidrug-resistant bacteria such as **methicillin-resistant *Staphylococcus aureus*** **(MRSA)**. Sterile, newly hatched larvae are placed on chronic wounds and held in place with dressings or a *biobag* for 2 to 5 days before removal. Biosurgery has been shown to remove devitalized tissue, decrease the risk of infection, and improve wound healing without side effects in a wide variety of wound types. Biosurgery is recommended for osteomyelitis and deep wound infections that remain unresponsive to more conventional antibiotic and surgical therapy. Although moist wound healing is compatible with biosurgery, a very wet wound environment has an adverse effect on larval survival. Certain types of moisture-retentive wound dressings are more compatible with larval survival than others.[134-141]

Medical-Grade Honey

The use of medical-grade honey as a wound dressing has been shown to enhance débridement and healing. Honey dressings are available in hydrocolloid, alginate, and liquid categories. They have been shown to facilitate **autolytic débridement**, decrease or eliminate wound odor, prevent biofilm (thin layer of bacteria) formation, and soften necrotic tissue.[142-145]

Autolytic

Autolytic débridement uses the endogenous enzymes on the wound bed to digest devitalized tissue and promote granulation tissue formation. In practice, the body's natural fluids are held in contact with the wound base with a moisture-retentive dressing for 3 to 7 days. By increasing the moisture content of slough and necrotic tissue with enzyme-rich body fluids, autolytic activity is facilitated. Although this method is the least invasive/most selective, as well as inexpensive, painless, and biocompatible, each patient is examined to determine if this type of débridement is best for the existing wound. The type of moisture-retentive dressing selected to promote autolytic débridement will be based on the health of the periwound tissues and the level of fungal or bacterial loads. The presence of infection does not rule out the use of occlusive dressings, as described earlier in the discussion on moist wound healing.

Topical Agents

Current standards for chronic wound care have decreased the use of topical agents even in the presence of infection. In the literature these agents may be referred to as *antiseptics, disinfectants,* and/or *antimicrobials.* Other topical agent categories include *antibiotics* and *analgesics.* Guidelines reveal that almost all human-made products are cytotoxic to WBCs even when diluted.[101] Many agents once thought to be safe are now known to be unsafe to healing tissue, causing adverse reactions at any concentration. Many agents once thought to be effective as antibacterial or decontaminating agents are now known to be ineffective. When striving for wound bed homeostasis, preserving cellular life in endogenous fluids is almost always more desirable than destroying it with additives. Many physicians and wound management experts use the following adage to guide in the decision making process: "It is desirable never to put anything in the wound that cannot be tolerated comfortably in the conjunctival sac."[15, p. 179] In plain terms, "If you can't put it in your eyes don't put it in the wound." Even under Direct Access, in most states physical therapists are not permitted to prescribe medications, even over-the-counter products, for wound care. If, during the examination or intervention, a physical therapist determines that a topical agent may be indicated, the patient's physician should be contacted and the findings discussed. Consideration of topical agents should always include the risks and benefits of the topical agent in relation to potential cytotoxicity, biocompatibility, safety, and efficacy.

Antiseptics

Povidone-Iodine Povidone-iodine (PVI) is a combination of iodine plus a polymer that provides bactericidal effects. One commonly known product name is Betadine (Purdue Products LP, Stamford, CT 06901). Used indiscriminately for many years on acute and chronic wounds, it is now recommended mainly for wounds infected with *Staphylococcus aureus.* The AHRQ guidelines published in 1994 state: "Do not clean ulcer wounds with skin cleansers or antiseptic agents (e.g., povidone-iodine, iodophor, sodium hypochlorite solution [Dakin's solution], hydrogen peroxide, acetic acid)."[101, p. 15] Although the guidelines address pressure ulcers, the wound-healing evidence is applicable to all wound treatments. This evidence implies that the use of PVI, as well as other antiseptics, is inconsistent with practice standards. In rare instances when such agents are recommended by a physician and are indeed appropriate, clinicians should document sound reasoning behind the use of these products because they will be held accountable to these published and respected guidelines. An example of a situation such as this would be when other, less cytotoxic treatments have failed to reduce the bacterial load in an infected wound. The literature does not provide adequate clinical or legal reasons to use PVI for managing wounds.[146] In addition, the FDA has not approved the use of PVI solution or PVI surgical scrub solution for wounds. PVI has been shown to reduce bacterial counts in infected wounds, and currently there is no antimicrobial resistance to PVI.[147] Its use is contraindicated for the noninfected wound.[101]

Sodium Hypochlorite Solutions: Dakin's Solution (Bleach and Boric Acid), Sodium Hypochlorite (Household Bleach) Sodium hypochlorite is cytotoxic even at very dilute concentrations. It damages fibroblasts and endothelial cells and causes cellular damage to granulation tissue. It is irritating to the skin and can initiate severe reactions in some individuals. It is used in the management of wounds with purulent exudate. Treatment should be discontinued when the wound is clean. Its use is contraindicated for the noninfected wound.[101]

Acetic Acid Solution Acetic acid is traditionally used to inhibit bacterial infections; however, the solution has been found to be more damaging to fibroblasts than to bacteria. A common form of acetic acid is found in vinegar. It is corrosive and cytotoxic at any dilution. Most recently, it has been used to manage contamination by ***Pseudomonas aeruginosa.*** Its use is contraindicated for the noninfected wound.[101]

Oxidizing Agents: Hydrogen Peroxide Solution When this solution comes in contact with tissue, there is a release of oxygen and temporary antimicrobial activity. Its bubbling action is used for nonselective débridement to loosen small debris. It is cytotoxic unless diluted to a very weak concentration. Its use is contraindicated in-wounds that are noninfected, tunneling, or granulating.[101]

Antibacterials

This section includes a sample of commonly used topical antimicrobials, antibiotics, and antibacterials. Each of these topical agents is effective against a variety of bacteria and is selected by the physician based on the species cultured for an individual patient. All share a risk of similar side effects such as burning, itching, contact dermatitis, and/or allergic sensitivity. There is little evidence in the literature to show levels of cytotoxicity in these topical agents. Examples include the following:

- Bacitracin/Baciguent: associated with allergic reactions.
- Neosporin/neomycin sulfate: causes greatest incidence of allergic reactions.
- Silvadene/silver sulfadiazine: primarily for thermal injuries, silver is selectively toxic to bacteria but may inactivate topical proteolytic enzymes.[148]
- Furacin/nitrofurazone: cytotoxic in animal studies.[149]
- Sulfamylon/mafenide acetate: diffuses easily through eschar, primarily for thermal injuries.
- Bactroban/mupirocin ointment: currently effective against all species of staphylococcus.
- Gentamicin/Geramycin: currently effective against all species of staphylococcus and streptococcus.

Owing to the paucity of information on cytotoxicity, the risk of side effects, and the growing incidence of antibiotic-resistant bacteria, use of these products for chronic wounds should be considered carefully and is usually contraindicated for the noninfected wound.

Creams and Ointments (Over-the-Counter) Some antibacterial ointments and creams such as Bacitracin and Neosporin can be purchased without a prescription. These are minimally bacteriostatic owing to their dilution. Once they lose their antibacterial strength, the ointments may trap bacteria and encourage bacterial growth from surface contamination. If ointments or creams are used, the wound should be cleansed regularly to remove potential contamination; however, frequent cleansing may disrupt the healing process. These preparations can be used to provide moisture to a dry wound, but they may create a greasy wound bed, making early epithelial cell migration difficult. A more biocompatible ointment that will provide moisture to a healing wound is Aquaphor® (Beiersdorf Inc., Wilton, CT 06897).

Analgesics

The use of topical anesthetics to control wound pain is controversial in the literature. Conflicting reports and the lack of substantial research have led to concerns about the impact of anesthetics on the wound bed. This issue is further complicated by the broad profile of patients with wounds, their etiologies, and comorbidities. The more common agents used topically are lidocaine and EMLA (eutectic mixture of local anesthetics) cream, which is a mixture of lidocaine and prilocaine (AstraZeneca, Wilmington, DE 19850). Amitriptyline, a tricyclic antidepressant, has local anesthetic properties and has shown promise as an option for treating wound pain.[150] While topical anesthetics may be under scrutiny for their effects, vasoconstriction in particular, there is a need for more investigation since pain is a major issue for most patients with wounds.

Growth Factors

Endogenous growth factors normally abound in the fluids of a wound. In most chronic wounds the normal timetable for healing has been delayed or stopped. Growth factors that are decreased or absent can be added topically to the wound bed. Increasing strength of evidence supports the practice of adding growth factors to a wound to facilitate healing. The application of exogenous growth factors in conjunction with good wound care increases wound healing outcomes and can convert a chronic wound into a healed wound.[19,151-156] Growth factors can be isolated from an individual's own tissue, added to a liquid formula in a laboratory, and then applied to the wound. An example of an autologous growth factor product with a name familiar to many clinicians is AutoloGel™ System (Cytomedix Inc., Gaithersburg, MD 20877).[157] Recombinant DNA technology has resulted in other products such as becaplermin gel, trade name Regranex® Gel (Ortho-McNeil-Janssen Pharmaceuticals, Inc., Titusville, NJ 08560). Reimbursement for application of growth factors varies and should be checked before use. For example, becaplermin gel is FDA approved for the treatment of LE diabetic neuropathic ulcers that extend into the subcutaneous tissue or beyond but currently not approved for the treatment of pressure, venous, or other nondiabetic-related wounds.

Topical Agents and Acute Wounds

The use of antiseptics and antibiotics to reduce bacterial levels in acute, traumatic wounds follows a different rationale from that of chronic wounds. For wounds resulting from trauma or thermal injury, the risk for contamination is high. It is accepted practice to use cytotoxic products such as povidone-iodine or Silvadene® (silver sulfadiazine) in the *early* management of acute traumatic wounds. The goal is to discontinue use of cytotoxic agents as soon as the wounds are clean and able to produce and support endogenous fluids.

Mechanical Modalities

Procedures for use of modalities vary based on unique patient characteristics and individual patient response. A useful place to begin is with protocols recommended in comprehensive wound management texts such as *Wound Healing: Evidence-Based Management* by McCulloch and Kloth[158] and *Wound Care: A Collaborative Practice Manual for Health Professionals* by Sussman and Bates-Jensen.[159] Owing to the ever-changing rules of reimbursement, it is prudent to check current reimbursement and documentation guidelines when billing for these services. The decision to use mechanical modalities rests in the hands of the physical therapist unless physician authorization is required in order to receive reimbursement. The reimbursement requirement may vary from state to state and sometimes between payers in the same state. In some cases, individual physicians may develop their own protocols that require physical therapists to contact them before changing a POC.

Ultrasound

Therapeutic ultrasound (US) application for wound management differs from its use as a modality to treat pain. Ultrasound stimulates cell activity, accelerating processes such as inflammation. Once thought to target only the sluggish wound in the inflammatory stage, evidence now demonstrates that the effects can be seen throughout all wound-healing phases. Basic science evidence and clinical research have established that skin repair and wound contraction can be accelerated, collagen secretion can be stimulated, and elastin properties can be affected to strengthen scar tissue. Standard procedure for the treatment is to cover the wound with a sheet of hydrogel or an application of amorphous hydrogel. US is then delivered with a handheld applicator (Fig. 14.21). Another option for treatment is to apply US transmission

Figure 14.21 Application of ultrasound to wound and periwound tissues with hydrogel sheet coupling. *(From Kloth, LC, and McCulloch, JM, Plate 15, with permission.)*

gel to the periwound area and treat from this region in addition to or instead of the wound bed.[160-164] Another option for delivery of US is to use a system that provides noncontact, nonthermal, low-frequency ultrasound (Fig. 14.22). A mist of sterile saline is propelled toward the wound and the ultrasound is transferred from the device to the patient without contact or pain. Studies have provided evidence that this type of US treatment reduces bacterial quantity in a wound and promotes healing, especially in wounds that have been slow to heal.[84,165-169]

Electrical Stimulation

The use of electrical stimulation (ES) to treat chronic and, more recently, acute wounds is well documented. Electrical stimulation is recommended to eliminate bacterial load, promote granulation, decrease inflammation, reduce edema, reduce wound-related pain, and augment blood flow. Human skin, wounds, and the cells that facilitate wound healing all have measurable electrical currents. Electrical stimulation affects various types of cells and their activities by supporting, altering, or providing electrical currents to accelerate wound healing. A clear understanding of medical electricity will assist the clinician in applying an appropriate ES treatment. The available literature is diverse and instructive.[170-177] There are a variety of options for treatment setup depending on the goals of treatment, the type of wound, and the condition of the patient. Standard equipment for the direct method of application will include an ES unit, treatment and nontreatment electrodes, and a substance such as saline-soaked gauze or a hydrogel dressing applied to the wound bed or cavity to enhance electrical conductivity under the treatment electrode (Fig. 14.23). For the indirect method, gel electrodes straddle the wound and interface with the periwound skin. Clinical decisions related to voltage, electrode placement, dosage, and other variables must be made on a case-by-case basis. Information about treatment protocols, strength of evidence, and guidelines for treatment can be found in detailed wound care texts.[178,179]

Thermal and Nonthermal Diathermy

Pulsed shortwave diathermy (PSWD), continuous shortwave diathermy (CSWD), and nonthermal pulsed radiofrequency stimulation (PRFS) have been used successfully to treat chronic open wounds, facilitating progress from one phase of wound healing to the next. These diathermy treatments utilize radio waves to provide thermal and nonthermal effects, respectively. All models transmit radiation from an applicator head to the target tissues. PSWD heats superficial and deep tissues. CSWD heats deep muscle and joint tissues. PRFS is nonthermal and can influence tissue at the cellular

Figure 14.23 Conductively coupled bipolar treatment electrodes of opposite polarity positioned on opposite sides of a wound. *(From McCulloch and Kloth: Wound Healing: Evidence-Based Management, ed 4. FA Davis, Philadelphia, Figure 26-28, with permission.)*

level. Individuals with arterial insufficiency are not good candidates for PSWD or CSWD because their tissues are not able to dissipate heat well enough to avoid burns. Wound sites treated with diathermy have demonstrated increased fibroblast proliferation, collagen formation, tissue perfusion, and metabolic rate. Although the number of clinical studies is smaller than that of other modalities, the evidence is mounting for the role diathermy plays in wound healing. Physical therapists are using diathermy more often since the publication of a number of studies regarding the nonthermal effects of pulsed diathermy and the production of smaller, more portable, user-friendly diathermy units.[180-182] Equipment needed for treatment includes a diathermy unit/electronic console and one or two applicator heads. Treatment is usually delivered without touching the skin. Wounds should be carefully prepared before treatment according to guidelines provided by the distributor. With newer units such as the Provant® Therapy System (Regenesis® Biomedical Inc., Scottsdale, AZ 85257), the pad can be placed over wound dressings, compression garments, and casts. Because the effects of heat may continue after the treatment, patients should be observed carefully and protocol guidelines should be followed closely (Fig. 14.24).

Ultraviolet Radiation

Ultraviolet (UV) radiation energy is a form of radiation between x-ray and visible light on the electromagnetic spectrum.[183] UV wavelengths have been divided into wavelengths and bands. The three bands most useful for their effects on human skin are UVA, UVB, and UVC. UV has cutaneous and bactericidal effects that include increased blood flow, enhanced granulation tissue formation, destruction of bacteria, stimulation of vitamin D production, and thickening of the stratum corneum. The varied physiological effects make this treatment appropriate for a variety of skin diseases, as well as acute and chronic wounds.[160] The effects of UV radiation on antibiotic-resistant bacteria make it a potentially effective tool in wound care; however, there are only a few up-to-date, well-controlled clinical studies emerging at this time.[184,185] Early supporting literature is now quite dated, leaving room for new clinical studies to provide evidence of the efficacy of the intervention. UVC in particular has been found to be effective in the treatment of *methicillin-resistant Staphylococcus aureus* (MRSA), *vancomycin-resistant Enterococcus* (VRE), and, more recently, some strains of *Pseudomonas aeruginosa*.[186,187] The treatment is typically delivered to a clean wound with dressings removed, using a UVB or UVC lamp. Treatment distance, dosage, frequency, and subsequent clinical outcomes will vary based on the goals of the treatment and the status of the wound. Due to manufacturing challenges in North America, portable, handheld UV units to treat wounds are not readily available at this time. Physical therapists planning to utilize UV for wound care might partner with a wound care team, a resourceful vendor, and the latest evidence to devise a treatment plan.

Figure 14.24 Leg wound covered with Provant® treatment pad. *(Courtesy of Regenesis® Biomedical Inc., Scottsdale, AZ 85257.)*

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy (HBOT) delivers 100% oxygen to an individual resting inside a sealed chamber. The oxygen is delivered at a pressure greater than the atmosphere. This *systemic* treatment increases the amount of oxygen available for cell metabolism, improving oxygen delivery to hypoxic tissue. Systemic HBOT is, however, associated with risks related to oxygen toxicity. The literature demonstrates positive responses to this treatment when used as an adjunct to other forms of wound care but few controlled, randomized trials have been completed.[160,188-191] Chambers to deliver *topical* oxygen have been available for at least a decade. These smaller chambers enclose a limb or a segment of the body instead of requiring coverage of the entire body.

Following physician referral, a physical therapist may assist or coordinate a systemic or topical treatment. Often, a trained technician will manage the equipment controls and the delivery chamber. Wound care may occur before or after the HBOT or the topical HBOT depending on the preferences of the physician and the protocol of the facility. Discussion among investigators comparing the effects of systemic versus topical oxygen is ongoing. In some studies, topical oxygen is also referred to as *topical hyperbaric oxygen (THBO)* and *O_2 therapy.*[13,192,193] Instead of the full-body chamber used for HBOT, THBO is portable and is delivered in a localized limb chamber.[13,192] THBO has been combined with electrical stimulation and also with cold laser for the treatment of pressure ulcers and neuropathic foot wounds.[193,194] Topical O_2 therapy has enhanced the effects of growth factors in investigations within the last few years.[12] Renewed interest by investigators has led to more refined protocols and improved strength of

evidence in the field. If investigations continue to provide positive results, the use of topical O_2 in wound care could result in more cost-effective and efficient care, fewer risks, and applicability to a wider population as compared to systemic O_2.

Negative Pressure Wound Therapy

Negative pressure wound therapy (NPWT) is used as an adjunct to wound healing to facilitate wound closure in acute surgical wounds, as well as with more challenging, slow-to-heal wounds. The procedure is known by several terms but the most well known is *vacuum-assisted closure* or *VAC*® (Kinetic Concepts, Inc., San Antonio, TX 78265). An open cell foam dressing is placed in the wound and a suction tube is connected from the foam to a portable pump. An airtight seal is created over the foam and the suction tube with a clear, occlusive film (Fig. 14.25). A controlled amount of negative (subatmospheric) pressure is applied through the foam to the entire wound bed. Typically, for the first few days (48 hours) the negative pressure is applied continuously via the portable pump system. After a significant amount of excess wound fluid has been withdrawn, the pump is programmed to apply pressure intermittently. The foam dressing is changed every 12 hours (infected wounds) to 48 hours or longer (clean wounds). The strength of evidence is mounting as basic research explores the effects of this treatment. NPWT has been shown to enhance granulation tissue formation, promote wound edge approximation, remove edema from wounds, and improve oxygen levels in the wound.[195-201] Studies have also shown that with the use of NPWT, the healing time for selected wounds decreased in comparison to standard wound care.[202,203] One claim that is still under investigation is the ability of the VAC to remove bacteria from the wound bed. Although a physician must order this type of therapy, many are unaware of this intervention and would be responsive to an appropriate recommendation by the therapist. In different environments, physical therapists, nurses, or other clinical staff may perform administration of the technique.

Figure 14.25 A Stage IV sacral pressure ulcer with reticulated foam dressing, tubing, and polyurethane sheet covering the entire wound to maintain the vacuum during treatment with vacuum-assisted closure. *(From Kloth, LC, and McCulloch, JM, Plate 14, with permission.)*

Cold Laser Therapy

Cold laser is also referred to in the literature as low-level cold laser, low-level infrared laser, or monochromatic infrared photo energy (MIRE). Low-energy laser treatment uses light in the infrared spectrum. This therapy has been promoted for augmenting wound healing[204] and reversing the symptoms of peripheral neuropathy in individuals with diabetes.[205,206] It is thought that the effects of laser increase circulation and reduce pain by increasing the release of nitric oxide into the microcirculation. Although supportive, peer-reviewed literature is modest at this point, published studies citing success with this treatment are mounting while debates continue.[207-210] Despite the term *cold laser*, light in the infrared spectrum can also be used to deliver heat as a treatment modality. Owing to the perceived lack of adequate evidence, some third-party payers do not cover cold laser treatment except when used as a heat modality. This may soon change as the strength of evidence increases for its use to treat peripheral neuropathy. The most well-known product on the market is called Anodyne® Therapy System (Anodyne® Therapy, LLC, Tampa, FL 33626). Figure 14.26 depicts use of a special foot pad to deliver infrared photo energy.

Dressings

The type of wound dressings selected for a wound may have a profound effect on healing time. There are hundreds of choices for the discerning clinician.

Figure 14.26 Application of infrared photo energy to the foot using an Anodyne® Therapy foot pad. *(Courtesy of Anodyne Therapy, LLC, Tampa, FL 33626.)*

Information on indications, contraindications, and expected outcomes can be obtained from individual vendors listed in Appendix 14.E, as well as from texts devoted entirely to wound care.[158,159] Physical therapists who are monitoring a wound on a regular basis and are knowledgeable about dressing alternatives are often the most appropriate clinicians to make the decision about dressing selections. This chapter includes introductory information necessary to make clinical decisions about dressings: the characteristics of the dressing categories and the effects of the dressings on the wound bed. Refer to Appendix 14.F for a listing of dressings categorized by treatment goal (purpose) or type of wound (indication).

Choosing or recommending appropriate dressings should be directed by the characteristics of the wound and periwound tissues, not by what is available in the supply closet. A product that preserves wound hydration and limits fluid loss is usually ideal. In addition to following the principles of moist wound healing in most dressing selections, the following list identifies wound characteristics and the corresponding action that a dressing should perform:

- Infection: absent or present; prevent or treat
- Necrosis: remove or not; autolytic or mechanical
- Drainage: dry (no drainage), adequate (moist) or excessive (too wet); restore, retain, or remove
- Granulation tissue: present or absent; protect, facilitate formation
- Epithelialization: present or absent; facilitate formation
- Periwound area: intact, at risk or macerated; protect or absorb
- Incontinence: present or absent; protect or absorb
- Cavities and tunneling: present or absent; fill and protect
- Friction: present, some risk, significant risk; cushion, protect, or prevent
- Odor: minimal or needs reduction; ignore or add odor-reducing dressings

The dressing that is applied directly to the wound is referred to as the *primary* dressing. The dressing that is applied over the primary dressing is referred to as the *secondary* dressing. Some advanced dressings serve as the primary and secondary, including adhesive and absorptive qualities in the same dressing.

Gauze/Fiber

Gauze dressings (Fig. 14.27) are considered by many wound management experts to be outside the description of modern wound dressings.[120] Used and misused for decades, there are more reasons not to use gauze than there are indications for use. As a primary dressing, gauze leaves contaminating fibers in the wound, contributes to desiccation, is permeable to bacteria, can be adherent to the wound, releases excessive amounts of bacteria into the air on removal, causes a loss of normothermia, and

Figure 14.27 Samples of gauze dressings.

is painful on removal if it adheres to the wound surface. Once thought to be cost-effective, it has been shown in more than one study to be more costly than other dressing choices (see Box 14.1 Evidence Summary). Gauze ribbon can be used to maintain an opening for drainage in a tunneling wound. It can also be used successfully to gently support a cavity wound but should not be used to aggressively pack any shape of wound. It was once thought that cavity wounds should be packed very full but it has since been established that granulation tissue and epithelial cells do not flourish with aggressive gauze packing. The additional pressure from a tightly packed wound will impede the flow of oxygen and nutrients to the granulating wound bed. Gauze can be an effective secondary dressing, especially if the dressings will be changed frequently or if exudate is heavy. Gauze 4 × 4s and a roll of gauze are typically used to create a WTD dressing. WTD dressings were previously discussed under the section on débridement because of their nonselective removal of tissue during dressing changes. Because WTD dressings can be classified as a tool for mechanical débridement or as a primary wound dressing, they are discussed in both categories. Refer to that section of the chapter for more details.

Impregnated Gauze

Designed to be less adherent, this category includes products made of tightly meshed synthetic fibers or woven products such as cellulose acetate. Fiber materials are impregnated with a petroleum emulsion such as Vaseline®, intended to prevent the gauze from sticking to the wound surface. Used as a primary dressing this choice is minimally absorptive, provides minimal protection, does not enhance a moist environment, and may create a greasy wound bed. One of its more appropriate uses is as a primary dressing over new sutures to prevent them from catching or sticking in a gauze secondary dressing.

Transparent Films

Films are made of a transparent membrane with an acrylic adhesive layer (Fig. 14.28). Transparent films do not allow

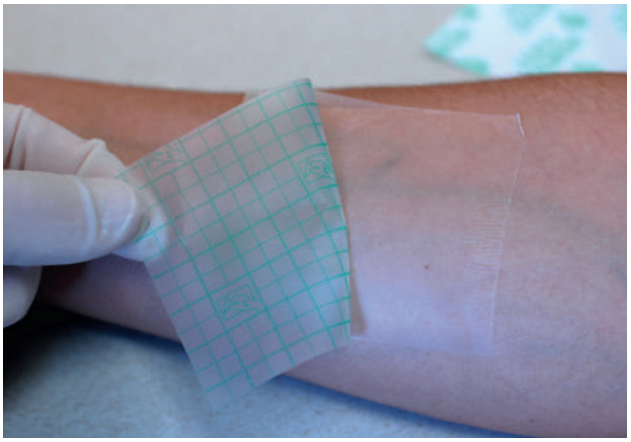

Figure 14.28 Application of a film dressing.

bacteria or moisture into the wound. They facilitate a moist wound environment, trapping endogenous fluids in the wound bed to assist with autolytic débridement, wound bed homeostasis, and *angiogenesis*. Films assist in protecting skin from the effects of shearing, friction, and the contaminating effects of incontinence. Removal of a film dressing must be done with great caution because this can cause skin tears, especially with fragile or aging skin. Currently, few films have absorptive qualities and cannot be used on highly exuding wounds.

Foam

Foams are highly absorbent pads, sheets, or ropes of polyurethane available in many sizes with many features (Fig. 14.29). They are available with or without adhesive backing so that they can be used as a primary and/or a secondary dressing. Foam dressings are highly absorptive but also help to create an occlusive environment for moist wound healing. They should not be used alone on a dry wound but could serve as a secondary dressing if the primary dressing was a gel product.

Figure 14.29 Samples of foam dressings.

Hydrogels

Hydrogels are categorized as *amorphous,* referring to a liquid-like gel, or as *sheets,* consisting of a thin, flexible sheet of polymer containing at least 90% water (Fig. 14.30). Both types are used to increase moisture in a dry wound bed, soften necrotic tissue, and support autolytic débridement. Both have some absorptive qualities and will swell slightly until they are saturated. The amorphous gel (Fig. 14.31) must be contained in the wound with a secondary dressing. The flexible sheets usually require a secondary dressing but are available through some vendors with tape attached to the borders. Patient response is usually very positive to the soothing sensation of the hydrogel application.

Hydrocolloids

Considered the most occlusive of the moisture-retentive dressings, hydrocolloids are also available in less occlusive or semipermeable styles as well. As with foams, these dressings come in a variety of styles and shapes including pastes, granules, powder, and sheets. They typically consist of an absorbent colloidal material combined with a film

Figure 14.30 Sample of a hydrogel sheet dressing.

Figure 14.31 Application of an amorphous gel dressing.

or foam backing (Fig. 14.32). Hydrocolloid dressings work best on mild to moderate exudating wounds. When wound exudate combines with the colloidal polymer, a soft, gelatinous, often yellow, and malodorous mass is formed. Patients, families, caregivers, and other health care providers must be informed about this harmless reaction so that infection is not assumed. Hydrocolloids have been used successfully as occlusive dressings over infected wounds without fulmination of existing bacteria. They are also the dressing of choice to cover and protect larvae during maggot débridement therapy.

Alginates

This dressing category is also known as *calcium alginate* because the dressings are manufactured using the calcium salts of alginic acid derived from marine algae and kelp (seaweed). The raw material is woven and then converted into flat sheets, ropes, or ribbon shapes (Fig. 14.33). Alginates absorb 20 to 30 times their own weight, are gentle to apply and remove, and are biocompatible with the wound bed. A chemical reaction between the dressing and wound exudate creates a gel substance that helps to maintain a moist wound environment while absorbing excess exudate. Because they are permeable, alginates do not provide a barrier against bacteria. This characteristic makes them an effective choice when an infected wound cannot be covered with an occlusive dressing. Most alginates currently require a secondary dressing to hold them in place. Several manufacturers are combining alginates with other products, such as hydrocolloids, to maximize their effectiveness. There is growing interest in the use of silver in advanced dressings to combine the antimicrobial action of silver with the absorptive qualities of alginates. Long-term effects remain unclear. There is a need for more clinical trials and longer follow-up times to look at the long-term effects on healing.[211] An example of this type of dressing is SILVER*CEL*® (Johnson & Johnson Wound Management, ETHICON, Inc., Somerville, NJ 08876).

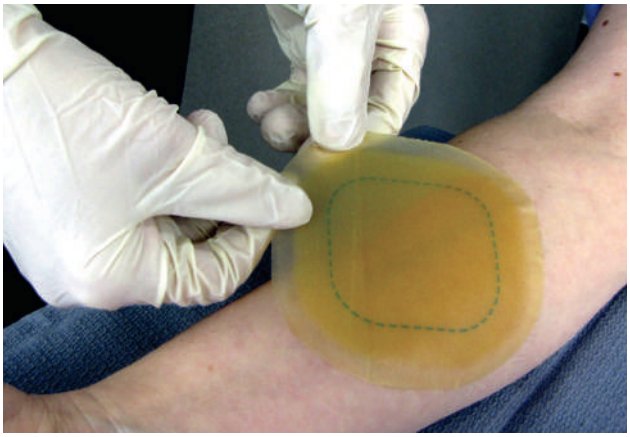

Figure 14.32 Sample of a hydrocolloid dressing.

Figure 14.33 Samples of alginate dressings.

Hydrofibers

Hydrofiber or hydroactive dressings are designed to have a selective absorptive capacity. They have the combined positive characteristics of alginate, foam, and gel dressings. When in contact with the wound, the synthetic fibers absorb exudate and align themselves perpendicular to the wound surface. This vertical wicking process keeps debris and wound fluid contained within the dressing.[212] There is considerably less pain on removal of a hydrofiber dressing because the fibers do not stick to the wound or dry out.[212,213] The dressing properties allow growth factors and other peptides to survive on the wound bed. Aquacel® is a spun Hydrofiber® dressing that readily absorbs moisture (Fig. 14.34). Aquacel® Ag adds ionic silver to the absorbent dressing (ConvaTec, Skillman, NJ 08558).

Skin Substitutes

Considered by some to be topical applications and by others to be dressings, human skin equivalents and

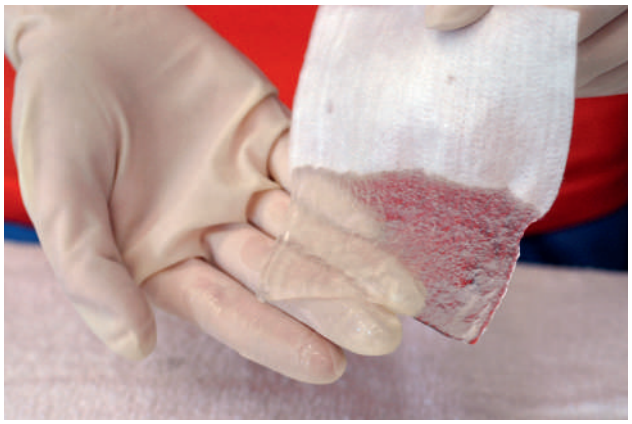

Figure 14.34 Sample of AQUACEL®, a Hydrofiber® dressing simulating the change in consistency from dry to gel as wound drainage is absorbed.

bioengineered tissues are finding their place in the wound care arena. Skin substitutes are created using a variety of techniques and substances. Cells are derived from sources such as neonatal male foreskin and porcine (pig) dermal collagen. The products are produced in laboratories, shipped either frozen or cooled, and then applied to the patient's wound by a member of the wound care team. Although a physician would prescribe the use of a skin substitute, other health care professionals can apply the product to the wound based on individual facility protocol. Skin substitutes consist of living skin applications that resemble skin structure and function and may include epidermal and dermal layers. They are useful as temporary coverage, providing skin protection for the wound bed. Some have been shown to stimulate endogenous cell activity. Most are marketed to use on wounds that have not responded to conventional therapy such as chronic diabetic foot ulcers, venous leg ulcers, and deep burn wounds.[214] Examples to look for when investigating skin substitutes are Apligraf (Novartis, East Hanover, NJ 07936), Dermagraft and Transcyte (Advanced Biohealing, LaJolla, CA 92037), and Biobrane (UDL Laboratories, Rockford, IL 61103).

Innovative Dressings

New products are entering the market yearly as research and development continue to grow and expand in the area of wound care. Too many to mention all, categories include options such as polysaccharide dressings, absorptive fillers, hydrophilic fiber, composite dressings, collagen, and biological products. Hyalofill-F (ConvaTec, Skillman, NJ 08558) is a hyaluronic acid derivative dressing that is applied directly to the wound. Hyaluronic acid is important for its role in cell proliferation. It is useful in helping a chronic wound to move through the stages of healing. First used on neuropathic foot ulcers, it has been used successfully in clinical trials for venous leg ulcers.[215,216]

Manual Lymphatic Drainage

MLD is a specialized manual therapy technique that affects primarily superficial lymphatic circulation. It is considered to be one of the five elements of an effective treatment intervention for lymphedema and many types of edema. This manual therapy provides a gentle stretch to the skin that enhances lymph capillary activity. MLD will increase the frequency of lymphangion contractions; improve lymph transport capacity; redirect lymph flow toward collateral vessels, anastomoses, and uninvolved lymph regions; and mobilize excess lymph fluid that has overwhelmed a body segment or region.[74,217,218] The techniques of MLD are gentle and specific, requiring specialized education to be performed accurately (Fig. 14.35). To obtain contact information for training facilities that provide specialized education in MLD as a part of CDT, refer to the special section in Appendix 14.D for contact information. The benefits of this treatment are not limited to the population with lymphedema. MLD is used successfully for edema from CVI, sports injury, neurological injury, and post-operative swelling, but there is a need for more well-designed randomized controlled trials to provide high-ranking evidence.[219,220] The use of MLD is contraindicated for treating cardiac-, pulmonary-, or renal-related edema because the amount of fluid that will be mobilized may overwhelm one or all of those systems when disease is present.[221]

Figure 14.35 Manual lymphatic drainage on the LE.

Compression Therapy

Controlling edema or lymphedema is critical to all stages of healing. Edema not only inhibits wound healing by affecting perfusion of tissues, but also inactivates the ability of the skin to manage bacteria.[222] Unless there are red flags, compression should be part of every treatment for individuals with lymphedema, edema, and CVI. Compression therapy should be introduced as soon as clinical signs of swelling or fibrosis appear. A physical therapist may find indications for compression therapy during the examination or later, during the intervention. In most situations the therapist will decide what type and/or style of compression should be applied. Physician authorization, however, may be necessary for reimbursement. When leg wounds are present, compression is essential for timely wound healing. For the individual with mixed arterial and venous disease, an ABI test is indicated to provide information about the safety of using compression on the LE. A greater understanding of how the lymphatic system functions has created a paradigm shift in the way intervention for all types of swelling is planned and delivered. Aggressive compression techniques were once used to "milk" the fluid out of a limb. It is now understood that deep pressure and mechanical "milking" techniques are counterproductive and harmful to the superficial capillary network that filters lymph and interstitial fluids.[4]

Elevation

Elevation is used as a means of controlling some types of swelling and is often a precursor to compression

therapy. Mild, acute swelling of the extremities may be relieved temporarily with elevation. Active ROM exercises (e.g., ankle pumps) can be added to elevation to facilitate blood flow in the extremities. Patients should be educated about how to elevate safely, paying attention to positioning so that optimal venous and lymphatic circulation is facilitated. Elevation should be viewed as a temporary or complementary measure while other means of controlling swelling are employed.

Unna's Boot

Compression for the LE with a venous wound can be applied using zinc paste–impregnated gauze or Unna's boot (Fig. 14.36). Examples of conveniently packaged products are Medicopaste (Graham-Field Inc., Bay Shore, NY 11706), Unna-FLEX (ConvaTec, Skillman, NJ 08558), and Gelo-Cast (BSN-JOBST, Charlotte, NC 28209). There is little information in the literature to support the topical application of zinc for wound healing. The success of this treatment application is most likely owing to the compression. It is an inexpensive means of covering a wound, providing compression and supporting the calf pump to empty venous blood from the LE. Unna's boot is not appropriate for arterial or mixed arterial/venous ulcers. Although the treatment is used frequently, there are other methods for combining compression with wound care to treat venous wounds.[223]

Four-Layer Bandage System

Four-layer bandage systems have been associated with leg ulcer closure. The system includes a wound covering with modest absorptive qualities and several layers of compression. The bandage system has been shown to be comfortable and cost-effective.[224] An example of a well-known system is Profore™ (Fig. 14.37) (Smith & Nephew, Inc., Largo, FL 33773). For the appropriate patient, a four-layer bandage system can be left in place for up to a week.

Figure 14.36 Unna's boot application.

Figure 14.37 Profore™ is a four-layer bandage system consisting of a cotton, crepe, and two compression layers *(top to bottom)*.

Long-Stretch and Short-Stretch Bandages

Both long-stretch and short-stretch bandages are used to control edema and to supply therapeutic levels of compression to support the venous and lymphatic systems. Long-stretch bandages such as Ace (3M, St. Paul, MN 55144) bandages provide a *high resting pressure,* which means that they continue to constrict when the wearer is resting. Owing to their extensibility or stretchiness, they do not provide significant *working pressure,* the ability to resist muscle contraction during activity. Long-stretch bandages are readily available and require minimal training to apply. Short-stretch bandages such as Comprilan (Smith & Nephew, Auckland 1140, NZ) and Rosidal (Lohmann & Rauscher, Topeka, KS 66619) provide *low resting pressure* and *high working pressure* (Fig. 14.38). They are less extensible or stretchy, providing a more rigid shell when applied to a limb. This feature makes short-stretch bandages more appropriate for treating edema and lymphedema. Higher working pressures increase the efficiency of the muscle pump during activity whereas lower resting pressures make the bandages more tolerable to wear. Short-stretch bandages require special training to apply. The amount of working and resting pressure delivered to a limb that is bandaged will depend on several important factors: the number of layers of bandage, the age and condition of the bandages,

Figure 14.38 Sample of short-stretch bandage.

the tension on the bandage when it is applied, and the skill of the clinician.[225]

Lymphedema Bandaging

This highly specialized form of bandaging utilizes multiple layers of unique padding materials and short-stretch bandages to create a supportive structure for edematous and lymphedematous body segments. Lymphedema bandaging provides support for tissues that have lost elasticity; facilitates a mild increase in tissue pressure, assisting lymph vessels to empty; prevents refilling of the interstitium between MLD treatments; improves the efficiency of the muscle pump during activity; and provides localized pressure where indicated to soften fibrotic tissue.

Bandaging protocols include techniques for applying compression to the head and neck, fingers, and hands (Figs. 14.39 and 14.40), UE (Fig. 14.41), and LE (Fig. 14.42). The chest, abdomen, genital area, and back can also receive specialized support from compression products.[225]

As with MLD, the benefits of this treatment are not limited to the population with lymphedema. When compression is indicated, standard or modified lymphedema bandaging can be beneficial to the population with edema (e.g., post-operative, CVI, venous ulcers, orthopedic injury).[226-231] To obtain contact information for training facilities that provide specialized education in bandaging as a part of CDT refer to Appendix 14.D.

Compression Garments

Many patient/client populations use compression garments (Fig. 14.43). Originally designed to assist venous

Figure 14.39 Application of lymphedema bandaging to fingers and hand.

Figure 14.40 Use of foam padding to enhance the effects of lymphedema bandaging.

blood flow in the LEs, they are now specifically designed to manage burn and surgical scars, provide support to venous circulation, and prevent reaccumulation of fluid in the lymphedematous limb. There are a variety of garment styles and fabrics, custom and off-the-shelf, to meet the unique needs of different populations. Varying amounts of pressure are woven into the fabric during manufacturing. The amounts of pressure are conveyed as millimeters of mercury (mm Hg). Low pressure would start at 12 to 25 mm Hg and higher pressures go up to 30 to 40 mm Hg. When appropriately selected and fitted by a trained professional and worn correctly by a prepared patient, the garments serve an essential role in managing chronic, life-long conditions such as CVI and lymphedema.[225,231]

Garments should not be used as a treatment to remove excess fluids from an extremity. If applied to an extremity that has not been adequately evacuated, the garments will be uncomfortable and may worsen the

Figure 14.41 Lymphedema bandaging of the UE.

Figure 14.42 Lymphedema bandaging of the foot, ankle, and calf.

Figure 14.43 Patient wearing custom-fitted UE compression sleeve and separate glove with open fingertips.

patient's symptoms.[232-234] Currently, manufacturers are participating in clinical research supporting the use of silver in compression garments. Juzo Silver (Juzo, Cuyahoga Falls, OH 44223) adds permanently bonded silver to the textile fiber of LE garments to inhibit bacterial growth and reduce odor.

Limb Containment Systems

Another option for some individuals is a quilted compression device or limb containment system. These unique compression options may be easier to don and doff, can be worn under short stretch wraps or alone, and can be custom made to any part of the body (Figs. 14.44 and 14.45). This option may be useful for a person who is unable to apply a more fitted support garment independently or whose skin is compromised or fragile. Patients find that these options are useful as part of their home program to retain reductions they have achieved through therapy. These specialized garments can be made to support venous circulation or lymphatic drainage through altering the style and the stitching channels to complement the diagnosis. A physical therapist can consult with the leading manufacturers to get advice on how to integrate the use of this type of compression into the POC or the after-care by contacting www.jovipak.com and/or www.solarismed.com.

Compression Guidelines

Compression treatment should be customized to the characteristics of each individual. Relative contraindications for compression should be evaluated, including

Figure 14.44 Individual wearing a custom arm garment for nighttime lymphedema management. *(Tribute™ garment Courtesy of Solaris Inc., West Allis, WI 53214.)*

Figure 14.45 Quilted channel compression garment for venous insufficiency. *(JoviPak® garment, Courtesy of JoviPak®, Kent, WA 98032.)*

history of DVT, acute local infection, CHF, cor pulmonale, and acute dermatitis. To assist in clinical decision making, the following is a summary of general guidelines for compression bandaging and garments for edema and lymphedema:

- Arterial wounds: No compression or very light compression with close involvement of the referring practitioner. Long-stretch bandaging or off-the-shelf low compression garment (12 to 25 mm Hg) can be used. Edema will not be great and will evacuate quickly.
- Venous wounds: Compression is an essential component of treatment for wound healing and support of the venous system. Short-stretch bandaging with high working pressure and low resting pressure will facilitate the effects of the calf pump during activity. High pressure of 40 mm Hg at the ankle has been suggested.[229] Compression garments at pressures of 20 to 30 mm Hg to 30 to 40 mm Hg are used depending on location and severity of swelling, as well as ability of the patient to don and doff garments.
- Neuropathic wounds: Compression is contingent on blood flow. Fifteen percent of patients with a neuropathic condition also have an arterial component to their disease and must have an ABI checked before compression is applied. If no arterial involvement, compress with short-stretch wrap. Follow up with compression garments for long-term use at lower compression of 12 to 25 mm Hg up to 20 to 30 mm Hg.
- Lymphedema: Short-stretch compression wrap until limb reduction goal reached then moderate to high compression garments at 20 to 30 mm Hg to 30 to 40 mm Hg depending on location and severity of swelling, as well as ability of the patient to don and doff garments.[225]
- Edema: Case studies and reports from the field establish that the compression treatment for lymphedema also works well for edema.[230] Short-stretch compression bandages are worn 23 hours/day, graduating to daytime only, decreasing as edema resolves. Off-the-shelf garments at lower levels of compression provide support for skin and help to retain reductions that therapy has achieved.

Intermittent Pneumatic Compression

Until the 1990s, intermittent pneumatic compression (IPC) was one of the few clinical interventions used to treat swelling (Fig. 14.46). Since then, new information about the physiology of edema and lymphedema, as well as lymphatic system function, has limited its value in treating some edema and most lymphedema. Intermittent compression pumps can facilitate venous return and may be an important adjunct to other forms of compression for the individual with a venous disorder.[3,235] A review of the evidence provided only modest support for the use of IPC for the treatment of venous leg ulcers.[236-238] Many individuals with long-standing venous insufficiency also have lymphedema. There is even less evidence and more controversy related to the use of IPC for lymphedema.[239-242] If a trial of IPC is indicated, MLD should be delivered before and after each treatment to offset the negative effects of fluid pooling that occurs adjacent to the edge of the limb sleeves. If indicated for treatment, IPC pressure settings must be kept very low to avoid collapse of the superficial lymph capillaries. Each client should be carefully examined by an experienced health care professional before IPC is applied. Blood pressure readings should be taken before each treatment to confirm that IPC will be safe to use. Increasing total peripheral resistance with pneumatic compression will increase the work

Figure 14.46 Intermittent pneumatic compression pump.

of the heart, increasing blood pressure. Pneumatic compression treatment is contraindicated for individuals with hypertension or a blood pressure reading greater than 140/90. Other contraindications to intermittent compression include acute inflammation or trauma, local infection, presence of thrombus, cardiac or kidney dysfunction, obstructed lymphatic channels, and impaired cognitive function.

Sequential Pneumatic Compression with Truncal Component

Advances in compression systems include more pneumatic chambers that inflate and deflate in a sequential pattern at very low pressures. The newest home use models include truncal decongestion and clearance in preparation for receiving lymph from affected areas. This appliance style mimics the benefits of MLD in the clinic setting (Fig. 14.47). Manual treatments clear the trunk proximally before treating more distal segments of the body. Stretch fabric is incorporated into the appliance design to further mimic the light stretch to the skin that is applied with MLD.[74,243-245]

Positioning

Positioning techniques are used to prevent or protect pressure ulcers, as well as other types of wounds, edema, lymphedema, and vascular disorders. This important aspect of intervention, as well as PRDs, should not be overlooked or underestimated during treatment planning. Devices and techniques selected for positioning should be compatible with the individual's health status. It is paramount that a personalized positioning and repositioning schedule be developed and prominently displayed for any patient who cannot position or reposition independently. The standard time intervals used for turning schedules (i.e., every 2 hours) are often too long for individuals who are frail, have fragile skin, or have existing wounds. A turning schedule could be as frequent as every 30 minutes in some cases whereas for other individuals, every 4 hours may be enough. Suggestions for patient positioning programs include the following:[246-248]

- The patient's heels should be protected and elevated off the surface of the bed.
- The head of bed should not be elevated past 30° unless medically necessary.
- An individualized turning schedule should be provided.
- PRDs should be used in conjunction with a turning schedule.
- Positioning with weight-bearing directly over the greater trochanter should be avoided.
- Positioning with full weight-bearing over an existing wound should be avoided.
- Donut-shaped devices for seating solutions should not be used.
- Pillows and wedges should be used to separate bony prominences from bed and other body parts.

Pressure-Redistributing Devices

Pressure has a direct influence on perfusion or vascularity of a wound site. PRDs should be used to prevent skin breakdown, during the wound healing phase, and during the self-management phase, for life-long protection and prevention (Fig. 14.48). Along with positioning, patients and their caregivers must be educated about pressure redistribution and prevention of pressure-related trauma.[249] Advances in support surfaces that redistribute weight have made them more sophisticated and effective (Fig. 14.49). Experts in positioning systems are readily available to advise and instruct clinicians working with special populations.[250] Groups such as the Consortium for Spinal Cord Medicine, NPUAP, and HHS have made recommendations and algorithms for positioning and pressure redistributing devices that can be used for intervention planning.[76,101,251,252]

Exercise

The physical therapist should educate patients and promote activities in the POC related to increasing activity levels as appropriate. Too often, exercise is neglected in the intervention plan for individuals with vascular, lymphatic, and integumentary disorders, especially those with wounds or edema. Exercise is indicated for a variety of reasons, including, but not limited to, the following: increase strength and joint ROM, improve quality of movement, increase ADL, improve QOL perceptions, increase blood flow to the extremities, improve calf pump activity, prevent pressure ulcers, and enhance the effects of lymphedema bandaging. Exercise might be contraindicated or planned with caution when medical issues arise such as the need to be non–weight-bearing on a foot wound, unstable cardiopulmonary conditions, or related orthopedic problems that would limit activity.

Exercise prescription should be customized to the patient's needs and medical status. A walking program can benefit most individuals who are able to ambulate even short distances. Water-based exercise programs can facilitate the transition from bed or chair to land-based exercise. Individuals with wounds can participate in water-based exercise if it is appropriate to cover the wounds with occlusive dressings. The hydrostatic pressure of water contributes to support of edematous and lymphedematous body segments and creates an ideal setting for exercise for most individuals with swelling.

Patients should be educated about the concept that movement, activity, and formal exercise are all important for long-term management of the conditions listed in this chapter. Physical therapists introduce these concepts, provide expert instruction, and develop appropriate home exercise programs. Patients are guided to accept responsibility for following the exercise prescriptions at home and for making them a part of their everyday lives.

Orthotics

Splinting

Patients who are immobile may benefit from resting splints to retain, or dynamic splints to regain, functional ROM. Splinting can also prevent skin breakdown by retaining normal positioning of joints during periods of immobility. Extra precautions (i.e., padding) must be taken to protect aging or fragile skin from breakdown when semi-rigid thermoplastic materials are used for splinting. The use of splinting to manage burn scar is an essential part of the POC for an individual with a thermal injury (see Chapter 24, Burns). Positioning and splinting pointers found there can also be applied to patients with other types of wounds.

Total Contact Casting

One method for reduction of weight-bearing stresses on the foot is the application of a *total contact cast (TCC)*. This method can be useful for the individual with a neuropathic ulcer on the plantar surface of the foot. After infection and swelling have been controlled, a plaster cast is applied from the toes to below the knee. A specially trained individual uses plaster, padding techniques, and the placement of a rubber insert on the weight-bearing part of the cast to complete the application. A TCC is usually worn for 7 to 10 days at a time, removed for skin care, and then reapplied. According to a classic article by Salsich et al,[253] TCC is effective at healing ulcers initially, but the rate of reulceration once the cast is removed is high.

Neuropathic Walker

A removable ankle-foot orthosis (AFO) can be custom fabricated or ordered prefabricated to provide weight distribution and cushioning for the individual with an insensate foot, a chronic foot ulcer, or Charcot joint (Fig. 14.50). This option is versatile in fit and allows skin checks, dressing changes, and pressure alterations as needed.

Cast Shoes

Cast shoes or post-operative (post-op) shoes can be utilized as an inexpensive, temporary alternative for wound off-loading. These shoes, however, do not provide any means of controlling foot motion and little cushioning protection for the chronic wound. This option should be considered temporary. Patients wearing cast shoes for pressure distribution should be monitored closely for signs of complications.

Figure 14.50 An ankle-foot orthosis specifically designed to allow distributed weight-bearing for individuals with neuropathy.

Extra-Depth Shoes

Extra-depth shoes have a roomy toe box and a deep sole to provide shock absorption and cushion. The shoes should redirect foot pressure away from bony prominences and wounds (Fig. 14.51).[254] Available in many styles, they can be purchased from an orthotist or at a specialty shoe store. Individuals with insensate feet, with or without wounds, should strongly consider wearing this type of shoe to support skin protection and ulcer prevention.

Figure 14.51 Extra-depth shoe.

Scar Management

As described earlier in this chapter, scar formation is a component of wound healing.[255] After the wound is filled with collagen, the tissue must be remodeled and shaped into the finely structured end product. Contraction of scar tissue can lead to disfigurement and loss of function, especially if the scar tissue is located over a joint surface. Issues of disfigurement and dysfunction are greatest following thermal injury (see Chapter 24, Burns). Currently, the mechanisms by which scar can be controlled are not completely understood. Although some interventions do seem to help, there is room for further investigation into how to achieve optimal control of scar formation. Most scar tissue is managed by a physical therapist using compression garments, stretching exercises, orthotics, positioning, specific types of massage, and the use of topical adjuncts such as silicone gel sheets (Fig. 14.52) and elastomer putty (Fig. 14.53). Topical creams, oils, and ointments have

Figure 14.52 Application of a silicone gel sheet to scar tissue during the maturation phase of wound healing.

Figure 14.53 Application of elastomer putty to scar tissue during the maturation phase of wound healing.

some positive effects on scar but it is not known if the massaging actions used to apply the agents or the agents themselves provide the therapeutic effects. Early and adequate intervention can prevent most of the complications of scarring. Since the process of scar formation usually continues for 6 to 24 months, follow-up care should be part of the intervention plan. Individuals with scar tissue must learn how to safely massage the skin at home because frequent pressure applications have the greatest influence on new connective tissue orientation. When conservative measures of scar management have not controlled scarring, surgical intervention may be indicated. Following surgery, the individual will have a new wound and subsequent new scar to manage.

SUMMARY

These are exciting times for clinicians interested in the care of patients with vascular, lymphatic, and integumentary disorders. Skin and wound care practices continue to advance with clinical trials, randomized controlled studies, and empirical data all contributing to the pool of knowledge. New information about the microcirculation of blood and lymph has changed intervention strategies. The role of the skin as an organ has gained new respect. It is not surprising that there is an explosion of research, literature, and products to serve the needs of individuals with disorders affecting these systems. Current and future generations are facing healthcare challenges of a magnitude never before seen in our society, including an increase in the number of individuals with conditions related to the disorders discussed in this chapter. The incidence of diabetes, obesity, vascular and lymphatic disease, chronic wounds, and antibiotic-resistant pathogens is on the rise. Issues compounding the challenges include a growing population of older individuals, health care reimbursement challenges, and numerous ethical dilemmas in daily practice.

This chapter provides support for clinicians in their efforts to provide excellent patient care. Topics of particular importance include current strategies for wound management, the importance of adequate and appropriate patient education, pressure ulcer prevention and precautions, advanced foot care for individuals with diabetic neuropathy, optimal compression for lymphedema, the essential role of moisture in wound healing, and the importance of exercise as part of the POC.

There is great need for ongoing research to establish the level of strength of evidence for a variety of topics that may or may not be important in the world of vascular, lymphatic, and integumentary disorders. Some of the concepts that deserve a second look are the impact of bio-burden on the wound infection continuum, the preparation of the wound bed, the use of exogenous oxygen applications, noncontact US, nonthermal radiofrequency stimulation, cold laser, biosurgery, bioengineered tissue, exogenous growth factors, medical-grade honey, and topical silver preparations. In addition to expanding the evidence, improvements in the standardizing of wound care education are needed. The interdisciplinary nature of wound care calls for more communication among health care professionals. Wise clinicians must keep abreast of new information and current standards of care, approaching new entries to the field with a strong sense of clinical intuition, as well as a firm grasp of the scientific evidence.

Questions for Review

1. Discuss the differences, similarities, and relationships among the arterial, venous, and lymphatic systems. Compare anatomy, method of fluid movement, and function.
2. Outline some of the unique characteristics that can be identified clinically for disorders of the vascular, lymphatic, and integumentary systems.
3. Prepare a list of factors that contribute to abnormal wound healing. Divide the list into intrinsic, extrinsic, and iatrogenic factors.
4. Review the annotated tests and measurements included in this chapter that should be used during a physical therapy examination. Identify tests and measurements routinely performed for patients with vascular, lymphatic, or integumentary disorders.
5. Design a checklist of examination categories for examining a patient with a disorder of the vascular, lymphatic, and/or integumentary systems.
6. Create a general list of the primary components of a POC for a patient with a wound.

7. Explain how a physical therapist should respond to the knowledge that many vascular, lymphatic, and integumentary disorders have a long latency period and require a heightened level of vigilance and proactivity in order to identify symptoms and begin treatment as early as possible.
8. Explain the rationale for each of the following treatments in skin and wound care: moist wound healing, arterial wound hydration, venous wound compression, lymphedema treatment, and foot care for the individual with diabetes.

CASE STUDY

REFERRAL

A 78-year-old woman with a primary diagnosis of Alzheimer's disease has been living in a residential facility for 10 months. The physician at the facility refers her to physical therapy. Referral is for advanced wound care.

PAST MEDICAL HISTORY

Unremarkable until onset of symptoms of Alzheimer's 3 years ago.

CURRENT MEDICAL HISTORY

Health conditions include mild hypertension controlled by medication and a Stage III pressure ulcer over the right ischial tuberosity.

MEDICAL INTERVENTION PREVIOUS TO CURRENT REFERRAL

Pressure ulcer treated for 4 weeks (30 days) with bid hydrogen peroxide flushes followed by dry gauze 4 × 4s covered with gauze pad and adhesive tape. No changes in wound bed for 4 weeks. No other intervention in place.

PSYCHOSOCIAL

Husband also resident of same facility, lives in same room. Husband is frail but mobile and contributes to care for wife. No children. Patient enjoys music and trips by wheelchair to activity center in facility.

COGNITIVE

Patient disoriented to place and time. Becomes agitated during wound care. She is unable to follow weight shift and turning schedules independently and has difficulty following instructions.

PHYSICAL THERAPY EXAMINATION DATA

Body Structure/Function

- *Wound:* Stage III pressure ulcer over right ischial tuberosity. Measures 6 × 4 cm (2.36 × 1.57 in) with depth of 4 cm (1.57 in). The wound bed is 50% necrotic yellow tissue and 50% red granulation tissue. Periwound tissue is intact. Drainage is moderate, yellow-brown, and thin with minimal odor. The wound is currently contaminated but not infected (i.e., colonized bacteria are present but not to the level of clinical infection).
- *Strength and ROM:* Patient unable to follow commands consistently for examination of strength but appears to have functional strength and ROM of bilateral upper extremities (BUEs). Gross bilateral lower extremity (BLE) strength is impaired perhaps owing to declining activity levels. Active ROM appears functional in BUEs. Bilateral hip flexion contractures of 30° can be reduced to 15° with passive ROM.

Activity Limitations—Mobility

Patient is either in wheelchair or bed 24 hours/day. Patient is unable to roll independently but can often assist using BUEs when instructed. Requires maximum assist of two to pivot transfer. The patient is unable to ambulate at this time.

Participation Restrictions

Requires close supervision during social engagement due to propensity to become agitated.

GUIDING QUESTIONS

1. What are the contributing factors that have most likely led to the chronicity of this wound?
2. What other factors might contribute to the slow healing time of this wound?
3. What combination of interventions to clean and débride would allow removal of necrotic tissue while protecting granulation tissue?

4. Clinically, which electromodalities are biocompatible for the treatment of this wound (irrespective of payment) and how will they contribute to wound healing?
5. Other than local wound care, what intervention will be essential for wound closure?
6. Once progress has been made in wound healing, if the wound were to become dry, what dressing types could be used to create a moist wound environment?
7. If using an occlusive dressing, why should this patient be closely monitored?
8. Assuming this patient's wound will close, what are the expectations for the condition of her skin over the wound site?

14.A Patient Education: Skin Care and Footwear Instructions

INSPECT YOUR SKIN

1. Look at your feet every day. Use a mirror, a magnifying glass, or the assistance of a family member to help you see all over your feet including between your toes and the bottoms of your feet.

2. Look for these things on your feet: blisters, sores, corns, calluses, red spots, swelling, pain, drainage from a sore, broken toenails, cracked skin, odor. Notify your health care provider if you see any of these things on your feet or if you injure either of your feet.

TAKE CARE OF YOUR SKIN

1. Wash your feet gently every day using lukewarm water and mild soap. Test the water temperature with your hand before you wash your feet. If your hand is not sensitive to temperature, use a thermometer. The temperature should be about 85° Fahrenheit (29.44° Celsius).

2. Dry your feet well, especially between your toes.

3. You may want to use a lanolin-based lotion or petroleum jelly to soften dry skin. Do not apply any lotion between your toes. You may use powder or cornstarch between your toes.

4. Never try to treat corns, calluses, or toenails with sharp instruments, home remedies, or store-bought foot care products. These items can all hurt your skin.

5. Cut toenails straight across; do not cut into corners. Use an emery board for sharp edges. A pumice stone can be used to treat small corns and calluses. Alert your health care provider about your foot care practices.

6. For padding and air circulation, use small bits of lamb's wool between the toes. Change the lamb's wool every day. Be sure to use new pieces after you wash your feet. Do not use cotton or cotton balls because the fibers may irritate your skin.

7. Put on a clean pair of white socks after your skin care routine.

8. Do not walk barefoot.

9. If your feet are cold at bedtime, wear cotton socks; do not use a hot water bottle or heating pad to warm your feet.

CHECK YOUR SHOES

1. Check your shoes every day before you put them on. Look inside for small things that could cause a sore on your foot. Alternate shoes each day to allow them to breathe and dry completely.

2. Be sure that your shoes are the right size and width.

3. Do not wear old worn-out shoes or socks.

4. Shop for shoes in the afternoon when your feet are the largest.

5. Break in your new shoes gradually.

SEE YOUR HEALTH CARE PROVIDER

1. Get help in controlling your diabetes.

2. Have regular appointments with your doctor.

3. Call your health care provider immediately if you find a wound on your foot.

Special Tests for Arterial and Venous Function

appendix **14.B**

Special Tests	Description
Rubor of dependency	A noninvasive test to examine the lower extremity (LE) for the presence of ischemia. Following elevation of the limb, lowering of the limb should return the skin of the limb to a pink color. If the color is dark red and takes more than 30 seconds to appear, the test is positive for arterial insufficiency.
Air plethysmography (APG)	A noninvasive test of both the arterial and venous circulation. Changes in LE volume are measured using a pressure cuff that quantifies volume changes during rest, standing, and light walking. Venous obstruction and arterial inflow can be observed with this test.
Transcutaneous oxygen ($TcPO_2$)	A noninvasive examination tool for arterial circulation. A special probe and a heating element measure profusion. Measurement of oxygen at the skin level gives information about what is happening at the cellular level. Also found in the literature as *transcutaneous partial pressure of oxygen* and *transcutaneous oxygen tension measurement*. The results are predictive for healing of ulcers and amputation wounds.
Skin perfusion pressure (SPP) measurement	A noninvasive test that measures blood flow in the skin. To take the measurements, a modified laser Doppler probe is secured in the bladder of a specialized blood pressure cuff. Results are predictive for healing of ulcers and amputation wounds.
Venous filling time	The extremity is elevated and then lowered into a dependent position. The time it takes for the veins on top of the foot to refill is recorded. Normal filling time is 15 seconds. Greater than 15 seconds indicates arterial disease whereas less than 15 indicates venous disease.
Percussion test	With LE in a dependent position, the greater saphenous vein is palpated distal to the knee with one hand while it is tapped 6 in (15.2 cm) proximal to the knee with the other hand. If a wave of fluid is detected under the distal palpation site, this indicates the possibility of valvular incompetency.
Trendelenburg test	Test measures the time required to refill the veins in the dorsum of the foot. The LE is elevated to allow venous blood to empty. A tourniquet on the thigh prevents backflow. After 1 minute, the individual stands. If veins fully distend within 5 seconds before the tourniquet is released, valvular incompetence in the deep veins is suspected. If distention occurs within 5 seconds after the tourniquet is released, incompetence of superficial veins is suspected.

Dressings by Treatment Goal (Purpose) and Wound Type (Indication)

I. Dressing by Treatment Goal

Purpose	Dressing
Space filling (cavities, undermining, tunnels, or sinuses)	Gauze Foams (some) Hydrogels (amorphous/sheets) Alginates Impregnated gauze Absorptive dressings (beads, powders, and pastes) Composite dressings (some)
Mechanical débridement	Gauze
Exudate absorption	Gauze Foams Absorptive dressings (beads, powders, and pastes) Alginates Hydrocolloids Collagen
Hydration	Hydrogels (amorphous/sheets) Saline-moistened gauze
Autolytic débridement	Transparent films Hydrocolloids Hydrogels (amorphous/sheets) Foams Alginates Impregnated gauze Absorptive dressings (beads, powders, and pastes) Composite
Protection against contamination	Transparent films Hydrocolloids Hydrogel sheets (some) Composite (some) Foams (some)
Hemostasis	Alginates Collagen
Site coverage	Transparent films Hydrocolloids Hydrogel sheets (some) Foams Composite Gauze

Friction reduction	Transparent films Hydrocolloids Hydrogels sheets (some)
Insulation	Transparent films Hydrocolloids Hydrogels (amorphous/sheet) Foams Composite (some) Gauze
Pain reduction	Transparent films Hydrocolloids Hydrogels (amorphous/sheet) Foams Alginates Composites
Odor reduction	Hydrocolloids Hydrogels (amorphous/sheets) (some) Alginates (some) Foams (charcoal) Absorptive dressings (beads, powders, and pastes) (some)
Cushioning	Hydrocolloids Hydrogel sheets (some) Foams Composite dressings (some) Gauze
Antibacterials	Silver-based dressings Iodine-based dressings Silver sulfadiazine

II. Dressings by Wound Type

Indication	Dressing
Infected wounds	Gauze Alginates Hydrogels Hydrogel sheets Impregnated gauze Foams
Burns	Alginates Hydrocolloids Hydrogels Transparent films Impregnated gauze Foams Biological dressings Collagen
Stage I pressure ulcers	Transparent films Foams

Continued

Stage II pressure ulcers	Alginates Hydrocolloids Hydrogels Transparent films Impregnated gauze Foams Collagen
Stage III pressure ulcers	Alginates Hydrocolloids Hydrogels Impregnated gauze Foams Collagen
Stage IV pressure ulcers	Alginates Hydrocolloids Hydrogels Impregnated gauze Foams Collagen
Venous ulcers	Alginates Hydrocolloids Hydrogels Foams

Stroke

Susan B. O'Sullivan, PT, EdD

Chapter 15

LEARNING OBJECTIVES

1. Describe the epidemiology, etiology, pathophysiology, symptomatology, and sequelae of stroke.
2. Identify and describe the examination procedures used to evaluate patients with stroke to establish a diagnosis, prognosis, and plan of care.
3. Describe the role of the physical therapist in assisting the patient in recovery from stroke in terms of interventions, patient/client-related instruction, coordination, communication, and documentation.
4. Identify and describe strategies of intervention during inpatient rehabilitation.
5. Analyze and interpret patient data, formulate realistic goals and outcomes, and develop a plan of care when presented with a clinical case study.

SUMMARY *704*

Stroke (**cerebrovascular accident** [CVA]) is the sudden loss of neurological function caused by an interruption of the blood flow to the brain. **Ischemic stroke** is the most common type, affecting about 80% of individuals with stroke, and results when a clot blocks or impairs blood flow, depriving the brain of essential oxygen and nutrients. **Hemorrhagic stroke** occurs when blood vessels rupture, causing leakage of blood in or around the brain. Clinically, a variety of focal deficits are possible, including changes in the level of consciousness and

impairments of sensory, motor, cognitive, perceptual, and language functions. To be classified as stroke, neurological deficits must persist for at least 24 hours. Motor deficits are characterized by paralysis (**hemiplegia**) or weakness (**hemiparesis**), typically on the side of the body opposite the side of the lesion. The term *hemiplegia* is often used generically to refer to the wide variety of motor problems that result from stroke. The location and extent of brain injury, the amount of collateral blood flow, and early acute care management determine the severity of neurological deficits in an individual patient. Impairments may resolve spontaneously as brain swelling subsides (reversible ischemic neurological deficit), generally within 3 weeks. Residual neurological impairments are those that persist longer than 3 weeks and may lead to lasting disability. Strokes are classified by etiological categories (thrombosis, embolus, or hemorrhage), specific vascular territory (anterior cerebral artery syndrome, middle cerebral artery syndrome, and so forth), and management categories (transient ischemic attack, minor stroke, major stroke, deteriorating stroke, young stroke).

EPIDEMIOLOGY AND ETIOLOGY

Stroke is the fourth leading cause of death and the leading cause of long-term disability among adults in the United States. An estimated 7,000,000 Americans older than 20 years of age have experienced a stroke. Each year approximately 795,000 individuals experience a stroke; approximately 610,000 are first attacks and 185,000 are recurrent strokes. Women have a lower age-adjusted stroke incidence than men. However, this is reversed in older ages; women over 85 years of age have an elevated risk compared to men. Compared to whites, African Americans have twice the risk of first-ever stroke; rates are also higher in Mexican Americans, American Indians, and Alaska Natives. The incidence of stroke increases dramatically with age, doubling in the decade after 65 years of age. Twenty-eight percent of strokes occur in individuals younger than 65 years of age. Between 5% and 14% of persons who survive an initial stroke will experience another one within 1 year; within 5 years stroke will recur in 24% of women and 42% of men. Current data reveal that stroke incidence has been declining in recent years in a largely white adult cohort.[1]

The incidence of stroke deaths is greater than 143,000 annually, and strokes account for 1 of every 18 deaths in the United States. The type of stroke is significant in determining survival. Of patients with stroke, hemorrhagic stroke accounts for the largest number of deaths, with mortality rates of 37% to 38% at 1 month, whereas ischemic strokes have a mortality rate of only 8% to 12% at 1 month. Survival rates are dramatically lessened by increased age, hypertension, heart disease, and diabetes. Loss of consciousness at stroke onset, lesion size, persistent severe hemiplegia, multiple neurological deficits, and history of previous stroke are also important predictors of mortality.[1,2]

Stroke is the leading cause of long-term disability in the United States. Of ischemic stroke survivors 65 or older, incidences of disabilities observed at 6 months include hemiparesis (50%), unable to walk without assistance (30%), dependent in activities of daily living (ADL) (26%), aphasia (19%), and depression (35%). Stroke survivors represent the largest group admitted to rehabilitation hospitals and about a third of patients receive outpatient rehabilitation services. Another indicator of disability is the fact that approximately 26% of patients with stroke are institutionalized in a long-term care facility. Direct and indirect costs of stroke are in the billions.[1]

Atherosclerosis is a major contributory factor in cerebrovascular disease. It is characterized by plaque formation with an accumulation of lipids, fibrin, complex carbohydrates, and calcium deposits on arterial walls that leads to progressive narrowing of blood vessels. Interruption of blood flow by atherosclerotic plaques occurs at certain sites of predilection. These generally include bifurcations, constrictions, dilations, or angulations of arteries. The most common sites for lesions to occur are at the origin of the common carotid artery or at its transition into the middle cerebral artery, at the main bifurcation of the middle cerebral artery, and at the junction of the vertebral arteries with the basilar artery (Fig. 15.1).

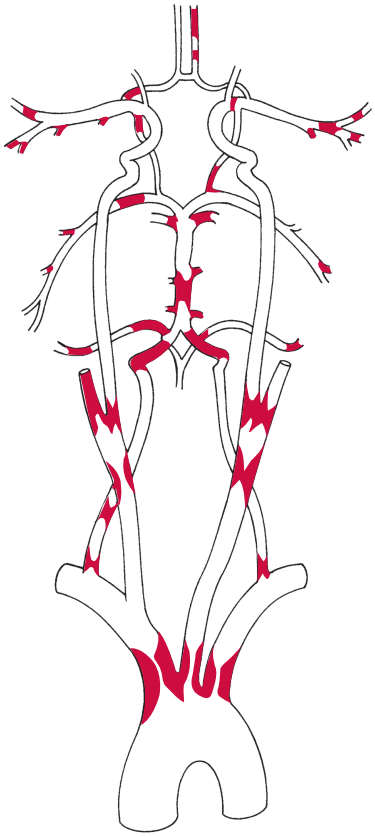

Figure 15.1 Preferred sites for atherosclerotic plaque. *(From American Heart Association: Diagnosis and Management of Stroke, 1979, p 4, with permission.)*

Ischemic strokes are the result of a thrombus, embolism, or conditions that produce low systemic perfusion pressures. The resulting lack of cerebral blood flow (CBF) deprives the brain of needed oxygen and glucose, disrupts cellular metabolism, and leads to injury and death of tissues. A thrombus results from platelet adhesion and aggregation on plaques. **Cerebral thrombosis** refers to the formation or development of a blood clot within the cerebral arteries or their branches. It should be noted that lesions of extracranial vessels (carotid or vertebral arteries) can also produce symptoms of stroke. Thrombi lead to ischemia, or occlusion of an artery with resulting **cerebral infarction** or tissue death (*atherothrombotic brain infarction [ABI]*). Thrombi can also become dislodged and travel to a more distal site in the form of an intra-artery embolus. **Cerebral embolus (CE)** is composed of bits of matter (blood clot, plaque) formed elsewhere and released into the bloodstream, traveling to the cerebral arteries where they lodge in a vessel, producing occlusion and infarction. The most common source of CE is disease of the cardiovascular system. Occasionally systemic disorders may produce septic, fat, or air emboli that affect the cerebral circulation. Ischemic strokes may also result from low systemic perfusion, the result of cardiac failure or significant blood loss with resulting systemic hypotension. The neurological deficits produced with systemic failure are global in nature with bilateral neurological deficits.

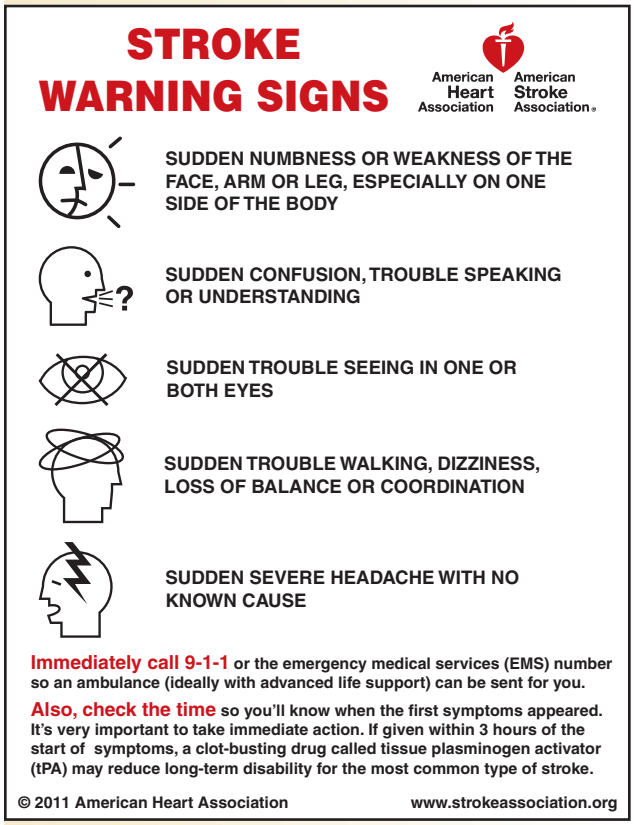
Hemorrhagic strokes, with abnormal bleeding into the extravascular areas of the brain, are the result of rupture of a cerebral vessel or trauma. Hemorrhage results in increased intracranial pressures with injury to brain tissues and restriction of distal blood flow. **Intracerebral hemorrhage (IH)** is caused by rupture of a cerebral vessel with subsequent bleeding into the brain. Primary **cerebral hemorrhage** (nontraumatic spontaneous hemorrhage) typically occurs in small blood vessels weakened by atherosclerosis producing an **aneurysm**. **Subarachnoid hemorrhage (SH)** occurs from bleeding into the subarachnoid space typically from a saccular or berry aneurysm affecting primarily large blood vessels. Congenital defects that produce weakness in the blood vessel wall are major contributing factors to the formation of an aneurysm. Hemorrhage is closely linked to chronic hypertension. **Arteriovenous malformation (AVM)** is another congenital defect that can result in stroke. AVM is characterized by a tortuous tangle of arteries and veins with agenesis of an interposing capillary system. The abnormal vessels undergo progressive dilation with age and eventually bleed in about 50% of cases. Sudden and severe cerebral bleeding can result in death within hours, because intracranial pressures rise rapidly and adjacent cortical tissues are compressed or displaced as in brainstem herniation.

RISK FACTORS AND STROKE PREVENTION

Cardiovascular diseases affecting the brain and heart share a number of common risk factors important to the development of atherosclerosis. Major risk factors for stroke are hypertension, heart disease (HD), disorders of heart rhythm, and diabetes mellitus (DM). In patients with ABI, approximately 70% have hypertension, 30% HD, 15% congestive heart failure (CHF), 30% peripheral arterial disease (PAD), and 15% DM.[2] This coexistence of multiple pathologies increases significantly with age. Individuals with hypertension (blood pressure [BP] (140/90 mm Hg or higher) have twice the lifetime risk of stroke. Risk is increased with elevated total blood cholesterol *(hypercholesterolemia),* defined as 240 mg/dL or greater. Lipid profiles are also important. Risk is increased with elevated low-density lipoprotein (LDL ["bad"]) cholesterol. LDL levels are defined as borderline high levels of 130 to 159 mg/dL, high levels of 160 to 189 mg/dL, and very high levels of 190 mg/dL or greater. Low levels of high-density lipoprotein (HDL ["good"]) cholesterol, defined as below 40 mg/dL in adult males and below 50 mg/dL in adult females, also increases stroke risk. Fasting triglyceride level of greater than 150 mg/dL in adults is considered elevated and a risk factor for HD and stroke. Patients with marked elevations of hematocrit are also at an increased risk of occlusive stroke owing to a generalized reduction of CBF. Cardiac disorders such as rheumatic heart valvular disease, endocarditis, or cardiac surgery (e.g., coronary artery bypass graft [CABG]) increase the risk of embolic stroke. Atrial fibrillation is a powerful risk factor for stroke with a fivefold increased risk. End-stage renal disease and chronic kidney disease also increase the risk of stroke. Sleep apnea is an independent risk factor for stroke, doubling the risk of stroke or death. Control of these chronic diseases and conditions is essential in reducing stroke risk.[1,2]

A number of stroke risk factors are specific to women. Women with early menopause (before 42 years of age) have twice the risk of ischemic stroke as women with later menopause. The use of estrogen alone or estrogen plus progestin increases the risk of ischemic stroke (up to 44% to 55% or higher). Pregnancy, birth, and the first 6 weeks postpartum can also increase risk of stroke, especially in older women and African Americans. Preeclampsia is an independent risk factor for stroke.[1]

Modifiable risk factors include cigarette smoking, physical inactivity, obesity, and diet. Current smokers have 2 to 4 times increased stroke risk compared to nonsmokers or those who have quit for more than 10 years. Physical activity (moderate to vigorous exercise) is associated with an overall 35% reduction in stroke risk whereas light exercise (walking) does not appear to have the same benefit. As with a cardiac risk profile, the more risk factors present or the greater the degree of abnormality of any one factor, the greater the risk of stroke. Stroke risk



factors considered nonmodifiable include family history, age, gender, and race (African American).

Lifestyle changes can greatly reduce the risk of stroke. Recommendations include controlling BP, diet (cholesterol and lipids), weight loss, quitting smoking, and increasing physical activity, as well as effective disease management.[1,2]

Effective stroke prevention depends on improving public awareness concerning the *early warning signs of stroke.* Only about 60% of Americans can recognize even one warning sign and only 55% can identify one stroke symptom.[1] Early warning signs identified by the American Heart Association and National Stroke Association are presented in Box 15.1.[3] The significance of recognizing early warning signs rests with prompt initiation of emergency care under the rule that *"time is brain."* Patients and families are encouraged to call 911 immediately, even if these symptoms go away quickly or are not painful. Early computed tomography (CT) is used to differentiate between atherothrombotic stroke and hemorrhagic stroke. If the stroke is atherothrombotic, clot-dissolving enzymes (e.g., tissue plasminogen activator [tPA]) can be used for thrombolysis. To be effective, thrombolytic therapy such as tPA must be given within 3 hours of the onset of symptoms and cannot be given with hemorrhagic stroke because the drug may worsen bleeding. Within this window of opportunity, the patient must recognize the situation as a medical emergency, be transported to an appropriate hospital, be evaluated by emergency department(ED) staff (including a CT scan of the brain), and be treated.[4,5] Although this treatment has been available since the mid-1990s and has been shown to be safe and to dramatically reduce death and disability, fewer than half of individuals experiencing stroke arrive at the ED within 2 hours of symptoms.[6] Women are less likely than men to arrive in time. Of those arriving at the ED within 2 hours of symptoms, only 65% received imaging within 1 hour of ED arrival.[7]

In the United States, there is a developing Stroke Center Network dedicated to providing the highest quality of acute stroke care. Direct access to a Comprehensive Stroke Center (CSC) is associated with a shorter onset-to-treatment time and better outcomes for ischemic stroke treated with thrombolysis.[8] Even with policy changes that allow emergency first responders to transmit individuals directly to a CSC, still only about half of patients have timely access.[9] A significant predictor in successfully accessing emergency care is the "executive" spouse or significant other who is able to make the decision to seek treatment immediately. Patients who do receive tPA within 3 hours are at least 33% more likely to recover from their stroke with little or no disability after 3 months as compared to those who do not receive the treatment.[10] Major heart and stroke organizations currently promote the use of the term *brain attack,* comparable to heart attack, to help individuals recognize the importance of seeking immediate emergency care.

PATHOPHYSIOLOGY

Sudden cessation of cerebral blood flow and oxygen-glucose deprivation sets in motion a series of pathological events. Within minutes neurons die within the ischemic core tissue, while the majority of neurons in the surrounding penumbra survive for a slightly longer time. Cell survival depends largely on the severity and the duration of the ischemic episode. For cells to survive, 20% to 25% of regular blood flow is required. Without timely reperfusion, cells in the penumbra will die, neuronal activity ceases, and the infarct expands. Ischemia triggers a number of damaging cellular events, termed **ischemic cascade**. The release of excess neurotransmitters (e.g., glutamate and aspartate) produces a progressive disturbance of energy metabolism and anoxic depolarization. This results in an inability of brain cells to produce energy, particularly adenosine triphosphate (ATP). This is followed by excess influx of calcium ions and pump failure of the neuronal membrane. Excess calcium reacts with intracellular phospholipids to form free radicals. Calcium influx also stimulates the release of nitric oxide and cytokines. Both mechanisms further damage brain cells. Research efforts

are ongoing toward development of drugs that might promote angiogenesis, restore blood supply, stimulate neuroprotective genes, and reverse the metabolic changes of the ischemic penumbra area.[11]

Ischemic strokes produce **cerebral edema**, an accumulation of fluids within the brain that begins within minutes of the insult and reaches a maximum by 3 to 4 days. It is the result of tissue necrosis and widespread rupture of cell membranes with movement of fluid from the blood into brain tissues. The swelling gradually subsides and generally disappears by 2 to 3 weeks. Significant edema can elevate intracranial pressures, leading to intracranial hypertension and neurological deterioration associated with contralateral and caudal shifts of brain structures (**brainstem herniation**). Clinical signs of *elevating intracranial pressure (ICP)* include decreasing level of consciousness (stupor and coma), widened pulse pressure, increased heart rate, irregular respirations (*Cheyne-Stokes respirations*), vomiting, unreacting pupils (cranial nerve [CN] III signs), and papilledema. Cerebral edema is the most frequent cause of death in acute stroke and is characteristic of large infarcts involving the middle cerebral artery and the internal carotid artery.

Management Categories

Transient ischemic attack (TIA) refers to the temporary interruption of blood supply to the brain. Symptoms of focal neurological deficit may last for only a few minutes or for several hours, but by definition do not last longer than 24 hours. After the attack is over there is no evidence of residual brain damage or permanent neurological dysfunction. TIAs may result from a number of different etiological factors, including occlusive episodes, emboli, reduced cerebral perfusion (arrhythmias, decreased cardiac output, hypotension, overmedication with antihypertensive medications, subclavian steal syndrome), or cerebrovascular spasm. The major clinical significance of TIA is as a precursor to susceptibility for both cerebral infarction and myocardial infarction. Approximately 15% of all strokes are preceded by a TIA, with the greatest risk of occurrence within 90 days.[1]

Patients are classified as having a *major stroke* in the presence of stable, usually severe, impairments. The term *deteriorating stroke* is used to refer to the patient whose neurological status deteriorates after admission to the hospital. This change in status may be due to cerebral or systemic causes (e.g., cerebral edema, progressing thrombosis). The category of *young stroke* is used to describe a stroke affecting persons younger than age 45. Causes of stroke in children include perinatal arterial ischemic stroke, sickle cell disease, congenital HD, thrombophlebitis and trauma.[1]

Vascular Syndromes

Cerebral blood flow (CBF) varies with the patency of the vessels. Progressive narrowing secondary to atherosclerosis decreases blood flow. As in coronary heart disease, symptomatic changes generally result from a restriction of flow greater than 80%. The severity and symptoms of stroke are dependent on a number of factors, including (1) the location of the ischemic process, (2) the size of the ischemic area, (3) the nature and functions of the structures involved, and (4) the availability of collateral blood flow. Presenting symptoms may also depend on the rapidity of the occlusion of a blood vessel because slow occlusions may allow collateral vessels to take over, whereas sudden events do not.

CBF is controlled by a number of *autoregulatory mechanisms* (cerebral) that modulate a constant rate of blood flow through the brain. These mechanisms provide homeostatic balance, counteracting fluctuations in systolic blood pressure while maintaining a normal flow of 50 to 60 mL per 100g of brain tissue per minute. The brain has high energy requirements and very little metabolic reserves. Thus, it requires a continuous, rich perfusion of blood to deliver oxygen and glucose to the tissues. Cerebral flow represents approximately 17% of available cardiac output. Chemical regulation of CBF occurs in response to changes in blood concentrations of carbon dioxide or oxygen. Vasodilation and increased CBF are produced in response to an increase in $PaCO_2$ or a decrease in PaO_2, whereas vasoconstriction and decreased CBF are produced by the opposite stimuli. Blood flow is also altered by changes in the blood pH. A fall in pH (increased acidity) produces vasodilation, and a rise in pH (increased alkalinity) produces a decrease in blood flow. Neurogenic regulation alters blood flow by vasodilating vessels in direct proportion to local function of brain tissue. Released metabolites probably act directly on the smooth muscle in local vessel walls. Changes in blood viscosity or ICP may also influence CBF. Changes in BP produce minor alterations of CBF. As pressure rises, the artery is stretched, resulting in contraction of smooth muscle in the vessel wall. Thus, the patency of the vessel is decreased, with a consequent decrease in CBF. As pressure falls, contraction lessens and CBF increases. Following stroke, autoregulatory mechanisms may be impaired.[12]

Knowledge of cerebral vascular anatomy is essential to understand the symptoms, diagnosis, and management of stroke. Extracranial blood supply to the brain is provided by the right and left internal carotid arteries and by the right and left vertebral arteries. The *internal carotid artery* begins at the bifurcation of the common carotid artery and ascends in the deep portions of the neck to the carotid canal. It turns rostromedially and ascends into the cranial cavity. It then pierces the dura mater and gives off the ophthalmic and anterior choroidal arteries before bifurcating into the middle and anterior cerebral arteries. The anterior communicating artery communicates with the anterior cerebral arteries of either side, giving rise to the rostral portion of the **circle of Willis** (Fig. 15.2). The *vertebral artery* arises as a branch off the subclavian artery. It enters the

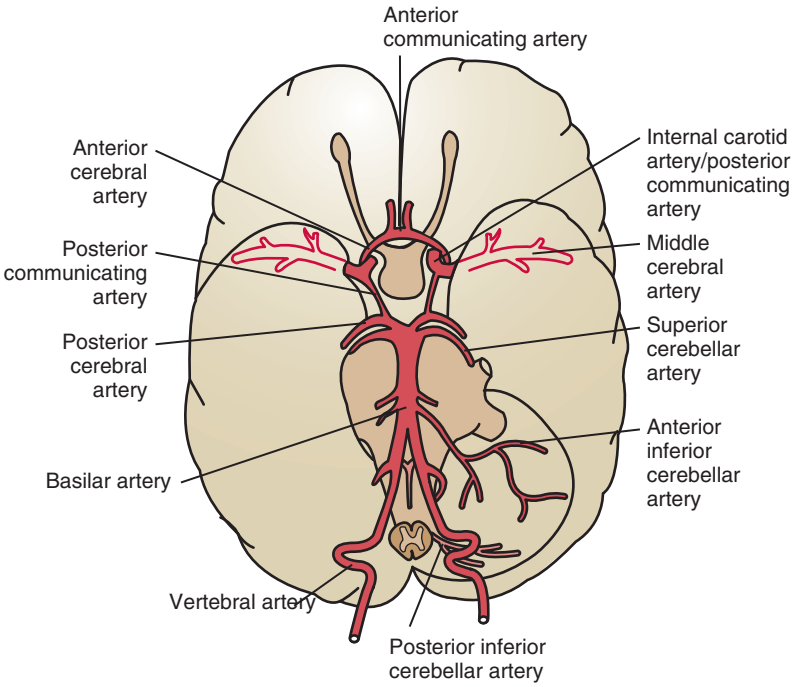

Figure 15.2 Cerebral circulation: circle of Willis.

vertebral foramen of the sixth cervical vertebra and travels through the foramina of the transverse processes of the upper six cervical vertebrae to the foramen magnum and into the brain. There it travels in the posterior cranial fossa ventrally and medially and unites with the vertebral artery from the other side to form the basilar artery at the upper border of the medulla. At the upper border of the pons, the basilar artery bifurcates to form the posterior cerebral arteries and the posterior portion of the circle of Willis. Posterior communicating arteries connect the posterior cerebral arteries with the internal carotid arteries and complete the circle of Willis.

Anterior Cerebral Artery Syndrome

The *anterior cerebral artery (ACA)* is the first and smaller of two terminal branches of the internal carotid artery. It supplies the medial aspect of the cerebral hemisphere (frontal and parietal lobes) and subcortical structures, including the basal ganglia (anterior internal capsule, inferior caudate nucleus), anterior fornix, and anterior four-fifths of the corpus callosum (Fig. 15.3). Because

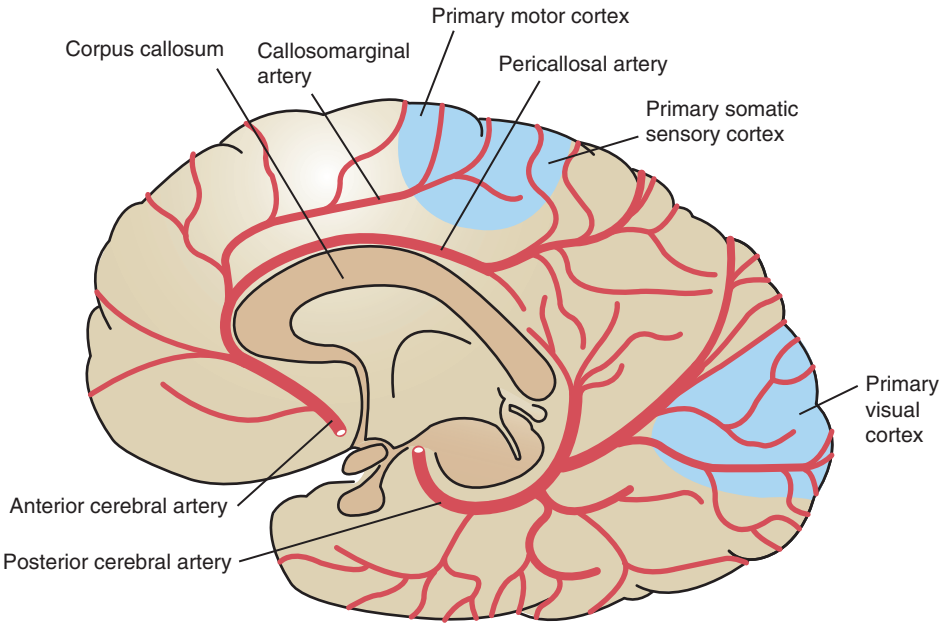

Figure 15.3 Cerebral circulation: a diagram of a midsagittal view of the brain illustrates the distribution of the anterior and posterior cerebral arteries.

the anterior communicating artery allows perfusion of the proximal ACA from either side, occlusion proximal to this point results in minimal deficit.

More distal lesions produce more significant deficits. Table 15.1 presents the clinical manifestations of *anterior cerebral artery (ACA) syndrome.* The most common characteristics of ACA syndrome include contralateral hemiparesis and sensory loss with greater involvement of the lower extremity (LE) than the upper extremity (UE) because the somatotopic organization of the medial aspect of the cortex includes the functional area for the LE.

Middle Cerebral Artery Syndrome

The *middle cerebral artery (MCA)* is the second of the two main branches of the internal carotid artery and supplies the entire lateral aspect of the cerebral hemisphere (frontal, temporal, and parietal lobes) and subcortical structures, including the internal capsule (posterior portion), corona radiata, globus pallidus (outer part), most of the caudate nucleus, and the putamen (Fig. 15.4). Occlusion of the proximal MCA produces extensive neurological damage with significant cerebral edema. Increased intracranial pressures typically lead to loss of consciousness, brain herniation, and possibly death. Table 15.2 presents the clinical manifestations of *middle cerebral artery (MCA) syndrome.* The most common characteristics of MCA syndrome are contralateral spastic hemiparesis and sensory loss of the face, UE, and LE, with the face and UE more involved than the LE. Lesions of the parieto-occipital cortex of the dominant hemisphere (usually the left hemisphere) typically produce aphasia. Lesions of the right parietal lobe of the nondominant hemisphere (usually the right hemisphere) typically produce perceptual deficits (e.g., **unilateral neglect, anosognosia, apraxia,** and **spatial disorganization**). **Homonymous hemianopsia** (a visual field defect) is also a common finding. The MCA is the most common site of occlusion in stroke.

Internal Carotid Artery Syndrome

Occlusion of the *internal carotid artery (ICA)* typically produces massive infarction in the region of the brain supplied by the middle cerebral artery. The ICA supplies both the MCA and the ACA. If collateral circulation to the ACA from the circle of Willis is absent, extensive cerebral infarction in the areas of both the ACA and MCA can occur. Significant edema is common with possible uncal herniation, coma, and death (mass effect).

Posterior Cerebral Artery Syndrome

The two posterior cerebral arteries (PCAs) arise as terminal branches of the basilar artery and each supplies the corresponding occipital lobe and medial and inferior temporal lobe (see Fig. 15.3). It also supplies the upper brainstem, midbrain, and posterior diencephalon, including most of the thalamus. Table 15.3 presents the clinical manifestations of *posterior cerebral artery (PCA) syndrome*. Occlusion proximal to the posterior communicating artery typically results in minimal deficits owing to the collateral blood supply from the posterior communicating artery (similar to ACA syndrome). Occlusion of thalamic branches may produce hemianesthesia (contralateral sensory loss) or **central post-stroke (thalamic) pain**. Occipital infarction produces homonymous hemianopsia, **visual agnosia, prosopagnosia**, or, if bilateral, cortical blindness. Temporal lobe ischemia results in amnesia (memory loss). Involvement of subthalamic branches may involve the subthalamic nucleus or its pallidal connections, producing a wide variety of deficits. Contralateral hemiplegia occurs with involvement of the cerebral peduncle.

Lacunar Strokes

Lacunar strokes are caused by small vessel disease deep in the cerebral white matter (penetrating artery disease). They are strongly associated with hypertensive hemorrhage and diabetic microvascular disease. Lacunar syndromes are consistent with specific anatomical sites. *Pure motor lacunar*

Table 15.1 Clinical Manifestations of Anterior Cerebral Artery Syndrome

Signs and Symptoms	Structures Involved
Contralateral hemiparesis involving mainly the LE (UE is more spared)	Primary motor area, medial aspect of cortex, internal capsule
Contralateral hemisensory loss involving mainly the LE (UE is more spared)	Primary sensory area, medial aspect of cortex
Urinary incontinence	Posteromedial aspect of superior frontal gyrus
Problems with imitation and bimanual tasks, apraxia	Corpus callosum
Abulia (akinetic mutism), slowness, delay, lack of spontaneity, motor inaction	Uncertain localization
Contralateral grasp reflex, sucking reflex Can be asymptomatic if circle of Willis is competent.	Uncertain localization

LE = lower extremity; UE = upper extremity.

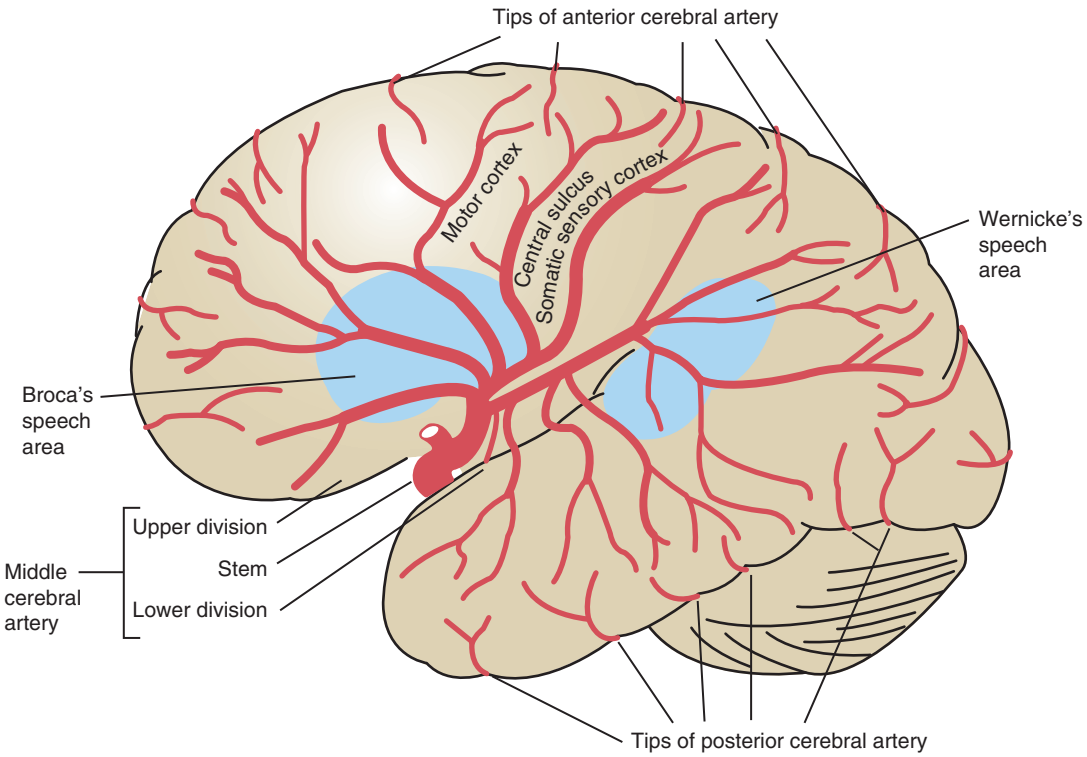

Figure 15.4 Cerebral circulation: diagram of a lateral view of the brain illustrates the distribution of the middle cerebral artery.

Table 15.2 Clinical Manifestations of Middle Cerebral Artery Syndrome

Signs and Symptoms	Structures Involved
Contralateral hemiparesis involving mainly the UE and face (LE is more spared)	Primary motor cortex and internal capsule
Contralateral hemisensory loss involving mainly the UE and face (LE is more spared)	Primary sensory cortex and internal capsule
Motor speech impairment: Broca's or nonfluent aphasia with limited vocabulary and slow, hesitant speech	Broca's cortical area (third frontal convolution) in the dominant hemisphere, typically the left hemisphere
Receptive speech impairment: Wernicke's or fluent aphasia with impaired auditory comprehension and fluent speech with normal rate and melody	Wernicke's cortical area (posterior portion of the temporal gyrus) in the dominant hemisphere, typically the left
Global aphasia: nonfluent speech with poor comprehension	Both third frontal convolution and posterior portion of the superior temporal gyrus
Perceptual deficits: unilateral neglect, depth perception, spatial relations, agnosia	Parietal sensory association cortex in the nondominant hemisphere, typically the right
Limb-kinetic apraxia	Premotor or parietal cortex
Contralateral homonymous hemianopsia	Optic radiation in internal capsule
Loss of conjugate gaze to the opposite side	Frontal eye fields or their descending tracts
Ataxia of contralateral limb(s) (sensory ataxia)	Parietal lobe
Pure motor hemiplegia (lacunar stroke)	Upper portion of posterior limb of internal capsule

LE = lower extremity; UE = upper extremity.

Table 15.3 Clinical Manifestations of Posterior Cerebral Artery Syndrome

Signs and Symptoms	Structures Involved
Peripheral Territory	
Contralateral homonymous hemianopsia	Primary visual cortex or optic radiation
Bilateral homonymous hemianopsia with some degree of macular sparing	Calcarine cortex (macular sparing is due to occipital pole receiving collateral blood supply from MCA)
Visual agnosia	Left occipital lobe
Prosopagnosia (difficulty naming people on sight)	Visual association cortex
Dyslexia (difficulty reading) without agraphia (difficulty writing), color naming (anomia), and color discrimination problems	Dominant calcarine lesion and posterior part of corpus callosum
Memory defect	Lesion of inferomedial portions of temporal lobe bilaterally or on the dominant side only
Topographic disorientation	Nondominant primary visual area, usually bilaterally
Central Territory	
Central post-stroke (thalamic) pain Spontaneous pain and dysesthesias; sensory impairments (all modalities)	Ventral posterolateral nucleus of thalamus
Involuntary movements; choreoathetosis, intention tremor, hemiballismus	Subthalamic nucleus or its pallidal connections
Contralateral hemiplegia	Cerebral peduncle of midbrain
Weber's syndrome Oculomotor nerve palsy and contralateral hemiplegia	Third nerve and cerebral peduncle of midbrain
Paresis of vertical eye movements, slight miosis and ptosis, and sluggish pupillary light response	Supranuclear fibers to third cranial nerve

LE = lower extremity; UE = upper extremity.

stroke is associated with involvement of the posterior limb of the internal capsule, pons, and pyramids. *Pure sensory lacunar stroke* is associated with involvement of the ventrolateral thalamus or thalamocortical projections. Other lacunar syndromes include *dysarthria/clumsy hand syndrome* (involving the base of the pons, genu of anterior limb, or the internal capsule), *ataxic hemiparesis* (involving the pons, genu of internal capsule, corona radiata, or cerebellum), *sensory/motor stroke* (involving the junction of the internal capsule and thalamus), or *dystonia/involuntary movements* (choreoathetosis with lacunar infarction of the putamen or globus pallidus; hemiballismus with involvement of the subthalamic nucleus). Deficits in consciousness, language, or visual fields are not seen in lacunar strokes because the higher cortical areas are preserved. A hypertensive hemorrhage affecting the thalamus can also produce central post-stroke pain.[12]

Vertebrobasilar Artery Syndrome

The *vertebral arteries* arise from the subclavian arteries and travel into the brain along the medulla where they merge at the inferior border of the pons to form the basilar artery. The vertebral arteries supply the cerebellum (via posterior inferior cerebellar arteries) and the medulla (via the medullary arteries). The basilar artery supplies the pons (via pontine arteries), the internal ear (via labyrinthine arteries), and the cerebellum (via the anterior inferior and superior cerebellar arteries). The basilar artery then terminates at the upper border of the pons giving rise to the two posterior arteries (see Fig. 15.2). Occlusions of the vertebrobasilar system can produce a wide variety of symptoms with both ipsilateral and contralateral signs, because some of the tracts in the brainstem will have crossed and others will not. Numerous cerebellar and cranial nerve abnormalities also are present. Table 15.4 presents the clinical manifestations of *vertebrobasilar artery syndromes*.

Locked-in syndrome (LIS) occurs with basilar artery thrombosis and bilateral infarction of the ventral pons. LIS is a catastrophic event with sudden onset. Patients develop acute hemiparesis rapidly progressing to tetraplegia and lower bulbar paralysis (CNs V through XII are involved). Initially the patient is dysarthric and dysphonic but rapidly progresses to mutism (anarthria). There is preserved consciousness and sensation. Thus the patient cannot move or speak but remains alert and oriented. Horizontal eye movements are impaired but

Table 15.4 Clinical Manifestations of Vertebrobasilar Artery Syndrome

Signs and Symptoms	Structures Involved
Medial medullary syndrome	Occlusion vertebral artery, medullary branch
Ipsilateral to lesion Paralysis with atrophy of half the tongue with deviation to the paralyzed side when tongue is protruded	CN XII, hypoglossal, or nucleus
Contralateral to lesion Paralysis of UE and LE	Corticospinal tract
Impaired tactile and proprioceptive sense	Medial lemniscus
Lateral medullary (Wallenburg's) syndrome	Occlusion of posterior inferior cerebellar artery or vertebral artery
Ipsilateral to lesion Decreased pain and temperature sensation in face	Descending tract and nucleus of CN V, trigeminal
Cerebellum or inferior cerebellar peduncle	Cerebellar ataxia: gait and limbs ataxia
Vertigo, nausea, vomiting	Vestibular nuclei and connections
Nystagmus	Vestibular nuclei and connections
Horner's syndrome: miosis, ptosis, decreased sweating	Descending sympathetic tract
Dysphagia and dysphonia: paralysis of palatal and laryngeal muscles, diminished gag reflex	CN IX, glossopharyngeal, and CN X, vagus, or nuclei
Sensory impairment of ipsilateral UE, trunk, or LE	Cuneate and gracile nuclei
Contralateral to lesion Impaired pain and thermal sense over 50% of body, sometimes face	Spinal lemniscus—spinothalamic tract
Complete basilar artery syndrome (locked-in syndrome)	Basilar artery, ventral pons
Tetraplegia (quadriplegia)	Corticospinal tracts bilaterally
Bilateral cranial nerve palsy: upward gaze is spared	Long tracts to cranial nerve nuclei bilaterally
Coma	Reticular activating system
Cognition is spared	
Medial inferior pontine syndrome	Occlusion of paramedian branch of basilar artery
Ipsilateral to lesion Paralysis of conjugate gaze to side of lesion (preservation of convergence)	Pontine center for lateral gaze paramedian pentine reticular formation (PPRF)
Nystagmus	Vestibular nuclei and connections
Ataxia of limbs and gait	Middle cerebellar peduncle
Diplopia on lateral gaze	CN VI, abducens, or nucleus
Contralateral to lesion Paresis of face, UE, and LE	Corticobulbar and corticospinal tract in lower pons
Impaired tactile and proprioceptive sense over 50% of the body	Medial lemniscus
Lateral inferior pontine syndrome	Occlusion of anterior inferior cerebellar artery, a branch of the basilar artery
Ipsilateral to lesion Horizontal and vertical nystagmus, vertigo, nausea, vomiting	CN VIII, vestibular, or nucleus
Facial paralysis	CN VII, facial, or nucleus
Paralysis of conjugate gaze to side of lesion	Pontine center for lateral gaze (PPRF)
Deafness, tinnitus	CN VIII, cochlear, or nucleus

Table 15.4 Clinical Manifestations of Vertebrobasilar Artery Syndrome—cont'd

Signs and Symptoms	Structures Involved
Ataxia	Middle cerebellar peduncle and cerebellar hemisphere
Impaired sensation over face	Main sensory nucleus and descending tract of fifth nerve
Contralateral to lesion Impaired pain and thermal sense over half the body (may include face)	Spinothalamic tract
Medial midpontine syndrome	Occlusion of paramedian branch of the mid-basilar artery
Ipsilateral to lesion Ataxia of limbs and gait (more prominent in bilateral involvement)	Middle cerebellar peduncle
Contralateral to lesion Paralysis of face, UE, and LE	Corticobulbar and corticospinal tract
Deviation of eyes	Abducent nerve nucleus, medial longitudinal fasciculus
Lateral midpontine syndrome	Occlusion of short circumferential artery
Ipsilateral to lesion Ataxia of limbs	Middle cerebellar peduncle
Paralysis of muscles of mastication	Motor fibers or nucleus of CN V, trigeminal
Impaired sensation over side of face	Sensory fibers or nucleus of CN V, trigeminal
Medial superior pontine syndrome	Occlusion of paramedian branches of upper basilar artery
Cerebellar ataxia	Superior or middle cerebellar peduncle
Internuclear ophthalmoplegia	Medial longitudinal fasciculus
Contralateral to lesion Paralysis of face, UE, and LE	Corticobulbar and corticospinal tract
Lateral superior pontine syndrome (occlusion of superior cerebellar artery, a branch of the basilar artery)	
Ipsilateral to lesion Cerebellar ataxia of limbs and gait, falling to side of lesion	Middle and superior cerebellar peduncles, superior surface of cerebellum, dentate nucleus
Dizziness, nausea, vomiting	Vestibular nuclei
Horizontal nystagmus	Vestibular nuclei
Paresis of conjugate gaze (ipsilateral)	Uncertain
Loss of optokinetic nystagmus	Uncertain
Horner's syndrome: miosis, ptosis, decreased sweating on opposite side face	Descending sympathetic fibers
Contralateral to lesion Impaired pain and thermal sense of face, limbs, and trunk	Spinothalamic tract
Impaired touch, vibration, and position sense, more in LE than UE (tendency to incongruity of pain and touch deficits)	Medial lemniscus (lateral portion)

CN = cranial nerve; LE = lower extremity; UE = upper extremity.

vertical eye movements and blinking remain intact. Communication can be established via these eye movements. Mortality rates are high (59%), and those patients who do survive are left with severe impairments associated with brainstem injury.[12]

Extracranial injuries to the vertebral arteries as they travel through the cervical spine can also produce vertebrobasilar signs and symptoms. Forceful neck motions (e.g., whiplash or aggressive neck manipulations) are among the more common types of injuries.

NEUROLOGICAL COMPLICATIONS AND ASSOCIATED CONDITIONS

Altered Consciousness

Altered level of consciousness (coma, decreased arousal levels) may occur with extensive brain damage (e.g., large proximal MCA occlusion). The *Glasgow Coma Scale* developed by Teasdale and Jennett[13] is the gold standard used to document level of coma (see Chapter 19, Traumatic Brain Injury). Three areas of function are examined: eye opening, best motor response, and verbal responses. The therapist should document levels of consciousness using standard descriptive terms: *normal, lethargy, obtundation, stupor*, and *coma* (see Chapter 5, Examination of Motor Function: Motor Control and Motor Learning). Since the patient's behaviors can be expected to fluctuate widely, frequent repeat observations are necessary.

Disorders of Speech and Language

Patients with lesions involving the cortex of the dominant hemisphere (typically the left hemisphere) demonstrate speech and language impairments. **Aphasia** is the general term used to describe an acquired communication disorder caused by brain damage and is characterized by an impairment of language comprehension, formulation, and use. Aphasia has been estimated to occur in 30% to 36% of all patients with stroke.[2] There are many different types of aphasias; major classification categories are fluent, nonfluent, and global. In **fluent aphasia (Wernicke's/sensory/receptive aphasia)**, speech flows smoothly with a variety of grammatical constructions and preserved melody of speech. Auditory comprehension is impaired. Thus, the patient demonstrates difficulty in comprehending spoken language and in following commands. The lesion is located in the auditory association cortex in the left lateral temporal lobe. In **nonfluent aphasia (Broca's/expressive aphasia)**, the flow of speech is slow and hesitant, vocabulary is limited, and syntax is impaired. Speech production is labored or lost completely whereas comprehension is good. The lesion is located in the premotor area of the left frontal lobe. **Global aphasia** is a severe aphasia characterized by marked impairments of both production and comprehension of language. It is often an indication of extensive brain damage. Severe problems in communication may limit the patient's ability to learn and often impede successful outcomes in rehabilitation. See Chapter 28, Neurogenic Disorders of Speech and Language, for a complete discussion of these impairments and their management.

Patients with stroke commonly present with **dysarthria** with a reported incidence ranging from 48% to 57%.[2] This term refers to a category of motor speech disorders caused by lesions in parts of the central or peripheral nervous system that mediate speech production. Respiration, articulation, phonation, resonance, and/or sensory feedback may be affected. The lesion can be located in the primary motor cortex in the frontal lobe, the primary sensory cortex in the parietal lobe, or the cerebellum. Volitional and automatic actions such as chewing and swallowing and movement of the jaw and tongue are impaired resulting in slurred speech. In patients with stroke, dysarthria can accompany aphasia, complicating the course of rehabilitation (see Chapter 28).

The patient's communication abilities should be fully ascertained before proceeding on with other examination procedures. It is not uncommon for family and staff to overestimate the patient's abilities to understand language, especially if the patient is cooperative. Close collaboration with the speech-language pathologist is important in making an accurate determination of the patient's communication impairments. Receptive language functions (auditory comprehension, reading comprehension) and expressive language function (word finding, fluency, writing) should be carefully examined. Neuromotor disorders (dysarthria) need to be clearly differentiated from aphasia. If communication is severely limited and alternate forms are required (gestures, demonstration, communication boards), therapists should be fully knowledgeable of such methods before the physical therapy examination.

Dysphagia

Dysphagia, an inability to swallow or difficulty in swallowing, occurs in about 51% of patients with stroke. It can be seen in hemispheric stroke, brainstem stroke, or pseudobulbar and suprabulbar palsy. In brainstem stroke, the reported incidence is as high as 81%. Cranial nerve involvement results in swallowing dysfunction of the oral stage (CN V [trigeminal], CN VII [facial]), the pharyngeal stage (CN IX [glossopharyngeal], CN X [vagus], and CN XI [accessory]), or oral and pharyngeal (CN XII [hypoglossal]). Dysphagia is also common in patients with multiple strokes. The most common problems seen in patients with dysphagia include delayed triggering of the swallowing reflex, reduced pharyngeal peristalsis, and reduced lingual control. Altered mental status, altered sensation, poor jaw and lip closure, impaired head control, and poor sitting posture also contribute to the patient's swallowing difficulties. Most patients demonstrate multiple problems that can include drooling, difficulty ingesting food, compromised nutritional status, and dehydration. **Aspiration**, the penetration of food, liquid, saliva, or gastric reflux into the airway, occurs in about one-third of patients with dysphagia. Aspiration is an important complication in that it can lead to acute respiratory distress within hours, aspiration pneumonia, and, if left untreated, death. Dysphagia can also lead to dehydration and compromised nutrition.[14,15]

A referral to a dysphagia specialist or multidisciplinary dysphagia team is indicated. Team members typically

include the physician, nurse, occupational therapist, speech-language pathologist, and dietitian. Clinical evaluation of dysphagia includes an examination of oral-motor function, pharyngeal function, functional status (e.g., upright sitting position, use of adaptive feeding equipment), examination of abnormal reflexes, and a feeding trial. Instrumental testing can include a *modified barium swallow* (MBS), *videofluoroscopic evaluation of swallowing*, and a *fiberoptic endoscopic evaluation of swallowing* (FEES).[16] If dysphagia is severe enough, patients may be placed on nothing-by-mouth (NPO) precautions. The use of tube feeding, either a nasogastric (NG) tube for short periods of time or an invasive gastrostomy (G) tube for more long-term care, is required. Nutrition can also be provided through an intravenous route (total parenteral nutrition [TPN]).

Cognitive Dysfunction

Cognitive dysfunction may be present with lesions involving the cortex and includes impairments in alertness, attention, orientation, memory, or executive functions. Premorbid changes associated with pathological aging may also account for some of the dysfunction noted and should be carefully determined from interviews with family, significant others, or caregivers. The patient with acute stroke may be largely unaware of what is going on in the external environment, a problem of impaired alertness that results from lesions in the prefrontal cortex and reticular formation. The patient may also be disoriented and unable to provide information about self, time of day, physical or geographical location, or disability, the result of lesions affecting the prefrontal cortex, limbic system, and limbic cortex. *Attention* is the ability to select and attend to a specific stimulus while simultaneously suppressing extraneous stimuli. Attention disorders include impairments in sustained attention, selective attention, divided attention, or alternating attention. Altered attention results from lesions in the prefrontal cortex and reticular formation. *Memory* is defined as the ability to store experiences and perceptions for later recall. Immediate and short-term memory impairments are common, occurring in about 36% of patients with stroke, whereas long-term memory typically remains intact.[2] Thus, the patient cannot remember the instructions for a new task given only minutes or hours ago but can easily remember events 30 years ago. Short-term memory loss is associated with lesions of the limbic system, limbic association cortex (orbitofrontal areas), or temporal lobes. Long-term memory loss is associated with lesions of the hippocampus of the limbic system. Memory gaps may be filled with inappropriate words or fabricated stories, an impairment termed *confabulation* that also results from lesions in the prefrontal cortex. The patient may be confused, demonstrating disorientation and an inability to understand the specific context of a conversation. *Confusion* is the result of disruption of the prefrontal cortex. *Perseveration* is the continued repetition of words, thoughts, or acts not related to current context. Thus, the patient gets "stuck" and repeats words or acts without much success at stopping. Preservation results from lesions in the premotor and/or prefrontal cortex.

Executive functions, defined as those abilities that enable a person to engage in purposeful behaviors, include volition, planning, purposeful action, and effective performance. Patients with lesions of the prefrontal cortex typically demonstrate impairments in executive function including some or all of the following: impulsiveness, inflexible thinking, lack of abstract thinking, impaired organization and sequencing, decreased insight, impaired planning ability, and impaired judgment. Patients are unable to realistically appraise their environment and the people and events in it. They also demonstrate difficulty in self-monitoring and self-correcting behaviors, thereby posing safety risks.[17,18] (See Chapter 27, Cognitive and Perceptual Dysfunction, for a complete discussion of these impairments and their management.)

Multi-infarct dementia (vascular dementia) results from multiple small infarcts of the brain and is seen in 6% to 32% of patients. It is more common in individuals over age 60 and is associated with episodes of cerebral ischemia (microvascular or small vessel disease) and hypertension. Other contributing factors include arrhythmias, myocardial infarct, TIAs, diabetes, obesity, and smoking. Scattered areas of the brain are involved, evidenced by focal neurological deficits. Onset is frequently abrupt. The patient exhibits impairments in memory and cognition and may fluctuate between periods of impaired function and periods of improved function. This stepwise and paroxysmal deterioration of intellectual function is in contrast to the gradual onset and steadier, widespread decline seen in Alzheimer's dementia.[17]

Delirium, also known as *acute confusional state*, is seen more commonly in the acute care setting and results from a number of factors following acute stroke. Deprivation of oxygen to the brain, metabolic imbalance, or adverse drug reactions can all induce confusion. Additional contributory factors can include sensory and perceptual losses coupled with an unfamiliar hospital environment and inactivity. Delirium is characterized by a clouding of consciousness or dulling of cognitive processes and impaired alertness. Thus, the patient is inattentive, incoherent, and disorganized with fluctuating levels of consciousness. Hallucinations and agitation are also common. Nighttime may be particularly problematic. Patients with significant sensory loss following stroke may experience sensory deprivation problems evidenced by irritability, confusion, psychosis, delusions, and even hallucinations. These problems are more frequently seen in the acute phase, especially with patients who have been confined to a bed or whose bed is positioned to limit social interaction (e.g., with the more

involved side toward the door). Some patients are equally unable to deal with a sensory overload, produced by too much stimulation. Altered arousal levels are implicated.

It is important to examine cognitive abilities early because they may affect the validity of other tests and measures. An examination of orientation (to person, place, time, and circumstance [e.g., awareness of event causing need for medical care]), attention (selective, sustained, alternating, divided), memory (immediate, short- and long-term), and ability to follow instructions (one-, two-, and three-level commands) can be made from observations of the patient's interactions and responses to specific questions. Higher cortical functions can be examined using tests of simple arithmetic and abstract reasoning (grasp of information, abstract thinking and problem solving, calculating ability, constructional ability). The *Mini-Mental Status Examination (MMSE)* provides a valid and reliable quick screen of cognitive function.[19] A determination of learning impairments (retention and generalization) usually requires repeat sessions with the patient before a complete picture can be ascertained. Difficulties arise in reaching an accurate determination of cognition when the patient presents with impairments in communication or perception. Close collaboration with the occupational therapist, speech-language pathologist, and the rest of team is essential.

Altered Emotional Status

Lesions of the brain affecting the frontal lobe, hypothalamus, and limbic system can produce a number of emotional changes. The patient with stroke may demonstrate **pseudobulbar affect** (PBA), also known as *emotional lability* or *emotional dysregulation syndrome*. PBA occurs in about 18% of cases and is characterized by emotional outbursts of uncontrolled or exaggerated laughing or crying that are inconsistent with mood. The patient quickly changes from laughing to crying with only slight provocation. The patient is typically unable to control these episodes or to inhibit the expression of spontaneous emotions. Frequent crying may also accompany depression. *Apathy* occurs in about 22% of cases and is characterized by a shallow affect and blunted emotional responses. In such patients, apathy is frequently misconstrued as depression or poor motivation. Patients can also demonstrate *euphoria* (exaggerated feelings of well-being), increased levels of irritability or frustration, and social inappropriateness. Changes in the ability to sense, move, communicate, think, or act as before are enormously frustrating by themselves and create high stress levels for the patient with stroke. Increased levels of anxiety, irritability, and frustration are the natural outcomes of high stress levels. These behaviors along with a poor perception of one's self and environment may lead to increasing isolation and social withdrawal.[18]

Depression is common, occurring in approximately 35% of stroke cases.[18] It is characterized by persistent feelings of sadness accompanied by feelings of hopelessness, worthlessness, and/or helplessness. Depressed patients may also experience a loss of energy or persistent fatigue, an inability to concentrate, and decreased interest in daily life along with changes in weight and sleep patterns, generalized anxiety, and recurrent thoughts of death or suicide. Depression is seen with lesions in the left frontal lobe (acute stage) and with lesions in the right parietal lobes (subacute stage).[20] Most patients remain significantly depressed for many months, with an average time of 7 to 8 months. The period from 6 months to 2 years after a CVA is the most likely time for depression to occur.[21] Depression occurs in both mildly and severely involved patients and thus is not significantly related to the degree of motor impairment. Patients with lesions of the left hemisphere may experience more frequent and more severe depression than patients with right hemisphere or brainstem strokes. These findings suggest that post-stroke depression is not simply a result of psychological reaction to disability but rather a direct impairment of the CVA.[22] Anxiety can coexist with depression during any phase of recovery.[20] Prolonged post-stroke depression can interfere with the success of rehabilitation and result in poorer long-term functional outcomes. The reader is referred to Chapter 26, Psychosocial Disorders, for a more complete discussion of psychosocial impairments and their management.

Hemispheric Behavioral Differences

Individuals with stroke differ widely in their approach to processing information and in their behaviors. Those with *left hemisphere lesions* (right hemiplegia) demonstrate difficulties in communication and in processing information in a sequential, linear manner. They are frequently described as cautious, anxious, and disorganized. This makes them more hesitant when trying new tasks and increases the need for feedback and support. They tend, however, to be realistic in their appraisal of their existing problems. Individuals with *right hemisphere lesions* (left hemiplegia), on the other hand, demonstrate difficulty in spatial–perceptual tasks and in grasping the whole idea of a task or activity. They are frequently described as quick and impulsive. They tend to overestimate their abilities while acting unaware of their deficits. This lack of insight and concreteness impairs the patient's ability to participate in rehabilitation. Safety is a far greater issue for patients with left hemiplegia, where poor judgment is common. These patients also require a great deal of feedback when learning a new task. The feedback should be focused on slowing down the activity, checking sequential steps, and relating them to the whole task. Patients also need help recognizing the consequences and risks of their actions. The patient with left hemiplegia frequently cannot attend to visuospatial cues effectively, especially in a cluttered or crowded environment. Table 15.5 summarizes the behavioral differences attributed to damage of the left and right hemispheres.

Table 15.5 Hemispheric Differences Commonly Seen Following Stroke

Right Hemisphere Lesion	Left Hemisphere Lesion
Left-side hemiplegia/paresis	Right-side hemiplegia/paresis
Left-side sensory loss	Right-side sensory loss
Visual–perceptual impairments: Left-side unilateral neglect Agnosias Visuospatial disorders Disturbances of body image and body scheme Difficulty processing visual cues	***Speech and language impairments:*** Dominant hemisphere: • Nonfluent (Broca's) aphasia • Fluent (Wernicke's) aphasia • Global aphasia Difficulty processing verbal cues, verbal commands
Behavioral deficits: Quick, impulsive behavioral style Poor judgment, unrealistic Inability to self-correct Poor insight, awareness of impairments, denial of disability Increased safety risk	***Behavioral deficits:*** Slow, cautious behavioral style Disorganized Often very aware of impairments, extent of disability
Intellectual deficits: Difficulty with abstract reasoning, problem solving Difficulty synthesizing information and grasping whole idea of task Rigidity of thought Memory impairments, typically related to spatial-perceptual information	***Intellectual deficits:*** Disorganized problem solving Difficulty initiating tasks, processing delays Highly distractible Memory impairments, typically related to language Perseveration
Emotional deficits: Difficulty with ability to perceive emotions	***Emotional deficits:*** Difficulty with expression of positive emotions
Difficulty with expression of negative emotions	
Task performance: Fluctuations in performance	***Task performance:*** Apraxia common: difficulty planning and sequencing movements • Ideational • Ideomotor
Deficits of either hemisphere depending on lesion location: Visual field defects: Homonymous hemianopsia Emotional abnormalities: Lability, apathy, irritability, low frustration levels, anxiety, depression Cognitive deficits: Confusion, short attention span, loss of memory, executive functions	

Emotional states and behavioral styles can best be examined through observation of the patient in a variety of situations over a number of sessions. It is important to correlate findings with those reported by other team members and by the family regarding premorbid behaviors and emotional characteristics. Families who report a "personality change" after stroke are likely responding to presenting emotional impairments and disinhibition. Episodes of euphoria and crying should be carefully documented and links to situational or environmental circumstances explored. Duration and frequency of these episodes should also be documented along with strategies that are successful in bringing about an end to the episode (redirecting strategies). The patient's response to new or stressful situations should also be carefully observed for evidence of anxiety (e.g., excessive worrying, restlessness, irritability). The therapist should examine for evidence of depression. Depressed patients can also be irritable, angry, or hostile and wish to be left alone.[18] The *Beck Depression Inventory*[23] is a useful instrument for depression screening. It consists of 21 statements that are scored on a scale from 0 to 3 (the short version has 13 questions and takes 5 minutes to complete).

Perceptual Dysfunction

Stroke can produce visual–perceptual deficits, with a reported incidence ranging from 32% to 41%.[2] They are frequently the result of lesions in the right parietal cortex and seen more with left hemiplegia than right. These may include disorders of **body scheme/body image, spatial relations,** and **agnosias**. Body scheme refers to a postural model of the body including the relationship of the body parts to each other and the relationship of the body to the environment. Body

image is the visual and mental image of one's body that includes feelings about one's body. Both may be distorted following stroke. Specific impairments of body scheme/body image include **unilateral neglect, anosognosia, somatoagnosia, right–left discrimination, finger agnosia,** and **anosognosia**. Spatial relations syndrome refers to a constellation of impairments that have in common a difficulty in perceiving the relationship between the self and two or more objects in the environment. It includes specific impairments in **figure–ground discrimination, form discrimination, spatial relations, position in space,** and **topographical disorientation**. Agnosia is the inability to recognize incoming information despite intact sensory capacities. Agnosias can include visual object agnosia, auditory agnosia, or tactile agnosia (astereognosis). Significant information on sensory and perceptual deficits will be gained by close collaboration with the occupational therapist. The reader is referred to Chapter 27, Cognitive and Perceptual Dysfunction, for a more complete discussion of these deficits and their management.

Because the patient with left hemiplegia may behave in ways that tend to minimize his or her disabilities, it is easy for staff to overestimate the patient's perceptual abilities. For the patient with visuospatial deficits, the use of gestures or visual cues may decrease this patient's ability to perform tasks, whereas verbal cues may increase chances for success. Equally important strategies include carefully structuring the environment to minimize clutter and activity, provide adequate lighting, and provide clear boundaries and reference points.

Problems in **unilateral neglect** (lack of awareness of part of the body or the external environment) will limit movement and use of the more involved extremities (usually the nondominant left side). The patient typically does not react to sensory stimuli (visual, auditory, or somatosensory) presented on the more involved side. Careful observation of spontaneous use of affected limbs, as well as specific responses to inquiries for movement on or toward the hemiplegic side, will provide important information about neglect. Persistent neglect may result in bruising or trauma to the hemiplegic limbs during activity and negatively affect rehabilitation outcomes.

Seizures

Seizures occur in a small percentage of patients with stroke and are slightly more common in occlusive carotid disease (17%) than in MCA disease (11%). Seizures are common right after stroke during the acute phase (e.g., in about 15% of cases with cerebral hemorrhage); late-onset seizures can also occur several months after stroke. They tend to be of the partial motor type. Seizures are potentially life threatening if not controlled. Anticonvulsant medications may be indicated (e.g., phenytoin [Dilantin], carbamazepine [Tegretol], phenobarbital [Solfoton]).[2]

Bladder and Bowel Dysfunction

Disturbances of bladder function are common during the acute phase, occurring in about 29% of cases.[2] Urinary incontinence can result from bladder hyperreflexia or hyporeflexia, disturbances of sphincter control, and/or sensory loss. A toileting schedule for prompted voiding is often implemented to reduce the incidence of incontinence and to accommodate for factors that cause functional incontinence such as inattention, mental status changes, or immobility. Generally, this problem improves quickly. Persistent incontinence is often due to a treatable medical condition (e.g., urinary tract infection). Absorbent pads and special undergarments or external collection devices may be used if incontinence proves refractory. Urinary retention can be controlled pharmacologically and with intermittent or indwelling catheterization. Early treatment is desirable to prevent further complications such as chronic urinary tract infection and skin breakdown. Patients who are incontinent often suffer embarrassment, isolation, and depression. Persistent incontinence is associated with a poor long-term prognosis for functional recovery.

Disturbances of bowel function can include incontinence and diarrhea or constipation and impaction. Patients who are constipated may require stool softeners and dietary/fluid modifications and medications to resolve this problem. Physical activity is also helpful.

Cardiovascular and Pulmonary Dysfunction

The majority of strokes are caused by vascular disease. Patients who suffer a stroke as a result of underlying coronary artery disease (CAD) may demonstrate impaired cardiac output, cardiac decompensation, and serious rhythm disorders. If these problems persist, they can directly alter cerebral perfusion and produce additional focal signs (e.g., mental confusion). Patients with stroke typically exhibit low peak VO_2 levels during exercise (about half of that achieved by age-matched healthy individuals).[24] These vary according to age, level of disability, number and severity of co-morbidities, secondary complications, and medications. Cardiac limitations in exercise tolerance may restrict rehabilitation potential and requires diligent monitoring and careful exercise prescription by the physical therapist.

Many patients with stroke are significantly deconditioned and exhibit low work capacities, the result of acute illness, bed rest, and limited activity levels. Some individuals may have been inactive before the stroke. Changes in the cardiovascular system associated with deconditioning include reduced cardiac output, decreased maximal heart rate, increased resting and exercise blood pressures, decreased maximal oxygen uptake, and decreased vital capacity. Changes in the musculoskeletal system (e.g., decreased muscle mass and strength, decreased bone mass, decreased flexibility) and decreased

glucose tolerance also affect exercise tolerance and endurance levels. Decreased activity levels may also be related to depression, a common finding in stroke.

Pulmonary function is often impaired in individuals with stroke. Decreased lung volume, decreased pulmonary perfusion and vital capacity, and altered chest wall excursion are all common findings. The decreased respiratory output is accompanied by increased oxygen demands required during activity using altered and unfamiliar movement patterns. For example, walking using an orthosis and assistive device dramatically increases the energy demands of the activity. The end result for the patient with stroke is increased fatigue and decreased endurance.

Deep Venous Thrombosis and Pulmonary Embolus

Deep venous thrombosis (DVT) and pulmonary embolus (PE) are potential complications for all immobilized patients. The incidence of DVT in patients with stroke is as high as 47% with an estimated 10% of deaths attributed to PE.[2] The dangers are particularly high during the acute phase when venous stasis from immobility and prolonged bed rest, limb paralysis, hemineglect, and reduced cognitive status significantly elevate the risk. About 50% of cases do not present with clinically detectable symptoms and can be identified only by Doppler duplex ultrasonography (the gold standard for rapid screening), radiocontrast venography, or impedance plethysmography. Patients with symptoms may report calf pain and tenderness, or a tight feeling in the calf. Swelling can vary from minimal to high and typically affects the foot and ankle. Prompt diagnosis and treatment of acute DVT are necessary to reduce the risk of fatal PE. About half of patients at time of diagnosis of DVT have already had a PE. Signs and symptoms of PE include chest pain, tachypnea, tachycardia, anxiety, restlessness, and apprehension together with persistent cough. About 10% to 15% of patients with PE will die. Symptomatic treatment of DVT consists of continuous infusion or subcutaneous injections of low-molecular-weight heparin (LMWH) followed by long-term oral anticoagulants (warfarin [Coumadin]). Bed rest is instituted (up to 24 hours) until anticoagulation from medications takes effect. The patient is then mobilized out of bed and will wear compression stockings. In select cases, surgical removal of the thrombus or placement of intracaval filters is undertaken. Treatment of PE involves supplemental oxygen or intubation in severe cases, anticoagulants, and thrombolytic drugs and, in some cases, surgical intervention. Primary prevention of DVT and PE involves prophylactic administration of anticoagulants, exercising the legs to improve blood flow, early mobilization, and use of elastic support stockings.[25]

Osteoporosis and Fracture Risk

Osteoporosis, a bone disease characterized by a loss of bone mass per unit volume, is common in the elderly and results from decreased physical activity, changes in protein nutrition, hormonal deficiency, and calcium deficiency. Patients with stroke who are immobilized and restricted in weight-bearing demonstrate increased risk of osteoporosis and disuse muscle atrophy. Fall risk is also increased with incidence rates ranging between 23% and 50% for individuals with chronic stroke.[26] Risk of falls in patients with stroke is multifactorial, arising from sensorimotor deficits, impaired balance, confusion, attention deficits, perceptual deficits, visual impairments, behavioral impulsivity, depression, and communication problems.[27-29] Increased risk of fracture, especially vertebral and hip fracture, is the natural outcome of osteoporosis and falls. In patients with stroke, osteoporosis and hip fracture are more likely on the more involved side.[30]

MEDICAL DIAGNOSIS OF STROKE

History and Examination

An accurate history profiling the timing of neurological events is obtained from the patient or from family members in the case of the unconscious or noncommunicative patient. Of particular importance are the exact time and pattern of symptom onset. An abrupt onset with worsening symptoms and decreasing level of consciousness is suggestive of cerebral hemorrhage. Severe headache described as "the worst headache of my life" is suggestive of subarachnoid hemorrhage. An embolus also occurs rapidly, with no warning, and is frequently associated with heart disease and/or heart complications. A more variable and uneven onset is typical with thrombosis. The patient's past history, including episodes of TIAs or head trauma, presence of major or minor risk factors, and medications, pertinent family history, and any recent alterations in patient function (either transient or permanent) are thoroughly investigated.[31] Stroke can mimic a number of other conditions that must be ruled out, including seizures, space-occupying lesions (e.g., subdural hematoma, cerebral abscess/infection, tumor), syncope, somatization, and delirium secondary to sepsis.[32]

The physical examination of the patient includes an investigation of vital signs (heart rate, respiratory rate, blood pressure), signs of cardiac decompensation, and function of the cerebral hemispheres, cerebellum, cranial nerves, eyes, and sensorimotor system. The presenting symptoms will help to determine the location of the lesion, and comparison of both sides of the body will reveal the side of the lesion. Bilateral signs are suggestive of brainstem lesions or massive cerebral involvement.[31]

Tests and Measures

The *National Institutes of Health Stroke Scale (NIHSS)* is a valuable screening tool that focuses on initial and serial examination of impairments following acute

stroke. The scale includes 11 items and uses a variable ordinal scale. Some items are scored 0–2 or 0–3 (level of consciousness, best gaze, visual fields, facial palsy, limb ataxia, sensory, best language, dysarthria, extinction, and inattention); other items are scored 0–4 (motor arm and motor leg). Specific descriptors are attached to each score. It was designed to be completed in 5 to 8 minutes. (The NIHSS is available at www.ninds.nih.gov/doctors/NIH_Stroke_Scale.pdf.)[33] An examination scoring service for the NIHSS is maintained by the National Stroke Association. The NIHSS has been used to discriminate between stroke subtypes.[34-36]

A number of biomarkers can be used to help identify acute cerebral ischemia. These include inflammatory mediators such as IL-6, matrix metalloproteinase [MMP-9], markers of glial activation, and so forth. Biomarker assays may play an increasing role in the diagnosis of acute stroke as more research becomes available.[32]

A standardized set of blood analyses is performed, including hematological studies, serum electrolyte levels, and renal and hepatic tests. These tests are used to rule out metabolic abnormalities, as well as blood, kidney, or liver conditions.

Cerebrovascular Imaging

Cerebrovascular imaging is the main tool to establish the diagnosis of suspected ischemic stroke and to rule out hemorrhagic stroke and other types of central nervous system (CNS) lesions (e.g., tumor or abscess). Advanced neuroimaging can rapidly identify the occluded artery and estimate the size of the core and the penumbra. It is also used to guide ischemic stroke therapy. Lack of imaging use is high in acute stroke primarily because many patients arrive beyond the strict 3-hour time window.[37]

Computed Tomography

Computed tomography (CT) scan is the most commonly used and readily available neuroimaging technique. CT resolution allows identification of large arteries and veins and venous sinuses. It demonstrates poor sensitivity for detecting small infarcts and infarction in the posterior fossa. Many times CT scans during the acute phase are negative with no clear evidence of abnormalities. However, acute bleeding and hemorrhagic transformation are visible on CT scanning (Fig. 15.5). In the subacute phase, CT scans can delineate the development of cerebral edema (within 3 days), which then fades over the next 2 to 3 weeks. Cerebral infarction (within 3 to 5 days) is visible with the addition of contrast material by showing areas of decreased density. Long-term parenchymal changes consistent with scar formation are also visible on CT. It is important to remember that the extent of CT lesion does not necessarily correlate with clinical signs or changes in function.

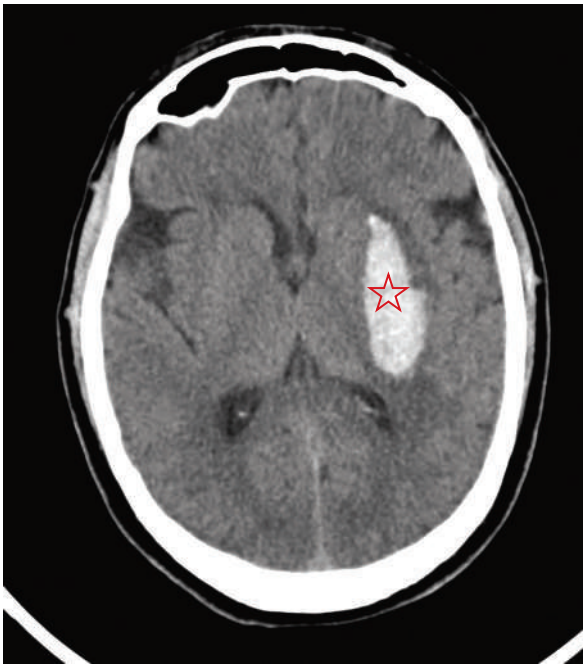

Figure 15.5 CT demonstrating an acute intracerebral hemorrhage (star). *(From Weber, E, Vilensky, J, and Fog, A: Practical Radiology: A Symptom-Based Approach. FA Davis, Philadelphia, 2013, with permission.)*

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has evolved to become the first-line imaging in some stroke centers, whereas in other facilities it is used when CT has not provided clear evidence of lesion location. MRI measures nuclear particles as they interact with a powerful magnetic field. MRI, especially diffusion/perfusion MRI, shows greater resolution of the brain and its structural detail than with a CT scan (Fig. 15.6). MRI is more sensitive in the diagnosis of acute strokes, allowing detection of cerebral ischemia as early as 30 minutes after vascular occlusion and infarction within 2 to 6 hours. It is also able to detail the extent of infarction or hemorrhage and can detect smaller lesions than a CT scan. Use of contrast enhancement allows documentation of changes in an infarct over the first 2 to 3 weeks. MRI scans cannot be performed on individuals with certain implantable devices (e.g., pacemakers) or with patients who are claustrophobic.[37]

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) is a type of magnetic resonance image that uses special software to create an image of the arteries in the brain. It is used to identify vascular abnormalities (e.g., stenosis), and alterations in blood flow as a result of embolus or thrombosis. It provides similar information as classical angiography (x-ray of blood vessels following dye injection) with increased sensitivity of detection and with lowered risks.[37]

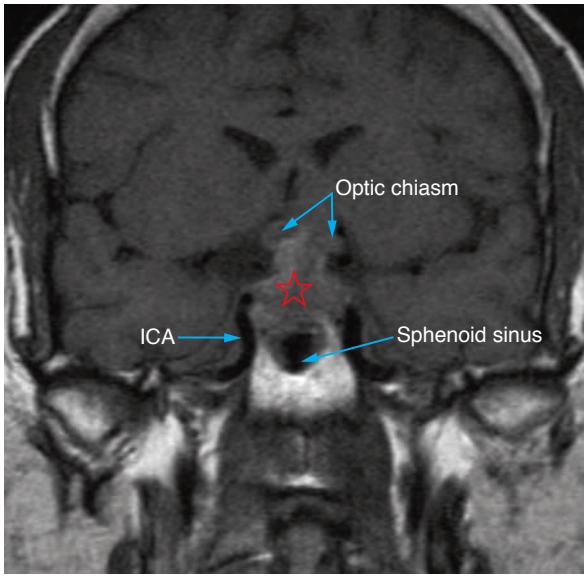

Figure 15.6 Coronal MRI without contrast enhancement on a pregnant patient with headache and visual field defect. The T1 hyperintensity of the greatly enlarged pituitary (star) indicates subacute hemorrhage. ICA = internal carotid artery. *(From Weber, E, Vilensky, J, and Fog, A: Practical Radiology: A Symptom-Based Approach. FA Davis, Philadelphia, 2013, with permission.)*

Doppler Ultrasound

Doppler ultrasound imaging is a noninvasive technique that sends sound waves into the body. Echoes bounce off the moving blood and artery and are formed into an image. Diagnostically, transcranial Doppler is used to examine the posterior circulation of the brain (the vertebrobasilar system). Carotid Doppler is used to examine the carotid arteries and typically precedes carotid endarterectomy. It is also used to examine the peripheral arteries in the diagnosis of PAD.

Arteriography and Digital Subtraction Angiography

Arteriography is an x-ray of the carotid artery with a special dye injected into an artery in the leg or arm. Digital subtraction angiography DSA is also an x-ray of the carotid artery with less dye used. These procedures are considered invasive and carry a small risk of causing a stroke.

MEDICAL, PHARMACOLOGICAL, AND NEUROSURGICAL MANAGEMENT OF STROKE

Medical Management

Medical management of completed stroke includes strategies to achieve the following:

- Improve cerebral perfusion by reestablishing circulation and oxygenation and assist in stopping progression of the lesion to limit deficits. Oxygen is delivered via mask or nasal cannula. Patients in a coma may require intubation or assisted ventilation and suctioning.
- Maintain adequate blood pressure. Hypotension or extreme hypertension is treated; antihypertension agents have the added risk of inducing hypotension and decreasing cerebral perfusion.
- Maintain sufficient cardiac output. If the causes of stroke are cardiac in origin, medical management focuses on control of arrhythmias and cardiac decompensation.
- Restore/maintain fluid and electrolyte balance.
- Maintain blood glucose levels within the normal range.
- Control seizures and infections.
- Control edema, intracranial pressure, and herniation using antiedema agents. Ventriculostomy may be indicated to monitor and drain cerebrospinal fluid.
- Maintain bowel and bladder function, which may include urinary catheter. Catheterization is typically short-term but may be long-term with the patient in coma.
- Maintain integrity of skin and joints by instituting protective positioning, a turning schedule every 2 hours, and early physical and occupational therapy.
- Decrease the risk of complications such as DVT, aspiration, decubitus ulcers, and so forth.

Pharmacological Management

Pharmacological interventions for completed stroke and its co-morbidities are summarized in Box 15.2.[38,39]

Neurosurgical Management

Neurosurgical interventions may include the following:[40]

- In hemorrhagic stroke, surgery may be indicated to repair a superficial ruptured aneurysm or AVM, prevent rebleeding, and evacuate a clot (hematoma). Larger, deeper intracranial or brainstem vascular lesions are generally not amenable to surgery. Surgery may also be indicated for resection of a superficial unruptured AVM when there is high risk of rupture and stroke.
- Patients who are not eligible for tPA or who do not respond to tPA may be candidates for surgical intervention using the Merci® Retriever System. This device is threaded via a catheter into a large artery just beyond the site of occlusion. It uses a tiny corkscrew-shaped device that wraps around and traps the clot. The clot is then retrieved and slowly removed from the artery. Blood flow is successfully restored. This system is not effective for smaller arteries and more distant locations.
- The Penumbra System® uses a catheter and separator that is threaded to the site of the clot. It suctions and grabs the clot and aspirates the site. This system can be used effectively within an 8-hour window of symptom onset.

Box 15.2 Medications Commonly Used to Treat Patients with Stroke[38,39]

- ***Thrombolytics*** (Alteplase [Activase or tPA]): Converts plasminogen to plasmin, degrades fibrin present in clots, dissolves clots and reestablishes blood flow (e.g., lysis of thrombi causing ischemic stroke; also to dissolve clots in coronary arteries, pulmonary emboli, deep vein thrombosis).
  Possible adverse effects: The most common complication is bleeding and brain hemorrhage.
- ***Anticoagulants*** (e.g., warfarin [Coumadin], heparin, dabigatran etexilate [Pradaxa]): Used to reduce the risk of blood clots and prevent existing clots from getting bigger by thinning the blood; indications include DVT prophylaxis, stroke prevention, peripheral vascular disease. With Coumadin, clotting times are closely monitored. Heparin is given intravenously and is faster acting.
  Possible adverse effects: Increased risk of bleeding and hemorrhage, hematomas.
- ***Antiplatelet therapy*** (e.g., acetylsalicylic acid [aspirin]; clopidogrel bisulfate [Plavix]; dabigatran etexilate [Pradaxa]; ticlopidine hydrochloride [Ticlid]): Prevent platelets (blood cells) from sticking together; long-term, low-dose is used to decrease the risk of thrombosis and recurrent stroke; higher doses may be used in place of anticoagulants and may be recommended for patients with atrial fibrillation.
  Possible adverse effects: Increased risk of gastric ulcers and bleeding.
- ***Antihypertensive agents*** (e.g., ACE inhibitors, alpha-blockers [Minipress], beta-blockers, calcium channel blockers, direct vasodilators, diuretics, postganglionic neuron inhibitors): Used to control hypertension.
  Possible adverse effects: Dizziness, hypotension, among other symptoms.
- ***Angiotensin II receptor antagonists*** (telmisartan [Micardis], losartan potassium [Cozaar]): Block angiotensin II, a chemical that triggers muscle contraction around blood vessels, narrowing them; enlarges blood vessels and reduces blood pressure.
  Possible adverse effects: Dizziness, hypotension, among other symptoms.
- ***Anticholesterol agents/statins*** (atorvastatin calcium [Lipitor], rosuvastatin calcium [Crestor], Zocor, Mevacor, Lescol): Lower cholesterol by inhibiting the enzyme in the blood that produces cholesterol in the liver; for management of hypercholesterolemia and mixed dyslipidemias.
  Possible adverse effects: Dizziness, headache, insomnia, weakness.
- ***Antispasmodics/spasmolytics*** (e.g., carisoprodol [Soma], chlorzoaxazone [Parafon Forte], cyclobenzaprine [Flexeril], diazepam [Valiu], methocarbamol [Robaxin], orphenadrine [Norflex/Norgesic]): Used to relax skeletal muscle and decrease muscle spasm.
  Possible adverse effects: May cause drowsiness, dizziness, dry mouth, among other symptoms.
- ***Antispastics*** (e.g., baclofen [Lioresal], dantrolene sodium [Dantrium], diazepam [Valium], tizanidine [Zanaflex]): Used to relax skeletal muscle and decrease muscle spasm.
  Possible adverse effects: May cause drowsiness, dizziness, confusion, weakness, among other symptoms.
- ***Anticonvulsants*** (e.g., carbamazepine [Tegretol], clonazepam [Klonopin], diazepam [Valium], phenobarbital [Luminal], phenytoin [Dilantin]): Used to control seizures; act as a generalized CNS depressant.
  Possible adverse effects: May cause drowsiness, ataxia, sedation, among other symptoms.
- ***Antidepressants*** (e.g., fluoxetine [Prozac], monoamine oxidase inhibitors, sertraline [Zoloft], tricyclics [Amitriptyline]): Used to control depression.
  Possible adverse effects: May cause anxiety, tremor, insomnia, nausea.

- Carotid endarterectomy is a surgical procedure used to remove fatty deposits from the carotid artery. It is a useful procedure to prevent recurrent strokes or the development of stroke in individuals with TIAs. Stenosis of 60% to 99% is the typical guideline used when surgery is considered and can reduce stroke risk by as much as 55%. It cannot be performed with acute stroke because altered pressures could subject ischemic areas to further damage.

FRAMEWORK FOR REHABILITATION

Rehabilitation has an important role in reducing disability and promoting independence. In addition, known complications of stroke can be reduced or prevented while quality of life is promoted. Optimal management involves a coordinated interdisciplinary team to oversee a *comprehensive plan of care* (POC). The team of rehabilitation specialists includes the physician, nurse, physical therapist, occupational therapist, speech-language pathologist, and social worker. Additional disciplines may include a neuropsychologist, nutritionist, and recreational therapist or vocational counselor. The patient/client, family, and caregivers are also important members of the team and should be involved in all decision making regarding the POC. Interdisciplinary communication is critical for effective team function and occurs through case conferences, informal interactions, patient care rounds, and patient/client family meetings. Effective

case management also includes a coordinated education plan and accurate and effective documentation. It is critical for the team to provide a supportive environment to assist patients and their family members in their adjustment to this life-altering event.

The National Stroke Association has instituted a process to certify stroke rehabilitation specialists. The designation of *clinical stroke rehabilitation specialist (CSRS)* ensures that therapists are expert stroke clinicians through a rigorous set of four-tiered courses culminating in a written examination and nationally recognized credential, the CSRS certification. Additional information can be found at www.stroke.org.

The rehabilitation POC considers the patient's history, course, and symptoms, together with impairments, activity limitations, and participation restrictions. Of equal importance are the patient's abilities (assets), priorities, and resources, including family, home, and community resources. Interventions are *restorative* (aimed at improving impairments, activity limitations, and participation restrictions), *preventive* (aimed at minimizing potential complications and indirect impairments), and *compensatory* (aimed at modifying the task, activity, or environment to improve function). See discussion in Chapter 1, Clinical Decision Making. The overall focus for patients with moderate to severe stroke is on long-range planning, with consideration of anticipated episodes of care that typically include hospital-based care (acute care, inpatient rehabilitation), outpatient rehabilitation, and home/community-based care.

The preferred practice pattern for patients with stroke from the *Guide to Physical Therapist Practice* is 5 D, *Impaired Motor Function and Sensory Integrity Associated with Nonprogressive Disorders of the Central Nervous System—Acquired in Adolescence or Adulthood.*[41, p. 365] In this document the reader will find relevant information on patient/client diagnostic classification; ICD-9-CM codes; examination components; considerations for evaluation, diagnosis, and prognosis; and suggested interventions. Thus, the *Guide to Physical Therapist Practice* serves as a primary resource for physical therapists in designing a comprehensive POC and documenting the services provided and outcomes achieved.

A therapeutic care continuum refers to the complete range of care, services, and/or programs provided for a patient. For patients with stroke, the care continuum is based on two important factors: (1) stage of recovery; and (2) degree of disability resulting from stroke.

Acute Phase

Low-intensity rehabilitation is begun in the acute care facility as soon as the patient is medically stabilized, typically within 72 hours. The patient may be first seen in a neurological intensive care unit (ICU) or specialized stroke care unit in a facility that also provides comprehensive rehabilitation services. Evidence supports the benefits of specialized stroke units in improving functional outcomes when compared to patients not receiving specialized care. Individuals who received this care were more likely to be alive, independent, and living at home 1 year after stroke.[42,43] The therapist needs to be aware of the patient's current status by reviewing the medical record and communicating with the medical team. During acute care, the therapist assists in ongoing monitoring of the patient's recovery and is alert for significant changes in the patient's status (e.g., changes in vital signs [heart rate (HR), blood pressure (BP, or respiratory rate (RR)], drop in O_2 saturation levels, skin changes, alterations in mental status and consciousness, and so forth). Early mobilization prevents or minimizes the harmful effects of bed rest and deconditioning. It may also increase the patient's level of consciousness and foster return to independence. Functional reorganization is promoted through early stimulation and use of the hemiparetic side. *Learned nonuse* of the hemiparetic extremities and maladaptive patterns of movement are minimized. Mental deterioration, depression, and apathy can be reduced through the fostering of a positive outlook toward the rehabilitation process. Interventions include but are not limited to positioning, functional mobility training (e.g., bed mobility, sitting, transfers, locomotion), ADL training, range of motion (ROM), splinting, and positioning.

Instruction, education, and training of patients and their families/caregivers is initiated early regarding current condition (pathophysiology, impairments, activity limitations) and risk factors for disability. It includes an overview of the recovery process, the rehabilitation POC, and expected transitions across care settings. It is important to remember that this is a highly stressful time for patients and families and information needs to be graded in appropriate amounts and repeated and reinforced throughout the course of treatment. The therapist needs to establish effective communication. This includes speaking to the patient in a normal tone and volume, speaking slowly and giving the patient enough time to respond, using simple yes/no questions, and using gesture and tactile cues whenever appropriate. Controlling the environment and reducing distractions will also help to ensure the patient's attention and promote good communication. The therapist also needs to be aware of the presence of visual field defect (homonymous hemianopsia) and perceptual changes (unilateral neglect) that will influence choice of position when interacting with the patient. The therapist needs to be sensitive to the devastating nature of these changes for both the patient and family members and work to help empower patients and their families to begin the recovery process. They need to understand that the therapist will work together with them as a team.

Current trends are toward shorter acute care hospital stays (average stay is about 5 days).[1] However, early discharge has resulted in an increase in the number of

serious medical complications seen during subacute rehabilitation or at home. These complications may result in delays during active rehabilitation and, for some, temporary cessation of therapy or transfer back to the acute hospital until medical complications are resolved. Therapists need to be vigilant in monitoring patients for potential risk of complications and medical emergencies (e.g., cardiac arrhythmias, DVT, uncontrolled BP, recurrent stroke, and so forth).

Subacute Phase

Patients with moderate or severe residual impairments or activity limitations may benefit from intensive inpatient rehabilitation provided in a freestanding rehabilitation facility or in a rehabilitation unit within the acute care hospital. Rehabilitation programs certified by the Commission on Accreditation of Rehabilitation Facilities (CARF) and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) can be expected to adhere to uniform standards and provide high-quality care.[2] Evidence supports the value of physical therapy in producing improved functional outcomes for patients with stroke.[43-52] Patients are referred to inpatient rehabilitation if they can tolerate an intensity of services consisting of two or more rehabilitation disciplines, 6 days a week for a minimum of 3 hours of active rehabilitation per day. If the patient requires less intensive services, transfer to a transitional care unit (TCU) within a skilled nursing facility is instituted. Here rehabilitation services are less intense, ranging from 60 to 90 minutes of therapy services 5 days per week.[2]

The timing of rehabilitation services is an important factor in predicting outcome. In general, a shorter onset-to-admission interval, within the first 20 days, has been shown to significantly improve functional outcomes when compared to longer intervals.[53] Additional factors that influence the timing of rehabilitation efforts include medical stability, severity of cognitive-perceptual deficits, motivation, patient endurance, and recovery. In an era of time-limited payment for comprehensive rehabilitation services, selecting the optimal time for rehabilitation services may prevent unnecessary patient failures and improve long-term functional outcomes.

Chronic Phase

Rehabilitation services during the chronic phase, generally defined to be more than 6 months post-stroke, are typically delivered in an outpatient rehabilitation facility, in a community setting, or at home. Outpatient services are prescribed for the patient who is discharged from inpatient rehabilitation, is in need of continuing rehabilitation, and can enter and exit the home with ease. Many of the interventions begun during inpatient rehabilitation are continued and progressed in order to sustain the gains made and improve functional performance.[44,46,48-52] Other interventions, including constraint-induced movement therapy (CIMT),[45] bilateral training,[47] virtual reality training,[53] and electromechanical-assisted walking,[54] may be implemented. Some patients with mild involvement who did not require intense inpatient rehabilitation also benefit from outpatient rehabilitation services. A complete record of past medical and rehabilitation services should be made available to these agencies. The intensity of services provided varies but is generally less than that of inpatient rehabilitation (e.g., 60 to 90 minutes per visit, two to three times per week). Outpatient intervention programs that target progressive improvements in flexibility, strength, balance, locomotion, endurance, and UE function have been shown to be effective in producing meaningful outcomes.[55] The patient and family are instructed in a home exercise program (HEP) and educated about the importance of maintaining exercise levels, health promotion, fall prevention, and safety.

The patient may receive home care rehabilitation services, typically for the patient who is unable to exit the home independently. The challenges of being home can impose additional daily stresses for the patient and family. Difficulties should be addressed promptly as they arise. The therapist needs to emphasize the development of problem solving skills to ensure successful adaptation to variable home and community environments. Fall risk factors should be eliminated or minimized as appropriate or possible. Examination of the environment and recommendations for modification of the environment are important parts of the preparation for return to home (see Chapter 9, Examination of the Environment).

Finally, the patient should be assisted in resuming participation in community and recreational activities. With increasing activity levels, it is important to monitor the patient's endurance levels carefully and provide instruction in activity pacing and energy conservation techniques as needed. Community fitness programs[51] and water-based activities[56] have been shown to improve function after stroke. A small number of stroke survivors can be evaluated and assisted in return to work. As the patient becomes successful in the home and community environments, services should be gradually phased out. Follow-up visits at periodic intervals are recommended to identify problems as they develop and to ensure long-term maintenance of function.

Note: Although there is a large body of research on the efficacy of stroke rehabilitation and more than 10 Cochrane Systematic Reviews,[43-56] the Cochrane researchers conclude that further high-quality research

(i.e., randomized controlled trials) is needed to determine the most effective interventions. Additional research is also needed to investigate the effect of rehabilitation interventions on quality of life, participation, and overall cost-benefit ratios, and the differential effects of stroke severity, latency, and age.

EXAMINATION

The three basic components of a comprehensive physical therapy examination include patient/client history, systems review, and tests and measures. The selection of examination procedures will vary based on a number of factors including patient's age, location and severity of stroke, stage of recovery, data from initial screenings, phase of rehabilitation, and home/community/work situation, as well as other factors.

The purposes of the examination are to

- Determine the diagnosis and classification within a specific practice pattern.
- Monitor recovery from stroke.
- Identify patients who are most likely to benefit from rehabilitation services and the most appropriate choice of a care setting.
- Develop a specific POC, including anticipated goals, expected outcomes, prognosis, and interventions.
- Monitor progress toward projected goals and outcomes through periodic reevaluation.
- Determine if referral to another practitioner is indicated.
- Plan for discharge.

The comprehensive examination provides the main source of information for clinical decision making. Examination findings should be coordinated with those of the rehabilitation team in order to arrive at an integrated POC. Box 15.3 presents Elements of the Examination of the Patient with Stroke[41] and possible impairments. Many of these examination procedures, tests, and measures are discussed in earlier chapters (see Chapters 2 through 9). This section discusses relevant aspects of the examination, including tests and measures and diagnosis-specific instruments developed for the patient with stroke. The therapist must differentiate between those impairments that are a direct consequence of the stroke and those that are indirect or secondary, resulting from sequelae or complications that originate from other systems. Aspects of functional performance, including activity limitations and restrictions in participation, are equally important to ascertain.

Data obtained through interview with the patient/family and review of the medical record should include information on general demographics, medical/surgical history, social and employment history, family history, living environment, general health status and risk factors, and social and health habits. Coexisting health problems and medications should also be identified. The older patient with stroke typically has a history of a number of cardiovascular and other co-morbidities. Data obtained from the history will help further focus the systems review and in-depth examination.

Cranial Nerve Integrity

The therapist should examine for facial sensation (CN V), facial movements (CNs V and VII), and labyrinthine/auditory function (CN VIII). The presence of swallowing difficulties and drooling necessitates an examination of the motor nuclei of the lower brainstem cranial nerves (CNs IX, X, and XII) affecting the muscles of the face, tongue, larynx, and pharynx. This includes determination of motor function of the lips, mouth, tongue, palate, pharynx, and larynx. The gag reflex should be examined because hypoactivity may lead to aspiration into the airway. Adequacy of cough mechanisms should also be carefully examined. The therapist needs to be able to recognize the presence of swallowing difficulties and initiate prompt referral.

The visual system should be carefully investigated, including tests for visual field defects (CN II, optic radiation, visual cortex), acuity (CN II), pupillary reflexes (CNs II and III), and extraocular movements (CNs III, IV, and VI). Ocular motility disturbances may be present with brainstem strokes, such as diplopia, oscillopsia, visual distortions, or paralysis of conjugate gaze. Visual field defects (homonymous hemianopsia) need to be differentiated from visual neglect, a perceptual deficit characterized by an inattention to or neglect of visual stimuli presented on the involved side. The patient with pure hemianopsia is typically aware of the deficit and may spontaneously compensate by moving the eyes or head toward the side of deficit; the patient with visual neglect will be unaware (inattentive) of the deficit (see Chapter 29). The use of prescriptive eyeglasses should be determined before any testing; the therapist should ensure that eyeglasses are worn and clean.

Sensation

Deficits in somatic sensations (touch, temperature, pain, and proprioception) are common after stroke. The type and extent of impairment are related to the location and size of the vascular lesion. Specific localized areas of dysfunction are common with cortical lesions, whereas diffuse involvement throughout one side of the body suggests deeper lesions involving the thalamus and adjacent structures. Impairment in touch sensation (64% to 94%), proprioception (17% to 52%), vibration (44%), and loss of pinprick sensation (35% to 71%) have been reported.[57-59]

Box 15.3 Elements of the Examination of the Patient with Stroke[41]

Patient/Client History

- Age, sex, race/ethnicity, primary langu.age, education
- Social history: cultural beliefs and behaviors, family and caregiver resources, social support systems
- Occupation/employment/work
- Living environment: home/work barriers
- Hand dominance
- General health status: physical, psychological, social, and role function, health habits
- Family history
- Medical/surgical history
- Current conditions/chief complaints
- Medications
- Medical/laboratory test results
- Functional activity level: premorbid

Systems Review

- Neuromuscular
- Musculoskeletal
- Cardiovascular/pulmonary
- Integumentary

Tests and Measures/Impairments

Tests and measures are selected based on their ability to quantify or describe each of the following:

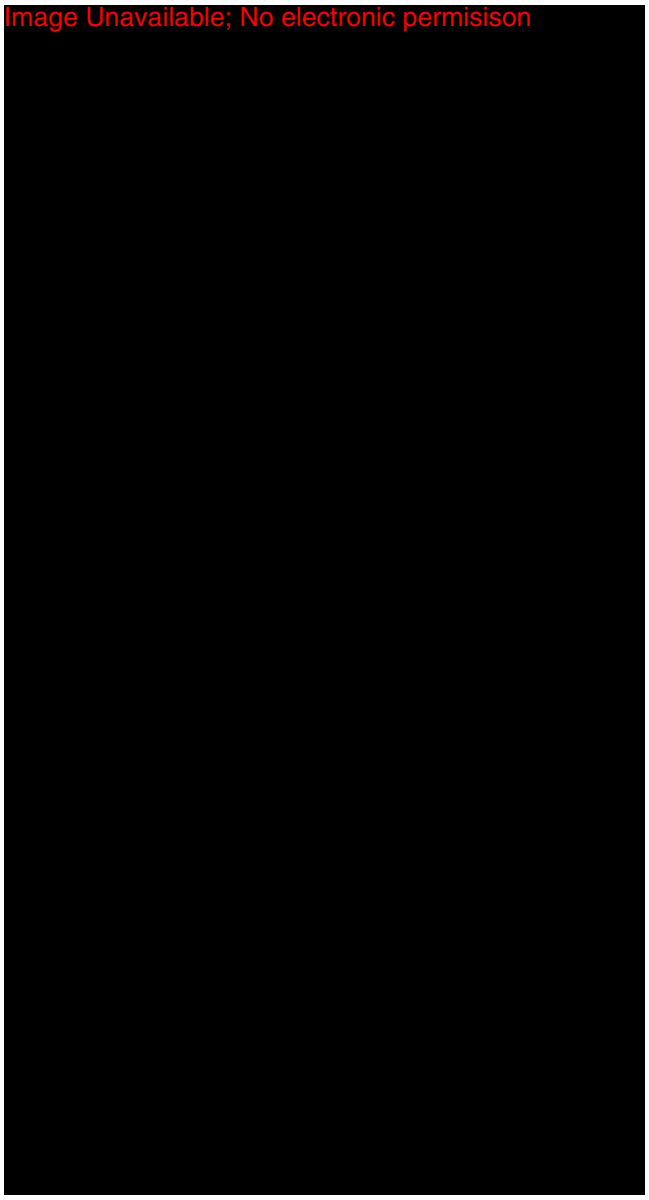
- Level of consciousness, arousal, attention, and cognition: mental status, insight, motivation
  Primary impairments: impaired alertness and attention, perseveration, confabulation, confusion, disorientation, distractibility, memory deficits, impaired judgment
- Emotional status
  Primary impairments: depression, pseudobulbar affect, apathy, euphoria
- Behavioral style
  Primary impairments: impulsive or cautious behavioral styles; frustration, irritability
- Communication and language: coordinate efforts with the speech-language pathologist
  Primary impairments: fluent, nonfluent, or global aphasia, dysarthria
- Circulation; cardiovascular signs and symptoms
  Common co-morbidities: hypertension, CAD, CHF, diabetes, DVT
- Ventilation and respiration/gas exchange: pulmonary signs and symptoms
  Common co-morbidities: chronic pulmonary disease
- Anthropometric characteristics: body mass index, girth, length
  Secondary impairments: edema, common in hand and foot
- Integumentary integrity: skin condition, pressure-sensitive areas; effectiveness of protective pressure-relieving devices
  Secondary impairments: altered skin integrity, decubitus ulcers
- Pain: intensity and location
  Primary impairments: central post-stroke pain
  Secondary impairments: hemiplegic shoulder and/or hand pain
- Cranial and peripheral nerve integrity.
  Primary impairments: dysphagia
- Sensory integrity and integration
  Primary impairments: homonymous hemianopsia, tactile/proprioceptive/kinesthetic losses, astereognosis
- Perceptual function: coordinate efforts with occupational therapist
  Primary impairments: spatial relations syndrome, body scheme/body image disorders, unilateral neglect, agnosia, topographical disorientation
- Joint integrity, alignment, and mobility: ROM (active and passive); muscle length and soft tissue extensibility
  Secondary impairments: altered biomechanical alignment; loss of joint ROM, muscle and soft tissue length
- Posture: alignment and position, symmetry (static and dynamic, sitting and standing); ergonomics and body mechanics
  Secondary impairment: altered biomechanical alignment
- Motor function: motor control and motor learning
  Primary impairments:
  Altered reflex integrity: hyperreflexia, tonic reflexes, associated reactions
  Abnormal tone: flaccidity initially; spasticity: spastic posturing
  Abnormal (obligatory) synergies: flexion and extension synergy patterns
  Altered voluntary movement patterns: altered initiation, sequencing, timing of muscle contractions; altered force production
  Coordination, dexterity, agility: coordination deficits
  Motor planning: ideomotor or ideational apraxia
- Muscle performance: strength, power, and endurance
  Primary impairments: paralysis or weakness; fatigue
  Secondary impairments: disuse atrophy
- Postural control and balance: sensorimotor integration, balance strategies (static and dynamic); safety
  Primary impairments: altered balance, increased fall risk
- Gait and locomotion: gait pattern and speed, use of assistive devices/orthotic devices, safety
  Primary impairments: altered sequencing, timing, balance, endurance
- Wheelchair management and mobility: safety and endurance
- Aerobic capacity and endurance: functional activity testing, graded exercise testing
  Secondary impairments: decreased endurance
- Orthotic, protective and supportive devices: fit, alignment, function, use, safety
- Functional status and activity level: performance-based examination of functional skills (FIM level), basic and instrumental ADL; functional mobility skills; home management skills; assistive or adaptive devices: fit, alignment, function, use; safety
  Primary impairments: loss of independent function
- Work, community, and leisure activities: ability to assume/resume activities, safety

Sensory loss has also been reported in the ipsilateral, less affected limbs though to a lesser extent (12% to 25%). Symptoms of crossed anesthesia (ipsilateral facial impairments with contralateral trunk and limb involvement) typify brainstem lesions. Disturbances in cortical sensory modalities (two-point discrimination, stereognosis, kinesthesia, graphesthesia) are also found.[60,61] Profound sensory impairments will negatively affect motor performance, motor learning, and rehabilitation outcomes and contribute to unilateral neglect and *learned nonuse* of limbs. Sensory impairment is also associated with pressure sores, abrasions, and shoulder pain and subluxation.

Central post-stroke pain (CPSP) is defined as pain arising as a direct consequence of a lesion or disease affecting the central somatosensory system and occurs in about 10% of strokes.[62] It can result from lesions at any level of the somatosensory pathways including the medulla, thalamus, and cortex. The thalamus is thought to play an important part in the underlying pathophysiology of central pain. CPSP can be severe and persistent (described as "burning," "aching"), spontaneous and intermittent (described as "lacerating" or "shooting" pain), or evoked by mechanical (stroking the skin, pressure) or thermal (heat or cold) stimuli. Symptoms may be focal, affecting the hand/arm or foot/leg, or in severe cases affect half the body. Development of pain is typically within the first few months after stroke though onset may be delayed for many months. Spontaneous recovery is rare and chronic suffering common. The debilitating nature of CPSP frequently limits participation in rehabilitation programs and outcomes.[63]

A sensory examination should include testing of superficial sensations (e.g., touch, pressure, sharp or dull discrimination, temperature) and deep sensations (proprioception, kinesthesia, vibration). Combined (cortical) sensations such as stereognosis, tactile localization, two-point discrimination, and texture recognition should also be examined once the integrity of the superficial sensations of touch and pressure is established. Sensory testing procedures are described in detail in Chapter 3, Examination of Sensory Function. The quality of sensory impairments experienced can range from mild altered perception to marked changes in sensory thresholds, delayed perceptions, uncertainty of responses, altered time for sensory adaptation, and sensory persistence.[57] Impairments may be evident in one sensory modality and not in others. Differences can also be expected between upper and lower hemiplegic extremities, depending on lesion location. Comparisons with the intact side should be viewed with caution because impairments may exist in the supposedly "normal" extremities due to aging and co-morbidities. Sensory testing may be difficult or need to be deferred owing to cognitive or communication deficits.

Flexibility and Joint Integrity



An examination of joint flexibility should include passive ROM using a goniometer, joint hypermobility/hypomobility, and soft-tissue changes (swelling, inflammation, or restriction). The shoulder and wrist should be examined closely because joint malalignment problems are common. Edema of the wrist often produces malaligned carpal bones with resulting impingement during wrist extension. Problems with spasticity may result in inconsistent ROM findings, because fluctuations in tone may occur from one testing session to the next. Thus, tonal abnormalities should be noted at the time of examination. Active ROM (AROM) may be limited or impossible for the patient in early or middle recovery in the presence of paresis, spasticity, or obligatory synergies that can preclude isolated voluntary movements. ROM limitations and developing contractures should be carefully documented.

Contractures can develop anywhere but are particularly apparent in the paretic limbs. As contractures progress, edema and pain may develop and further restrict mobility. In the UE, limitations in the shoulder motions of flexion, abduction, and external rotation are common. Contractures are likely in the elbow flexors, wrist and finger flexors, and forearm pronators. In the LE, plantarflexion contractures are common.

Motor Function

Stages of Motor Recovery

Initially, flaccid paralysis is present (*stage 1*). This is replaced by the development of spasticity, hyperreflexia, and mass patterns of movement, termed **obligatory synergies**, all characteristics of upper motor neuron syndrome. Muscles involved in obligatory synergy patterns are strongly linked in a highly stereotyped, abnormal pattern; isolated joint movements outside the obligatory pattern are not possible. During *stage 2* (early synergy), facilitatory stimuli will elicit synergies with minimal voluntary movement. As recovery progresses, spasticity is marked with full strong obligatory synergies (*stage 3*). Synergy influence begins to decline in *stage 4* as some isolated out-of-synergy joint movements emerge. During *stage 5*, relative independence of synergy, spasticity continues to wane and isolated joint movements become more apparent, and during *stage 6* patterns of movement are near normal. This general pattern of recovery was initially described by Twitchell[64] and Brunnstrom[65,66] and confirmed by additional investigators[67,68] (Box 15.4). Several important points merit consideration. An overall pattern of motor recovery exists though individual recovery is highly variable. Some patients experience mild involvement with early full recovery whereas other patients demonstrate severe involvement with incomplete recovery.

The degree of recovery depends on a number of factors, including lesion location and severity and capacity for adaptation through training. Finally, recovery differs within patients. For example, the UE may be more involved and demonstrate less complete recovery than the LE as is seen in MCA syndrome. For examination of recovery stages, see discussion of the *Fugl-Meyer Assessment of Physical Performance* later in this section and Appendix 15.A.

Tone

Flaccidity (hypotonicity) is present immediately after stroke and is due primarily to the effects of cerebral shock. It is generally short-lived, lasting a few days or weeks. Flaccidity may persist in a small number of patients with lesions restricted to the primary motor cortex or cerebellum. **Spasticity** (hypertonicity) emerges in about 90% of cases and occurs on the side of the body opposite the lesion. Spasticity in upper motor neuron syndrome occurs predominantly in antigravity muscles (see Chapter 5, Table 5.3). In the patient with stroke, UE spasticity is frequently strong in scapular retractors; shoulder adductors, depressors, and internal rotators; elbow flexors and forearm pronators; and wrist and finger flexors. In the neck and trunk, spasticity may cause increased lateral flexion to the hemiplegic side. In the LE, spasticity is often strong in the pelvic retractors, hip adductors and internal rotators, hip and knee extensors, plantarflexors and supinators, and toe flexors. Spasticity results in tight (stiff) muscles that restrict volitional movement. Posturing of the limbs (e.g., a tightly fisted hand with the elbow flexed and held tightly against the chest or a stiff extended knee with a plantarflexed foot) is common with moderate to severe spasticity. Spastic posturing can lead to development of painful spasms (similar to muscle cramping), degenerative changes, and fixed contractures. The automatic adjustment of postural muscles that occurs normally in preparation for and during a movement task is also impaired. Thus, patients with stroke may lack the ability to adjust and stabilize proximal limbs and trunk appropriately during movement, with resulting postural abnormalities, balance impairments, and increased risk for falls.

An examination of tone is essential. Passive motion testing can be used to determine the presence of hypotonicity or spasticity. Severity of spasticity can be graded on the basis of resistance to passive stretch using the *Modified Ashworth Scale (MAS)* (see Chapter 5, Table 5.4). The position of the affected limbs at rest (resting postures) and during voluntary movements should be observed for tonal influences.

Reflexes

Reflexes are altered and also vary according to the stage of recovery. Initially, stroke results in hyporeflexia with flaccidity. When spasticity and synergies emerge, hyperreflexia is seen. Deep tendon reflexes are hyperactive and patients may demonstrate clonus, clasp-knife response, and a positive Babinski, all consistent findings of upper motor neuron syndrome (see Chapter 5, Table 5.5).

Tonic reflexes may appear in a readily identifiable form similar to that seen in other types of neurological insult (e.g., traumatic brain injury [TBI], cerebral palsy [CP]). Thus, movement of the head or position of the body may elicit an obligatory change in resting tone or movement of the extremities. The most commonly seen is the asymmetrical tonic neck reflex (ATNR) in which head rotation causes elbow extension of the UE on the jaw side with elbow flexion of the opposite skull limb (see Chapter 5, Table 5.7).

Associated reactions are also typically present in patients with stroke who exhibit strong spasticity and

obligatory synergies. These consist of unintentional movements of the hemiparetic limb caused by voluntary action of another limb or by other stimuli such as yawning, sneezing, or coughing. For example, the patient vigorously contracts the elbow flexors of the stronger UE; the hemiparetic elbow also flexes. Or the patient flexes the hip to lift the hemiparetic LE in sitting; the hemiparetic UE also flexes. Associated reactions can limit functional performance, especially in the UE. An examination of stretch reflexes and pathological reflexes (e.g., Babinski, tonic reflex activity, associated reactions) should be performed (see Chapter 5, Table 5.7).

Voluntary Movements

Abnormal and highly stereotyped obligatory synergies emerge with spasticity following stroke. Thus, the patient is unable to perform an isolated movement of a single limb segment without producing movements in the remainder of the limb. For example, efforts to flex the elbow also result in shoulder flexion, abduction, and external rotation. The patient is severely limited in the ability to adapt movements to varying task or environmental demands. Obligatory synergies can appear reflexively during very early recovery, or as voluntary movements. As recovery progresses they become stronger and are linked to the presence and severity of spasticity. Two distinct abnormal synergy patterns have been described for each extremity: a flexion synergy and an extension synergy (Table 15.6). An inspection of the synergy components reveals that certain muscles are not usually involved in either the flexion or extension synergy. These muscles include the (1) latissimus dorsi, (2) teres major, (3) serratus anterior, (4) finger extensors, and (5) ankle evertors. These muscles, therefore, are generally difficult to activate while the patient is exhibiting these patterns. Obligatory synergies are often incompatible with normal ADL and functional mobility skills. For example, the patient with a strong LE extensor synergy will have difficulty walking owing to foot plantarflexion and inversion with hip and knee extension and adduction (scissoring gait pattern). As recovery progresses, spasticity and obligatory synergies begin to disappear and more normal synergies with isolated joint control become possible.

Voluntary movement patterns should be examined for synergy influence. The therapist bases the examination of synergy dominance on knowledge of the typical components of the synergies. It is possible for one limb to vary significantly from the other (e.g., the UE may demonstrate more synergistic dominance than the LE). Synergistic dominance versus isolated joint control may also vary within a limb (e.g., the shoulder may demonstrate more isolated control than the wrist and hand). During later recovery, voluntary movements demonstrate isolated joint control and appear more normal in the absence of spasticity and synergy restrictions. See discussion of the *Fugl-Meyer Assessment of Physical Performance* later in this section.

Coordination

Proprioceptive losses can result in sensory ataxia. Strokes affecting the cerebellum typically produce cerebellar ataxia (e.g., lateral medullary syndrome, basilar artery syndrome, pontine syndromes) and motor weakness. The resulting problems with timing and sequencing of muscles can significantly impair function and limit adaptability to changing task and environmental demands. Basal ganglia involvement (posterior cerebral artery syndrome) may lead to slowed movements (bradykinesia) or involuntary movements (choreoathetosis, hemiballismus).

Coordination tests can be used to examine control. The therapist focuses on elements of speed/rate control, steadiness, response orientation, and reaction and movement times. Fine motor control and dexterity should be examined using writing, dressing, and feeding tasks (see Chapter 6, Examination of Coordination and Balance). Although more significant impairments can be

Table 15.6 Obligatory Synergy Patterns Following Stroke

	Flexion Synergy Components	Extension Synergy Components
Upper extremity	Scapular retraction/elevation or hyperextension Shoulder abduction, external rotation Elbow flexion* Forearm supination Wrist and finger Flexion	Scapular protraction Shoulder adduction,* internal rotation Elbow extension Forearm pronation* Wrist and finger flexion
Lower extremity	Hip flexion,* abduction, external rotation Knee flexion Ankle dorsiflexion, inversion Toe dorsiflexion	Hip extension, adduction,* internal rotation Knee extension* Ankle plantarflexion,* inversion Toe plantarflexion

*Generally the strongest components.

expected on the hemiparetic side, it is important to remember that subtle deficits can occur on the less involved side. Thus, it is important to examine both unilateral and bilateral movements, including symmetrical, asymmetrical, and unrelated movements. Performance may vary as the patient moves from supine to sitting to standing positions with the resultant increased postural demands and greater degrees of freedom.

Motor Programming

Motor praxis is the ability to plan and execute coordinated movement. Lesions of the premotor frontal cortex of either hemisphere, left inferior parietal lobe, and corpus callosum can produce **apraxia**. Apraxia is more evident with left hemisphere damage than right and is commonly seen with aphasia. The patient demonstrates difficulty planning and executing purposeful movements that cannot be accounted for by any other reason (i.e., impaired strength, coordination, sensation, tone, cognitive function, communication, or uncooperativeness). There are two main types of apraxia. **Ideational apraxia** is an inability of the patient to produce movement either on command or automatically and represents a complete breakdown in the conceptualization of the task. The patient has no idea how to do the movement and thus cannot formulate the required motor programs. With **ideomotor apraxia** the patient is unable to produce a movement on command but is able to move automatically. Thus, the patient can perform habitual tasks when not commanded to do so and often perseverates, repeating the activity over and over. Significant information on apraxia will be gained by close collaboration with the occupational therapist. The reader is referred to Chapter 27 for a more complete discussion of these deficits and their management.

Muscle Strength

Paresis is found in 80% to 90% of all patients after stroke and is a major factor in impaired motor function, activity limitation, and disability. Patients are unable to generate the force necessary for initiating and controlling movement. The degree of primary weakness is related to the location and size of the brain injury and varies from a complete inability to achieve any contraction (**hemiplegia**) to **hemiparesis** with measurable impairments in force production.[69] Deficits on the contralateral side typically include hemiparesis (opposite UE and LE). Owing to the high incidence of MCA strokes, the UE is frequently more affected than the LE. About 20% of individuals with MCA strokes fail to regain any functional use of the affected UE. Typically, distal muscles exhibit greater strength deficits than proximal. This can be explained by the greater facilitation of distal muscles than proximal by the corticospinal system. Mild weakness also occurs on the ipsilateral, "supposedly normal" side.[70,71] This can be explained by the fact that only 75% to 90% of the corticospinal fibers cross in the medulla to the contralateral side. The remainder are transmitted to the spinal cord ipsilaterally in the anterior or ventral corticospinal tract. Once in the spinal cord some of these fibers cross while the rest remain uncrossed, thereby explaining bilateral weakness.[72] The amount of weakness experienced by the patient may also vary according to the extent and level of inactivity (disuse atrophy) and the specific functional tasks attempted. Thus, a patient may appear stronger in some tasks than others.[73]

Post-stroke weakness is associated with a number of changes in both the muscle and the motor unit. Changes occur in muscle composition, including atrophy of muscle fibers. There is a selective loss of type II fast-twitch fibers with subsequent increase in the percentage of type I fibers (a finding also reported in the elderly). This selective loss of type II fibers results in slowed force production, difficulty with initiation and production of rapid, high-force movements, and rapid onset of fatigue.[60,73-75] The number of functioning motor units and discharge firing rates also decrease. This is explained by the presence of transsynaptic degeneration of alpha motor neurons that occurs with loss of corticospinal innervation. Abnormal recruitment of motor units with altered timing occurs.[76-78] Thus, patients demonstrate inefficient patterns of muscle activation and higher levels of co-contraction. This opposing muscle activation can contribute to muscle weakness and incoordination. These impairments in force production and coordination have been reported in both paretic and less affected UEs after stroke.[79,80] Patients demonstrate increased effort and fatigability with frequent complaints of feelings of weakness. Denervation potentials on electromyography (EMG) are common, also the result of denervation changes in the corticospinal tracts. Overall reaction times are increased, a finding also reported in the less affected extremities and for the elderly in general. Movement times are prolonged, a timing abnormality that contributes to impairment of coordinated motor sequences.

Although an examination of strength is necessary, the traditional manual muscle test (MMT) poses problems of validity in the presence of strong spasticity, reflex, and synergy dominance. The patient who is not able to isolate specific movements should not be examined using MMT. In this situation, an estimation of strength can be made from observation of active movements during functional activities (functional strength testing). The patient's self-report can also yield important indicators of weakness and fatigue. The patient in later recovery with improving motor control and isolated movement can be examined using traditional MMT or handheld dynamometry. Use of a computerized isokinetic dynamometer can reveal important objective data regarding forces generated, peak torque, time to peak torque, and total work normalized to body weight. See Chapter 4, Musculoskeletal Examination.

Postural Control and Balance

Postural control and balance are disturbed following stroke with impairments in alignment, stability, symmetry, and dynamic balance common. Common postural alignment deviations following stroke are presented in Table 15.7.

Balance impairments may exist when reacting to a destabilizing external force (*reactive postural control*) and/or during self-initiated movements (*proactive or anticipatory postural control*). Thus, the patient may be unable to maintain stable balance in sitting or standing or to move in the posture without loss of balance. Disruptions of central sensorimotor processing contribute to an inability to recruit effective postural strategies and adapt postural movements to changing task and environmental demands. Patients with stroke typically demonstrate uneven weight distribution and increased postural sway in standing (a finding characteristic of the elderly in general). Delays in the onset of motor activity, abnormal timing and sequencing of muscle activity, and abnormal co-contraction result in disorganization of normal postural synergies. For example, proximal muscles are typically activated in advance of distal muscles or, in some patients, very late (a finding also found in many elderly). Compensatory responses typically include excessive hip and knee movements. Corrective responses to perturbations or destabilizing forces are inadequate and result in loss of balance and frequent falls. Patients with hemiplegia typically fall in the direction of weakness.[80-85]

Static and dynamic balance control should be examined in sitting and standing. The patient's ability to maintain a stable position (steadiness) and position (symmetry) within the base of support (BOS) is determined. Dynamic stability control can be examined by having the patient move within a given posture (weight shift) or reach within his or her limits of stability (LOS). The patient should be encouraged to shift weight in all directions, especially to the more involved side where greater impairments are expected. Functional tasks that utilize moving from one posture to another (e.g., supine-to-sit, sit-to-stand) can also be used to examine dynamic postural control.[86]

Performance-based tests can be used to examine postural control and balance following stroke. These tests have been examined for reliability and/or validity and are reviewed in Chapter 6.

- The *Berg Balance Scale (BBS)*
- The *Performance-Oriented Mobility Assessment (POMA, Tinetti)*
- The *Functional Reach Test (RT)* and the *Multidirectional Reach Test (MDRT)*
- The *Timed Up and Go Test (TUG)*
- The *Clinical Test for Sensory Interaction in Balance (CTSIB)*

Stroke-specific tests of postural control and balance include the following:

- The *Postural Assessment Scale for Stroke Patients (PASS)* was developed to examine the postural abilities of patients with acute stroke. It includes 12 items that examine sitting and standing without support, standing on the paretic LE, and changing posture

Table 15.7 Common Postural Alignment Deviations Associated with Stroke

Body Segment	Postural Alignment Deviations
Pelvis	• Asymmetrical weight-bearing with majority of weight borne on the stronger side • Reluctance (fear) of shifting weight toward the more affected side • In sitting, posterior pelvic tilt (sacral sitting) • In standing, unilateral retraction and elevation on the more affected side
Trunk	• With sacral sitting, a flattened lumbar curve with exaggerated thoracic curve and forward head • Lateral flexion with trunk shortening on more affected side
Shoulders	• Unequal height with more affected shoulder depressed • Humeral subluxation with scapular downward rotation and lateral flexion of trunk • Scapular instability (winging) may be present
Head/Neck	• Protraction with lateral trunk flexion • Lateral flexion of the head with rotation away from the more affected side
Upper Extremities	• More affected UE typically held in a flexed, adducted position, with internal rotation and elbow flexion, forearm pronation, wrist and finger flexion; limb is non–weight-bearing • Stronger UE used for postural support
Lower Extremities	• In sitting: more affected LE typically held in hip abduction and external rotation with hip and knee flexion (flexion synergy pattern) • In standing: more affected LE typically held in hip and knee extension with adduction and internal rotation (scissoring pattern); ankle plantar flexion • Unequal weight bearing on feet, similar to pelvis in sitting

(supine–to–affected side, supine–to–unaffected side, supine-to-sitting, sitting-to-standing, and standing picking a pencil off the floor). It is scored using an ordinal scale with descriptors ranging from cannot perform to perform with little help, to perform without help. It demonstrates good construct validity and high interrater and intrarater reliability (0.88 and 0.72, respectively).[87]

- The *Trunk Impairment Scale* was developed to evaluate motor impairment of the trunk after stroke. It includes 3 items of static control, 10 items of dynamic balance control, and 4 items of coordination. The items are tested in the sitting position (edge of bed or treatment table) without back or arm support. Each item is performed three times with the highest score accepted. Scores range from a minimum of 0 (unable) to a maximum of 23.[88]
- The *Function in Sitting Test (FIST)* was developed by expert consensus as a test for sitting balance deficits in adults after acute stroke. It includes 14 items that examine static and dynamic balance function. Static sitting (steady state) is examined by having the patient sit with eyes open and eyes closed. Reactive challenges are introduced using sternal nudges (anterior, posterior, and lateral). Dynamic, anticipatory (proactive) challenges are introduced using body segment motions (head turns, lifting foot up on the least involved side, turning and picking an object up placed behind the patient, forward and lateral reach, picking an object up off the floor), and scooting movements (posterior, anterior, lateral). Eleven items examine anterior/posterior control and three items examine lateral/rotational control. Scoring is based on a 5-point ordinal scale that includes the following: No Balance (0/4), Poor (1/4), Fair (2/4), Good (3/4) to Normal (4/4). Specific descriptive criteria are given for each grade for static and dynamic control. Maximum score is 56 (similar to the BBS). Initial reliability and validity of the FIST has been demonstrated; however, additional testing is indicated.[89]

Ipsilateral Pushing

Ipsilateral pushing (also known as *pusher syndrome or contraversive pushing*) is an unusual motor behavior characterized by active pushing with the stronger extremities toward the hemiparetic side with a lateral postural imbalance.[90] The end result is a tendency to fall toward the hemiparetic side. Ipsilateral pushing occurs in about 10% of patients with acute stroke and results from stroke affecting the posterolateral thalamus.[91,92] The result is an altered perception of the body's orientation in relation to gravity. Karnath et al[90] found that patients experienced a misperception of subjective postural vertical position, perceiving their body as vertical when it was actually tilted about 20° toward the hemiparetic side. They also found that the visual and vestibular input for orientation perception to vertical remained intact as patients were able to align their bodies with the help of visual cues and conscious strategies. No significant association between ipsilateral pushing and hemineglect, anosognosia, aphasia, or apraxia has been found.[91]

Functional skills are significantly impaired for patients with ipsilateral pushing. During sitting, the push results in a strong lateral lean toward the weaker side; when sitting in a wheelchair, this often thrusts the patient over onto the wheelchair arm. In standing, a strong push creates an unstable situation with a high risk of falls because the hemiparetic LE typically cannot support the body weight. The patient shows no fear even when active pushing leads to instability and strongly resists any attempts to passively correct posture to midline, symmetrical weight-bearing. This pattern is totally opposite the expected postural deficiency seen in most patients after stroke, that is, increased weight-bearing to the stronger side to compensate for deficits on the hemiparetic side. Patients also typically demonstrate severe problems in transfers and gait. During transfers to the less involved side, the patient demonstrates increased pushback away from that side.

During walking, the patient typically exhibits inadequate extension of the hemiparetic LE with inability to transfer weight toward the less involved LE. During swing, strong scissoring (adduction) of the more involved LE is typically evident. The use of a cane during ambulation is problematic because patients use the cane to increase push to the hemiplegic side. Pedersen et al[91] demonstrated that patients with ipsilateral pushing behavior have poorer rehabilitation outcomes with longer hospital stays and prolonged recovery times. They also had significantly lower functional scores on admission and discharge with increased levels of dependence at discharge. However, with training, the brain can compensate well. The syndrome is rarely still evident at 6 months.[93]

Examination of the patient with ipsilateral pushing should include a focus on several criteria of behavior, including the following: (1) spontaneous body posture with tilting toward the more paretic side, (2) an increase of pushing force by the less involved extremities evidenced by increased abduction and extension, and (3) resistance to passive correction of the posture. Broetz and Karnath[94] developed the *Clinical Assessment Scale for Contraversive Pushing (SCP),* which scores each of these three criteria in both sitting and standing. A subjective rating scale is used. The scores for each criteria range from 0 to 1. Because the criteria are examined in both sitting and standing, the maximum for each is 2 with a maximum possible overall score of 6. Patients are diagnosed with pushing behaviors if all three criteria are present and a score of 1 or more exists in each of the three criteria. Functional examination will reveal consistent difficulties with transfers to the less affected side, and difficulties with independent sitting, standing, and walking.[95]

Gait and Locomotion

Gait is altered following stroke owing to a number of factors. Some of the more common problems in hemiplegic gait and their possible causes are summarized in Box 15.5. An examination of gait typically includes an *observational gait analysis* (OGA). The therapist examines the movements occurring at the ankle, foot, knee, hip, pelvis, and trunk during walking (kinematic gait analysis). Gait is observed from the different planes of motion and deviations are identified. Digital video recording of a patient's gait for subsequent OGA can improve identification of gait deviations, provides a visual record of performance, and offers a useful teaching tool (patient feedback) to assist with remediation of gait problems. Quantitative measures of distance and time, cadence, velocity, and stride times should also be

Box 15.5 Gait Deviations Commonly Seen Following Stroke

Stance Phase

Trunk/pelvis
Unawareness of affected side: poor proprioception
Forward trunk:

- Weak hip extension
- Flexion contracture

Hip
Poor hip position (typically adduction or flexion): poor proprioception
Trendelenburg limp: weak abductors
Scissoring: spastic adductors
Knee
Flexion during forward progression:

- Flexion contracture
- Weak hip and knee extensors
- Poor proprioception
- Ankle dorsiflexion range past neutral
- Weakness in extension pattern or in selective motion of hip and knee extensors and plantarflexors

Hyperextension during forward progression:

- Plantarflexion contracture past 90°
- Impaired proprioception: knee wobbles or snaps back into recurvatum
- Severe spasticity in quadriceps
- Weak knee extensors: compensatory locking of knee in hyperextension

Ankle/foot
Equinus gait (heel does not touch the ground): spasticity or contractures of gastrocnemius soleus
Varus foot (patient bears weight on the lateral surface of the foot): hyperactive or spastic anterior tibialis, post tibialis, toe flexors, and soleus
Unequal step lengths: hammer toes caused by spastic toe flexors prevent the patient from stepping forward onto the opposite foot because of pain/weight-bearing on flexed toes
Lack of dorsiflexion range on the affected side (approximately 10° is needed)

Swing Phase

Trunk/pelvis
Insufficient forward pelvic rotation (pelvic retraction): weak abdominal muscles
Inclination to sound side for foot clearance: weakness of flexor muscles
Hip
Inadequate flexion:

- Weak hip flexors
- Poor proprioception
- Spastic quadriceps
- Abdominal weakness (hip hikers)
- Hip abductor weakness of opposite site

Abnormal substitutions include circumduction, external rotation/adduction, backward leaning of trunk/dragging toes; momentum/uncontrolled swing
Exaggerated hip flexion: strong flexor synergy
Knee
Inadequate knee flexion:

- Inadequate hip flexion and poor foot clearance
- Spastic quadriceps

Exaggerated but delayed knee flexion: strong flexor synergy
Inadequate knee extension at weight acceptance

- Spastic hamstrings
- Sustained total flexor pattern

Weak knee extensors or poor proprioception
Ankle/foot
Persistent equinus and/or equinovarus

- Plantarflexor contracture or spasticity
- Weak dorsiflexors
- Delayed contraction of dorsiflexors
- Toes drag during midswing

Varus: spastic anterior tibialis, weak peroneals, and toe extensors
Equinovarus: spasticity of post tibialis and/or gastrocnemius soleus
Exaggerated dorsiflexion: strong flexor synergy pattern

Adapted from educational materials used at Rancho Los Amigos Medical Center, Downey, CA, and Spaulding Rehabilitation Hospital, Boston, MA.

obtained using measured walkways and a stopwatch (e.g., the *10-Meter Walk Test*). Kinetic gait analysis examines the forces involved in the production of movement during walking and requires sophisticated instrumentation (force plates). See Chapter 7, Examination of Gait.

Ambulation profiles and scales can be used to determine locomotor function following stroke. These tests have been examined for reliability and/or validity and are reviewed in Chapter 7.

- *Functional Ambulation Profile (FAP)* and modifications
- The *Iowa Level of Assistance Score*
- The *Community Balance and Mobility Scale*
- The *Gait Abnormality Rating Scale (GARS)* and the *Modified GARS*

- *Dual Tasking: Walks while Talking Test*

Perry et al[96] constructed a walking ability questionnaire and surveyed a group of 147 patients with chronic stroke about the effects of their limited walking ability. They then developed the *Classification of Walking Handicap After Stroke* (Box 15.6). The use of functional categories (physiological walker, household walker, and community walker) provides a useful method of identifying customary level of walking at home and in the community. *Walking handicap,* defined as the social disadvantage as a result of limitations in walking ability, can also be identified. Factors that differentiated household from community ambulators included strength, proprioception, isolated knee control (flexion and extension), and velocity. This classification system can be used to improve communication among clinicians, treatment planning, and documentation. It also forms the basis for the *Functional Ambulation Classification Scale*.[97]

Box 15.6 Functional Walking Categories

Physiological Walker

- Walks for exercise only either at home or in parallel bars during physical therapy.

Household Walker

Limited household walker:

- Relies on walking to some extent for home activities.
- Requires assistance for some walking activities, uses a wheelchair, or is unable to perform others.

Unlimited household walker:

- Able to use walking for all household activities without any reliance on a wheelchair.
- Encounters difficulty with stairs and uneven terrain.
- May not be able to enter or leave the house independently.

Community Walker

Most-limited community walker:

- Can enter and leave the home independently.
- Can ascend and descend a curb independently.
- Can manage stairs to some degree.
- Independent in at least one moderate community activity (e.g., appointments, restaurants) and needs assistance or is unable in no more than one other low-challenge activity (e.g., church, neighborhood, visiting friend).

Least-limited community walker:

- Demonstrates independent stair management.
- Independent in all moderate community activities without assistance or use of wheelchair.
- Independent in either local stores or uncrowded shopping centers.
- Independent in at least two other moderate community activities.

Community walker:

- Independent in all home and community activities.
- Can accept crowds and uneven terrain.
- Demonstrates complete independence in shopping centers.

Note: Patients in each higher category can perform all activities of the previous group as well as the additional level of challenge listed.

From Perry et al,[96 p. 985] with permission.

Integumentary Integrity

Ischemic damage and subsequent necrosis of the skin results in skin breakdown and pressure ulcers (decubitus ulcers). The skin breaks down typically over bony prominences from pressure, friction, shearing, and/or maceration. Intense pressure for a short time or low pressure for a long time results in pressure ulcers. Friction occurs as the skin rubs or is dragged against the supporting surface, for example, when the patient slides down in bed or is pulled up. Spasticity and contractures also contribute to increased friction. Shearing occurs from sliding of adjacent structures in opposite directions (skin vs. underlying bone), for example, during transfers from bed to wheelchair. Maceration is caused by excess moisture, for example, with urinary incontinence. Additional risk factors include reduced activity (bedfast or chairfast), immobility, decreased sensation, abnormal patterns of movement, poor nutrition, and decreased level of consciousness. The incidence of

pressure sores is increased with co-morbid medical conditions such as infections, peripheral vascular disease, edema, and diabetes.

Daily systematic inspection of the skin is indicated for high-risk patients, particularly over areas prone to breakdown. The skin must be kept clean, dry, and protected from injury. Adherence to proper techniques for positioning, turning, and transferring is essential. The therapist needs to check the posted positioning schedule and time in each position. Assumption of upright postures (sitting and standing) is promoted as soon as possible. Pressure-relieving devices (PRDs) are used to minimize high concentrations of pressure. These include foam pads, alternating pressure mattress, water mattress, air-fluidized bed, sheepskin, heel and elbow protectors, multipodus boots, and wheelchair cushions. Proper use of PRDs and positioning (seating) in the wheelchair should be closely examined.

Aerobic Capacity and Endurance

A supervised exercise test with electrocardiogram (ECG) monitoring may be indicated for survivors of stroke with cardiovascular disease in the subacute phase. Performance measures include significant ECG changes, HR, BP, *Rating of Perceived Exertion (RPE)*, and other signs of ischemic intolerance. The mode of testing will depend on the individual patient and can include leg cycle ergometry, semirecumbent cycle ergometry, a combination arm-leg ergometer, treadmill (TM) walking, or a seated stepper. If balance is impaired, recumbent equipment or an overhead safety harness on a TM should be used. Test protocols are individualized and are generally submaximal with a gradual progression in intensity. An intermittent protocol with rest periods may be required for some patients. Clinical endpoints of testing are similar as for other patients with cardiovascular disease (serious dysrhythmias, greater than 2 mm ST-segment depression or elevation, systolic BP [SBP] greater than 250 mm Hg or diastolic BP [DBP] greater than 115 mm Hg, volitional fatigue).[24]

For ambulatory patients, walking endurance can be measured using a *6- or 12-minute walk test* (see discussion in Chapter 7). The time, total distance, number of rest stops, and symptoms at rest stops are recorded. Shorter distances (e.g., a 2-minute walk test) have been used for patients with acute stroke.[98]

Functional Status

Functional measures are used to determine the impact of impairments and activity limitations, inform the POC, monitor progress, ascertain efficacy of stroke rehabilitation efforts, and make recommendations for long-term care or placement. Instruments can include items to examine *functional mobility skills* (bed mobility, movement transitions, transfers, locomotion, stairs), *basic ADL (BADL) skills* (feeding, hygiene, dressing), and *instrumental ADL (IADL) skills* (communication, home chores). Information on functional disability following stroke is typically gained through performance-based measures. The *Barthel Index*[99] and the *Functional Independence Measure (FIM)*[100] have been extensively tested and demonstrate excellent reliability, validity, and sensitivity. The FIM is now in widespread use in rehabilitation facilities across the United States. Higher FIM scores have been correlated to successful outcomes, discharge home, and return to the community for patients with stroke.[101] See Chapter 8, Examination of Function, for a more detailed discussion of these instruments.

Stroke-Specific Instruments

Fugl-Meyer Assessment of Physical Performance (FMA)

The pioneering work of Twitchell[64] and Brunnstrom[65,66] on motor recovery and behavior following stroke led to the development of the FMA.[102] This is an impairment-based test with items organized by sequential recovery stages. A three-point ordinal scale is used to measure impairments of volitional movement with grades ranging from 0 (item cannot be performed) to 2 (item can be fully performed). Specific descriptions for performance accompany individual test items. Subtests exist for UE function, LE function, balance, sensation, ROM, and pain. The cumulative test score for all components is 226 with availability of specific subtest scores (e.g., UE maximum score is 66, LE score 34; balance score 14). This instrument has good construct validity and high reliability (r = 0.99) for determining motor function following stroke (a gold standard instrument).[103,104] Quantifiable outcome data, standardized measurement methods, and therapist training was used to ensure high interrater reliability for documenting stage wise recovery and outcomes in a large, multicenter clinical trial research (LEAPS trials).[105] The instrument requires an estimated 30 to 40 minutes to administer (see Appendix 15.A). A shortened version consists of combining the UE and LE sections to form the *Fugl-Meyer Motor Scale*. This version has also been shown to be a useful measure of stage wise recovery and outcomes with a shortened administration time.[106]

Stroke Rehabilitation Assessment of Movement (STREAM)

The *STREAM* is a clinical measure of voluntary movements and basic mobility following stoke. It consists of 30 items (test movements) distributed equally among three subscales: upper-limb movements, lower-limb movements, and basic mobility items. Voluntary movement items explore out-of-synergy control and are scored using a 3-point ordinal scale (unable to

perform, partial performance, complete performance). The basic mobility section includes a variety of items (rolling, bridging, sit-to-stand, standing, stepping, walking, and stairs) and is scored using a 4-point ordinal scale (unable, partial, complete/with aid, complete/no aid). The maximum STREAM score is 70 with each limb subscore worth 20 points and the functional mobility subscore worth 30 points.[107] The instrument has good construct validity and high reliability.[108] It has been used to document motor recovery over time and predict discharge destination following stroke.[109,110]

Chedoke-McMaster Stroke Assessment

The Chedoke-McMaster Stroke Assessment examines physical impairment and disability after stroke. It includes two components: the Impairment Inventory and the Activity Inventory.

There are 14 items scored using a 7-point scale with a 2-point score used for walking distance. The Impairment Inventory examines the presence and severity of impairments in six areas (shoulder pain, postural control, and control of the arm, hand, foot, and leg). The Activity Inventory is subdivided into the Gross Motor Function Index (with items including moving in bed and transferring to a chair) and the Walking Index (with items including walking on rough terrain and climbing stairs).[109]

Stroke Impact Scale (SIS)

The SIS is a self-report measure developed to assess function and quality of life after stroke. It includes 59 items organized into 8 subgroups: strength, memory and thinking, emotions, communication, ADL, mobility, hand function, and participation. The final item asks the person to rate perceived recovery on a scale of 0 to 100 with 100 representing full recovery and 0 representing no recovery. It takes about 30 minutes to complete. The SIS is a valid, reliable, and sensitive measure of change in this population.[111,112] Responses can also be accurately provided by proxy.[113] The form and user agreement is available at the following website: www2.kumc.edu/coa/SIS/Stroke-Impact-Scale.htm.

GOALS AND OUTCOMES

Examples of general goals and outcomes for patients with stroke (Preferred Practice Pattern 5D) as adapted from the *Guide to Physical Therapist Practice*[41] are presented in Box 15.7. These general goals will provide the basis for development of specific anticipated goals and expected outcomes for an individual patient.

PHYSICAL THERAPY INTERVENTIONS

Therapists select interventions based on an accurate examination of existing impairments, activity limitations, and goals. Functional, task-specific training is the mainstay of therapy and is designed to assist patients in regaining control of functional movement patterns. Improved motor control and strength of the trunk and limbs, with an emphasis on the more involved side, is achieved through specific reeducation strategies. Intense practice both during therapy sessions and outside of therapy is needed to effect meaningful change. The therapist needs to incorporate motor learning principles and behavioral shaping techniques to effectively support learning. It is also important to create an environment that supports learning and provides the typical challenges of everyday life. In cases of severe deficits, limited recovery, and/or multiple co-morbidities, compensatory training strategies may be necessary to promote resumption of function using the less involved extremities and alternate movement patterns. Strategies to improve motor function are discussed fully in Chapter 10.

Evidence-based practice (EBP) promotes the use of current best research evidence along with individual clinical expertise in order to reach informed decisions about patient care. EBP allows therapists to identify the best (most effective) techniques and to take responsibility for evaluating their practice on an ongoing basis. Studies designed to delineate differences between exercise approaches for the patient with stroke (e.g., neuromuscular reeducation and facilitation approaches [neurodevelopmental treatment (NDT), proprioceptive neuromuscular facilitation (PNF)], motor relearning program, functional training) have often failed to demonstrate clear superiority of one approach over another.[44,46,114–117] Conclusions from Cochrane reviewers state, "There is insufficient evidence to conclude that any one physiotherapy approach is more effective in promoting recovery of lower limb function or postural control following stroke than any other approach. We recommend that future research should concentrate on investigating the effectiveness of clearly described individual techniques and task-specific treatments, regardless of their historical or philosophical origin."[44, p. 4] Many studies are subject to methodological flaws. For example, studies used small sample sizes, failed to include a control group or to control for experimenter bias and co-interventions, and/or utilized poorly defined treatments and/or inappropriate outcome measures. There are a limited number of large, multicenter, randomized controlled trials (RCTs) that offer clinicians a higher level of confidence. Some will be discussed later in this section (e.g., STEPS trial, LEAPS trial, EXCITE trial). Evidence concerning the effectiveness of task-oriented training is presented in Chapter 10, Box 10.1, and Box 15.9 (later in this chapter). Important conclusions to be drawn from these studies are that (1) collectively they provide consistent evidence for the beneficial effects of physical therapy when compared to no treatment or placebo control; and (2) studies on

Box 15.7 Examples of General Goals and Outcomes for Patients with Stroke

Impact of pathology/pathophysiology is reduced.

- Patient/client, family, and caregiver knowledge and awareness of the disease, prognosis, and plan of care are enhanced.
- Symptom management is enhanced.
- Changes associated with recovery are monitored.
- Risk of secondary impairments and recurrence of condition is reduced.
- Intensity of care is decreased.

Impact of impairments is reduced.

- Cognitive function is improved.
- Communication is improved.
- Sensory awareness and skin integrity are improved.
- Perceptual function is improved.
- Awareness and use of the hemiplegic side is improved.
- Pain is decreased.
- Joint integrity and mobility are improved.
- Motor function (motor control and motor learning) is improved.
- Muscle performance (strength, power, and endurance) is improved.
- Postural control and balance are improved.
- Gait and locomotion are improved.
- Aerobic capacity is increased.

Ability to perform physical actions, tasks, or activities is improved.

- Independence in ADL is increased.
- Tolerance of upright postures and activities is increased.
- Problem solving and decision making skills are enhanced.
- Safety of patient/client, family, and caregivers is improved.

Disability associated with chronic illness is reduced.

- Ability to assume/resume self-care and home management is improved.
- Ability to assume work (job/school/play), community, and leisure roles is improved.
- Awareness and use of community resources are improved.

Health status and quality of life are improved.

- Sense of well-being is enhanced.
- Stressors are reduced.
- Insight, self-confidence, and self-management skills are improved.
- Health, wellness, and fitness are improved.

Patient/client satisfaction is enhanced.

- Access and availability of services are acceptable to patient/client and family.
- Quality of rehabilitation services is acceptable to patient/client and family.
- Care is coordinated with patient/client, family, caregivers, and other professionals.
- Discharge placement needs are determined.

Adapted from the *Guide to Physical Therapist Practice*.[41]

task-oriented training have yielded positive results in terms of improving locomotor function (post-stroke locomotor training studies) and UE function (CIMT training studies). Specificity of training and increased intensity of training are important factors in these positive results.

It is important to point out that there is no one intervention optimal for all patients with stroke. Because patients with stroke are a diverse group with variable levels of function, interventions must be carefully selected based on individual abilities and needs. Therapists need to select interventions that have the greatest chance of successfully remediating existing impairments and promoting functional recovery. The choice of interventions must also take into consideration a number of other factors, including phase of post-stroke recovery (acute, postacute, chronic), age of the patient, number of co-morbidities, social and financial resources, and potential discharge placement. Early emphasis on improving functional independence provides an important source of motivation for both the patient and family.

Strategies to Improve Motor Learning

Motor skill learning is based on the brain's capacity for recovery through mechanisms of reorganization and adaptation. An effective rehabilitation plan capitalizes on this potential and encourages active participation—*the patient must be fully engaged*. Activities are selected that are meaningful and important to the patient. Optimal motor learning can be promoted through attention to a number of factors, most importantly, strategy development, feedback, and practice. Carr and Shepherd[118] describe many of these strategies in their book *A Motor Relearning Programme for Stroke*.

Strategy Development

The therapist first assists the patient in learning the desired task (cognitive stage). Explicit verbal instructions are used to direct the patient's attention to the task.

More specifically, critical task elements and successful outcomes are identified. The desired task is demonstrated at the ideal performance speeds. The patient then begins to practice. If the task has a number of interrelated steps, practice of component parts may precede practice of the whole task. It is important, however, not to delay practice of the integrated task because this may interfere with effective transfer of learning. The therapist should give clear, simple verbal instructions and not overload the patient with excessive or wordy instructions. There is some evidence to suggest that providing excessive information about the task can be disruptive to learning, especially for patients with MCA stroke involving the sensorimotor cortex. This interference may block formation of the implicit motor plan.[119,120] Correct performance should be reinforced and intervention provided when movement errors become consistent. Active participation is essential for learning; *there is no learning with passive movements*. Practicing the movements on the less affected side first can yield important transfer effects.

Mental practice or mental rehearsal is the systematic application of imagery techniques for improving performance and learning. The patient is instructed to visualize the movement and imagine himself or herself functionally using the affected limb. Mental practice can be facilitated through the use of audiotapes and has been successfully combined with physical practice to enhance UE recovery[121] and LE recovery and walking ability (gait speed) in patients with stroke.[122] When used in an RCT of early post-stroke patients, recovery of hand movements was not superior using motor imagery than with an equally intense conventional therapy.[123]

As practice progresses, the patient is asked to self-examine performance and identify problems, specifically, what difficulties exist, what can be done to correct the difficulties, and what movements can be eliminated or refined. If a complex task is practiced, the patient is asked to identify if the correct components were performed, how the individual components fit together, and if they were appropriately sequenced. If the patient is unable to provide an accurate assessment of problems, the therapist can prompt the patient in decision making using guiding questions and utilize demonstration to help identify problems. For example, if the patient consistently falls to the right while standing, questions can be directed toward this problem (e.g., "In what direction did you fall?" "What do you need to do to prevent yourself from falling?"). The patient is thus actively involved in developing task analysis and problem-solving skills leading to improved ability to self-correct movements. These skills are essential in ensuring independence in the home and community.

Feedback

Feedback can be intrinsic (naturally occurring as part of the movement response) or extrinsic (provided by the therapist). During early motor learning the therapist provides extrinsic feedback (e.g., verbal cueing, manual cueing), and manual guidance to shape performance. It is important to monitor performance carefully and provide accurate feedback. The patient's attention should be directed to naturally occurring intrinsic feedback. During early intervention visual inputs are critical for motor learning. This can be facilitated by having the patient look at the movement (a central concept of PNF).[124,125] During later learning (associative phase), proprioception becomes important for movement refinement. This can be encouraged by early and carefully reinforced weight-bearing (approximation) on the more affected side during upright activities. Additional proprioceptive inputs (manual contacts, tapping, stretch, light tracking resistance, antigravity postures) can be used to improve feedback and stimulate learning. The patient should be encouraged to "feel the movement" while learning to distinguish correct movement responses from incorrect ones. Surface EMG biofeedback can be used to provide augmented feedback. Exteroceptive inputs (light rubbing, stroking) may be used to provide additional sources of sensory inputs, particularly where distortions of proprioception exist. As treatment progresses, the emphasis again shifts from extrinsic to intrinsic feedback and to self-monitoring and self-correcting movement responses. Great care must be taken to avoid dependence on the therapist (i.e., the patient is only able to move with the therapist's manual or verbal assistance) by providing decreasing amounts of physical guidance and augmented feedback. This requires careful consideration during each treatment session. Therapists should allow the patient adequate time for introspection about the movements and available feedback.

The use of a mirror can be an effective adjunct for some patients to improve motor function using visual feedback. *Mirror therapy (MT)* is a therapeutic intervention that focuses on moving the less impaired limb while watching its mirror reflection. A mirror is placed in the patient's midsagittal plane, presenting the patient with the mirror image of his or her less affected limb as if it were the hemiparetic limb. It was first introduced by Ramachandran et al[126] for individuals with arm amputation. For patients with stroke, MT has been shown to improve LE recovery and ankle dorsiflexion.[127] MT has also been shown to improve UE recovery and distal motor function and recovery from hemineglect.[128,129] In these studies, both the mirror groups and the control groups also participated in a conventional stroke rehabilitation program. It is important to note that use of mirrors is contraindicated in patients with marked visuospatial perceptual impairments.

Practice

Practice, practice, and more practice is essential for motor skill learning and recovery. The therapist needs

to organize the patient's therapy session to ensure optimal practice. *Blocked practice* (constant repetition of a single task) is used to improve *initial* performance and motivation, especially for patients with disorganized movements. Most hospitalized patients also initially require a *distributed practice schedule* with adequate rest periods owing to limited endurance as both physical and cognitive fatigue can result in decreased performance. The patient should be encouraged to self-monitor practice sessions and recognize when fatigue may be setting in and rest is required. The therapist needs to progress the patient to *variable practice* (practice of more than one task within a session) using a serial or random order as soon as possible. Variable practice improves performance and results in better retention of learned skills and improved ability to adapt to changing task demands. Patient, staff, and family efforts should be coordinated to ensure continued and consistent practice during off-therapy times.

Careful attention to the learning environment will also yield important therapeutic gains. Distractions should be reduced and a consistent and comfortable environment provided in which the patient can learn. For many patients with stroke and cognitive/perceptual deficits, this will initially be a *closed environment* with limited distractions. Later the environment can be varied, providing an appropriate level of *contextual interference*. Thus the patient is progressed toward performing the same skill in a more *open environment*, with variable and real-life challenges. The addition of *Easy Street Environments* to many rehabilitation centers provides an important tool to simulate community environments.

Motivation is key to successful learning. The patient should be fully involved in collaborative goal-setting from the beginning and continually reminded of the goal, the task, what progress has been made, and the expected outcomes. Treatment sessions should include positive experiences, ensuring the patient experiences success in therapy and instilling self-confidence. Beginning and ending the therapy session on a positive note (a successful activity) is a helpful strategy. Self-efficacy ratings and summary comments can be used to monitor progress (e.g., "What successes did you achieve in therapy today?"). Supportive strategies should be discussed with family and caregivers. Finally, the therapist needs to continually communicate support and encouragement. Recovery from stroke is an extremely stressful experience that will challenge the coping abilities of both patient and family.

Interventions to Improve Sensory Function

Patients who have significant sensory impairments may demonstrate impaired or absent spontaneous movement. The more the patient can be encouraged to use the affected side, the greater the chance of increased awareness and function. Conversely, the patient who refuses to use the hemiplegic side contributes to the problems imposed by lack of sensorimotor experience. Without attention during treatment, this *learned nonuse* phenomenon can contribute to further deterioration.[130]

Multiple interventions for UE sensory impairment after stroke have been described. These can be categorized into sensory retraining or sensory stimulation approaches. *Sensory retraining programs* include use of mirror therapy (previously discussed), repetitive sensory discrimination activities, bilateral simultaneous movements, and repetitive task practice (e.g., *sensorimotor integrative treatment* with its focus on normalizing tone, practice of functional activity, and use of augmented sensory cues). *Sensory stimulation intervention* includes compression techniques (weight-bearing, manual compression, inflatable pressure splints, intermittent pneumatic compression), mobilizations, electrical stimulation, thermal stimulation, or magnetic stimulation. In a review of 13 studies, Cochrane reviewers[48] found significant clinical and methodological diversity, limited RCT trials, generally small sample sizes with inadequate data, variability in outcome measures, and limited used of functional performance and participation outcome measures. They concluded there was insufficient evidence to support or refute the effectiveness of many of these interventions in improving sensory function. Limited evidence was found in support of the following:

- Mirror therapy for improving detection of light touch, pressure, and temperature pain
- Thermal stimulation intervention for improving rate of recovery of sensation
- Intermittent pneumatic compression for improving tactile and kinesthetic sensation

The results of a systematic review of sensory retraining by Schabrun and Hillier[131] were similar with additional support found for electrical stimulation interventions.

During functional training, the therapist needs to maximize weight-bearing and compression of the sensory deficient limbs. Approximation can be applied with the sensory-deficient UE weight-bearing in sitting or standing/modified plantigrade position and to the pelvis during standing activities. While sitting on a ball, the patient can practice bouncing. The compression and approximation that occur through the spine enhances activity in the postural extensors. During the application of sensory stimulation to the more involved limbs, the therapist directs the patient's attention and assists in shaping the patient's responses.[132,133]

A safety education program should be instituted early for patients, family, and caregivers to improve awareness of sensory impairments and ensure protection of anesthetic limbs. This is particularly important for preventing UE trauma during transfer and wheelchair activities.

Interventions to Improve Hemianopsia and Unilateral Neglect

Patients with hemianopsia or unilateral neglect demonstrate a lack of awareness of the contralesional side. The impairments are more pervasive in patients with neglect and in its most severe form (anosognosia) may extend to a total unawareness of the disability or the extent of the problems. These patients benefit from training strategies that encourage awareness and use of the environment on the hemiparetic side and use of the hemiparetic extremities. It is important to teach active visual scanning movements through turning of the head and axial trunk rotation to the more involved side. Cueing (e.g., visual, verbal, or motor cues) is used to direct the patient's attention. For example, a red anchor line can be taped on the floor and the patient directed to visually follow the line from one side to the other. Or a red ribbon can be attached to the patient's hemiparetic wrist and the patient directed to keep the red ribbon in sight. Scanning movements can also be stimulated using visual tracking tasks using a computer. Patients are given feedback about the success of their efforts and reinforcement for each successful performance (shaping). Imagery has also been shown to help (e.g., "Imagine you are a lighthouse beam; use your beam to sweep and scan the floor from one side to the other"). During therapy, the therapist stimulates and encourages active voluntary movements of the neglected limbs while encouraging the patient to look at his or her limbs while moving. UE exercises that involve crossing the midline toward the hemiparetic side (e.g., reaching activities or PNF chop or lift patterns) are important. Functional activities that encourage bilateral interaction are also valuable (e.g., pouring a drink and drinking from a cup; picking up an object with the more involved hand and placing it in the other; "dusting a tabletop" with a cloth held by both hands). The therapist needs to maximize the patient's attention by optimizing visual, tactile, or proprioceptive stimuli on the more affected side. These can include stroking, brushing, tapping, or vibrating the hemiparetic limbs. The therapist also needs to consistently reorient the patient as inattention develops. Patients with very low levels of arousal are likely to be less responsive to therapy efforts.[134-136]

Interventions to Improve Flexibility and Joint Integrity

Soft tissue/joint mobilization and ROM exercises are initiated early to maintain joint integrity and mobility and prevent contractures. Passive ROM (PROM), and AROM when possible, with terminal stretch should be performed daily in all motions. If a contracture is developing, more frequent ROM (twice daily or more) is necessary.

Positioning strategies are also important in maintaining soft tissue length (Box 15.8). Effective positioning of the hemiparetic extremities encourages proper joint alignment while positioning the limbs out of the abnormal postures typically assumed. The use of protective devices such as resting splints may be necessary. Coordination with staff, family, and caregivers is essential for long-term management.

In the UE, correct PROM techniques require careful attention to external rotation and distraction

Box 15.8 Positioning Strategies to Reduce Common Malalignments

Supine Position

- Head/neck: Neutral and symmetrical; supported on pillow.
- Trunk: Aligned in midline.
- More affected UE: Scapular protracted, shoulder forward and slightly abducted; arm supported on a pillow; elbow extended with hand resting on a pillow; wrist neutral, fingers extended, and thumb abducted.
- More affected LE: Hip forward (pelvis protracted); knee on a small pillow or towel roll to prevent hyperextension; nothing against the soles of feet. For persistent plantarflexion, a splint can be used to position the foot and ankle in neutral position.

Side-lying on Less Affected Side

- Head/neck: Neutral and symmetrical.
- Trunk: Aligned in midline; small pillow or towel can be placed under the rib cage to elongate the hemiplegic side.
- More affected UE: Scapular protracted, shoulder forward; arm on a supporting pillow with elbow extended, wrist neutral, fingers extended, and thumb abducted.
- More affected LE: Hip forward and flexed, knee flexed and supported on a pillow.

Side-lying on More Affected Side

- Head/neck: Neutral and symmetrical.
- Trunk: Aligned in midline.
- More affected UE: Scapular protracted; shoulder forward; arm placed in slight abduction and external rotation; elbow extended, forearm supinated, wrist neutral, fingers extended, and thumb abducted.
- More affected LE: Hip extended and knee flexed and supported by pillows. An alternative position is slight hip and knee flexion with pelvic protraction.

Sitting in an Armchair or Wheelchair

- Head/neck: Neutral and symmetrical; head directly above pelvis.
- Trunk: Spine extension.
- Pelvis: Aligned in neutral with weight-bearing on both buttocks.
- More affected UE: Shoulder protracted and forward; elbow supported on an arm trough or lapboard; forearm, wrist neutral, fingers extended, and thumb abducted (resting splint as needed).
- Both LEs: Hips flexed to 90°, positioned in neutral with respect to rotation.

of the humerus, especially as ranges approach 90° of flexion or more. The scapula should be mobilized on the thoracic wall with an emphasis on upward rotation and protraction to prevent soft tissue impingement in the subacromial space during overhead movements of the arm (Fig. 15.7) and to prepare for forward reach patterns. The use of overhead pulleys for self-ROM is contraindicated because of failure to achieve the above requirements for scapulohumeral movement. Full extension of the elbow is important because the majority of patients with stroke develop tightness in elbow flexors as a result of excess flexor spasticity. Normal length of wrist and finger extensors should also be maintained as tightness is typical in flexion. This can be achieved functionally through sitting, weight-bearing on the extended paretic UE with the wrist extended and fingers open and extended (Fig. 15.8). Edema and tonal changes may produce impingement with wrist extension. In this situation, the carpal bones should be mobilized before stretching at the wrist.

Figure 15.7 Range-of-motion exercises for the hemiparetic UE. The therapist carefully mobilizes the scapula during arm elevation.

Figure 15.8 Sitting, with extended arm support. The therapist assists in stabilizing the elbow and fingers in extension.

Strategies to teach patients safe self-ROM activities should be instituted early. Suggested activities include the following:

- *Arm cradling*: The stronger UE cradles and lifts the more affected UE to 90° humeral flexion; the arm is moved into positions of horizontal abduction and adduction. Active trunk rotation is combined with the arm movements.
- *Table-top polishing*: The more affected UE is positioned in humeral flexion with scapular protraction and elbow extension; both hands are positioned on a towel. The less affected hand moves the paretic hand by pulling on the towel (forward, and side-to-side). Trunk movements and ROM are optimized by placing the chair slightly back from the table.
- Sitting, the patient leans forward and reaches both hands down to the floor. This position encourages forward flexion of the humerus with scapular protraction, and extension of the elbow, wrist, and fingers.
- Supine, hands are clasped together and placed behind the head, the elbows fall flat to the mat. This activity should be considered only if scapula upward mobility is present. Hands clasped, self-overhead movements are contraindicated if scapulohumeral rhythm is lacking.

When sitting in a wheelchair, the patient's paretic UE can be positioned on an arm trough (shallow elbow/forearm support) attached to the armrest. The shoulder is positioned in 5° of abduction and flexion and neutral rotation; elbow in 90° flexion and slightly forward; forearm pronated; and hand in a functional resting position. Splinting the hand is also common. *A volar resting (pan) splint* positions the forearm, wrist, and fingers in a functional position (20° to 30° of wrist extension, metacarpophalangeal [MP] flexion 40° to 45°, interphalangeal [IP] flexion 10° to 20°, and thumb opposition). A resting splint is appropriate for nighttime use, allowing patients daytime use of their hand. In the presence of spasticity, tone-reducing devices can be considered (e.g., finger abduction splint, firm cone, spasticity reduction splint, or inflatable pressure splint).

As most patients regain some use of their LEs early in recovery, ROM techniques focus on individual patient needs with attention to several common areas of impairment. For many patients, voluntary movement in the foot and ankle is limited owing to plantarflexor spasticity and/or dorsiflexor weakness. Weight-shifting activities in modified plantigrade (forward shift stretches the plantarflexors) or prolonged static positioning using adaptive equipment (i.e., tilt table with toe wedges) can be used to gain range. Facilitation of active contraction of dorsiflexors can also be combined with stretching to provide reciprocal inhibition to plantarflexors. If synergistic influence is strong, the patient can be effectively positioned while supine on a mat with the paretic LE abducted off the side

with knee flexed and foot flat on the floor or a stool. This position of hip abduction and extension with knee flexion serves to breakup synergistic dominance and position the limb out of the typical spastic scissoring posture. If the patient spends considerable time sitting in a wheelchair, care should be taken to stretch the hip flexors. If hip flexor contractures are allowed to develop, they can lead to increased difficulty with standing, transfers, and ambulation.

Interventions to Improve Strength

Muscle weakness is a major impairment after stroke and contributes to significant activity limitations (e.g., walking, sit-to-stand transfers, stair climbing, UE activities). Progressive resistive strength training has been shown to improve muscle strength in individuals with stroke,[137-149] with no evidence of a detrimental increase in spasticity or reduction in ROM.[137,138] Most studies have indicated improvements in function,[138,142,143,145,149] although some have failed to demonstrate carryover to improved function.[137] Specificity of training as well as variable intensities of training may explain this inconsistency.

Exercise modalities for strengthening include free weights, elastic bands or tubing, and machines (PRE, isokinetics). For patients who are very weak (less than 3/5), gravity-minimized exercises using powder boards, sling suspension, or aquatic exercise is indicated. Gravity-resisted active movements are indicated for patients who demonstrate 3/5 strength (e.g., arm lifts, leg lifts). Patients who demonstrate adequate strength in independent gravity-resisted movement (e.g., 8 to 12 repetitions) can be progressed to exercise using added resistance (e.g., free weights, bands, or machines). Ideally resistance training should occur 2 to 3 times a week; three sets of 8 to 12 repetitions per exercise should be used.[24]

Combining resistance training with task-oriented functional activities enhances carryover in terms of improving function (e.g., sit-to-stand transfers, partial wall squats [Fig. 15.9], step-ups, stair climbing while the patient is wearing weighted cuffs). Circuit training workstations can be used to maximize muscle training.[145] Lifting free weights or using elastic bands places added demands for postural stability in sitting and standing and is an important element of training to improve postural control.

Exercise Precautions

Many patients with stroke demonstrate poor hand function with no effective grasp. Specially designed gloves may be necessary to ensure maintained contact with exercise equipment (e.g., leather mitts with Velcro®, wrist cuffs). Patients with impaired sensation are at increased risk for injury and should be monitored closely. Patients with postural deficits should be safely positioned to prevent falls (e.g., stable seat, corner standing while lifting free weights).

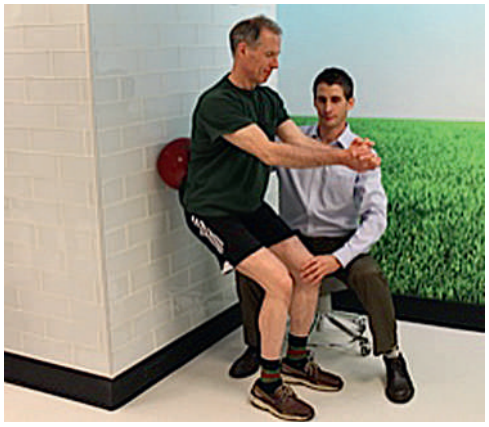

Figure 15.9 Partial wall squats using a small ball; the therapist assists in control of knee.

In determining a safe exercise prescription, it is important to remember the high incidence of hypertension and cardiac disease in patients with stroke. High-intensity strengthening exercises (sustained maximal effort) is generally contraindicated in patients with recent stroke and unstable BP. Isometric exercise that is accompanied by the Valsalva maneuver and dangerous elevations in BP is also contraindicated. Dynamic exercises performed in an upright position (sitting) produce less elevations in BP than recumbent/supine exercises. For patients at risk, submaximal protocols using low-intensity exercises (e.g., 30% to 50% of maximal voluntary contraction) are appropriate for initial exercise. Varying the exercises is also an effective strategy to reduce cardiovascular risk. The therapist needs to ensure that warm-ups and cool-downs are adequate and the overall exercise progression is gradual.

Interventions to Manage Spasticity

Patients who demonstrate spasticity can benefit from interventions designed to manage the effects of spasticity (immobility, soft-tissue contracture, and deformity). These include early mobilization and daily stretching to maintain the length of spastic muscles and soft tissues and promote optimal positioning.[150] It is important to note that the methodological quality of research studies in this area is diverse and not well controlled, and available evidence about the effectiveness of stretching is inconclusive.[151,152] The technique of *rhythmic rotation*, a manual technique that incorporates slow gentle rotations of the limb while progressively moving the limb into its lengthening range, can be effective in gaining initial range.[153] Once full range is achieved, the limb is positioned in the lengthened position. For example, the shoulder is extended, abducted, and externally rotated

with the elbow, wrist, and fingers extended. The hand is positioned in weight-bearing to the patient's side (see Fig. 15.8) and maintained for several minutes. The benefits of *sustained stretching* include relaxation through mechanisms of autogenic inhibition. In sitting, slow rocking movements can be added to increase relaxation effects from influences of slow vestibular stimulation. Spasticity in the quadriceps can be similarly inhibited through prolonged positioning and weight-bearing in kneeling or quadruped positions. A reduction in truncal stiffness can be promoted using techniques of rhythmic rotation or rhythmic initiation combined with axial trunk rotation (e.g., in side-lying, sitting or hook-lying, segmental trunk rotation).[153] PNF upper trunk patterns (chopping or lifting) that emphasize rotational movements of the trunk can also be effective in maintaining range and reducing trunk stiffness.[125] Side sitting on the hemiparetic side provides sustained stretch to the spastic side flexors. The patient, family members, and caregivers should be taught safe ROM and stretching techniques.

Active exercise should focus on the activation of the weak antagonist muscles using slow, controlled movements. Local facilitation techniques (e.g., stretch, tapping, light resistance) can be added to enhance the action of very weak antagonist muscles. Contraction helps reduce agonist tone through the effects of reciprocal inhibition. Thus, in the UE, efforts are directed toward active contractions of the elbow extensors in the presence of flexor spasticity, whereas in the LE efforts are directed toward active contractions of the knee flexors with extensor spasticity. It is important to remember that reciprocal relationships may not be within normal ranges, particularly in the presence of strong spastic co-contraction. Excessive effort should be avoided because it can have a negative effect on spasticity. Soothing verbal commands and cognitive relaxation techniques (mental imagery) can be used to provide an overall calming influence and generally relax tone while pain has the opposite effect.

Modalities can be used to treat spasticity. These include the application of cold, massage, and electrical stimulation. Cold slows nerve conduction and decreases muscle spindle activity. These factors can lead to a temporary reduction of tone. Cold can be applied with ice packs or ice massage (duration 10 to 20 minutes) or using vapocoolants. The effects of cold are short-lived, generally lasting for about 20 to 30 minutes. Functional electrical stimulation (FES) can be used to target the weak antagonist muscles (e.g., peroneal nerve stimulators) and works to decrease tone through the effects of reciprocal inhibition. FES has been used with some success to decrease tone during the treatment time.[152]

Orthotic devices can be used to maintain the spastic muscle in its lengthened position and help decrease hypertonia and increase or maintain PROM. These include inflatable pressure splints,[154] static or resting splints, and serial casts.[155,156] Air splints can also help control unwanted synergistic movements and stabilize limbs during early weight-bearing activities (e.g., sitting, modified plantigrade). Patients with a flaccid, hypotonic limb may also benefit from the use of pressure splints to provide sensory input and initial stabilization. Long or full limb pressure splints also assist in controlling edema, a common problem of paralyzed limbs. Positioning the splinted limb in elevation can assist in reducing edema.

Interventions to Improve Movement Control

Activities that promote voluntary movement control, postural control, and functional use of the extremities are the primary focus of initial movement training. Patients with stroke typically present with loss of dissociated or fractionated movements with obligatory synergy patterns. For example, coordinated grasp and manipulation are lost as the fingers respond with strong flexion when lifting the arm results in elbow flexion with flexion, abduction, and external rotation of the shoulder. Interlimb and intralimb control is also abnormal with movements of one limb linked to movements of the other through associated reactions. During initial training, the therapist needs to focus on *dissociation* of different body segments (the ability to isolate and move the different parts of the body or limb separately) and *selective* (out-of-synergy) movement patterns. For example, the more affected UE is stabilized in an extended weight-bearing position while the patient practices stepping movements in modified plantigrade position.

The linking together of the proper components of movement and the refinement of isolated control requires a great deal of concentration and volitional control. Movements that are performed too quickly or with too much force will be ineffective in producing the control needed. Thus, the therapist needs to instruct the patient to avoid excessive effort during movement. The therapist should aim for as much normalcy in movement as possible and select postures that assist the desired movements through optimal biomechanical stabilization and/or use of the optimal point in the range. As control develops, postures can be changed to more difficult ones that challenge developing control. For example, initial elbow extension can be first attempted in side-lying with the shoulder flexed to 90° (e.g., the patient pushes the arm forward, extending the elbow). The posture can then be changed to sitting, and finally standing.

The therapist may need to assist (guide) initial movement attempts or use facilitation techniques (e.g., stretch, resistance, electrical stimulation). Movements should shift to active control as soon as possible. Often the resistance of gravity acting on the body or slight manual resistance is enough to initiate or facilitate correct movement responses through proprioceptive loading.

Repetitive task-specific training is the main focus of the rehabilitation program. The tasks selected should be relevant and important to the patient (e.g., reaching and manipulation, walking, stair climbing). Normal function implies variability of movements. Muscles need to be activated in varied activities using varied types of contractions. All three types—eccentric, isometric, and concentric—are important to include in an exercise program. For the patient with stroke who demonstrates very weak movements, isometric and eccentric contractions should be practiced before concentric contractions because they utilize elastic elements and muscle spindle support more efficiently. For the same amount of tension, fewer motor units are required. Practice of functional tasks that utilize variations of contractions should also be implemented. For example, the patient who practices modified wall squats in standing is utilizing a sequence of eccentric (lowering), isometric (holding), and concentric (extending) contractions of the hip and knee extensors (Fig. 15.9). Weak muscles (typically antagonistic to strong spastic muscles) should be activated first in unidirectional movements. As control develops, exercises can shift to include slow active reciprocal contractions of agonist and antagonist muscles first in limited ranges, then in full range. This emphasis on balanced interaction of both agonists and antagonists is crucial for normal coordination and function. Proprioceptive neuromuscular facilitation patterns can be effective for the patient with limited voluntary control with its emphasis on normal synergistic patterns (e.g., D1 patterns), reversals of antagonists, and proprioceptive loading through light resistance.[124,125] Excellent resources for exercise and training for patients with stroke can be found in the works of Carr and Shepherd,[157] Davies,[158,159] and Howle.[160]

Strategies to Improve Upper Extremity Function

Patients with MCA syndrome may exhibit severe sensory, motor, and functional impairments of the UE with limited recovery. These patients benefit from early mobilization, ROM, and positioning strategies, previously discussed in this chapter. Compensatory training strategies and environmental adaptations should be considered to maximize function. For patients who achieve some recovery of voluntary movement, training strategies should focus on repetitive, task-specific practice. UE training activities should be closely coordinated with the occupational therapist.

UE Weight-Bearing as a Postural Support

Postural shift toward the more affected side with weight-bearing on the extended arm and stabilized hand on a support surface is an important early activity to promote proximal stabilization and counteract the effects of excess flexor hypertonus and a dominant flexion synergy. Approximation can be used to increase activity of shoulder/scapular stabilizers and tapping can facilitate the elbow extensors. Weight-bearing activities are performed in sitting (see Fig. 15.8), modified plantigrade (Fig. 15.10), and standing positions. Control should progress from holding to dynamic stabilization activities. For example, the patient stabilizes with the more affected UE while performing weight shifts and functional tasks with the stronger UE (e.g., reaching). As previously mentioned, the more affected UE should also be recruited for postural assistance during functional training activities (e.g., pushing up from side-lying into sitting).[161]

Task-Oriented Reaching and Manipulation

Patients with stroke have difficulty regaining control of scapular upward rotation and protraction, elbow extension, and wrist and finger extension necessary for forward reach and manipulation. Reaching and manipulation also requires accurate processing and use of visual–perceptual information. Patients with limited voluntary control can practice initial reaching in a supported position (e.g., side-lying with arm supported by therapist or on a powder board, sitting with the UE resting on a tabletop). The patient is encouraged to slide the hand forward over tabletop, recruiting shoulder flexors, scapular protractors, and elbow extensors. A cloth can be used to decrease friction effects as the patient practices wiping or polishing a table. The patient can also practice reaching forward and downward touching the floor. More advanced reaching activities include independent lifting and reaching forward (e.g., UE placed into a shirt sleeve), overhead, or sideward. A PNF D1 thrust pattern can

Figure 15.10 Standing in modified plantigrade, both UEs extended and weight-bearing; the therapist assists elbow extension of the hemiparetic UE while providing approximation through the shoulder.

be practiced (reverse thrust is contraindicated as the limb is moving into a flexion synergy pattern). Combining reaching with increased balance challenges in modified plantigrade or standing should also be incorporated. For example, the patient can practice pushing a ball side-to-side or forward-backward while standing in modified plantigrade (Fig. 15.11). Or in standing the patient can practice reaching to pick an object up off a shelf, a low stool, or the floor. Varying the height and distance reached, increasing the weight of objects held in the hand, or increasing the speed and accuracy requirements can increase difficulty. Substitution movements (e.g., trunk or head lateral movements) should not be allowed. Excessive shoulder elevation should also be discouraged.[161]

Meaningful task-oriented practice involving grasp and manipulation is important for stimulating recovery. Initial hand movements typically include gross grasp and release while advanced hand patterns (fine motor control) may not be present unless there is more advanced recovery. Voluntary release is generally much more difficult to achieve than voluntary grasp, and stretching/positioning and inhibitory techniques may be necessary to facilitate extension movements. Initial hand tasks can include using the more affected hand to stabilize (e.g., hand stabilizes paper while the stronger hand writes, hand stabilizes food while the stronger hand cuts) or holding a book with both hands for reading. The patient should be encouraged to use the weaker hand to assist in ADL (e.g., washing the upper body with a washcloth, bringing food to mouth). Forks, toothbrushes, and pens may need to have built-up handles for grasp. Task training should combine reach patterns with hand activity (e.g., picking sock off floor, reaching for an object off a shelf). Advanced hand activities include practice of wrist and finger extension, opposition, and manipulation of objects (e.g., using utensils to eat, drinking from a cup, writing, picking up and reorienting coins, paperclips, or other objects). Pronation often predominates while active supination without elbow and shoulder flexion is difficult to achieve. The therapist must observe movements carefully and assist in eliminating those aspects of movement patterns that interfere with effective and efficient control. Graded physical assist and use of mental practice/imagery techniques can be helpful to improve learning and performance.[157,161,162]

Figure 15.11 Standing in modified plantigrade with hemiparetic hand positioned on small ball; the patient practices rolling the ball from side-to-side; the therapist stabilizes the elbow and shoulder.

Constraint-Induced Movement Therapy

Constraint-induced movement therapy (CIMT) is a multifaceted intervention designed to promote increased use of the more affected UE. The patient is engaged in intense task-oriented practice of the more affected UE for up to 6 hours a day, performed on consecutive weekdays for 10 to 15 days (Fig. 15.12). The less affected UE is restrained from use by having the patient wear a safety mitt up to 90% of waking hours.[163] The therapist uses shaping techniques to modify and progress performance (e.g., an object is lifted and placed at increasing distances away from the patient). Feedback, coaching, modeling, and encouragement are provided during practice. Behavioral methods designed to ensure adherence to exercise and developing task-oriented behaviors include engaging the patient in:

- Self-monitoring of target behaviors (e.g., mode of activity, duration, frequency, perceived exertion, and overall response to activity)
- Problem-solving to identify obstacles and generate potential solutions

Figure 15.12 Constraint-induced movement therapy (CIMT). The patient practices a pegboard task using the hemiparetic hand while the less affected hand wears a mitt. The therapist times the activity while encouraging the patient.

- Behavioral contracting to engage the patient in carrying out behaviors throughout the day
- Social support strategies to educate and enlist caregivers in provident optimal support

The reader is referred to the work of Morris and Taub[164,165] for a more complete description of these techniques. *Modified CIMT* (mCIMT) has also been used for patients with stroke. For example, Page et al[166,167] used 30 minutes of functional task practice and shaping techniques 3 days per week, and restraint of the less affected UE for up to 5 hours per day. Training occurred over an extended 10-week period. This outpatient protocol increased the use and function of the more affected arm.[166,167]

Significant gains in motor function and a moderate reduction in disability following CIMT have been demonstrated in patients with stroke.[45,168,169] The *EXCITE trial* was a large prospective, single-blind, randomized, multisite study that included 222 patients after stroke. CIMT was compared to customary care and found to significantly improve outcomes as measured by the Wolf Motor Function test and the Motor Activity Log.[170] Associated changes in brain organization with CIMT have also been demonstrated on functional magnetic resonance imaging (fMRI), including an apparent shift in motor cortical activation toward other ipsilateral areas and the contralesional hemisphere.[171] Significant gains have also been reported in the patients receiving mCIMT.[165,166,172] It is important to note that patients were included in the studies if they had potential for recovery and some residual upper arm and hand movement (active wrist and finger extension) but tended not to use the arm. Limited pain or spasticity and absence of cognitive impairment were also inclusion criteria. Many early studies involved patients with chronic stroke (greater than 1 year). Evidence also exists for positive results with subacute stroke patients (less than 1 year)[170] and acute patients (less than 2 weeks after stroke).[173] The Cochrane researchers in their review of the literature concluded that evidence supporting maintained improvement from CIMT over 6 months is lacking.[45] The reader is referred to additional discussion in Chapter 10 and a summary of research findings presented in Box 10.1 Evidence Summary CIMT.

Simultaneous Bilateral Training

Simultaneous bilateral training involves using both arms simultaneously alone or in combination with augmented sensory feedback. Bilateral arm training with rhythmic auditory cueing (BATRAC) is an example of this intervention.[174] It is theorized that similar movement in the less affected extremity facilitates movement in the more affected extremity. Positive results have been reported in improving motor recovery after stroke.[174-176] When compared to usual or conventional care, simultaneous bilateral training was not shown to be significantly better than other UE interventions in terms of improvements in ADL, arm or hand movements, or scores on motor impairment measures. The Cochrane reviewers cited lack of high-quality evidence in these findings.[47]

Electromyographic Biofeedback

Electromyographic biofeedback (EMG-BFB) has been used to improve motor function in patients following stroke. The technique allows patients to alter motor unit activity based on augmented audio and visual feedback information. Training can focus on voluntary inhibition of spastic muscles (e.g., reducing firing frequency of spastic finger flexors), or on increasing kinesthetic awareness and recruitment of motor units in weak, hypoactive muscles (e.g., wrist/forearm extensor muscles). Patients in late recovery for whom spontaneous recovery is more or less complete (greater than 6 months post-stroke) have demonstrated positive results that have been attributed to biofeedback therapy.[177,178] Reported benefits include improvements in ROM, voluntary control, and function. Researchers indicate that effectiveness of biofeedback neuromuscular reeducation is greatest when used as an adjunct to task-specific training.

Electrical Stimulation

Neuromuscular electrical stimulation (NMES) has been used with patients recovering from stroke to reduce spasticity, improve sensory awareness, prevent or reduce shoulder subluxation, and stimulate volitional movements.[179-182] NMES has been shown to increase the ability of muscle to exert force by preferentially activating the fast-contracting motor units. Effective treatment results have been reported for improving function in wrist extensors and the deltoid and supraspinatus muscles. In the latter example, glenohumeral alignment was improved and subluxation reduced. As with the biofeedback research, optimal results have been obtained when combined with task-specific training.[182]

Robot-Assisted Therapy

Robotic devices have been developed to assist the patient with moderate to severe motor impairments in improving UE function and recovery. They are used in conjunction with task-oriented training and motor learning principles. Robots work to restore lost motor function and can include pneumatic actuators (acting as muscles) to power the device or passive robotic systems using elastic bands or springs. Reach and grasp/release movements are typically targeted. These devices are used to augment therapist-patient interventions and enable high levels of intensive practice.[183] Limited evidence exists of treatment efficacy that can be generalized to arm and

hand use during ADL. High cost of equipment limits widespread use in the clinical setting.[184]

Management of Shoulder Pain

Several causes of hemiplegic shoulder pain have been identified that can be broadly divided into flaccid and spastic presentations. In the flaccid stage, proprioceptive impairment, lack of tone, and muscle paralysis reduce the support and normal seating action of the rotator cuff muscles, particularly the supraspinatus. The ligaments and capsule thus become the shoulder's sole support. The normal orientation of the glenoid fossa is upward, outward, and forward, so that it keeps the superior capsule taut and stabilizes the humerus mechanically. In the absence of supporting musculature, any abduction or forward flexion of the humerus, or scapular depression and downward rotation, reduces this stabilization and causes the humerus to sublux. Initially the subluxation is not painful, but mechanical stresses resulting from traction and gravitational forces produce persistent malalignment and pain. Glenohumeral friction–compression stresses also occur between the humeral head and superior soft tissues during flexion or abduction movements in the absence of normal scapulohumeral rhythm (*shoulder impingement syndrome*). During the spastic stage, abnormal muscle tone may contribute to poor scapular position (depression, retraction, and downward rotation) and to subluxation and restricted movement. Secondary tightness in ligaments, tendons, and joint capsule can develop quickly. *Adhesive capsulitis* (intracapsular inflammation and "frozen shoulder") can occur. Poor handling and positioning of the more affected UE have been implicated in producing joint microtrauma and pain. Activities that traumatize the shoulder include PROM without adequate mobilization of the scapula (promoting normal scapulohumeral rhythm), traction or pulling on the UE during a transfer, or using reciprocal pulleys.[185-187] An incorrectly aligned joint can significantly impair the patient's ability to move. Additional interventions aimed at reducing subluxation can include NMES therapy, EMG biofeedback, taping, and slings.

Complex regional pain syndrome type 1 (CRPS-1), also known as shoulder-hand syndrome (SHS) or reflex sympathetic dystrophy, is caused by proximal trauma to the shoulder or neck or can occur with stroke and may be the result of autonomic nervous system (ANS) changes. Clinical factors associated with its development include motor deficits, spasticity, sensory deficits, and initial coma.[188] Early on, pain is intermittent and limited to the shoulder. During later stages pain is intense and involves the whole extremity. CRPS-1 is associated with a range of other symptoms. Stiffness and limitations in ROM occur. The wrist tends to assume a flexed position with intense pain likely during wrist extension movements. The elbow is not typically involved. Early *stage 1* vasomotor changes include discoloration (pale pink or cool) and alterations in temperature. The skin may be hypersensitive to touch, pressure, or temperature variations. The patient typically guards against movement attempts. *Stage 2* is characterized by subsiding pain and early dystrophic changes: muscle and skin atrophy, vasospasm, hyperhidrosis (increased sweating), and coarse hair and nails. There is radiographic evidence of early osteoporosis. In *stage 3,* the atrophic phase, pain and vasomotor changes are rare. There is progressive atrophy of the skin, muscles, and bones (severe osteoporosis is evident). Pericapsular fibrosis and articular changes become pronounced. The hand typically becomes contracted in a clawed position with MP extension and IP flexion (similar to the intrinsic minus hand). There is marked atrophy of thenar and hypothenar muscles with flattening of the hand. Chances of reversal of signs and symptoms are high for stage 1 and variable for stage 2, whereas stage 3 changes are largely irreversible.[188]

Early diagnosis and identification of factors that cause CRPS is essential. Interventions are selected based on examination findings. Because of close daily contact with the patient, the physical therapist is frequently one of the first to recognize and report early signs and symptoms. A prevention protocol should be implemented.[189] In the flaccid stage, the arm should be supported at all times. Proper positioning and handling are essential. In bed, patients should be positioned so they cannot roll onto the more affected UE, compressing it. In supine and wheelchair sitting the scapula/shoulder should be supported with the arm forward in slight abduction and neutral rotation. During transfers and standing supportive devices should be considered to prevent traction injury (see section below). Interventions aimed at reducing pain and stiffness include appropriate PROM and mobilization techniques (gentle grade 1 to 2 mobilizations). PROM to the UE without scapular mobilization is *not* permitted. PROM of the shoulder should be limited to 90 degrees during flexion and abduction or to the point of pain, not beyond the pain position. The therapist needs to ensure that everyone involved in assisting the patient (e.g., family member, caregiver, nurses, and aides) has been instructed in proper handling/mobilization of the UE and recognizes the importance of avoiding trauma and traction injuries during PROM, transfers, and wheelchair activities. Active movements of the UE are encouraged to promote shoulder ROM (e.g., pushing away a tabletop therapy ball while standing). Interventions to manage edema are also a consideration. Additional considerations include no infusions into the veins of the hemiplegic hand. Persistent pain may be managed with oral analgesics or local injection techniques (corticosteroids). Repeat steroid injections are not recommended due to likely weakening of the rotator cuff. With intractable pain, surgical nerve blocks may be considered.[187]

Supportive Devices

A patient with hypotonia is at increased risk of shoulder *traction injury*. Slings can be used to prevent soft-tissue stretching (e.g., supraspinatus, capsular stretching) and relieve pressure on the neurovascular bundle (e.g., brachial plexus/brachial artery). They support the weight of the arm and protect the patient. They also free up the therapist to attend to postural/trunk control during functional activities. However, slings have a number of negative features. They do little to reduce subluxation or improve shoulder function, especially if scapular and trunk malalignment are not adequately addressed. Most slings have the additional negative feature of positioning the arm close to the body in adduction, internal rotation, and elbow flexion. With prolonged use, contractures and increased flexor tone may develop. Slings also contribute to body scheme disorders and body neglect. Prolonged use of slings blocks spontaneous use of the UE and contributes to learned nonuse. Slings may also block balance reactions involving the UE.

There are considerable differences in the effectiveness of the various types of slings. A pouch sling or single strap hemisling with two cuffs that support the elbow and wrist provides minimal mechanical support of the humerus. An alternate approach to the traditional sling is a humeral cuff sling. This device has an arm cuff on the distal humerus supported by a figure-eight harness. It provides humeral support with slight external rotation while allowing elbow extension, and may also provide some reduction of subluxation. This style of sling can be worn for longer periods because it does not restrict the elbow in a flexed position or limit distal function.[190-192]

Close collaboration with the occupational therapist is important in the appropriate selection and use of slings. Gillen[161] suggests the following guidelines:

- Therapists should minimize sling use during rehabilitation.
- Slings may be useful for initial transfer and gait training.
- Slings that position the UE in flexion are less desirable and should be used only for select upright activities and only for short time periods.
- No one sling is appropriate for all patients; selection and use should be carefully evaluated and sling effectiveness carefully reevaluated.
- Effective alternatives to use of a sling should be considered: humeral taping (strapping) to facilitate or inhibit musculature surrounding the scapula; NMES. The hand can also be positioned in a garment pocket.

The patient, family members, and caregivers should be instructed in and allowed to practice proper use of the support. As recovery progresses and spasticity and voluntary movement emerge, spontaneous reduction of shoulder subluxation may occur. Slings have no value at this point in recovery.

For patients using a wheelchair, an arm board or lap tray can provide support for the flaccid arm. A lateral elbow guard and/or straps may be necessary if the patient's arm slips off the side. Patients with decreased sensation are at risk for hand injury if the hand becomes stuck in the spokes of the wheelchair; elbow trauma can occur if the elbow slips off the side (e.g., the elbow hits as the patient is going through a doorway).

Strategies to Improve Lower Extremity Function

LE training activities essentially prepare the patient for the gait. This requires breaking up the obligatory synergy patterns. For example, during midstance hip and knee extensors need to be activated with hip abductors and dorsiflexors. Suggested activities include PNF LE D1 extension pattern; holding against elastic band resistance around the upper thighs in supine or standing positions; and standing, lateral side-steps. Hip adduction should be stressed during flexion movements of the hip and knee. Suggested activities include supine, PNF LE D1 flexion pattern; sitting, crossing, and uncrossing the more affected LE over the less affected; and standing step-ups. Hip extension with knee flexion is needed to allow for toe-off at the end of stance. Activities that can be used to promote knee flexion with hip extension include bridging (Fig. 15.13), supine hip extension with knee flexion over the side of the mat pushing down through the heel, or standing, unilateral heel rises. Pelvic control is important and can be promoted through lower trunk rotation (LTR) activities that emphasize forward pelvic rotation (protraction); post-stroke, the patient typically demonstrates a retracted and elevated pelvis. Lower trunk rotation can be practiced in

Figure 15.13 The patient practices bridging, combining hip extension with knee flexion; the therapist assists using tactile and proprioceptive cues to stimulate the hip extensors on the hemiparetic LE.

side-lying; supine, modified hook-lying; kneeling; or standing. Sitting on a therapy ball, pelvic shifting is another useful activity to promote pelvic control. Control of knee motions is often problematic; post-stroke, the patient with knee weakness typically exhibits hyperextension when standing. Reciprocal action (smooth reversals of flexion and extension movements) should be stressed early, beginning first in supine (e.g., foot slides in hook-lying), sitting (e.g., foot slides under the chair), partial sitting, or partial wall squats in standing.

An effective progression increases the challenge to the patient gradually by modifying postures while reducing synergy influence (e.g., hip abduction can be performed first in hook-lying, then supine, side-lying, modified plantigrade, and finally standing). Dorsiflexors can be activated in sitting by first having the patient hold and slowly let the forefoot move down, then pull the forefoot up. This simulates the functional expectations of the normal gait cycle as the foot goes from swing phase through stance. The sequence can then be repeated in standing, a much more difficult position in which to control dorsiflexors. Voluntary control of eversion is often the most difficult motion to achieve because these muscles do not function in either synergy. The application of stretch and resistance to these muscles during an activity that recruits dorsiflexors and evertors may be effective in initiating a response (e.g., in bridging, knee rocks side-to-side).

Interventions to Improve Functional Status

The loss of sensory and motor function on one side will present a tremendous challenge for the patient struggling to relearn postural control and functional mobility. Initial treatment strategies should focus on trunk symmetry and use of both sides of the body. Progression is from guided movements to active movements as soon as the patient is able to assume independent control. Suggested functional training activities include the following.

Bed Mobility

Rolling to both sides should be practiced; rolling onto the less affected side will prove more difficult. Extremity movement patterns (e.g., PNF D1 flexion of the LE) can be used to enhance the movement. Care must be taken to ensure the patient does not leave the more affected UE behind but rather brings it forward. This can be accomplished by having the patient clasp the hands together first. The more affected LE can be used to assist in rolling by pushing off from a flexed and adducted, hook-lying position (Fig. 15.14). Rolling onto the more affected side and into a side-lying–on–elbow position is important to promote early weight-bearing. This position also has the added benefit of elongating the lateral trunk flexors, which may be spastic.

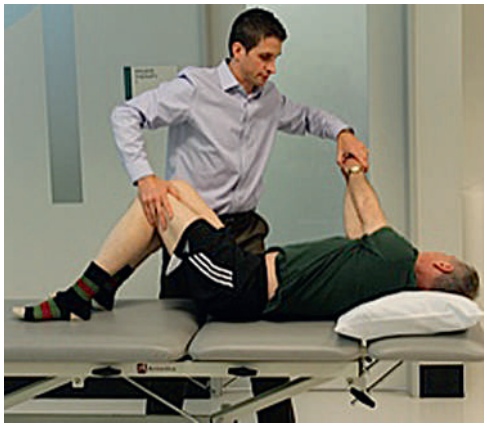

Figure 15.14 Early mobility activities: rolling onto the unaffected side. The therapist assists the movement through contacts on the knees and clasped hands.

The patient should practice moving from supine-to-sit leading from both sides, with an emphasis on rising with the more involved side leading (closest to the edge of bed or mat). The therapist can provide assistance from side-lying on the more affected side by shifting the LEs over the edge of the bed or mat while the patient pushes up into sitting using both UEs for support. Controlled lowering should also be practiced.

Bridging activities help develop trunk and hip extensor control important for use of a bedpan, pressure relief on the buttocks, initial bed mobility (scooting), and sit-to-stand transfers. It also develops advanced LE out-of-synergy control (hip extension with knee flexion) and stimulates early weight-bearing through the foot (see Fig. 15.13). Bridging activities include independent assumption of the posture, holding in the posture, and moving in the posture (lateral weight shifts, bridge-and-placing hips to one side). If the more affected LE is unable to hold in a hook-lying position, the therapist will need to assist by stabilizing the foot. Lifting the less affected foot off the surface (placing it on a small ball) while maintaining the pelvis level significantly increases the difficulty and can be used to increase demands on the more affected side. Difficulty can also be increased by varying the position of the UEs, from extended and abducted at the sides, to arms folded across the chest or hands clasped together overhead in a prayer position.

Sitting

Early training in sitting should focus on achieving a symmetrical posture with proper spine and pelvic alignment. The pelvis should be neutral, spine straight. Feet should be flat on the support surface. Typically, patients with stroke will sit asymmetrically with weight borne more on the less affected side, pelvis in a posterior tilt, and upper trunk flexed (kyphotic). Lateral flexion to the affected side is also common. The therapist can manually

guide the patient into the correct sitting position and provide verbal and tactile cues. Early sitting can be assisted by having the patient use the UEs for bilateral support at sides or in front on tabletop, a large ball, or the therapist's shoulders with the therapist sitting directly in front of the patient. Sitting on a therapy ball can also be used to promote pelvic alignment and mobility (pelvic rotations) and trunk upright alignment (gentle bouncing). Sitting control should be progressed from first holding steady in the posture (stability) to moving in the posture (dynamic stability), and finally to dynamic challenges (reaching). A common problem with hemiplegia is the inability of the upper trunk to move independently of the lower trunk (dissociate). Upper trunk mobility with reciprocal flexion/extension, lateral flexion, and rotation movements should therefore be practiced. PNF lift/reverse patterns with the less involved arm leading can be used to promote upper trunk rotation and bilateral UE activity with the more involved arm moving out of synergy, and crossing the midline (important for unilateral neglect) (Fig. 15.15). Lateral weight shifts to the more affected side typically are the most difficult. Manual contacts in the direction of the movement combined with gentle resistance can provide important early learning cues. The patient should also practice scooting in sitting ("butt walking") to ensure mobility for dressing (putting pants on) and practice initial positioning for sit-to-stand transitions (coming to the edge of the seat to place the feet back and under the body).

Sit-to-Stand and Sit-Down Transfers

Sit-to-stand transfers should be practiced with a focus on symmetrical weight-bearing, coordinated muscular responses, and adequate timing. Initially the patient must actively flex the trunk and use momentum to shift the body mass forward (*flexion-momentum phase*). The feet should be placed well back to allow ankle dorsiflexors to assist with forward rotation. The patient with stroke typically demonstrates decreased forward movement and momentum. The therapist should focus the patient's eyes on a visual target directly in front at eye level and use verbal cues to facilitate the desired movements ("move your shoulders forward and stand up"). The patient can be assisted in this phase by keeping both UEs forward with hands clasped together. Pushing off with both hands on the support surface is not effective in producing the forward weight shift and should be discouraged. The patient's movements must then be directed into the *extension phase,* which requires hip and knee extensors to produce vertical movement into the upright position. The therapist can provide tactile and proprioceptive cues to assist knee extension (Fig. 15.16). The height of the seat can be elevated at first to decrease the extensor force required. Progression is then to lower seat heights. Increased weight-bearing on the stronger LE can be achieved by varying the initial foot position, placing the stronger foot slightly behind the weaker foot. As the patient improves, the position of the feet can be reversed to focus attention on increased use of the weaker side. The patient with stroke typically accomplishes standing up very slowly. With repetitive practice, the patient should be encouraged to focus on increasing the speed of the movement and to not pause between the two phases. Using a prayer position (hands clasped together and held straight ahead with elbows extended) reduces UE push-off. The patient with stroke also demonstrates decreased control in sitting down owing to lack of eccentric control and will sit down abruptly after moving partially through the range.

Eccentric movements (small range movements) can be practiced with the patient positioned back against a

Figure 15.15 Sitting, patient practices PNF lift pattern (less affected UE leading). The pattern promotes upper trunk rotation, bilateral UE activity with the hemiparetic UE moving out of synergy, and crossing the midline.

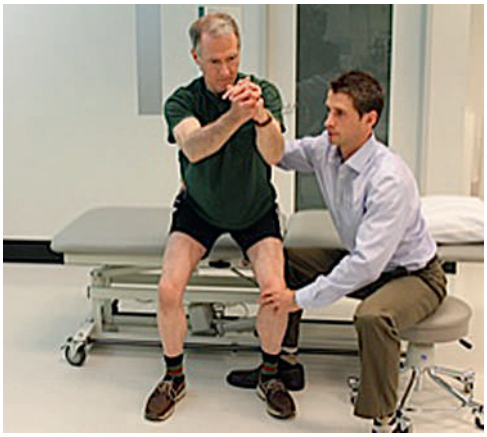

Figure 15.16 Sit-to-stand transitions. The therapist assists the patient in straightening the hemiparetic knee while bringing the center of mass forward. Hands are clasped together.

wall doing partial wall squats. Lower trunk rotation can be promoted by having the patient practice sit-to-stand using a platform mat. From standing, the patient shifts the pelvis laterally to the more affected side, and then sits down. By using this activity, the patient can move all the way around the mat alternating standing and controlled sitting, focusing on moving toward the weaker side.

Standing

Modified plantigrade is an ideal early standing posture to develop postural and extremity control. The more affected UE is extended and weight-bearing (an out-of-synergy posture), while the more affected LE is holding in extension (also an out-of-synergy pattern of hip flexion with knee extension). The forward trunk position creates an extension moment at the knee, thus assisting weak knee extensors. In addition, the posture has a wide (four-limb) BOS and is very stable (see Fig. 15.10). Progression should again be from holding in the posture to moving in the posture (weight shifts) to reaching tasks.

Initial upright standing can be enhanced using fingertip light touch-down support on a high table or wall. As soon as possible, the patient should be encouraged to practice standing with unilateral UE support (more affected side) and then free standing (no UE support). As in other postures, an appropriate progression includes first holding in the posture, to moving in the posture (weight shifts), and finally withstanding challenges to dynamic balance (e.g., reaching in all directions, stepping). The patient is instructed in proper symmetry and alignment. Gentle resistance can be applied to assist in holding, using the PNF technique of rhythmic stabilization. Weight shifts should incorporate moving forward-backward, side-to-side, and diagonally (incorporating upper trunk rotation). Lateral weight shifts to the more affected side are the most difficult. Manual contacts in the direction of the movement combined with gentle resistance can provide important early learning cues.

Transfers

During early transfers, the patient may require maximal assistance. Adjusting the hospital bed to the height of the chair or wheelchair will help to decrease the difficulty of the transfer. Staff often emphasize the sound side by placing the chair to that side and having the patient stand and pivot a quarter turn on the stronger LE before sitting down. Although this compensatory strategy promotes early transfers, it neglects the weaker side and may make subsequent training more difficult. The patient should be taught to transfer to both sides, with emphasis on moving toward the more affected side. Practice to both sides has functional significance, because most bathrooms are not large enough to allow positioning of the wheelchair on both sides of a tub or toilet. Also, the patient is not likely to be able to reposition the wheelchair once he or she transfers into bed so that a transfer toward the same side can be achieved when getting out of bed. When transferring, the patient's affected arm can be stabilized in extension and external rotation against the therapist's body. Alternatively, the patient's UEs (hands in prayer position) can be placed in front or to one side on the therapist's shoulders. The therapist can then assist by using manual contacts, either at the upper trunk or pelvis. The more affected LE may be stabilized by the therapist's knee exerting a counterforce on the patient's knee as needed. Transfer training should include practice in transferring to various different surfaces and heights (e.g., wheelchair, toilet, tub seat, car).

Functional training is begun early and continued throughout the course of rehabilitation. Training activities and postures are varied according to individual needs. Additional postures such as modified prone-on-elbows (tabletop weight-bearing), quadruped, side-sitting, kneeling, and half-kneeling may be appropriate and can be used to increase the level of difficulty and focus on specific body segments and deficiencies in control. Some postures may not be appropriate (e.g., prone-on-elbows for the patient with cardiorespiratory compromise or a flaccid, subluxed UE, or kneeling for the patient with osteoarthritis). Advanced functional training should include practice in getting down to and up from the floor in the event of a fall. See Improving Functional Outcomes in Physical Rehabilitation[150] for more complete descriptions and additional training activities.

Interventions to Improve Postural Control and Balance

Stroke results in significant changes in postural control and balance. Patients typically exhibit delayed, varied, or absent balance responses with impairments in latency, amplitude, and timing of muscle activity. Falls and fracture can occur and lead to a loss of confidence in balance and locomotor skills.[193] It is therefore important to proceed slowly in training and to select challenges appropriate for the patient's level of control. The goals of training are to progressively increase the level of difficulty (e.g., range and speed of self-initiated movements) while encouraging consistency, symmetry, and maximum use of the more affected side. Supportive devices such as a posterior leg splint, gait belt, or body-weight-support harness can be used to assist in early standing to instill confidence and prevent falls.

Once postural alignment and static stability is achieved in upright postures, the patient is ready for center-of-mass (COM) control training. In sitting and standing, the patient is instructed to explore his or her LOS through low-frequency weight shifting.

The patient learns how far in any one direction he or she can safely move and how to align the COM within the BOS to maintain upright stability. The therapist needs to stress symmetrical weight-bearing, as well as activities that promote shifting toward the more affected side. Weight-bearing on the more affected hip (sitting) and foot (standing) is encouraged while unnecessary activity of the less affected limbs (grabbing for support) is discouraged. The therapist increases the difficulty of the activity by manipulating the following:

- *Base of support:* Sitting, LEs uncrossed to crossed; standing, wide to narrow to tandem position; standing on one LE (beginning with less affected, progression to more affected LE)
- *Support surface:* Sitting on a mat to sitting on a therapy ball; standing on the floor to standing on dense foam
- *Sensory inputs:* Eyes open (EO) to eyes closed (EC); feet on firm surface or foam
- *UE position/support:* Light touch-down support; UEs extended out to the side to UEs folded across the chest
- *UE movements:* Single UE raises to bilateral UE raises (symmetrical, asymmetrical); reaching movements with emphasis to the more affected side; picking objects off table, stool, floor
- *LE movements:* Single LE support, stepping (forward-backward, side; step-ups); marching in place; foot on ball, moving ball
- *Trunk movements:* Head and trunk rotations; looking up at ceiling or down to floor
- *Destabilizing functional activities:* Sit-to-stand, sit-down, turning, floor-to-standing, lunges
- *Walking activities:* Forward, backward, sideward, crossed step
- *Dual-task training:* Standing while catching or kicking a ball; standing while talking; standing while holding a tray with a glass of water
- *Modifying environmental conditions:* Closed to open environments

Postural strategy training is an important component of intervention. Ankle strategies can be promoted through small range anterior-posterior shifts or by applying a small perturbation at the hips (forward-backward). Standing on a half-foam roller or wobble board also promotes ankle strategies, but may be too advanced for some patients during early rehabilitation. Hip strategies can be promoted through larger anterior-posterior shifts or stronger perturbations. Medial-lateral hip strategies are promoted by tandem stance (on floor or foam roller). Stepping strategies are promoted by increased displacements of the COM (e.g., forward, backward, or sideward leans that move the COM outside of the BOS). The therapist can apply an elastic band around the hips, offering resistance to the forward lean. Resistance that is quickly released once the patient achieves the desired lean will necessitate a step to control balance. Step-ups (small step to large; foam surface) should also be practiced.

The patient's full attention and concentration is required and should be directed toward completion of the task at hand. The therapist provides well-timed feedback to help the patient correct alignment and adjust postural control while minimizing hands-on support (only as needed). During balance training, the patient should be encouraged to actively problem solve. The patient is presented with challenges, identifies potential problems, and recruits safe strategies to maintain balance. Adaptability of skills needed for successful community reentry is promoted. Safety education about fall prevention is a critical factor in ensuring maintenance of the patient's hard-won functional independence.[194]

Research supports the effectiveness of balance training programs in improving balance ability for patients with stroke. Programs that demanded high frequency and duration had a high dropout rate for patients with acute stroke, largely due to medical reasons or fatigue. A reasonable exercise prescription for this group might include a frequency of 5 sessions per week for 45 to 60 minutes per session. For patients with subacute and chronic stroke, more intense individualized programs are possible. A combination of interventions that focused on static and dynamic balance was most often used. Both one-on-one training and group programs have produced positive results. Finally, there is limited evidence that balance performance may deteriorate once the intervention is stopped.[195,196]

Force Platform Biofeedback

Force platform biofeedback (center-of-pressure biofeedback) provided to the patient while standing on a computerized forceplate system can be used to improve balance. The patient practices voluntary movement shifts in response to computer generated visual feedback. Patients can also practice responding to unexpected platform tilts (perturbations) in order to improve reactive balance control. A safety harness may be required during early training; holding on with one or both hands is discouraged.

Improvements with biofeedback/forceplate training have been found in steadiness (reduced sway),[197,198] postural symmetry,[197,198] and dynamic stability.[198-200] Evidence is stronger and more consistent for the latter two parameters than for changes in steadiness.[201] There is limited evidence of carryover of improved balance during functional skills, specifically transfer skills and endurance,[200] functional reach,[202] and measures of ADL and mobility.[198] Carryover to improved locomotor performance has not been demonstrated.[197,200] Failure to find significant correlations to gait is most

likely related to specificity of training, specifically a dissimilarity between training mode and outcome measure. Studies comparing conventional balance training with biofeedback/forceplate training based on improvements on functional balance measures (Berg Balance Scale, Timed Up and Go) have failed to show any significant differences between the training modes; both interventions were effective in improving balance.[203,204]

The Patient with Ipsilateral Pushing (Pusher Syndrome)

The patient with ipsilateral pushing presents with an entirely different set of postural control and balance problems. The patient sits or stands asymmetrically, but with most of the weight shifted toward the weaker side. The patient uses the stronger UE or LE to push over to the weaker side, often resulting in instability and falls. Efforts by the therapist to passively correct the patient's tilted posture often result in the patient pushing stronger. Training needs to emphasize upright positions with *active* movement shifts toward the stronger side. Use of visual stimuli is effective as patients retain the ability to correct posture with such stimuli but may not be able to do so spontaneously. Patients should be asked to look at their posture and see if they are upright. Environmental prompts can be used to assist orientation. These can include use of a mirror if visuospatial deficits are not present or vertical structures in the environment. For example, the therapist can sit on the patient's less involved side and instruct the patient to "lean over to me." Or the patient can be positioned with the stronger side next to a wall and instructed to "lean toward the wall."[95] Therapists can provide verbal and tactile cues for postural orientation. To improve sitting posture, training activities can include sitting on a therapy ball to promote symmetry and sitting. In early standing the weaker LE is often flexed and has difficulty supporting the body on that side. Extension can be assisted by the use of an air splint or a posterior leg splint or by direct tapping over the quadriceps muscle. The modified plantigrade position is effective for early supported standing; however, the therapist should focus on unilateral support using the weaker UE. Again, an air splint can be used to assist extension of the weaker arm. If a cane is used, it can be shortened to encourage weight shift to the stronger side. An environmental boundary can be used to achieve symmetrical standing (e.g., standing in a doorway or corner standing). It is important to limit pushing with the sound extremities. For example, in sitting or standing, the therapist should block the stronger limb from drifting laterally into abduction and extension and pushing.[205,206] During wheelchair sitting, the patient should be assisted to maintain upright posture and midline orientation. Motor learning strategies are very effective in reducing the effects of this disorder and enhancing recovery. In particular, the therapist should demonstrate correct orientation to vertical, provide consistent feedback about body orientation, and practice correct orientation and weight shifts. The patient should be fully involved in problem solving. For example, the therapist should ask questions such as "what direction are you tilted?" and "what direction do you have to move in order to achieve vertical?" Karnath et al[93] indicate that the prognosis for recovery is good with effective training.

Interventions to Improve Gait and Locomotion

Task-Specific Overground Locomotor Training

An accurate analysis of a patient's walking pattern is critical to planning effective interventions (see Box 15.5). These abnormalities arise as a result of impairments in flexibility, strength, movement control, coordination, and balance. Critical areas of stance phase control that will need to be addressed include initial weight acceptance, midstance control, and forward weight advancement during stance on the more involved limb. During swing, control of knee and foot for toe clearance and foot placement are key requirements (Fig. 15.17). Finally, persistent posturing of the UE in flexion and adduction during gait should be addressed. This latter problem can be effectively controlled through positioning the hemiplegic UE in extension and abduction with the hand open.

Task-specific overground locomotor training (LT) focuses on practicing a variety of activities and on improving the quality of walking and walking endurance. Appropriate stretching, particularly of the calf muscles, and strengthening exercises for LE muscles are important preparatory interventions. Parallel bars and ambulation aids (e.g., walkers, hemiwalkers, quad

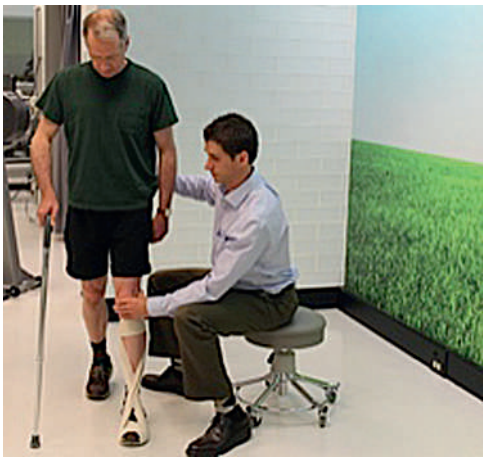

Figure 15.17 Assisted overground gait training. The therapist provides assistance in stabilizing the hemiparetic knee and weight transfer onto the more affected side.

canes) can assist in early gait stability and safety. However, prolonged use of these devices can be problematic for a patient who has the potential to walk without the device. There is increased loading on UEs and the stronger LE. With prolonged use, the patient also fails to develop appropriate balance mechanisms while asymmetry is promoted. There is an excessive weight shift toward the less affected side with the use of a hemiwalker or quad cane. Prolonged use of a walker encourages a forward trunk position with maximum loading on the UEs. Gait is typically slower with assistive devices and overall locomotor rhythm is impaired. It is important to progress patients as quickly as possible to the least restrictive device and to no device whenever possible. Gait practice with an overhead harness and partial body weight support provides the least interference with early balance and walking activities.

The patient should practice functional, task-specific skills, including the following:

- Walking forward: Focus is on moving out of synergy by combining hip and knee extension with hip abduction (scissoring is common).
- Walking backward: Focus is on moving out of synergy by combining hip extensors with knee flexors.
- Side stepping: Focus is on moving out of synergy by combining hip abductors with hip and knee extensors.
- Crossed stepping: The PNF activity of braiding combines side-stepping and cross-stepping.
- Step-up/step-down activities; lateral step-ups.
- Stair climbing, step-over-step.
- Walking in a simulated home environment: Through doorways, over and around obstacles, stairs in/out of the home.
- Walking in a community environment: Walking on ramps, curbs, uneven terrain, over and around obstacles.
- Activities that involve coincident timing: Crossing at a streetlight; stepping on and off elevators or escalators; walking through automatic doors.
- Dual-task activities: Walking while holding a ball, bouncing a ball, carrying a tray, carrying on a conversation.
- Balance activities: Tandem walking on a line, walking on/off foam.

Initially walking will be slow and deliberate. As control develops, the patient is encouraged to improve rhythm and speed of walking. Even steps can be facilitated by the use of real-time, rhythmic auditory cues (e.g., verbal cues, clapping, metronome) and foot markers placed on the floor. Progression is to longer steps and to increased overall distances with faster speeds. The patient should also practice walking in varying complex environments. This encourages the development of the patient's skills to adapt walking as needed (e.g., vary speeds, direction, navigate changing support surface). Timing and reciprocity of LE movements can be improved with the use of a motorized treadmill, cycle ergometer, and Kinetron® isokinetic training. Functional practice in real-life environments will assist the patient in developing the confidence needed for meeting the demands of community reentry.

A Cochrane Systematic Review of research on overground LT for individuals with chronic stroke included nine studies involving 499 participants. Results were mixed. Improvements in walking speed and functional performance (Timed Up and Go Test, 6-Minute Walk Test) were found in some studies. Overall, the researchers felt there was insufficient evidence to determine the benefits on broad measures of walking function. Again, lack of high-quality research (RCTs) was cited.[207] Limited data exist with subacute stroke patients.

Locomotor Training using Body Weight Support and Motorized Treadmill Training

While locomotor control is distributed across discrete regions of the CNS, walking is primarily a brainstem and spinal cord function. For example, locomotor central pattern generators (CPGs) have been identified as existing in the ventral spinal cord while integrating command centers have been identified in the medial medullary reticular formation. Thus, patients with cortical stroke may be able to regain the ability to walk. The CNS is responsive to training-induced plastic changes in locomotor function and recovery. Thus, patients with limited recovery who lack voluntary isolated control can still be trained to walk. Although sensation is normally used for walking, patients can also learn to walk with limited sensation.

Body weight support (BWS) and motorized treadmill training (TT) allows the clinician to improve recovery of walking ability after stroke using intensive task-oriented training. Normal kinematics and phase relationships of the full gait cycle are promoted, including limb loading in midstance and unweighting and stepping during swing. Initially, manual assistance can be provided by trainers to normalize gait in the presence of muscle weakness and impaired balance. For example, one therapist provides manual assistance to foot placement during stepping movements of the weaker LE while a second therapist stands behind the patient and provides manual assistance to pelvic rotation movements (Fig. 15.18). An overhead harness is used to support a portion of the patient's weight (e.g., 30% progressing down to 20%, and 10%). The harness controls the upright position of the patient in the absence of good postural stability and reduces fear of falling. The use of a harness also eliminates the need for adaptive UE support to compensate for LE weakness (e.g., as seen with the use of a walker).

Figure 15.18 Locomotor training using body weight support and a motorized treadmill. One therapist manually assists pelvic motions while a second therapist assists stepping of the hemiparetic left LE.

As improvements in walking occur, the harness is removed and full weight-bearing is allowed. At this point, the patient is practicing supervised walking on a treadmill. Initially the treadmill speeds are slow (e.g., 0.52 mph [0.23 m/sec]) and are gradually increased as the patient's walking ability is improved (e.g., 0.95 mph [0.42 m/sec]).[101] Progression is to task-specific practice and overground walking. See Chapter 11, Locomotor Training, for additional discussion.

Treadmill training and BWS is a relatively safe task-oriented LT activity that has been extensively studied in patients recovering from stroke.[208-223] In a Cochrane Systematic Review,[49] the researchers identified 15 high-quality trials with 622 post-stroke participants. They concluded that there were no significant statistical differences between TT, with or without BWS, and other physiotherapy interventions on outcomes of walking dependency, speed, and endurance. For people who were independent walkers at the start of treatment, higher walking speeds were evident, though not significantly so. Patients with stroke who were dependent in walking at the start of treatment may benefit from TT with BWS, though data were limited to support this conclusion. Serious adverse events were uncommon. Individual studies have reported improvements in walking speed,[211-215,222] distance,[211,215,216] endurance,[211,218,219] and walking function.[211] Treadmill training is a safe intervention for patients with acute and subacute stroke,[208,209,216-218,221] as well as for chronic stroke[210-212, 219] (see Box 15.9 Evidence Summary).

The *Locomotor Experience Applied Post-Stroke (LEAPS)* trial was a large, multicenter randomized controlled trial.[223,224] Four hundred eight participants were recruited from six inpatient rehabilitation centers and stratified according to walking impairment. Those with moderate impairment were able to walk 0.4 to less than 0.8 m per second while those in the severe group were able to walk less than 0.4 m per second. Participants were randomly assigned to one of three treatment groups: (1) early locomotor training using BWS TT 2 months after stroke, (2) late locomotor training using BWS TT 6 months after stroke, and (3) home exercise using therapist-directed exercise training 2 months after stroke. The latter group received exercises designed to improve flexibility, strength, coordination, and balance along with encouragement for daily walking. Each intervention had similar intensity and duration (36 sessions of 90 minutes each for 12 to 16 weeks). The researchers found that all participants increased in their functional walking ability. No significant differences were found between the groups in terms of improvements in walking speed, motor recovery, balance, functional status, and quality of life. Outcomes of participants in the early and late locomotor training (LT) groups also revealed no significant differences at 1 year. The researchers concluded that early intervention may accelerate gains in walking ability after stroke. The research reviewed supports the benefits of physical therapy in improving walking outcomes. There is no clear evidence of the superiority of one type of intervention over another.

Robotic-Assisted Locomotor Training

Electromechanical, robotic-assisted LT is used in rehabilitation to improve walking after stroke. In a Cochrane Systematic Database review, Mehrholz et al [54] reviewed 17 trials involving 837 participants. When combined with conventional physiotherapy, these devices were found to increase the odds of patients becoming independent walkers. Increases in gait speed or walking capacity were not found. Study differences were noted in variations of (1) initial level of patient independence in walking, (2) duration and frequency of treatment, and (3) use of electrical stimulation used in some devices. In a systematic review of 16 studies that included a total of 558 patients, Tefertiller et al found that no studies demonstrated a significantly improved functional ambulatory capacity with conventional LT or TT with BWS and manual assistance versus TT with BWS and robotic assistance.[225] Lewek et al[226] found that therapist-assisted LT when compared to robotic-assisted LT resulted in significant improvements in coordination of intralimb kinematics, lending support to the value of

Box 15.9 Evidence Summary Post-Stroke Locomotor Training Using Body Weight Support and Motorized Treadmill Training

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Richards et al[209] (1993)	27 subjects	RCT; compared early task-based PT (standing, weight-shifting, and Kinetron exercises; TT), 1.74 hr/day with conventional PT intervention groups (1.79 hr/day and 0.73 hr/day) Outcome measures: FMA, BI, BBS, gait velocity at 6-month follow-up	Daily	Significant improvement in gait velocity for task-based PT group	Small sample size One of the pioneering early studies
Visintin et al[211] (1998)	100 subjects postacute phase	RCT; TT: compared BWS (BWSTT) with no-BWS (no-BWSTT) Outcome measures: balance (BBS); motor recovery (STREAM); OG walking speed and endurance	4/wk for 6 wk	BWSTT group demonstrated significant improvement over no-BWSTT in balance, motor recovery, and OG walking speed and endurance	79% BWSTT group progressed to full weight-bearing OG walking; improvements were sustained; good sample size; one of the pioneering early studies
Nilsson et al[213] (2001)	60 subjects postacute stage	RCT; compared walking using BWSTT with OG walking training (motor relearning approach) Outcome measures: FIM, FMA, FAC, 10-m walk test, and BBS	30 min/day, 5/wk for 2 months	Both groups improved on function (FIM, FAC), balance (BBS), and walking speed	10-month follow-up Good sample size
Sullivan et al[215] (2002)	24 subjects with chronic stroke	Nonrandomized cohort design Intervention program: BWSTT, 3 groups of varying speeds (slow speeds 0.22 m/sec; variable speeds 0.22 m/sec to 0.89 m/sec; fast speeds greater than 0.89 m/sec) Outcome measures: FMA, 10-m walk; self-selected walking speed OG	12 sessions, 20-min duration, over 4–5 wk	Training at fast speeds was more effective at improving speeds of OG walking than training at slow or variable speeds	No control group Gains maintained at 3 months Small sample size
Dean et al[218] (2010) (the *MOBILIZE trial*)	12 subjects, within 4 weeks of stroke, undergoing inpatient rehab, unable to walk	RCT 2 groups: (1) BWSTT, (2) OG walking	30 min/day	At 6 months, no difference between indep walkers from both groups in terms of speed or stride; indep walkers in BWSTT group walked 57 m further (6-Minute Walk Test) and rated their walking 1 point (out of 10) higher than OG group	BWSTT is safe and feasible for patient with subacute stroke; supports better walking capacity and perception of walking compared to OG walking

Box 15.9 Evidence Summary Post-Stroke Locomotor Training Using Body Weight Support and Motorized Treadmill Training—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Sullivan et al[222] (2007) (the *STEPS trial*)	80 subjects, ambulatory; 4 mo–5 yr post-stroke	RCT; 4 groups of combined interventions: (1) BWSTT with UE ergometry (BWSTT/UE-EX), (2) leg cycle ergometry with UE-EX (CYCLE/UE-EX), (3) BWSTT with leg cycling (BWSTT/CYCLE), and (4) BWSTT with LE progressive resistive exercise (BWSTT/LE-EX)	Exercise sessions were 4/wk for 6 wk (24 total sessions) Outcome measures: self-selected and fast walking speeds, 6-Minute Walk Test	The BWSTT/UE-EX group had significantly greater increases in walking speed compared to CYCLE/UE-EX group; both groups improved walking distance; all BWSTT groups increased walking speed and distance	Task-specific BWSTT was more effective in improving walking speed and maintaining gains at 6 mo than leg cycling (CYCLE/UE-EX) LE strength training alternated daily with BWSTT (BWSTT/LE-EX) did not provide an added benefit
Moseley et al[49] (2009) (*Cochrane Database Systematic Review*)	15 high-quality studies, 622 subjects	Meta-analysis of LT studies Outcomes: walking dependency, speed, and endurance	Variable by study	No significant statistical differences between TT, with or without BWS, and other physiotherapy interventions on outcomes; indep walkers at start of treatment tended to develop higher walking speeds; dep walkers at start of treatment may benefit from BWS; few adverse events reported	Physiotherapy, both BWSTT and conventional LT, were effective in improving walking function in patients post-stroke
Franceschini et al[221] (2009)	97 subjects, within 6 weeks of stroke onset	RCT; 2 intervention groups: (1) conventional rehab plus BWSTT, (2) conventional rehab plus OG gait training Outcome measures = Motricity Index, Trunk Control Test, Barthel Index, Functional Ambulation Categories, 10-Meter and 6-Minute Walk Tests, Walking Handicap Scale	60-min sessions every weekday for 4 weeks	After treatment, all patients were able to walk Both groups showed significant improvement on all outcome measures	In subacute patients, BWSTT is as feasible and effective as conventional gait training
Lewek et al[227] (2009)	19 subjects with chronic stroke (> 6 mo)	RCT; comparing therapist-assisted versus robotic-assisted LT Outcome measures: gait analysis (kinematic coordination), self-selected speed during OG walking	4 wk of LT, 3 sessions of LT per week for 4 weeks	LT with therapist assistance resulted in significant improvements in consistency of intralimb movements of the impaired limb	Providing consistent (fixed) kinematic assistance during robotic-assisted LT did not result in improvements in intralimb consistency Small sample size

Box 15.9 Evidence Summary Post-Stroke Locomotor Training Using Body Weight Support and Motorized Treadmill Training—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Duncan et al[224] (2011) (the *LEAPS trial*)	408 subjects with stroke (2 months; stratified into 2 groups: (1) moderate impairment (able to walk 0.4 to (0.8 m/sec); and (2) severe impairment (able to walk (0.4 m/sec)	RCT; 3 intervention groups: (1) BWSTT 2 mo after stroke (early LT), (2) BWSTT 6 mo after stroke (late LT), and (3) home-based exercise program Outcome measure: proportion of participants with improvement in walking ability at 1 yr (walking speed, motor recovery, balance, functional status, and quality of life)	36 sessions of 90 min each for 12–16 wk	52% of all participants improved in walking ability; no significant differences between groups in terms of walking function; multiple falls were more common in severe impairment group receiving early LT	LT using BWSTT was *not* found superior to progressive exercise at home managed by a physical therapist

BBS = Berg Balance Scale; BI = Barthel Index; BWS = body weight support using an overhead harness; dep = dependent; FAC = Functional Ambulation Category; FIM = Functional Independence Measure; FMA = Fugl-Meyer Assessment of Physical Performance; indep = independent; LT = locomotor training; mAS = Modified Ashworth Scale; MCA = middle cerebral artery syndrome; OG = overground; PT = physical therapy; RCT = randomized controlled trial; rehab = rehabilitation; STREAM = Stroke Rehabilitation Assessment of Movement; TT = treadmill training.

variable practice versus constant practice. In a systematic review of studies recruiting nonambulatory patients early after stroke (6 studies involving 549 participants), Ada et al[227] found that mechanically assisted LT with BWS resulted in more people walking independently at 4 weeks and at 6 months.

Functional Electrical Stimulation

Functional Electrical Stimulation (FES) can be used to stimulate dorsiflexor function and improve the gait pattern of patients with drop foot. Sufficient strength in the quadriceps muscle is needed to prevent the knee from buckling. This requirement limits the number of patients who can successfully use the device. The patient wears a small, lightweight cuff that fits just below the knee. Electrodes are positioned to stimulate the anterior tibialis and the peroneus longus muscles. A gait sensor attaches to the patients shoe and transmits a wireless signal to the stimulator. The level of stimulation can be adjusted by a handheld remote control, which also allows the patient to turn the device off and on. The device can be used as a bridge to the recovery of normal motor function or, in the absence of recovery, can be used indefinitely. FES training should be paired with a comprehensive physical therapy POC. In a systematic review of the literature (30 studies), Roche et al[228] reported that FES had a significant positive effect on gait with improvements noted in gait speed and physiological cost index (PCI) in patients with chronic stroke. FES is theorized to have a positive effect on brain plasticity with its provision of high-level sensory-motor input into the CNS.[229] This may explain research findings of improved gait function with FES when compared to orthotic intervention.[230]

Orthotics and Assistive Devices

An orthosis may be required when persistent problems prevent safe ambulation (e.g., inadequate ankle dorsiflexion during swing, mediolateral ankle instability, and insufficient push-off during late stance). Prescription will depend on the unique problems each patient presents. The pattern of instability and weakness at the ankle and knee and the extent and severity of spasticity and sensory deficits of the limb are major considerations when prescribing an orthosis. Temporary devices (e.g., dorsiflexor assists) may be used during the early stages while recovery is proceeding to allow the patient to practice standing and walking. Use of a temporary orthosis also provides insight into the type of components that will most effectively address the patient's needs. Permanent devices are prescribed once the patient's status stabilizes. Consultation with a certified orthotist and clinic team is initiated if a permanent orthosis is needed.

- ***Foot-Ankle Controls.*** An *ankle-foot orthosis* (AFO) is commonly prescribed to control impaired ankle/foot function. These may include a custom-molded polypropylene AFO (*posterior leaf spring, modified AFO, or solid ankle AFO*), or *conventional double upright/dual channel AFO*. The least restrictive AFO is the posterior leaf spring (PLS) used to control drop foot. An AFO of higher-density plastic that

covers more surface area can provide additional control of calcaneal and forefoot inversion and eversion. A solid ankle molded AFO provides maximum stabilization through its lateral trim lines that project more anteriorly. Movement in all planes (dorsiflexion, plantarflexion, inversion, and eversion) is limited. The conventional double upright metal AFO may be indicated for patients who cannot tolerate plastic AFOs owing to sensory impairments, girth fluctuations, or diabetic neuropathy, or who require additional controls. A posterior stop can be added to limit plantarflexion while a spring assist can be added to assist dorsiflexion (Klenzak joint). Advantages of a conventional AFO include better stabilization of the ankle, allowing improved heel-strike and push-off.[231] Disadvantages include heavier weight, less cosmetic appearance, and increased difficulty donning and doffing.

- ***Knee Controls.*** Knee instability following stroke can be controlled with an AFO by adjusting the position of the ankle. An ankle set in 5° dorsiflexion limits knee hyperextension, while an ankle set in 5° plantarflexion decreases the flexor moment and stabilizes the knee during midstance. A patient with knee hyperextension without foot and/or ankle instability may benefit from the application of a *Swedish Knee Cage* or strapping to protect the knee. Extensive bracing using a knee-ankle-foot orthosis (KAFO) is rarely indicated or successful. The added weight and restrictions in normal knee joint motion significantly increase energy costs and limit independent function.

The need for an orthosis or a particular type of orthosis may change with continuing recovery. The therapist may need to recommend a change in prescription or discontinuing the use of a device. With limited reimbursements, ordering a new orthosis may prove problematic and speaks to the need to anticipate changes when ordering the initial device. For example, a good option for the patient who needs a custom-molded solid AFO is to order a hinged AFO with a plantarflexion stop. As the patient regains sufficient knee and dorsiflexor control, the device can be adjusted to remove the stop and allow the hinges to work. Orthotic training includes donning and doffing, skin inspections, and education in safe use of the device during gait. See Chapter 30, Orthotics, for a more complete description of orthotic devices, examination, and training.

Wheelchairs

Most patients require the use of a wheelchair for mobility at some point during their recovery. Patients with stroke exhibit typical postural asymmetries, which need to be carefully evaluated. These include the following:

- Trunk laterally flexed to the weaker side; head may also be flexed to the weaker side.
- Pelvic posterior tilt with some obliquity (lower on the unaffected side).
- LE rolled out into abduction and external rotation; if spasticity is present, increased hip extension, adduction, and internal rotation with knee extension may occur; foot is typically plantarflexed and inverted.
- UE held flexed and adducted to the trunk with increased elbow, wrist, and finger flexion. With flaccidity, the shoulder is subluxed with the hand dangling in a dependent position.

Positioning in a wheelchair needs to correct for these postural asymmetries and ensure correct sitting posture. The reader is referred to Chapter 32, The Prescriptive Wheelchair, for a more complete discussion of general principles of prescription and wheelchair adaptations.

A patient with stroke can learn to propel a wheelchair using the stronger UE and LE. The seat-to-floor height is critical in ensuring successful use of the foot for steering and propulsion. A *hemi-height wheelchair* with a lower seat-to-floor height (17.5 in [44.45 cm]) may be required. A standard wheelchair has a seat-to-floor height of 19.5 in (49.53 cm). One-arm drive chairs in which both handrims are placed on one wheel were designed for individuals with only one functional UE. The patient with stroke is rarely successful in using this type of chair because it takes a great deal of strength and coordination to propel the wheelchair in a forward direction. It is contraindicated in patients with significant perceptual and cognitive impairments. A power wheelchair may be required for some individuals who cannot successfully use a manual wheelchair and will depend on a wheelchair as their primary means of locomotion. The therapist needs to consider individual needs and reimbursement policies when ordering a wheelchair. It is important to balance both present and future needs as providers restrict frequent reordering of a new wheelchair. It is also important to remember that prolonged used of a wheelchair contributes to learned nonuse and may limit recovery, especially if walking is a primary goal of therapy. Wheelchair training activities include patient and caregiver instruction in the use, maintenance, and safety of all parts of the wheelchair (e.g., brakes, leg rests, removable armrests). The patient needs to be instructed in methods of propulsion and given the opportunity to practice on level and varied surfaces (e.g., ramps, outdoor terrain). Transfers (to and from bed, toilet, tub, car) should also be practiced once the patient receives the prescriptive wheelchair.

Interventions to Improve Aerobic Capacity and Endurance

Patients with stroke demonstrate decreased levels of physical conditioning following periods of prolonged immobility and reduced activity. The energy costs to complete many functional tasks are higher than normal owing to the abnormal ways in which the activities are

performed. Many patients also demonstrate concomitant cardiovascular disease and may experience hypertension, serious dysrhythmias, and volitional fatigue. Patients with stroke require careful determination of cardiopulmonary responses during exercise and appropriate monitoring.

Individuals recovering from stroke can benefit from endurance (aerobic) training to improve cardiovascular function. During the early acute stages, functional activity training is appropriate (e.g., overground walking). During the postacute stage, patients/clients may be able to engage in more traditional exercise training modes such as treadmill walking, cycle ergometry (upper and lower body ergometer), or seated stepper. Patients with balance impairments will benefit from treadmill training or overground walking with a safety harness, or a recumbent cycle ergometer. To ensure safety, patients should receive a thorough examination and supervised exercise test before starting a training program (e.g., symptom-limited graded exercise test). Prescriptive elements include mode (type of exercise), frequency, intensity, and duration (see Chapter 13, Heart Disease). Choice of training mode depends on the individual's abilities and interests. Intensities are typically in the range of 40% to 70% of maximal oxygen uptake. Suggested frequency is three to five days per week for 20 to 60 minutes per session. Frequency may be increased to daily if lower intensities are used. Because of the level of deconditioning, patients with stroke should begin with intermittent training protocols but can be progressed to 30 minutes of continuous exercise. The use of a training log or exercise diary is an excellent way to help the patient keep track of prescriptive elements, objective measurements (heart rate, BP), and subjective reactions (RPE, perceived enjoyment). Adequate supervision, monitoring, and safety education about warning signs for impending stroke and heart attack are critical components.[24,232]

Exercise Precautions

Careful monitoring of exercise is essential. For patients at risk, BP, heart rate (HR), and RPE should be taken initially, during, and after each exercise. As exercise progresses, less frequent monitoring can be implemented. The therapist also needs to monitor breathing rate and pattern, ensuring breath holding and Valsalva do not occur. Patients should be instructed in how to measure their own HR and RPE. They should also be taught the warning signs for when to stop exercising. These include the following:

- Lightheadedness or dizziness
- Chest heaviness, pain, or tightness; angina
- Palpitations or irregular heart beat
- Sudden shortness of breath not due to increased activity
- Volitional fatigue and exhaustion

Patients who are on medications that limit cardiac output (e.g., beta-blockers) will demonstrate reduced HR responses and lower peak HRs. Patients taking diuretics to reduce fluid volume may demonstrate altered electrolyte balance with resulting dysrhythmias. Patients taking vasodilators may require a longer cool-down period after exercise to prevent post-exercise hypotension.[24]

Patients undergoing an aerobic conditioning program demonstrate improvements in physical fitness, functional status, psychological outlook, and self-esteem. Regular exercise may also have the additional benefit of reducing risk of recurrent stroke or heart attack. Patients who participate in a regular conditioning program may be more successful in adopting continuing, life-long exercise habits and in moving beyond the disability associated with stroke. In a Cochrane Database Systematic Review, Brazzelli et al[51] reviewed 32 trials with 1,414 participants and found that cardiorespiratory fitness training after stroke can improve walking performance including maximal walking speed, preferred gait speed, and walking capacity while reducing dependence during walking. Training effects were retained at follow-up. Adverse effects including death were infrequent.

Circuit class training (CCT) for improving mobility after stroke was the subject of a Cochrane Systematic Database Review.[52] English and Hillier[52] reviewed 6 trials with 292 participants (inpatients or community-dwelling) and found that CCT was safe and effective for improving mobility for people after moderate stroke. It may also reduce inpatient length of stay. Rose et al[233] reported on the effectiveness of a circuit training physical therapy (CTPT) program in the acute rehabilitation setting. Patients received a 60-minute training session, 5 days/wk, using four task-specific stations. Activities were stratified and tailored to patients' specific mobility levels (nonambulatory, severe, moderate, and mild groups). In addition, a 30-minute daily session was dedicated to critical inpatient rehabilitation issues (family and home program education, wheelchair and orthotic prescription). When compared to standard physical therapy (SPT) of the same intensity, the CTPT groups showed significantly greater improvements in gait speed, primarily in ambulatory patients.

PATIENT/CLIENT-RELATED INSTRUCTION

Stroke represents a major health crisis for patients and their families. Ignorance about the cause of the illness or the recovery process and misconceptions concerning the rehabilitation program and potential outcomes can negatively influence coping responses and progress in rehabilitation. Frequently the problems seem unmanageable and overwhelming for the family, especially when faced with alterations in the patient's behavior, cognition, and emotion. Patients may feel depressed, isolated, irritable, or demanding. Families often demonstrate reactions that include initial relief and hope for full recovery, followed

by feelings of entrapment, depression, anger, or guilt when complete recovery does not occur. These changes and feelings can strain even the best of relationships. Therapists can often have a dramatic influence on this situation because of the high frequency of contact and the often close relationships that develop with patients and their families. There are a number of important guidelines to follow when planning educational interventions:

- Give accurate, factual information; counsel family members about the patient's capabilities and limitations; *avoid* predictions that categorically define expected function or future recovery.
- Structure interventions carefully, giving only as much information as the patient or family need or can assimilate; provide reinforcement and repetition.
- Adapt interventions to ensure they are appropriate to the educational and cultural background of the patient and family.
- Offer a variety of educational interventions: didactic sessions, books, brochures, and videotapes, and family participation in therapy. (See Appendix 15.B.)
- Provide a forum for open discussion and communication.
- Be supportive and sensitive, and maintain a positive, hopeful manner.
- Assist patients and families in confronting alternatives and developing problem solving abilities.
- Motivate and provide positive reinforcement in therapy; enhance patient satisfaction and self-esteem.
- Refer patients and families to support and self-help groups such as the following national associations:

American Stroke Association—A Division of the American Heart Association
7272 Greenville Avenue
Dallas, TX 75231
1-800-AHA-USA1 (1-800-242-8721)

National Stroke Association
9707 East Easter Lane
Englewood, CO 80112
1-800-STROKES (1-800-787-6537)

Psychotherapy and counseling (e.g., sexual, leisure, vocational) can assist in improving overall quality of life and should be recommended as needed.

DISCHARGE PLANNING

Planning for discharge begins early in rehabilitation and involves the patient and family. Potential placement (safe place of residence), level of family and community support, and need for continued medical and rehabilitation services should be explored. Family members should regularly participate in therapy sessions to learn exercises and activities designed to support the patient's independence. Discharge should be considered when reasonable treatment goals/outcomes are attained. Indication of the attainment of a functional ceiling can be considered when there is lack of evidence of progress at two successive evaluations. Home visits should be made before discharge to determine the home's physical structure and accessibility. Potential problems can be identified and corrective measures initiated. See Chapter 9 for additional discussion. Home adaptations, assistive devices, and supportive services should be in place before the patient is discharged to home. Several trial home stays may be helpful in smoothing the transition from rehabilitation center to home. A home exercise program coupled with patient and caregiver training should be instituted. Patients with residual impairments or activity limitations who will be receiving outpatient or home therapy should be given all the necessary information concerning these services. Community services should be identified and information provided to the patient and family. Long-term follow-up at regularly scheduled intervals should be initiated in order to maintain patients at their highest possible functional level.

RECOVERY AND OUTCOMES

Recovery from stroke is generally fastest in the first weeks and months after onset. Patients can continue to make measurable functional gains generally at a reduced rate for months or years after insult. Late recovery of function has been consistently demonstrated for patients with chronic stroke (defined as greater than 1 year post-stroke) who undergo extensive task-specific functional training that emphasizes use of the more involved extremities. Prolonged recovery with improvements occurring over a period of years is especially apparent in the areas of language and visuospatial function. Rates of motor recovery vary across management categories: patients suffering minor stroke recover rapidly with few or no residual deficits whereas severely impaired individuals demonstrate more limited and prolonged recovery. The initial grade of paresis, measured on initial hospital admission, is an important predictor of motor recovery. In the case of complete paralysis on admission, complete motor recovery occurs in less than 15% of patients. In an extensive review of the literature, Hendricks et al[234] found no significant difference in potential for motor recovery between type of stroke (hemorrhage vs. infarction) and location (brainstem vs. hemispheric infarction).

Functional mobility skills are impaired following stroke and vary considerably from individual to individual. During the acute stroke phase, 70% to 80% of patients demonstrate mobility problems in ambulation whereas 6 months to 1 year later the figures are reversed, with only 20% of patients needing help to walk independently. Basic ADL skills such as feeding, bathing, dressing, and toileting are also compromised during acute stroke, with 67% to 88% of patients demonstrating partial or complete dependence. Independence in ADL also improves with time with only 31% of survivors requiring partial

or total assistance a year later.[2] The ability to recover functional tasks is influenced by a number of factors. Motor and perceptual impairments have the greatest impact on functional performance, but other limiting factors include sensory loss, disorientation, communication disorders, and decreased cardiorespiratory endurance. Enablement factors include high motivation, stable supportive family, financial resources, and intensive training with repetitive practice.[235-240]

Patients who receive inpatient stroke rehabilitation (skilled occupational, physical, and speech therapy) demonstrate improved motor recovery, functional status, and quality of life at discharge.[234-244] In a systematic review of the literature (151 studies), Van Peppen et al[243] found strong evidence in support of task-oriented exercise and intensive training. Inpatient rehabilitation admission averages a little over 2 weeks. Approximately 80% of patients are discharged home.[236] Post-discharge outpatient treatment or home care for stroke survivors is often indicated because functional status is typically not stabilized at discharge from a rehabilitation hospital and effects diminish over time with no treatment. Patients who demonstrate less successful rehabilitation outcomes tended to include those with (1) advanced age; (2) severe motor impairments (prolonged paralysis, apraxia); (3) persistent medical problems (incontinence); (4) impaired cognitive function (decreased alertness, poor attention span, judgment, memory, learning difficulty); (5) severe language disturbances; (6) severe visuospatial hemineglect; and (7) other less well-defined social and economic problems.[241-244] Researchers who studied long-term follow-up at 2 years post-stroke (148 patients) found that only 12% demonstrated a decline in mobility. Depression was cited as the single major risk factor for mobility decline.[245]

SUMMARY

Stroke results from a number of different vascular events that interrupt cerebral circulation and impair brain function, including cerebral thrombosis, emboli, or hemorrhage. The location and size of the ischemic process, the nature and functions of the structures involved, the availability of collateral blood flow, and effectiveness of early emergency medical management all influence the symptomatology that evolves. For many patients, stroke represents a major cause of disability, with diffuse problems affecting widespread areas of function. From a practical standpoint, patients with stroke present a tremendous challenge for clinicians. Effective rehabilitation should take advantage of the brain's capacity for repair and recovery. Rehabilitation interventions seek to promote recovery and independence through neurofacilitation, functional, and compensatory training strategies. Interventions also focus on the prevention of secondary impairments. The utilization of effective motor learning strategies with task-oriented training for real-life environments is critical for the successful attainment of functional outcomes.

Questions for Review

1. Differentiate between anterior cerebral artery syndrome and middle cerebral artery syndrome in terms of expected deficits.
2. Differentiate between lesions of the right and left hemispheres in terms of expected behavioral deficits.
3. Describe the role of the CT scan in the diagnosis of acute stroke and the implementation of emergency medical measures.
4. What are the major types of aphasia that can result from stroke? Where are the lesions located?
5. Differentiate between the following stroke-specific instruments: the Fugl-Meyer Assessment of Physical Performance (FMA) and the Stroke Rehabilitation Assessment of Movement (STREAM).
6. Describe the behaviors of the patient with stroke who demonstrates ipsilateral pushing. What is the primary focus of rehabilitation intervention?
7. Describe the role of force platform biofeedback (center-of-pressure biofeedback) in promoting improve postural control and balance in patients post-stroke.
8. What are the essential elements of constraint-induced movement therapy to improve UE function post-stroke?

9. What are the elements of task-specific overground gait training to improve function post-stroke?
10. What are the required elements of locomotor training using body weight support to improve function post-stroke?
11. What important guidelines should be followed when planning an educational program for the patient with stroke and family members?

CASE STUDY

HISTORY

The patient/client is a 41-year-old man admitted to an acute care hospital with a diagnosis of CVA with R hemiparesis (L MCA). Admitted to a rehabilitation facility 7 days later.

PAST MEDICAL HISTORY

- Seizure disorder since childhood. Dilantin was discontinued 5 years ago.
- History of mild hypertension well controlled with medication.
- Smokes 1 pack/day; 20-year history.

MEDICATIONS

- Persantine 50 mg po tid
- Tenormin 25 mg po qd
- Aspirin 10 grains po bid

TESTS

- Carotid angiography: complete occlusion of left internal carotid artery.
- Cardiac ultrasound: intermittent mitral valve prolapse.
- EKG: nonspecific ST wave changes.
- CT scan: initial scan unremarkable; repeat CT scan consistent with a large left middle cerebral artery ischemic infarction.

SOCIAL HISTORY

Patient lives with his wife and three teenage children and was independent and active before CVA. He has a college education and has worked for 20 years as a computer programmer. There is a two-step access to a rented, single-family house.

COGNITION

- Mild disorientation to time and place.
- Limited attention span for up to 3 minutes on task.
- Difficult to examine further owing to language impairment; cognitive deficits likely.
- Patient has difficulty following directions for motor responses; two- or three-step commands.

LANGUAGE/COMMUNICATION

- Auditory comprehension: moderate to severe decrease in understanding words and simple concrete sentences; unreliable yes/no responses.
- Verbal expression: severely decreased to nonfunctional; limited to only occasional automatic words.
- Reading comprehension: severely decreased to nonfunctional at a word level. Unable to match word to object.
- Written expression: to be determined.
- Gestures: spontaneous use of gestures not evident.

PHYSICAL THERAPY EXAMINATION

Passive Range of Motion

- BUEs WNL; R shoulder pain at end ranges
- BLEs WNL except R dorsiflexion 0° to 5°

Sensation

- RUE: likely impaired, unable to test fully owing to communication deficits; no apparent sensation to sharp/dull stimuli.
- RLE: likely impaired, unable to test fully owing to communication deficits; few consistent responses to sharp/dull stimuli proximally.
- Patient reports pain in RUE, end ranges of shoulder motions.

Tone
- RUE increased tone (moderate to severe) in elbow flexors; shoulder adductors and internal rotators.
- RLE increased tone (moderate) in hip and knee extensors, plantar flexors.

Motor Control
- RUE: partial motion (1/2 range) in extensor synergy pattern (shoulder and elbow extension); no voluntary motion of hand; limited in flexor synergy pattern.
- RLE: full motion in both extensor and flexor synergy patterns with extensor pattern dominating; LE flexion synergy achieved with associated reaction of RUE (increased flexion).

Strength
- LUE and LLE: full isolated movement with G+ to N strength.
- RUE and RLE limited movements; unable to MMT.

Coordination
- LUE and LLE intact.
- RUE and RLE: limited movements; unable to test.

Motor Planning
- Suspected mild motor apraxia; unable to test.

Postural Control/Balance
- Head control: good.
- Sitting static control: good, able to maintain balance without support; maintains centered alignment (COM) for 5 minutes.
- Sitting dynamic control: fair, able to maintain balance; weight shifting with reduced limits of stability (LOS); shifts to R are reduced 50%; shifts to L are normal.
- Standing static control: fair, able to maintain independent standing in parallel bars for up to 1 minute with LUE handhold.
- Standing dynamic control: poor; unable to weight shift to R without loss of balance; weight shifts to L are reduced 50%.

Functional Status
- Rolls to R: independent with bed rail
- Rolls to L: min assist
- Scoots up in bed: supervision
- Supine-to-sit: min assist
- Sit-to-supine: min assist
- Transfers bed-to-chair: stand pivot transfer, mod assist (FIM 3)
- Eating: supervision (FIM 5)
- Bathing: mod assist RUE and RLE (FIM 3)
- Dressing: mod assist RUE and RLE (FIM 3)

Gait and Locomotion
- W/C mobility: propels 150 ft with supervision (FIM 5); uses LUE and L foot for propulsion.
- Locomotion: ambulates 10 ft in parallel bars with max assist of one (FIM 1).
- Requires assist in initiation of movement of RLE.
- Requires assist with R knee control for extension.
- R foot is plantarflexed and supinated during stance, foot drop during swing.
- Uses temporary dorsiflexor assist (elastic wrap); AFO ordered (solid ankle AFO).
- Stairs: unable to test.

Endurance
- Tolerates 3/4-hour treatment session with frequent rests.

PSYCHOSOCIAL

Patient is motivated and cooperative. He appears anxious about his future and exhibited a brief episode of crying during the initial therapy session. His main goal is to walk again. Family is supportive and anxious to have him home again.

GUIDING QUESTIONS

1. Identify/categorize this patient's problems in terms of:
   a. Direct impairments.
   b. Indirect impairments.

c. Activity limitations.

d. Participation restrictions.

2. Identify three anticipated goals (remediation of impairments) and three expected outcomes (remediation of activity limitations) for this patient.
3. Formulate three treatment interventions that could be used during the first 2 weeks of therapy. Provide a brief rationale that justifies your choice.
4. Identify relevant motor learning strategies appropriate for the initial physical therapy sessions with this patient.

DavisPlus | For additional resources, including answers to the questions for review and case study guiding questions, please visit **http://davisplus.fadavis.com**

The reader is referred to the following video case studies for additional review and study:

- **Case Study 9: Patient with Right Hemorrhagic CVA**
- **Case Study 10: Patient with Left Ischemic CVA**
- **Case Study 11: Patient with Right Thalamic Ischemic Infarct and Left Lateral Medullary Ischemia**
- **Case 12: Patient with Right Basal Ganglia Intraparenchymal Hemorrhage**

A written case summary appears in the final Appendix at the end of the text. The full written case study including all tables, figures, charts, and 3 video segments (examination, intervention, and outcome) appears online at DavisPlus. The case studies pose questions for the reader's consideration with suggested answers to the case study questions, also posted online at DavisPlus.

Fugl-Meyer Assessment of Physical Performance

appendix **15.A**

SUMMARY OF SCORES

MOTOR

Upper arm _____		Maximum Score	36
Wrist & hand _____	_____	Maximum Score	30
TOTAL UPPER EXTREMITY SCORE	_____	MAXIMUM SCORE	66
TOTAL LOWER EXTREMITY SCORE	_____	MAXIMUM SCORE	34

TOTAL MOTOR SCORE	_____	TOTAL MAXIMUM SCORE	100	PERCENTAGE OF RECOVERY
BALANCE				
TOTAL SCORE	_____	MAXIMUM SCORE	14	
SENSATION				
TOTAL SCORE	_____	MAXIMUM SCORE	24	
JOINT RANGE OF MOTION				
TOTAL SCORE	_____	MAXIMUM SCORE	44	
PAIN				
TOTAL SCORE	_____	MAXIMUM SCORE	44	
TOTAL FUGL-MEYER SCORE	_____	TOTAL MAXIMUM SCORE	226	PERCENTAGE OF RECOVERY

Area	Test	Scoring Criteria	Maximum Possible Score	Attained Score
Upper Extremity (sitting)	*Motor* I. Reflexes a. biceps _____ b. triceps _____	0—No reflex activity can be elicited. 2—Reflex activity can be elicited.	4	
	II. Flexor Synergy elevation _____ shoulder retraction _____ abduction (at least 90°) _____ external rotation _____ elbow flexion _____ forearm supination _____	0—Cannot be performed at all. 1—Performed partly. 2—Performed faultlessly.	12	
	III. Extensor Synergy shoulder adduction/internal rotation _____ elbow extension _____ forearm pronation _____	0—Cannot be performed at all. 1—Performed partly. 2—Performed faultlessly.	6	

Continued

Area	Test	Scoring Criteria	Maximum Possible Score	Attained Score
	IV. Movement Combining Synergies a. Hand to lumbar spine _____	a. 0—No specific action performed. 1—Hand must pass anterior superior iliac spine. 2—Action is performed faultlessly.		
	b. Shoulder flexion to 90° elbow at 0° _____	b. 0—Arm is immediately abducted or elbow flexes at start of motion. 1—Abduction or elbow flexion occurs in later phase of motion. 2—Faultless motion.		
	c. Pronation/supination of forearm with elbow at 90° and shoulder at 0° _____	c. 0—Correct position of shoulder and elbow cannot be attained, and/or pronation or supination cannot be performed at all. 1—Active pronation or supination can be performed even within a limited range of motion, and at the same time the shoulder and elbow are correctly positioned. 2—Complete pronation and supination with correct positions at elbow and shoulder.	6	
	V. Movement Out of Synergy a. Shoulder abduction to 90° elbow at 0° and forearm pronated _____	a. 0—*Initial* elbow flexion occurs or any deviation from pronated forearm occurs. 1—Motion can be performed partly, or if during motion, elbow is flexed or forearm cannot be kept in pronation. 2—Faultless motion.		
	b. Shoulder flexion, 90–180° elbow at 0° and forearm in mid position _____	b. 0—Initial flexion of elbow or shoulder abduction occurs. 1—Elbow flexion or shoulder abduction, occurs during shoulder flexion. 2—Faultless motion.		
	c. Pronation/supination of forearm elbow at 0° and shoulder between 30–90° of flexion _____	c. 0—Supination and pronation cannot be performed at all or elbow and shoulder position cannot be attained. 1—Elbow and shoulder properly positioned and pronation and supination performed in a limited range. 2—Faultless motion.	6	
Upper Extremity	VI. Normal Reflex Activity biceps and/or finger flexors and triceps _____	(This stage, which can render the score of two, is included only if the patient has a score of 6 in stage V.)		

Area	Test	Scoring Criteria	Maximum Possible Score	Attained Score
		0—At least 2 of the 3 phasic reflexes are markedly hyperactive. 1—One reflex markedly hyperactive or at least 2 reflexes are lively. 2—No more than one reflex is lively and none are hyperactive.	2	
Wrist	VII. a. Stability, elbow at 90°, shoulder at 0°	a. 1—Dorsiflexion is accomplished, but no resistance is taken. 2—Position can be maintained with some (slight) resistance.		
	b. Flexion/extension, elbow at 90°, shoulder at 0° _____	b. 0—Volitional movement does not occur. 1—Patient cannot actively move the wrist joint throughout the total ROM. 2—Faultless, smooth movement.		
	c. Stability, elbow at 0°, shoulder at 30° _____	c. Scoring is the same as for item a.		
	d. Flexion/extension, elbow at 0°, shoulder at 30° _____	d. Scoring is the same as for item b.		
	e. Circumduction _____	e. 0—Cannot be performed. 1—Jerky motion or incomplete circumduction. 2—Complete motion with smoothness.	10	
Hand	VIII. a. Finger Mass Flexion _____	a. 0—No flexion occurs. 1—Some flexion, but not full motion. 2—Complete active flexion (compared with unaffected hand).		
	b. Finger Mass Extension _____	b. 0—No extension occurs. 1—Patient can release an active mass flexion grasp. 2—Full active extension.		
	c. Grasp #1—MP joints extended and PIPS & DIPS are flexed. Grasp is tested against resistance.	c. 0—Required position cannot be acquired. 1—Grasp is weak. 2—Grasp can be maintained against relatively great resistance.		
	d. Grasp #2—Patient is instructed to adduct thumb, 1st carpometacarpophalangeal and interphalangeal joint at 0°	d. 0—Function cannot be performed. 1—Scrap of paper interposed between the thumb and index finger can be kept in place, but not against a slight tug. 2—Paper is held firmly against a tug.		

Continued

Area	Test	Scoring Criteria	Maximum Possible Score	Attained Score
	e. Grasp #3—Patient opposes the thumb pad against the pad of index finger. A pencil is interposed _____	e. Scoring procedures are the same as for Grasp #2.		
	f. Grasp #4—The patient should grasp a cylinder shaped object (small can), the volar surface of the 1st and 2nd finger against each other _____	f. Scoring procedures are the same as for Grasp #2 and #3.		
	g. Grasp #5—A spherical grasp.	g. Scoring procedures are the same as for Grasp #2, 3, and 4.	14	
Hand	IX. Coordination/Speed—Finger-to-nose (five repetitions in rapid succession).			
	a. Tremor _____	a. 0—Marked tremor. 1—Slight tremor. 2—No tremor.		
	b. Dysmetria _____	b. 0—Pronounced or unsystematic dysmetria. 1—Slight or systematic dysmetria. 2—No dysmetria.		
	c. Speed _____	c. 0—Activity is more than 6 seconds longer than unaffected hand. 1—2 to 5 seconds longer than unaffected hand. 2—Less than 2 seconds difference.	6	
		TOTAL MAXIMUM UPPER EXTREMITY SCORE	66	
Lower Extremity (supine)	I. Reflex activity—tested in supine position. Achilles _____ atellar _____	0—No reflex activity 2—Reflex activity	4	
Supine	II. a. Flexor Synergy Hip flexion _____ Knee flexion _____ Ankle dorsiflexion _____	a. 0—Cannot be performed 1—Partial motion 2—Full motion	6	
	b. Extensor synergy—(motion is resisted) Hip extension _____ Adduction _____ Knee extension _____ Ankle plantarflexion _____	b. 0—No motion 1—Weak motion 2—Almost full strength compared to normal	8	
Sitting (knees free of chair)	III. Movement Combining Synergies a. Knee flexion beyond 90° _____	a. 0—No active motion 1—From slightly extended position knee can be flexed but not beyond 90°		

Area	Test	Scoring Criteria	Maximum Possible Score	Attained Score
	b. Ankle dorsiflexion _____	b. 0—No active flexion 1—Incomplete active flexion 2—Normal dorsiflexion	4	
Standing	IV. Movement Out of Synergy Hip at 0° a. Knee flexion _____	a. 0—Knee cannot flex without hip flexion 1—Knee begins flexion without hip flexion, but doesn't get to 90°, or hip flexes during motion 2—Full motion as described		
	b. Ankle dorsiflexion _____	b. 0—No active motion 1—Partial motion 2—Full motion	4	
Sitting	V. Normal Reflexes Knee flexors _____ Patellar _____ Achilles _____	0—2 of the 3 are markedly hyperactive 1—One reflex is hyperactive or 2 reflexes are lively 2—No more than 1 reflex lively	2	
(Supine)	VI. Coordination/Speed Heel to opposite knee (5 repetitions in rapid succession) a. Tremor _____	a. 0—Marked tremor 1—Slight tremor 2—No tremor		
	b. Dysmetria _____	b. 0—Pronounced or unsystematic 1—Slight or systematic 2—No dysmetria		
	c. Speed _____	c. 0—Six seconds slower than unaffected side 1—Two to 5 seconds slower 2—Less than 2 seconds difference	6	
		TOTAL MAXIMUM LOWER EXTREMITY SCORE	34	
Balance	a. Sit without support _____	a. 0—Cannot maintain sitting without support 1—Can sit unsupported less than 5 minutes 2—Can sit longer than 5 minutes		
	b. Parachute reaction, non-affected side _____	b. 0—Does not abduct shoulder or extend elbow 1—Impaired reaction 2—Normal reaction		
	c. Parachute reaction, affected side _____	c. Scoring is the same as #2		
	d. Supported standing	d. 0—Cannot stand 1—Stands with maximum support of others 2—Stands with minimum support of one for 1 minute		

Continued

Area	Test	Scoring Criteria	Maximum Possible Score	Attained Score
	e. Stand without support	e. 0—Cannot stand 1—Stands less than 1 minute or sways 2—Stands with good balance more than 1 min.		
	f. Stand on unaffected side _____	f. 0—Cannot be maintained longer than 1–2 sec. 1—Stands balanced 4–9 seconds 2—Stands balanced more than 10 sec.		
	g. Stand on affected side _____	g. 0—Scoring is the same as #6		
		MAXIMUM BALANCE SCORE	14	
Upper and Lower Extremities	*Sensation* I. Light Touch a. Upper arm _____ b. Palm of hand _____ c. Thigh _____ d. Sole of foot _____ II. Proprioception a. Shoulder _____ b. Elbow _____ c. Wrist _____ d. Thumb _____ e. Hip _____ f. Knee _____ g. Ankle _____ h. Toe _____	Light Touch Scoring 0—Anesthesia 1—Hyperaesthesia/dyesthesia 2—Normal Proprioception Scoring 0—No sensation 1—Three quarter of answers are correct, but considerable difference in sensation compared with unaffected side. 2—All answers are correct, little or no difference	8 16	
Shoulder ***Elbow*** ***Wrist*** ***Fingers*** ***Forearm*** ***Hip***	Motion/Pain Motion Pain Flexion _____ _____ Abduction to 90° _____ _____ External rotation _____ _____ Internal rotation _____ _____ Flexion _____ _____ Extension _____ _____ Flexion _____ _____ Extension _____ _____ Flexion _____ _____ Extension _____ _____ Pronation _____ _____ Supination _____ _____ Flexion _____ _____ Abduction _____ _____ External rotation _____ _____ Internal rotation _____ _____	Motion Scoring 0—Only a few degrees of motion 1—Decreased passive range of motion 2—Normal passive range of motion Pain Scoring 0—Marked pain at end of range or pain through range 1—Some pain 2—No pain	Motion 44 44	

Area	Test	Scoring Criteria	Maximum Possible Score	Attained Score
Knee	Flexion _____ _____ Extension _____ _____			
Ankle	Dorsiflexion _____ _____ Plantarflexion _____ _____			
Foot	Pronation _____ _____ Supination _____ _____

Multiple Sclerosis

Susan B. O'Sullivan, PT, EdD
Robert J. Schreyer, PT, DPT, NCS, MSCS, CSCS

Chapter 16

LEARNING OBJECTIVES

1. Describe the etiology, epidemiology, pathophysiology, signs and symptoms, diagnosis, and course of multiple sclerosis (MS).
2. Describe elements of the medical management of patients with MS.
3. Identify and describe the examination procedures used to inform the evaluation of patients with MS to establish the physical therapy diagnosis, prognosis, and plan of care.
4. Describe the role of the physical therapist in the management of patients with MS in terms of direct interventions and patient/client-related instruction to maximize function and quality of life.
5. Describe appropriate elements of the exercise prescription for patients with MS.
6. Review current research findings concerning the rehabilitation of patients with MS.
7. Identify the psychosocial impact of MS and describe appropriate interventions.
8. Analyze and interpret patient data, formulate realistic goals and outcomes, and develop a plan of care when presented with a clinical case study.

SUMMARY *756*

Multiple sclerosis (MS) is an autoimmune disease characterized by inflammation, selective demyelination, and gliosis. It causes both acute and chronic symptoms and can result in significant disability and impaired quality of life. MS affects approximately 400,000 persons in the United States; worldwide MS affects approximately 2.1 million people.[1] It was first defined by Dr. Jean Charcot in 1868 by its clinical and pathological characteristics: paralysis and the cardinal symptoms of intention tremor, scanning speech, and nystagmus, later termed *Charcot's triad*. Using autopsy studies he identified areas of hardened plaques and termed the disease *sclerosis in plaques*.[2]

The onset of MS typically occurs between ages 20 and 40 years. MS is rare in children, as is the onset of symptoms in adults older than age 50 years. The disease is more common in woman than in men by a ratio of 2:1 to 3:1. Although the incidence and prevalence of MS overall have increased over the last 5 decades, this increase appears to be mostly related to an increased prevalence in women.[3] There are also ethnic differences. MS affects predominantly white populations; African Americans demonstrate approximately half the risk of acquiring the disease. Low rates are also reported in Asians and Native Americans.[1]

Epidemiological studies have established a geographical pattern of MS prevalence with areas of high, medium, and low frequency. High-frequency areas include the temperate zones of the northern United States, the Scandinavian countries, northern Europe, southern Canada, New Zealand, and southern Australia. Areas of medium frequency closer to the equator include

the southern United States and Europe and the rest of Australia, and low-frequency tropical areas include Asia, Africa, and South America. Migration studies indicate that the geographical risk associated with an individual's birthplace is retained if emigration occurs after age 15 years. Individuals migrating before this age assume the risk of their new location.[4,5]

ETIOLOGY

The risk of MS is increased in persons with an affected family member. The risk is 3.0% for a sibling, 5.0% for a fraternal co-twin, and rises to 25.0% for an identical co-twin. Genetic studies have revealed many interacting alleles that may contribute to MS susceptibility with mutations in the human leukocyte antigen major histocompatibility complex (MHC) gene most strongly correlated. It appears that although individuals do not inherit the disease, they may inherit a genetic susceptibility to immune system dysfunction.[1]

When persons with a genetic susceptibility are exposed to a viral agent, the immune system responds with activated myelin-reactive lymphocytes, a concept known as *molecular mimicry*. Implicated viruses in this process under investigation include the Epstein-Barr virus, measles, canine distemper, human herpesvirus-6, and *Chlamydia pneumoniae,* though none have been definitely proven to trigger MS. The viruses may be retained in the body, resulting in a self-perpetuating autoimmune process. Risk of MS may also be increased with vitamin D deficiency and smoking.[1]

PATHOPHYSIOLOGY

In patients with MS, the immune response triggers activation of immune cells (e.g., T cells, CD4+ helper T cells, B cells) that cross the blood–brain barrier. In turn, these cells activate autoantigens, producing autoimmune cytotoxic effects within the central nervous system (CNS) (this process can be viewed as a form of "friendly fire"). Phagocytic activity of macrophages may also contribute to demyelination.[1] **Myelin** serves as an insulator, speeding up the conduction along nerve fibers from one node of Ranvier to another (termed *saltatory conduction*). It also serves to conserve energy for the nerve because depolarization occurs only at the nodes. Disruption of the myelin sheath and active **demyelination** slows neural transmission and causes nerves to fatigue rapidly. With severe disruption, conduction block occurs with resulting disruption of function.

An acute inflammatory event emerges. Edema and infiltrates (e.g., monocytes, macrophages, and microglia) surround the acute lesion and can cause a *mass effect* (abnormally high pressures), further interfering with the conductivity of the nerve fiber. Conceivably, this inflammation (which gradually subsides) may, in part, account for the pattern of fluctuations in function that characterize this disease. With repeat attacks, the anti-inflammatory processes become less effective and are unable to keep up. During the early stages of MS, *oligodendrocytes* (myelin-producing cells) survive the initial insult and can produce remyelination. This process is often incomplete and, as the disease becomes more chronic, stalls altogether. Eventually the oligodendrocytes become involved and myelin repair cannot occur. One form of MS, primary-progressive MS, appears to be associated exclusively with disease of the oligodendrocytes.[6] Demyelinated areas eventually become filled with fibrous astrocytes and undergo a process called gliosis. **Gliosis** refers to the proliferation of neuroglial tissue within the CNS and results in glial scars *(plaques).* At this stage, the axon itself becomes interrupted and undergoes neurodegeneration. This is believed to be the main cause of permanent neurological disability. In advanced cases, there are both acute and degenerative lesions of varying size scattered throughout the CNS (brain, brainstem, cerebellum, and spinal cord). Lesions primarily affect white matter early, with lesions of gray matter evident in more advanced disease (type 1 lesions). Lesions may also include small perivascular areas of demyelination (type 2 lesions) and pial surface lesions (type 3). Brain atrophy, the loss of axons and myelin throughout the brain, is evident even in early stages of the disease and is progressive.[1] There are certain areas of predilection, such as the optic nerves, periventricular white matter, spinal cord (corticospinal tracts, posterior white columns), and cerebellar peduncles.[6]

DISEASE COURSE

MS is highly variable and unpredictable from person-to-person and within a given individual over time. At one end of the continuum, there is *benign MS,* defined as disease in which the patient remains fully functional in all neurological systems 15 years after onset. Benign MS affects fewer than 20% of cases. At the other end of the continuum, there is *malignant MS (Marburg disease),* a relatively rare disease course characterized by rapid onset and almost continual progression leading to significant disability or death within a relatively short time after onset.

There are four major disease courses (clinical subtypes) of MS. *Relapsing-remitting MS (RRMS)* is the most common course, affecting approximately 85% of patients with MS. It is characterized by discrete attacks or *relapses,* defined as periods of acute worsening of neurological function. Relapses are followed by *remissions,* defined as periods without disease progression and partial or complete abatement of signs and symptoms. Before the advent of disease-modifying medications, the majority of patients with RRMS went on to develop *secondary-progressive MS (SPMS*). SPMS begins with a relapsing-remitting course followed by progression to steady and irreversible decline with or without occasional acute attacks. *Primary-progressive MS (PPMS)* is a rare form occurring in about 10% of cases. It is characterized by a nearly continuous worsening of the disease from the

onset without distinct attacks. Patients may experience modest fluctuations. *Progressive-relapsing MS (PRMS)* begins with a progressive disease course from the onset and steady deterioration (similar to PPMS), but with occasional acute attacks. It affects approximately 5% of patients with MS. Because the course of the disease may alter (RRMS to SPMS), clinicians need to be alert to changes in signs or symptoms in terms of severity, frequency, and impact on function.[1,7] Box 16.1 summarizes the clinical subtypes of multiple sclerosis.

Exacerbating Factors

MS relapses (exacerbations) are defined by new and recurrent MS symptoms lasting more than 24 hours but generally of longer duration that are unrelated to another etiology. Several exacerbating factors have been identified. Avoiding these factors is important in ensuring the patient's optimal function. An individual whose overall health deteriorates is more likely to have a relapse than one who remains healthy. Viral or bacterial infections (e.g., cold, flu, urinary tract infection, sinus infection) and diseases of major organ systems (e.g., hepatitis, pancreatitis, asthma attacks) are associated with relapses of disease. There is also a modest link between stress and acute attacks. Both major life stress events (divorce, death, losing a job, trauma) and minor stresses (exhaustion, dehydration, malnutrition, and sleep deprivation) can affect the immune system and an already compromised nervous system.

Pseudoexacerbation refers to the temporary worsening of MS symptoms. The episode typically comes and goes quickly, usually within 24 hours. The overwhelming majority of individuals with MS demonstrate an adverse reaction to heat, known as *Uthoff's symptom*. Anything that raises the body temperature can bring on a pseudo-attack. External heat stressors include sun exposure, hot muggy environmental temperatures, or a hot bath. Internal elevations in temperature can be produced by fever or prolonged exercise. The effects are usually immediate and dramatic in terms of reduced function and increased fatigue. Most pseudo-attacks resolve within 24 hours of cooling off and/or the end of a fever.

Box 16.1 Four Major Clinical Subtypes of MS[1]

Relapsing-Remitting MS (RRMS)

- Characterized by discrete attacks of neurological deficits (relapse) with either full or partial recovery (remission) in subsequent weeks to months.
- The periods between relapses are characterized by lack of disease progression.
- The stable patient may have local inflammatory activity that is clinically silent.
- Affects approximately 85% of patients with MS at diagnosis.

Secondary-Progressive MS (SPMS)

- Characterized by an initial relapsing-remitting course, followed by a change in clinical course with progression to steady and irreversible decline with or without continued acute attacks.
- May be the result of progressive axonal loss rather than new lesions.
- Before newer treatments, the majority of patients with RRMS progressed to SPMS.

Primary-Progressive MS (PPMS)

- Characterized by disease progression and steady functional decline from onset; patients may experience modest fluctuations in neurological disability but discrete attacks do not occur.
- PPMS is associated with later onset (mean age 40 years) and more equal gender distribution.
- Affects approximately 10% of patients with MS.

Progressive-Relapsing MS (PRMS)

- Characterized by a steady deterioration in disease from onset (similar to PPMS) but with occasional acute attacks.
- Intervals between attacks are characterized by continuing disease progression.
- Affects approximately 5% of patients with MS.

SYMPTOMS

Symptoms of MS vary considerably, depending on the location of specific lesions. Early symptoms typically include minor visual disturbances (e.g., episodes of double vision) and paresthesias progressing to numbness, weakness, and fatigability. In more advanced stages, patients demonstrate multiple symptoms with varying involvement. Common MS symptoms are presented in Box 16.2.[8,9] The onset of symptoms can develop rapidly over a course of minutes or hours; less frequently, onset is insidious, occurring over a period of weeks or months. An early remission may lead the individual to postpone initial neurological workup for months or longer.

Sensory

Complete loss of any single sensation (anesthesia) is rare. Focal deficits can produce limited areas of diminished sensation. Altered sensations are far more common and can include *paresthesias* (pins-and-needles sensation) or numbness of the face, body, or extremities. Disturbances in position sense are also common, as are lower extremity (LE) impairments of vibratory sense.[9]

Pain

Approximately 80% of patients with MS experience pain, with clinically significant pain occurring in about 55%. Almost half experience chronic pain.[10] Patients often experience acute, paroxysmal pain characterized by sudden and spontaneous onset. The pains are described

Box 16.2 Common Symptoms in Multiple Sclerosis

Sensory Symptoms
- Hypoesthesia, numbness
- Paresthesias

Pain
- Paroxysmal limb pain, dysesthesias
- Headache
- Optic or trigeminal neuritis
- Lhermitte's sign
- Hyperpathia
- Chronic neuropathic pain

Visual Symptoms
- Blurred or double vision (diplopia)
- Diminished acuity/loss of vision
- Scotoma
- Nystagmus
- Lateral gaze palsy

Cognitive Symptoms
- Short-term memory deficits

Bowel Symptoms
- Diminished attention, concentration
- Diminished executive functions
- Diminished information processing
- Diminished visual–spatial abilities

Affective Symptoms
- Depression
- Anxiety
- Pseudobulbar affect
- Anxiety

Motor Symptoms
- Paresis or paralysis
- Fatigue
- Spasticity, spasms
- Ataxia: incoordination, intention tremor
- postural tremor
- Impaired balance and gait

Speech and Swallowing
- Dysarthria
- Diminished verbal fluency
- Dysphonia
- Dysphagia

Bladder Symptoms
- Spastic bladder
- Flaccid bladder
- Dyssynergic bladder
- Constipation
- Diarrhea and incontinence

Sexual Symptoms
- Impotence
- Decreased libido
- Impaired ability to achieve orgasm

Pattern of Symptoms
- Varies greatly from person to person
- Varies over time in each individual affected
- First symptoms usually transient; typically sensory and visual
- Diagnosis involves evidence of damage occurring in at least two separate areas of CNS and at two separate points in time at least one month apart (*dissemination of lesions in space and time)*

CNS = central nervous system.

as intense, sharp, shooting, electric shock–like, and burning. The most common types are trigeminal neuralgia, paroxysmal limb pain, and headache. *Trigeminal neuralgia* (tic douloureux) results from demyelination of the sensory division of the trigeminal nerve innervating the face, cheek, and jaw. Eating, shaving, or simply touching the face may trigger painful episodes. A common sign of posterior column damage in the spinal cord is **Lhermitte's sign** in which flexion of the neck produces an electric shock–like sensation running down the spine and into the LEs. Paroxysmal limb pain presents as abnormal burning, aching pain (dysesthesias) that can affect any part of the body but is more common in the LEs. It is the most common type of pain in MS and is worse at night and after exercise. It can be aggravated by temperature elevations. *Hyperpathia*, a hypersensitivity to minor sensory stimuli, can occur. For example, a light touch or light pressure stimulus elicits a severe pain reaction. Headache is more frequent in MS than in the general population and can be migraine or tension type. Chronic *neuropathic pain* can result from demyelinating lesions in spinothalamic tracts or in the sensory roots. It is more common in patients with minimum disability and is described as a burning pain similar to pain described by individuals with disk herniation. Musculoskeletal pain associated with muscle and ligament strain can develop from mechanical stress, abnormal postures, and immobility, often the result of weak muscles, powerful spasticity, and tonic spasms. Anxiety and fear can worsen pain symptoms.[10]

Visual

Visual symptoms are common with MS and are found in approximately 80% of patients. Involvement of the optic nerve produces altered visual acuity; blindness is rare. *Optic neuritis,* inflammation of the optic nerve, is a common problem, and produces an icepick-like pain behind the eye with blurring or graying of vision or blindness in one eye. A *scotoma* or dark spot may occur in the center of the visual field. Neuritis rarely affects both eyes and is usually self-limiting. Vision generally improves within 4 to 12 weeks. Damage to the optic nerve will also affect light reflexes. *Marcus Gunn pupil* often develops in individuals with MS who have had an episode of optic neuritis. Shining a bright light into the healthy eye will produce reflex contraction in both eyes (consensual light reflex). If the light is then shone in the affected eye only, a paradoxical widening (dilation) of both pupils occurs.

Eye movements can be disturbed in a variety of ways. *Nystagmus* is common in patients with MS and results from lesions affecting the cerebellum or central vestibular pathways. This involves involuntary cyclical movements of the eyeball (horizontal or vertical) that develop when the patient looks to the sides or vertically (gaze-induced nystagmus) or when the patient moves the head. *Internuclear ophthalmoplegia* (INO) produces incomplete eye adduction (lateral gaze palsy) on the affected side and nystagmus of the opposite abducting eye with gaze to one side. It is caused by demyelination of the pontine medial longitudinal fasciculus (MLF). Additional impairments in conjugate gaze and control

of eye movements may also be present with brainstem lesions affecting cranial nerves III, IV, and VI or the MLF. *Diplopia,* double vision, occurs when the muscles that control the eyes are not well coordinated. Visual disturbances frequently remit and are seldom the primary cause of disability. The effects of impaired vision on balance and movement should be carefully examined.[11]

Motor

Patients with corticospinal lesions demonstrate signs and symptoms of upper motor neuron (UMN) syndrome. Paresis, spasticity, brisk tendon reflexes, involuntary flexor and extensor spasms, clonus, Babinski's sign, exaggerated cutaneous reflexes, and loss of precise autonomic control all characterize UMN involvement. (See discussion in Chapter 5, Examination of Motor Function: Motor Control and Motor Learning.)

Weakness

Patients with UMN syndrome demonstrate movements that are slow, stiff, and weak, the result of loss of orderly recruitment and reduced firing rate modulation of motor neurons. Reduced muscle strength, power, and endurance, along with impaired synergistic relationships, are evident. Patients with cerebellar lesions demonstrate asthenia or generalized muscle weakness along with ataxia. Patients can also experience muscle weakness secondary to inactivity. Muscle weakness can vary from a mild paresis, often transient at first, to total paralysis of the involved extremities.[9]

Spasticity

Spasticity is an extremely common problem in patients with MS, occurring in 75% of all cases. Spasticity can range from mild to severe, depending on the duration of the disease, number of relapses, and worsening symptoms in recent months. It occurs in the muscles of the upper extremities (UEs) and particularly the LEs. Clinical indications of spasticity include impaired voluntary control of movement (abnormal co-contraction); increased deep tendon reflexes (DTRs); clonus; and decreased range of motion (ROM). Spasticity also results in increased fatigue, impaired functional mobility, and impaired activities of daily living (ADL). Spasticity can cause pain, disabling contractures, abnormal posturing, problems in maintaining skin integrity, and falls. For some patients, spasticity can be beneficial to sitting and standing.[11] Spasticity fluctuates on a daily basis and can be exacerbated by certain factors, such as fatigue, stress, overheating (fever, environmental), infections, or noxious stimuli (e.g., pain, bladder, renal, bowel, skin lesions/injury).[12] Certain antidepressant agents (serotonin-reuptake inhibitors such as fluoxetine, sertraline, and paroxetine) can exacerbate spasticity.[13] Spasticity does not typically abate during spontaneous remissions. In patients with advanced disease, spasticity can be quite disabling and difficult to manage.[12]

Fatigue

Fatigue has been defined by the *Panel on Fatigue of the MS Council for Clinical Practice Guidelines* as "a subjective lack of physical and/or mental energy that is perceived by the individual or caregiver to interfere with usual and desired activities."[13, p. 1] Fatigue comes on abruptly without warning and typically worsens throughout the day. Patient complaints may include feelings of overwhelming tiredness, exhaustion, and weakness together with difficulty concentrating and mental dullness.[8] Fatigue is a daily event, experienced by 75% to 95% of individuals with the disease. Approximately 50% to 60% of patients report that fatigue is one of their most troubling symptoms. Patients consistently report that fatigue interferes with physical functioning (79% of patients), overall role performance (67% of patients), social participation, and perceived health status. Severity of disease does not seem to be related to fatigue severity; that is, individuals mildly affected by disease (ambulatory patients) report disabling fatigue as often as more severely disabled patients.[14] Fatigue is the result of central activation failure (*central fatigue*). Aggravating factors contributing to fatigue include physical exertion, exposure to heat and humidity (reported by 92% of patients), disturbed or reduced sleep, depression, low self-esteem and mood disorders, and medical conditions (e.g., respiratory infection). Side effects of medications also affect fatigue, including analgesics, anticonvulsants, antidepressants, antihistamines, antihypertensive agents, and anti-inflammatory agents.[12] Sense of mastery (control) is a strong psychosocial predictor of fatigue. Individuals with a low sense of mastery reported significantly more fatigue and fatigue-related distress.[15]

Coordination and Balance

Demyelinating lesions in the cerebellum and cerebellar tracts are common in MS, producing cerebellar symptoms. Clinical manifestations include ataxia, postural and intention tremors, hypotonia, and truncal weakness. **Ataxia** is a general term used to describe uncoordinated movements characterized by **dysmetria, dyssynergia,** and **dysdiadochokinesia.** Progressive ataxia of the trunk and LEs is often apparent. During sitting or standing, when a limb or the body must be supported against gravity, the patient typically presents with *postural tremor* (shaking, back-and-forth oscillatory movements). *Intention (action) tremors* are involuntary, rhythmic, shaking movements that occur when purposeful movement is attempted and results from the inability of the cerebellum to dampen motor movements (see Chapter 6, Examination of Coordination and Balance). Tremors vary in severity from slight, barely perceptible quivering (fine tremor) to wide oscillations (gross tremors). Severe tremors impose significant limitations in performance of functional activities, particularly in such areas as

eating, speaking clearly, writing, personal hygiene, and walking. Tremor can be exacerbated by stress, excitement, and anxiety, all adrenalin-releasing conditions producing a temporary aroused condition.[9] Severe numbness of the feet can contribute to difficulty with standing balance or walking (sensory ataxia).

Lesions affecting the cerebellum (archicerebellum) or central vestibular pathways can produce vestibular dysfunction. Patients may experience symptoms of dizziness, disequilibrium, vertigo, nausea, and so forth. Symptoms are precipitated or made worse by movements of the head or eyes (see Chapter 21, Vestibular Disorders).

Gait and Mobility

Individuals with MS experience difficulty walking as a result of muscle weakness, fatigue, spasticity, impaired balance, impaired sensation, visual problems, and ataxia. Approximately half of patients with RRMS will require some form of assistance during walking within 15 years of their diagnosis. Staggering, uneven steps, poor foot placement, uncoordinated limb movements, and frequent loss of balance characterize ataxic gait. It is often mistaken for drunkenness, a finding that frequently results in the patient revealing the disease for the first time ("outing"). Severe LE extensor spasticity may produce a scissoring gait pattern. Gait and balance impairments increase the risk of falls and fall injury. Approximately half of patients with MS report recent falls. Fear of falling is associated with self-imposed restrictions in mobility and contributes to disability and social isolation.[8]

Speech and Swallowing

Speech problems are the result of muscle weakness, spasticity, tremor, or ataxia and affect as many as 40% of individuals with MS. **Dysarthria** is characterized by slurred or poorly articulated speech with low volume, unnatural emphasis, and slow rate. **Dysphonia** is characterized by changes in vocal quality including harshness, hoarseness, breathiness, or hypernasal sounds. Poor coordination of the tongue and oral muscles can also result in **dysphagia,** difficulty in swallowing. Signs of swallowing dysfunction include difficulty chewing and maintaining a lip seal, inability to swallow (ingest food), and spitting or coughing during or after meals. Aspiration pneumonia is a serious complication that can develop if foods or liquids are inhaled into the trachea. Signs of this include a wet voice quality with gurgling or sounds of congestion, and fever. The patient is also at risk for poor nutritional intake and dehydration and may experience weight loss. Poor coordination of breath control and posture contributes to speech and feeding difficulties.[16]

Cognitive

Cognitive symptoms in MS are common, with approximately 50% of patients demonstrating measurable impairments. Only 10% of patients experience problems severe enough to interfere with daily activities. Cognitive impairments are related to the specific location of the lesions rather than to the overall severity of the disease, its course, or the patient's disability status. Cognitive functions likely to be affected in MS include short-term memory, attention and concentration, information processing, executive functions (concept formation, abstract reasoning, problem solving, and planning and sequencing), visuospatial functions, and verbal fluency. Long-term memory, conversational skills, and reading comprehension are typically intact. Focal frontal lobe lesions can produce cognitive inflexibility and poor impulse control. Significant mental deterioration (global dementia) is relatively rare and may be seen in rapidly progressing disease (malignant MS) or in patients with significant cerebral lesions. Secondary factors that can influence cognition include depression, fatigue, medications, and co-morbid conditions (e.g., cardiovascular or cerebrovascular disease). Level of cognitive dysfunction is a major factor in determining quality of life, social functioning, employment status, and function.[8,17]

Depression

Clinical depression is common in patients with MS, with at least 50% of individuals experiencing a major depressive episode. Depressive symptoms can include feelings of hopelessness or despair, diminished interest or pleasure in activities, changes in appetite and significant weight loss or gain, insomnia or hypersomnia (daytime sleepiness), feelings of lethargy or worthlessness, fatigue or loss of energy, decreased concentration, and recurrent thoughts of death and suicide.[18] It can occur as a direct result of MS lesions, as a side effect of some drugs (e.g., corticosteroids, possibly interferon), or as a psychological reaction to the stresses of this far-reaching and unpredictable disease.[19] Anxiety, denial, anger, aggression, or dependency can also occur. Patients with MS face enormous issues related to the ambiguity of their health status, the unpredictable course of disease activity, unpredictable future status, and the loss of effective functioning during the prime of their lives. Feelings of learned helplessness and low self-efficacy are common and have been linked to depression.[20] Moreover, many of the symptoms of MS (tremor, scanning speech, incontinence) are socially embarrassing, causing additional emotional distress.

Emotional

Affective disorders occur in approximately 10% of cases and can include changes in mood, feelings, emotional expression, and control. **Pseudobulbar affect** (PBA), also known as *involuntary emotional expression disorder* or *emotional incontinence,* is characterized by sudden and unpredictable episodes of crying, laughing, or other emotional displays. It may occur when the disease

damages the area of the brain that controls normal expression of emotion. **Euphoria** consists of an exaggerated feeling of well-being, a sense of optimism incongruent with the patient's incapacitating disability. Bipolar affective disorders (alternating periods of depression and mania) can also occur. Affective symptoms have been linked to more advanced disease and greater intellectual impairment.[21,22]

Bladder

Urinary bladder dysfunction occurs in about 80% of patients. Demyelinating lesions affecting the lateral and posterior spinal tracts unmask the sacral reflex arc producing loss in volitional and synergistic control of the micturition reflex. Types of bladder dysfunction in MS can include a small, spastic bladder (a failure to store problem), a flaccid or big bladder (a failure to empty problem), or a dyssynergic bladder. The dyssynergic or conflicting bladder represents a problem with coordination between the bladder contraction and sphincter relaxation. Common symptoms include urinary urgency, urinary frequency, hesitancy in starting urination, nocturia (frequency at night), dribbling, and incontinence. The severity of bladder symptoms is associated with severity of other neurological symptoms, particularly pyramidal tract involvement. Progressive loss of functional mobility (e.g., hand skills, sitting balance and transfer skills, ambulation) contributes to personal hygiene problems, emotional distress, and functional incontinence (inability to toilet or manage dysfunction). Emptying dysfunction with large residual urine volume increases the risk of recurrent urinary tract infections (UTIs) and kidney damage from frequent UTIs.[23]

Bowel

Constipation is the most common bowel complaint in MS and results from lesions affecting control of the gastrocolic reflex. It is associated with the presence of spasticity of the pelvic floor muscles and is also a frequent consequence of inactivity, lack of fluid intake, poor diet and bowel habits, depression, and medication side effects. Bowel impaction is a serious complication that requires immediate attention. Diarrhea and incontinence are less problematic but can also occur as a result of loss of rectal control, sphincter abnormalities, or other, secondary problems (e.g., gastroenteritis, inflammatory bowel disease).[24]

Sexual

Sexual dysfunction is common, affecting as many as 91% of men and 72% of women. In women, symptoms can include changes in sensation, vaginal dryness, trouble reaching orgasm, and loss of libido. In men, symptoms can include impotence, decreased sensation, difficulty or inability to ejaculate, and loss of libido. Sexual activity is also affected by the appearance of other symptoms such as spasticity, uncontrollable spasms, pain, weakness and fatigue, bladder or bowel incontinence, losses in functional mobility, and changes in self-image. Psychological factors have a large impact on function. Sexual dysfunction has tremendous functional and psychosocial implications for both patient and partner.[25]

DIAGNOSIS

The diagnosis of MS is made by the neurologist based on a careful medical history, a complete neurological examination, and supportive laboratory tests. Evidence of damage must be present in at least two separate areas of the CNS (dissemination of lesions in space) and damage must have occurred at two separate points in time at lease 1 month apart (dissemination of lesions in time). In addition, other possible diagnoses must be ruled out. The revised 2010 *McDonald Criteria of the International Panel on Diagnosis of MS* has resulted in earlier diagnosis of MS with improved specificity and sensitivity (TipSheet is available at www.nationalmssociety.org/).[26, 27]

Laboratory tests used to help confirm the diagnosis include magnetic resonance imaging (MRI), evoked potentials (EP), and lumbar puncture (LP) with cerebrospinal fluid (CSF) analysis.

MRI is highly sensitive for detecting MS plaques in the white matter of the brain and spinal cord (Fig. 16.1). New lesions with active inflammation that occur during the preceding 6 weeks or so are seen as areas of increased signal intensity, "bright spots." Contrast-enhanced T1-weighted images (gadolinium-enhanced) are used to

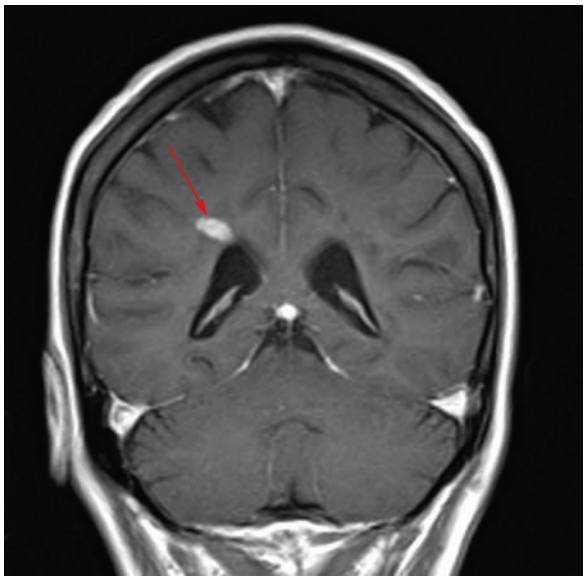

Figure 16.1 Coronal contrast-enhanced T1 MRI. The contrast enhancement of a periventricular white matter lesion (arrow) indicates that this is an active MS plaque. Other (older) plaques in this case that were T2 hyperintense showed no enhancement. *(From Weber et al,[29] with permission.)*

detect more long-term disease activity (i.e., loss of myelin and axons, gliosis). These lesions are seen as "black holes" on the MRI; the darker the lesion, the more extensive the tissue damage. Approximately 95% of patients with clinically defined MS have well-defined MRI changes. Excessive MRI activity includes three or more enhancements on repeat scans separated by at least quarterly intervals. Lesions revealed on MRI do not always correlate with clinical disability. "Silent attacks" documented by MRI changes outnumber the attacks that cause active symptoms such as paralysis or vision loss by 10:1. Misdiagnosis can occur, because 5% of individuals with confirmed MS do not exhibit MRI changes. In addition, other diseases can cause similar lesions evident on MRI (e.g., disseminated encephalomyelitis) and some healthy individuals can exhibit bright spots on MRI. Neurology guidelines call for MRIs to be performed at predefined intervals to document disease progression and response to disease-modifying medications.[28,29]

Up to 90% of individuals with MS demonstrate abnormal EP. The presence of demyelinating lesions on visual, auditory, and somatosensory pathways produces slowed conduction. Of the three, visual evoked potentials (VEPs) have been found to be the most helpful in the diagnostic process.[26]

Patients with MS show elevated total immunoglobulin (IgG) in CSF and the presence of oligoclonal IgG bands (seen in 90% to 95% of patients) in response to inflammatory demyelinating lesions. Patients with PPMS have higher levels of immunoglobulins in spinal fluid than patients with RRMS.[26]

MEDICAL MANAGEMENT

A number of medications are used to help treat and prevent relapses and slow the progression of neurological disability. Medications are also given to provide symptom relief.

Management of Acute Relapses

Corticosteroid therapy (methylprednisolone) is used to treat acute disease relapses (exacerbations), shortening the duration of the episode. These drugs exert powerful anti-inflammatory and immunosuppressive effects, including diminished swelling within the CNS, decreased T-cell activation, limited immune cell penetration of the CNS, and enhanced apoptosis of activated immune cells. The drugs do not modify the disease course or degree of recovery. Typically, corticosteroids are given in high doses (500 to 1,000 mg/day), administered intravenously for a brief course (e.g., 3 to 5 days), followed by tapered dosage of oral medication over a period of 1 to 3 weeks. There are a number of potential adverse side effects, including mood changes, increased blood pressure, fluid retention, hyperglycemia, acne, and insomnia. Chronic use is associated with hypertension, diabetes, aseptic femoral necrosis, osteopenia, and peptic ulcer.[30]

Plasmapheresis (plasma exchange) may be used to enhance recovery from an acute relapse in patients who fail to respond to steroids. It is used for an exacerbation of RRMS and is not recommended for PPMS or SPMS.

Disease-Modifying Therapeutic Agents

Since 1993 the U.S. Food and Drug Administration (FDA) has approved drugs to reduce disease activity in people with MS. Synthetic interferon drugs (interferon beta-1b [Betaseron, Extavia], interferon beta 1-a [Avonex and Rebif]) are first-line injectable drugs that have substantial immunomodulating properties. These are close copies of a naturally occurring human chemical, interferon beta. Interferons slow down the immune system response by reducing inflammation, swelling, and rapid proliferation of T and B cells. They also block activated T cells from crossing the blood–brain barrier and damaging myelin. Other disease-modifying drugs include glatiramer acetate (Copaxone), fingolimod (Gilenya), natalizumab (Tysabri), and mitoxantrone (Novantrone). Daily pills have also been approved by the FDA to treat MS (e.g. Aubagio, Tecfiderа). Patients may show reduced relapses, reduced number of new lesions on MRI, and reduced severity of attack as evidenced by acquired neurological deficits. For patients with new and suspected MS (clinical isolated syndrome [CIS]), the medications may delay time to a second clinical episode and a confirmed diagnosis of MS. Continued, frequent relapses or excessive MRI activity may indicate the need to switch drug therapy to higher doses or combination therapies. These agents cannot, however, reverse existing deficits. All of these medications are contraindicated for women who are pregnant or trying to become pregnant, or who are breastfeeding.[20,31] Table 16.1 presents an overview of the disease-modifying drugs.

Common adverse effects of the injectable interferon drugs include injection-site skin reactions (soreness, redness, pain, bruising, or swelling) and flu-like symptoms following injection that lessen over time (fever, chills, sweating, muscle aches, and fatigue). Injection sites are varied to reduce adverse effects. Rare and more severe adverse reactions include depression, allergic reactions, and liver reactions. Copaxone can produce similar injection-site reactions and an initial flushing reaction immediately after injection (anxiety, chest pain, palpitations, shortness of breath). It has the advantage of not causing flu-like symptoms or depression. Patients receive Novantrone by intravenous (IV) infusion in a medical facility and must be closely monitored for serious heart and liver damage. Tysabri poses serious risks for a rare brain infection (progressive multifocal leukoencephalopathy [PML]). An additional disadvantage is the significant annual cost of these drugs (in the thousands of dollars) that may not be covered fully by private insurance plans.[30,31]

Problems with adherence using immunomodulating agents are well documented, especially for the injectable medications. Health professionals can have a significant impact on promoting acceptance and maintenance of

Table 16.1 Disease-Modifying Therapeutic Agents for MS

Agent	FDA-Approved Indications	Delivery System and Frequency
Interferon beta-1b	RRMS, CIS	
Betaseron		SC injections, every other day
Extavia		SC injections, every other day
Interferon beta-1a	RRMS	
Avonex		IM injection, once/week
Rebif		SC injection, 3 times/week
Glatiramer acetate (Copaxone)	RRMS, CIS	SC injection, every day
Gilenya (Fingolimod)	RRMS	Capsule, once daily
Tysabri (natalizumab)	RRMS Not used as an initial treatment	IV infusion in a medical center, monthly
Novatrone (mitoxantrone)	SPMS, PRMS, worsening RRMS Not approved for PPMS Not for use as an initial treatment or for individuals with heart dysfunction	IV infusion in a medical center, once every 3 months Maximum of 8–12 doses over 2–3 years
Tecfidere	RRMS	Oral: twice daily capsule
Aubagio (teriflunomide)	RRMS	Oral: once-daily pill

CIS = clinical isolated syndrome; FDA = Food and Drug Administration; IM = intramuscular; IV = intravenous; PPMS = primary-progressive MS; PRMS = progressive-relapsing MS; RRMS = relapsing-remitting MS; SC = subcutaneous; SPMS = secondary-progressive MS.

immunomodulating therapy. In discussions with the patient the therapist needs to determine the patient's understanding of the treatment benefits and risks, perception of his or her illness, general mood and level of self-esteem, lifestyle and daily living situation, and level of family and community support. Professionals need to support the patient's hope for a positive outcome from drug therapy and emphasize the benefits of early treatment and the importance of consistency in management.[32]

Management of Symptoms

Pharmacological agents are used for symptomatic relief of a wide range of symptoms in MS. The clinician should have a thorough understanding of the medications the patient is taking, the expected benefit, and potential adverse reactions.

Spasticity

Management of spasticity and spasms includes the use of muscle relaxants. Oral baclofen (Lioresal) is commonly used and is highly effective in reducing muscle tone and decreasing the frequency of spasms and clonus. Dosage is progressed gradually to obtain optimal effects. Other examples of oral agents include tizanidine (Zanaflex), dantrolene sodium (Dantrium), and diazepam (Valium). The reduction in spasticity must be balanced with the possibility of adverse effects from overdosing that may include sedation (drowsiness), weakness, and fatigue. The therapist must be alert to these changes and communicate with the physician to achieve optimal dosing for rehabilitation. The therapist must also recognize that at times spasticity can be used to enhance function, substituting for lack of strength. For example, extensor spasticity can be used to assist standing during a stand-pivot transfer. Significant reduction of spasticity with medications might serve to produce loss of function. Carbamazepine (Tegretol) can be effective in reducing paroxysmal (sudden, sharp-onset) spasms. Patients who do not adequately respond to standard drug treatment (e.g., those with intractable spasticity or spasms) may benefit from intrathecal administration of baclofen directly into the CSF of the lumbar spine via a catheter. A programmable implanted pump controls the dosage. Significant reduction in spasticity and spasms has been reported in the LEs and trunk with less improvement reported in the UEs. Adverse effects can include sedation, dizziness, impaired vision, and impaired speech. Pump failure, infection, and lead displacement can also occur.[8,33]

Botulinum toxin (BT) injections are used to provide localized relief of muscle tone and spasms. Efficacy is short term and generally lasts up to 3 months. Excessive use of BT can overly weaken muscles, so it is typically reserved for patients with significant problems. Physical therapy stretching of the limb for at least 4 weeks after injection is an important adjunct. Phenol injections have also been used but are more unpredictable in degree and duration of response and are associated with sensory side effects.[8]

Surgical intervention may be considered for patients with intractable spasticity. The typical surgical candidate presents with spastic paralysis for many years resulting in a nonfunctional limb and serious complications (e.g., contractures and skin breakdown). Interventions include

severing tendons (*tendonotomy*), nerves (*neurectomy*), or nerve roots (*rhizotomy*).[8]

Pain

A variety of drugs are available to manage pain and clinical decisions are based on type of pain. Tricyclic antidepressants are used to treat burning, central neuropathic pain similar to the use with peripheral neuropathic pain. Paroxysmal pain responds to carbamazepine (Tegretol), amitriptyline (Elavil), phenytoin (Dilantin), diazepam (Valium), or gabapentin (Neurontin). Dysesthesias are managed with low doses of amitriptyline (Elavil), imipramine (Tofranil), or desipramine (Norpramin). Antiepileptic drugs (carbamazepine) are used with trigeminal neuralgia. The discomfort and pain associated with spasticity and spasms may be managed with over-the-counter or prescription anti-inflammatory drugs. Sometimes pain can be managed with mild painkillers (acetaminophen or ibuprofen). Strong opioids (oxycodone, methadone, morphine) have limited effectiveness and are not typically prescribed.[10,30]

Fatigue

Amantadine (Symmetrel) and modafinil (Provigil) have demonstrated moderate benefit in managing MS-related fatigue in some patients. In patients receiving disease-modifying agents, glatiramer acetate is associated with less fatigue than interferon beta-1b.[8]

Tremor

Agents to decrease tremor have been used with varying degrees of success. Some patients respond well to a single drug, some to combinations of drugs, and some find no benefit. Medications used to decrease tremor include hydroxyzine (Atarax, Vistaril), clonazepam (Klonopin), propranolol (Inderal), buspirone (Buspar), ondansetron (Zofran), and primidone (Mysoline). Dizziness and vertigo can be managed with antinausea drugs (meclizine [Antivert]) or with scopolamine patches. Severe tremor can also be treated with deep brain stimulation, which involves implanting electrodes into the thalamus.[28]

Cognitive and Emotional Impairments

Cognitive rehabilitation training has been used to improve function in patients with MS. Compensatory training strategies (e.g., memory aids, organizational tools) can improve function in everyday activities together with modifying the home environment to limit distractions. Medications approved for the treatment of Alzheimer's disease (donepezil [Aricept]) have been shown to provide only modest benefits in memory deficits and verbal learning in some patients.[8]

Depression can be managed effectively with antidepressant medications (e.g., fluoxetine [Prozac], Paxil, sertraline [Zoloft]). Some antidepressants can also decrease fatigue. Patients with pseudobulbar affect can be effectively treated with the antidepressant medication amitriptyline (Elavil). Professional counseling and participation in support groups often help the patient cope with the stresses of this unpredictable disease. Exercise and an active lifestyle are important components to reduce depression and anxiety.

Bladder and Bowel Impairments

Urinary problems require a complete urodynamic workup to identify the specific cause of the problem and to arrive at the appropriate course of treatment. Treatment for an overactive, spastic bladder (storage dysfunction) typically involves pharmacological management with anticholinergic medications (propantheline [Pro-Banthine], oxybutynin [Ditropan], imipramine [Tofranil]) to regulate bladder emptying. Adverse effects can include dry mouth, tachycardia, blurred vision, and accommodation disturbances. Dietary recommendations include drinking 8 glasses of fluid per day (water) while limiting intake of caffeine or alcohol. A flaccid bladder (emptying dysfunction) is managed with alternate techniques for emptying, including instruction in the *Crede maneuver* (the application of manual downward pressure over the lower abdomen) or intermittent self-catheterization (ISC) performed four to five times per day. Pharmacological agents may include cholinergic stimulation with urecholine. Dietary recommendations include limiting intake of citrus juices while drinking cranberry juice daily or taking cranberry tablets. A dyssynergic bladder (combined dysfunction) is managed with alpha-adrenergic blocking agents (e.g., terazosin [Hytrin], prazosin [Minipress], tamsulosin [Flomax]) and antispasticity agents (e.g., baclofen [Lioresal], tizanidine hydrochloride [Zanaflex]). On rare occasions when bladder symptoms cannot be controlled with medication and/or ISC, continuous catheterization (indwelling or Foley catheter; condom, or Texas catheter) or surgical urinary diversion (suprapubic catheter) may be necessary. For example, the patient with advanced disease and significant ataxia of the UEs may be unable to manually perform self-catheterization. Urinary tract infections result from retention of urine in the bladder and from catheterization procedures. Antibiotic therapy is the mainstay of treatment.[8]

Constipation is a common problem and may be associated with medications that can exacerbate constipation (e.g., antihypertensives, analgesics/narcotics, tricyclic antidepressants, anticholinergics, diuretics, sedatives/tranquilizers, antacids). It is typically managed with dietary changes including increased fluid intake (six to eight glasses daily) and fiber in the diet. Bulk-forming supplements (Metamucil, FiberCon, Citrucel, Benefiber), or stool softeners (Colace [docusate], Surfak [docusate], miraLax [polyethylene glycol]) can also be used. Regular or continuous use of stimulant laxatives and enemas is not recommended. Bowel training may also include manual disimpaction. Incontinence management includes dietary changes such as avoidance of irritants (caffeine, alcohol); adjustment of medications used to reduce spasticity, which can contribute to the problem; or addition

of medications to control bowel spasms (tolterodine [Detrol], propantheline [Pro-Banthine]).[34]

FRAMEWORK FOR REHABILITATION

The chronicity of this disease, along with its variable and unpredictable course, may lead some to view individuals with MS as poor rehabilitation candidates. Although the disease or its direct impairments cannot be altered, there is strong evidence to support rehabilitation in producing significant gains in enhancing levels of activity and participation.[35-50] In a Cochrane Database Systematic Review of multidisciplinary rehabilitation for adults with MS, researchers identified 10 trials (9 randomized controlled trials [RCTs] and 1 controlled clinical trial [CCT] with 954 participants and 73 caregivers) that met the inclusion criteria. Support was strong for producing both short- and long-term gains (up to 12 months) following rehabilitation in activity and participation for both inpatient and outpatient programs. Low-intensity programs conducted over longer time periods produced stronger evidence in improving quality of life. Evidence of benefits to caregivers was limited. The researchers concluded that suggestions for "best dose" of therapy or optimal therapy are not possible given the current level of clinical trials.[51]

According to the National MS Society's Medical Advisory Board, rehabilitation referral should be initiated whenever there is an "abrupt or gradual worsening of function or an increase in impairment that has a significant impact on the individual's mobility, safety, independence, and/or quality of life."[52, p. 1]

Individuals with neurodegenerative diseases such as MS benefit from *restorative intervention,* aimed at remediating or improving impairments, activity limitations, and participation restrictions.[53] Direct CNS impairments are not responsive to intervention whereas indirect impairments caused by evolving multisystem dysfunction from inactivity and disuse can be modified (Fig. 16.2). For example, strength training can result in meaningful improvements in balance and gait. Goals and outcome statements reflective of restorative intervention focus on remediating impairments and regaining functional independence while promoting self-management skills. As the disease progresses, important goals and outcomes also include assisting the patient in effective coping skills by promoting acceptance and adjustment to limitations and disabilities and enhancing quality of life. The enhancement of quality of life may in fact be the most meaningful outcome for patients in the face of chronic neurodegenerative disease.

Preventative intervention is aimed at minimizing potential complications, impairments, activity limitations, or disabilities as the disease progresses. Preventative interventions for the patient with MS are geared toward decreasing the duration and severity of symptoms or delaying the

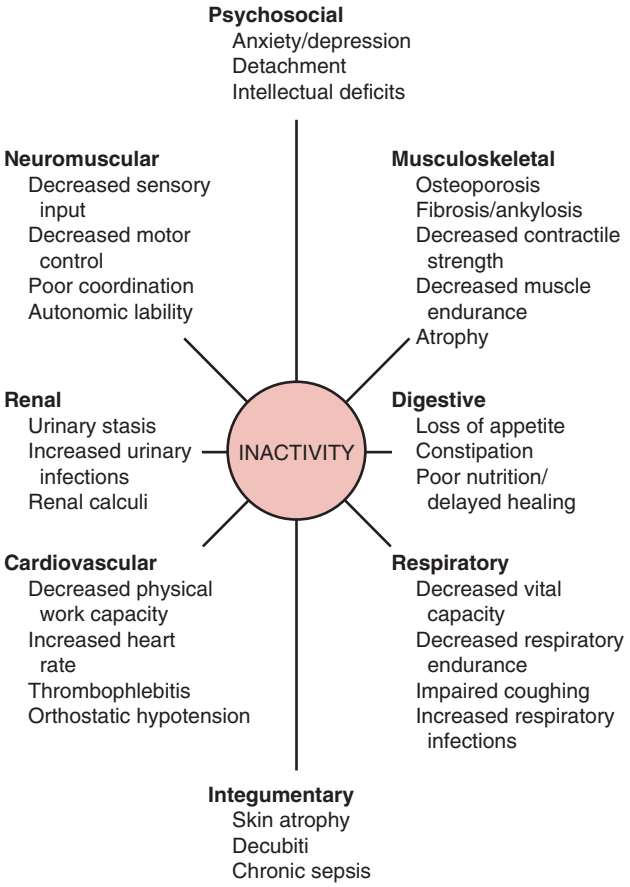

Figure 16.2 Clinical manifestations of inactivity.

emergence of disease sequelae through early detection and intervention, termed *secondary prevention*. Prevention is also aimed at minimizing the degree of disability, termed *tertiary prevention*. Goal and outcome statements reflective of preventative intervention focus on promotion of health, wellness, and fitness, and preservation of optimal function.[53]

Compensatory intervention is aimed at modifying the task, activity, or environment to maintain optimal function within the scope of existing impairments and limitations. Goal and outcome statements reflective of compensatory intervention focus on regaining/maintaining function.[53]

Maintenance therapy is defined as a series of occasional clinical, educational, and administrative services designed to maintain the patient's current level of function. Individuals with MS who benefit from maintenance therapy typically are in the late stages of the disease (Expanded Disability Status Scale [EDSS] stages 7.0 to 9.5; the EDSS is discussed later in the section titled Tests and Measures). Maintenance programs are not well funded by insurance and require careful documentation. Medicare, which covers services for the elderly and the disabled, covers maintenance therapy if the *professional skills of a therapist* (specialized knowledge and judgment) are needed to

maintain a person's condition because of identified dangers.[54] For example, risk of secondary impairment and loss of functional capabilities is reduced or safety of caregivers is enhanced. A variety of interventions are used to achieve goals and outcomes, including limited direct interventions, patient/client-related instruction, and supportive counseling. The therapist tapers the frequency of the visits as the patient or family/caregivers are able to assume independent self-management of the care plan.

A coordinated interdisciplinary team is necessary to oversee the comprehensive examination and management needed to address the patient's complex and multifaceted problems. The team typically includes the physician, nurse, physical therapist, occupational therapist, speech-language pathologist, nutritionist, and social worker. As with any team, the patient is the central figure, with family and caregivers being key members. The ideal rehabilitation program considers the patient's disease history, course, and symptoms, including impairments, activity limitations, and disability. Of equal importance are the patient's abilities (assets), priorities, and resources (e.g., family, home, community). The focus is on long-range planning with anticipated episodes of care, including hospital-based, outpatient, and home/community-based care. Dal Bello-Haas[55] discusses a continuum of care based on disease stage (early, middle, and late) for individuals with neurodegenerative diseases. Considerations for the patient with MS are presented in Table 16.2.

PHYSICAL THERAPY EXAMINATION

Because many different areas of the CNS may be affected, it is imperative that a careful examination is performed to determine the extent of neurological and functional involvement. Subsequent reexaminations at specified intervals are used to distinguish change in status as well as effects of treatment. It may not always be possible to differentiate change in status associated with remission of symptoms from treatment outcomes. Considering the variability of symptoms of any individual patient, it is often beneficial to observe performance over a period of a few days to obtain a representative sample of baseline functioning. Fatigue and exacerbating factors should be taken into account when scheduling the examination.

Physical therapy examination data can be obtained through the patient's history and systems review and relevant tests and measures. The selection of examination procedures and level of inquiry are determined by the patient's unique status. The severity of problems, stage of disease (early/mild, middle/moderate, and late/advanced), age, setting of rehabilitation, and other factors must all be taken into account in structuring the examination.

Patient/Client History

Data obtained through interview with the patient/family and review of the medical record will provide information on general demographics, medical/surgical history, social and employment history, family history, living environment, general health status, and social and health habits. The patient's current/primary complaints and current functional status and activity level should be ascertained. Coexisting health problems and medications should also be identified.

Systems Review

Data obtained from the history and medical record will inform the systems review and help focus selection of appropriate tests and measures (Box 16.3). Review of the following systems is included: (1) cardiovascular, (2) integumentary, (3) musculoskeletal, (4) neuromuscular, and (5) cognitive, emotional, and communication.

Tests and Measures

The following are specific areas and relevant tests and measures that can be used to examine function in patients with MS (for more detailed descriptions, see earlier chapters in this text focusing on examination).

Cognition

Memory function, attention, concentration, conceptual reasoning, problem solving, and speed of information processing should be examined, as well as the effects of fatigue on cognitive performance. An expert panel convened by the Consortium of MS Centers in 2001 developed the *Minimal Examination of Cognitive Function in MS (MACFIMS).* This 90-minute battery of seven neuropsychological tests examines processing speed/working memory, learning and memory, executive function, visual–spatial processing, and word retrieval.[56] A brief screen of cognitive function can be achieved using the *Mini-Mental Status Examination (MMSE)*.[57]

Affective and Psychosocial Function

Emotional stability should be examined. The presence of emotional lability, euphoria, emotional dysregulation, or depression (symptoms, severity, length, effect on functional performance); the level of stress and anxiety; coping strategies; and presence of sleep disorders should be documented. A useful instrument is the *Beck Depression Inventory*.[58] As previously mentioned, it is imperative that the physical therapist be familiar with the patient's medications, because numerous medications will have effects on the affective and psychosocial domain.

Sensation

Given the extent of variability in sensory deficits in individuals with MS, a detailed examination of superficial and deep sensations should be completed (see Chapter 3,

Table 16.2 Stages of MS: Common Impairments, Activity Limitations, and Intervention Strategies

Stage of MS	Common Impairments and Activity Limitations	Intervention Strategies
Early/Mild	• Few/minimal impairments and activity limitations with independence maintained • Motor symptoms present but do not interfere with daily activities • Symptoms for RRMS are more variable and do not progress at the same rate as PPMS or PRMS • SPMS initially presents with relapsing-remitting course (RRMS) followed by a more progressive course	***Preventive and Restorative*** • Regular exercise to improve/maintain motor performance, strength, mobility, flexibility, range of motion (ROM), balance, locomotion, endurance, and perceived quality of life • Community classes to improve/maintain socialization, camaraderie, positive outlook, and life purpose ***Compensatory*** • Patient/family/caregiver education about disease process, rehabilitation, energy conservation • Determine need for adaptive or assistive devices • Determine need for environmental modification of home/workplace • Provide psychological support with early referral to support groups for patient and family/caregiver • Referral to other health care professionals as needed
Middle/Moderate	• Progressive course with increasing number and severity of impairments • Minimal to moderate activity limitations, participation restrictions • Activities of daily living (ADL) with modified dependence (assistance) • Difficulty with balance and gait, postural instability	***Preventative and Restorative*** • Regular exercise to maintain/improve motor performance, strength, mobility, flexibility, ROM, balance, locomotion, endurance, and perceived quality of life • Community classes to improve/maintain socialization, camaraderie, positive outlook and life purpose ***Compensatory*** • Assistive devices to maintain function • Motorized wheelchair or scooter for community mobility • Environmental modifications to home • Patient/family/caregiver education and training • Psychological support for patient and family/caregiver • Referral to other health care professionals as needed

Late/Advanced	• Progressive course with numerous impairments with increasing severity
	• Severe activity limitations with dependence in most activities
	• Great difficulty walking; typically in wheelchair or bed most of the day
	• Assistance needed with all ADL
	• Severe participation restrictions:
	  • Not able to live alone
	  • Typically requires full-time assistance or placement in chronic care facility
	• Social interactions restricted
	• Cognitive problems may be prominent, including dementia, hallucinations, and delusions
		Preventive
		• Maximize upright posture, out-of-bed time
		• Maximize participation in ADL
		• Prevention of contractures, pressure wounds, pneumonia, and so forth
		Compensatory
		• Family/caregiver education and training: safety education, transfers, positioning, turning, skin care
		• Pressure-relieving devices
		• Hospital bed, wheelchair, mechanical lift
		• Psychological support for patient and family/caregiver
		• Referral to other health care professionals as needed

Adapted from Dal Bello-Haas.[55]

PPMS = primary-progressive multiple sclerosis; PRMS = progressive-relapsing multiple sclerosis; RRMS = relapsing-remitting multiple sclerosis; SPMS = secondary-progressive multiple sclerosis.

Box 16.3 Elements of the Examination of the Patient with Multiple Sclerosis[53]

Patient/Client History

- Age, sex, race/ethnicity, primary language, education
- Social history: cultural beliefs and behaviors, family and caregiver resources, social support systems
- Occupation/employment/work
- Living environment: home/work barriers
- Hand dominance
- General health status: physical, psychological, social, and role function, health habits
- Family history
- Medical/surgical history
- Current conditions/chief complaints
- Medications
- Medical/laboratory test results
- Functional status and activity level: premorbid and current

Systems Review

- Neuromuscular
- Musculoskeletal
- Cardiovascular/pulmonary
- Integumentary

Tests and Measures/Impairments

- Cognition: mental status, memory
- Communication
- Anthropometric characteristics: body mass index, girth, length
- Circulation: response to position change/degree of orthostatic hypotension
- Aerobic capacity and endurance: during functional activities and standardized exercise protocols; cardiovascular signs and symptoms in response to exercise and activity; pulmonary signs and symptoms in response to exercise and activity
- Ventilation and gas exchange
- Integumentary integrity: skin condition, pressure sensitive areas; activities, positioning, and postures to relieve pressure
- Sensory integrity and integration
- Pain: intensity and location
- Perceptual function: visuospatial skills
- Joint integrity, alignment, and mobility: range of motion (active and passive); muscle length and soft tissue extensibility
- Posture: alignment and position, symmetry (static and dynamic, sitting and standing); ergonomics, and body mechanics
- Muscle performance: strength, power, and endurance
- Motor function: motor control and motor learning
- Postural control and balance: degree of postural instability, balance strategies; safety
- Gait and locomotion: gait pattern and speed, safety
- Functional status and activity level: performance-based examination of functional skills (FIM level), basic and instrumental ADL; functional mobility skills; home management skills
- Psychosocial function: motivation
- Assistive or adaptive devices: fit, alignment, function, use; safety
- Environment, home, and work barriers
- Work, community, and leisure activities: ability to participate in activities, safety

Examination of Sensory Function). Additionally, sensory deficits and their effects on quality of life (QOL) in individuals with MS can be quantified by using the *Nottingham Sensory Assessment*[59] or *Guy's Neurological Disability Scale*.[60] The latter is a comprehensive multidimensional scale designed to assess the wide range of disability in patients with MS. It is a questionnaire driven by patient interview and can be administered by any health care personnel.[61]

Pain

The presence of acute, paroxysmal pain (Lhermitte's sign, dysesthesias) and chronic pain including pain behaviors and reactions during specific movements and

provoking stimuli should be documented. The *McGill Pain Questionnaire*[62] or the *Neuropathic Pain Scale,*[63] developed to assess distinct pain qualities associated with neuropathic pain, can be used. (See discussion in Chapter 25, Chronic Pain.)

Visual Acuity

Acuity, tracking, and accommodation should be examined; the presence of visual deficits (blurred vision, field defects [scotoma], diplopia) should be documented.

Cranial Nerve Integrity

Motor and sensory cranial nerve function should be examined; the presence of deficits (optic pain [optic neuritis], oculomotor dyscontrol, dysphagia, impaired gag reflex, trigeminal neuralgia) should be documented.

Range of Motion

Passive range of motion (PROM) and active range of motion (AROM) should be examined; the presence of specific range of motion (ROM) impairments should be documented.

Muscle Performance

Functional strength using manual muscle testing (MMT) and dynamometers (isokinetic, grasp and pinch dynamometers) should be examined; strong spasticity may be a contraindication to standard MMT positions.

Fatigue

The frequency, duration, and severity of fatigue should be examined; precipitating factors, activity levels, and efficacy of rest attempts should be documented.[64] The *Modified Fatigue Impact Scale (MFIS)* developed by Fisk et al[65,66] is a structured, self-report, 21-item questionnaire addressing the effects of fatigue on cognitive, physical, and psychosocial function using a 5-point ordinal scale with 0 equal to never and 4 equal to almost always. Each area (subscale) can be scored separately; the total MFIS score range is from 0 to 84 (see Appendix 16.A). The MFIS can be downloaded in PDF format (www.nationalmssociety.org/MUCS_fatigue.asp). An abbreviated version of the MFIS has five items (the *MFIS-5*). Additionally, the *Fatigue Scale for Motor and Cognitive Functions (FSMC)* is a 20-item scale developed as a measure of cognitive and motor fatigue for people with MS.[67] To measure fatigue during the examination and treatment process, the Visual Analog Scale—Fatigue can be used as a single-item self-report of fatigue.[68]

Temperature Sensitivity

The degree of temperature sensitivity and its effect on fatigue and weakness should be examined. A tympanic membrane thermometer (ear thermometer) can be used before, during, and after moderate-intensity exercise. A determination of the correlation between temperature changes and worsening of neurological symptoms can be made. This transient increase in symptoms following a raise in core temperature has been more accurately termed a *pseudoexacerbation*, and occurs due to transient increased blockade of nerve conduction in demyelinated fibers.[69,70]

Motor Function

The therapist should examine for the presence of corticospinal signs (paresis, spasticity, hyperactive DTRs, positive Babinski's sign, and involuntary spasms [flexor or extensor]). The *Amended Motor Club Examination (AMCA)* was developed to examine the nature and degree of motor and functional deficits in patients with MS.[71]

Spasticity can be examined using a subjective rating scale. The *Ashworth Spasticity Scale*[72] led to the more widely used *Modified Ashworth Scale*.[73] These are ordinal scales designed to measure tone intensity; the modified Ashworth has an additional grade at the lower end allowing for more discrete rating. A determination should be made of the differences between lower limbs versus upper limbs; right and left sides; and factors that influence tone.

The therapist should examine for the presence of cerebellar signs (ataxia, intention tremor, nystagmus, dysarthria). The effects of position change (e.g., sitting-to-standing) may produce an increase in ataxic movements with increased demands for postural stability and should be documented.

The therapist should examine for the presence of vestibular dysfunction (dizziness, vertigo, nystagmus, blurred vision with head and body movements, and postural imbalance; see Chapter 21, Vestibular Disorders).

Posture

Static and dynamic postural control in various different positions (e.g., sitting, standing) should be examined. The presence of postural abnormalities and postural tremor should be documented. Instruments can include posture grids, plumb lines, and still photography with light-emitting diodes.

Balance, Gait, and Locomotion

The therapist should examine static and dynamic balance, reactive and anticipatory control, sensory interaction, and synergistic strategies. Useful instruments include the *Clinical Test for Sensory Interaction in Balance,*[74] dynamic posturography,[75,76] the *Berg Balance Scale,*[77,78] the *Tinetti Performance Oriented Mobility Examination (POMA),*[79] and the *Balance Evaluation Systems Test* (BESTest).[80]

Gait parameters and characteristics should be examined including gait speed, kinematics, stability, safety, and endurance. Examination of patients with significant ataxia can be enhanced by use of videotaped performance.

Useful tests include timed walk tests (10-Meter Walk Test or 6-Minute Walk Test); the *Dynamic Gait Index;* [81] and the *Ambulation Index (AI).*[82] The *Rivermead Visual Gait Examination (RVGA)* was developed to examine gait in patients with MS.[83]

Alignment and fit, safety, practicality, and ease of use of orthotic and assistive devices should be examined along with energy conservation and expenditure. Wheelchair skills, including functional mobility, management, safety, transfers, and energy conservation and expenditure, should be examined.

Aerobic Capacity and Endurance

Vital signs (heart rate, blood pressure, respiratory rate) and breathing patterns should be examined at rest and during exercise. Exertional symptoms (dyspnea; elevated blood pressure, heart rate, respiratory rate) and perceived exertion during and after activity should be documented. Useful scales include the *Rating of Perceived Exertion Scale (the Borg RPE Scale)*[84] and the *Dyspnea Scale*.[85]

Skin Integrity and Condition

Skin integrity and condition should be examined. Areas of insensitivity, bruising, moisture buildup, and skin breakdown should be examined and documented, along with level of urinary continence; bed and wheelchair positioning; effectiveness of pressure-relieving compensatory strategies and pressure-relieving devices (PRDs); and cognitive status and safety awareness.

Functional Status

An examination of functional mobility skills (FMS), basic activities of daily living (BADL), and instrumental activities of daily living (IADL) is indicated, together with social functioning and community and work adaptive skills. A commonly used instrument for patients undergoing active rehabilitation is the *Functional Independence Measure (FIM)*[86,87] (see Chapter 8, Examination of Function).

Environment (Home, Community, and Work)

Physical space for barriers, access, and safety should be examined; a specific task-analysis (patient performance-based examination) in relevant environments (home, work) may be included (see Chapter 9, Examination of the Environment).

General Health Measures

General health measures are used to examine outcomes across a broad spectrum of global or long-term health outcomes. Instruments involve self-report of the patient's perceptions of limitations and quality of life (e.g., physical and social function, general health and vitality, emotional well-being, bodily pain, and so forth). The *Health Status Questionnaire (SF-36)*[88] is widely acknowledged as the gold standard of generic measures of health status. The properties of this instrument have been investigated in patients with MS. Freeman et al[89] found limitations in evaluating change in moderate to severely disabled patients participating in inpatient rehabilitation with significant floor and ceiling effects in four of eight SF-36 dimensions. The *Sickness Impact Profile*[90] and the *Examination of Motor and Process Skills*[91] are also general health measures.

Disease-Specific Measures

Disease-specific measures are designed to examine attributes common in a specific disease entity. Items are included to provide information about the disease process and outcomes, and ideally document clinically meaningful change over time. Thus, the instruments have greater responsiveness or sensitivity to change than general health measures.

Expanded Disability Status Scale (EDSS) for Patients with Multiple Sclerosis

In 1955, Kurtzke developed a 10-point scale for rating overall disability in MS (the Disability Status Scale or DSS).[92] This scale was expanded in 1983 to increase its clinical sensitivity by including half-point increments, becoming the EDSS (Appendix 16.B).[93] This scale has been widely adopted by clinicians and has been used as a standard in MS research. Based on a standard neurological examination, patients are first graded on presenting symptoms in seven specific functional systems (pyramidal, cerebellar, brainstem, sensory, bowel and bladder, visual, mental), plus other functions. Functional system scores (FSS) are obtained using an ordinal clinical rating scale ranging from 0 to 5 or 6. The EDSS is based on the grades obtained from the FSS and uses a 0 to 10 ordinal scale graded in half-point increments, with 0 equal to normal neurological function and 10.0 equal to death owing to MS. For example, patients classified in EDSS step 2.5 demonstrate minimal disability in two FSS (two FSS grade 2, others 0 or 1). The EDSS focuses on ambulation as the primary indicator of disability (see scores 3.0 through 6.5 for levels of ambulation; patients with scores 7.0 or greater are unable to walk). Criticisms of the EDSS include its lack of sensitivity to changes that do not include functional mobility (ambulation) and problems in interrater reliability with patients whose performance is less impaired (scores in the lower ranges, ambulation less impaired).[94] Copies of the EDSS can be obtained from the National Multiple Sclerosis Society at www.nationalmssociety.org/MUCS_FSS.asp.

The Minimum Record of Disability (MRD)

The Minimum Record of Disability (MRD) was developed by the International Federation of Multiple Sclerosis Societies in 1985.[95] This instrument has three subscales: the EDSS with FSS, the *Incapacity Status Scale (ISS),* and the *Environmental Status Scale (ESS).* It is

widely used and includes classification of dysfunction according to World Health Organization (WHO) terminology. Thus, the instrument addresses impairments (the FS and EDSS), disability (ISS), and handicap (ESS). The ISS includes 16 items that address functional disability in ADL. The ESS measures social performance, including work status, financial status, and economic status, and place of residence, personal assistance, transportation, community assistance, and social activity. Solari et al[96] examined the validity of the self-administered version of the MRD and found that determination of ambulatory ability, ADL skills, and social activities was both accurate and cost-effective.

MS Functional Composite (MSFC)

The MS Functional Composite (MSFC) is a 21-item test that includes 3 different functional subtests: the Timed 25-Foot Walk (T25FW), the 9-Hole Peg Test (9HPT), and the Paced Auditory Serial Addition Test (PASAT). The *MSFC Administration and Scoring Manual* can be obtained from the National Multiple Sclerosis Society at www.nationalmssociety.org/search-results/index.aspx?q=MSFC&x=28&y=14&start=0&num=20.

Multiple Sclerosis Quality of Life—54 (MSQOL-54)

The Multiple Sclerosis Quality of Life—54 (MSQOL-54) is a multidimensional health-related quality-of-life measure that combines both generic and MS-specific items into a single instrument.[97] The generic items are from the SF-36 to which 18 items were added to provide more information regarding MS-specific issues.[98] No overall summary score is used: the MSQOL-54 consists of 12 subscales, 2 combined summary scores, and 2 single-item measures. The subscales are physical function, role limitations—physical, role limitations—emotional, pain, emotional well-being, energy, health perceptions, social function, cognitive function, health distress, overall quality of life, and sexual function. The summary scores are the physical health composite summary and the mental health composite summary. The single-item measures are satisfaction with sexual function and change in health.

MS Quality of Life Inventory (MSQLI)

The Consortium of Multiple Sclerosis Centers, Health Science Research Subcommittee, developed the MS Quality of Life Inventory (MSQLI) as a comprehensive outcomes examination package.[99] It includes a battery of 10 self-report scales (138 items) that provide information about health-related quality of life in MS, including the Health Status Questionnaire (SF-36), Modified Fatigue Impact Scale (MFIS), MOS Pain Effects Scale (PES), Sexual Satisfaction Scale (SSS), Bladder Control Scale (BLCS), Bowel Control Scale (BWCS), Impact of Visual Impairment Scale (IVIS), Perceived Deficits Questionnaire (PDQ), Mental Health Inventory (MHI), and MOS Modified Social Support Survey (MSSS). The battery can be administered in approximately 45 minutes in most cases. Abbreviated versions of some of the scales can reduce the set to 81 items requiring approximately 30 minutes to administer. A *User's Manual* can be obtained from www.nationalmssociety.org/for-professionals/researchers/clinical-study-measures/msqli/index.aspx.

Functional Examination of Multiple Sclerosis (FAMS)

The Functional Examination of MS (FAMS) is a 59-item index of health-related quality-of-life measures developed by Cella et al.[100] There are six subscales (mobility, symptoms, emotional well-being [depression], general contentment, thinking/fatigue, and family/social well-being). The mobility subscale strongly correlates with the EDSS.

Multiple Sclerosis Impact Scale (MSIS-29)

The MS Impact Scale (MSIS-29) measures the physical and psychological impact of MS.[101] The scale was primarily developed for community-based populations though testing with hospital-based populations (patients admitted for inpatient rehabilitation, IV corticosteroid treatment for MS relapses, and patients admitted with PPMS) revealed consistency of psychometric properties.[102]

The *Neurology Section Multiple Sclerosis Outcome Measures Taskforce* of the American Physical Therapy Association (APTA) has compiled a list of measures for each relevant International Classification of Functioning, Disability, and Health (ICF) category together with instrument analysis, recommendations for use, and relevant references. The document can be found at www.neuropt.org/files/FINAL_EDGE_DOCUMENT.pdf.

Goals and Outcomes

The general goals and outcomes for patients with progressive disorders of the CNS, adapted from the *Guide to Physical Therapist Practice,*[53] are presented in Box 16.4. These general goals will provide the basis for development of specific anticipated goals and expected outcomes for an individual patient.

The preferred practice pattern for patients with MS from the *Guide to Physical Therapist Practice* is 5E, *Impaired Motor Function and Sensory Integrity Associated with Progressive Disorders of the Central Nervous System.*[53] In this document the reader will find relevant information on patient/client diagnostic classification; ICD-9-CM codes; examination components; considerations for evaluation, diagnosis, and prognosis; and suggested interventions. Thus the *Guide to Physical Therapist Practice* serves as a primary resource to help physical therapists design an appropriate plan of care (POC) and document the services provided and outcomes achieved.

Box 16.4 Examples of General Goals and Outcomes for Patients with Progressive Disorders of the Central Nervous System[53]

Impact of pathology/pathophysiology is reduced.

- Patient/client, family, and caregiver knowledge and awareness of the disease, prognosis, and plan of care is enhanced.
- Symptom management is enhanced.
- Risk of secondary impairment is reduced.
- Intensity of care is decreased.

Impact of impairments is reduced.

- Cognitive function is improved.
- Joint integrity and mobility are improved.
- Sensory awareness and skin integrity are improved.
- Pain is decreased.
- Motor function is improved.
- Muscle performance (strength, power, and endurance) is improved.
- Postural control and balance are improved.
- Gait and locomotion are improved.
- Management of fatigue is enhanced.
- Aerobic capacity is increased.

Ability to perform physical actions, tasks, or activities is improved.

- Independence in activities of daily living is increased.
- Tolerance of positions and activities is increased.
- Activity pacing and energy conservation are enhanced.
- Problem solving and decision making skills are enhanced.
- Safety of patient/client, family, and caregivers is improved.

Disability associated with chronic illness is reduced.

- Ability to assume/resume self-care and home management is improved.
- Ability to assume work (job/school/play), community, and leisure roles is improved.
- Patient/client and family knowledge and awareness of personal and environmental factors associated with worsening of the condition is enhanced.
- Awareness and use of community resources are improved.

Health status and quality of life are improved.

- Sense of well-being is enhanced.
- Stressors are reduced.
- Insight, self-confidence, and self-management skills are improved.
- Health, wellness, and fitness are improved.

Patient/client satisfaction is enhanced.

- Access and availability of services are acceptable to patient/client and family.
- Quality of rehabilitation services is acceptable to patient/client and family.
- Care is coordinated with patient/client, family, caregivers, and other professionals.

Adapted from the *Guide to Physical Therapist Practice*.[53]

PHYSICAL THERAPY INTERVENTIONS

Management of Sensory Deficits and Skin Care

In patients with MS, inflammation causes a disruption in neuronal signaling, causing a variety of sensory symptoms.[103] Strategies should be instituted to increase awareness of sensory deficits, compensate for sensory loss, and promote safety.[104] It is important to remember that sensory deficits may remit, so ongoing examination is necessary. The success of compensatory training strategies depends on the availability of other intact sensory systems. For example, visual compensation techniques can be instituted when deficits in proprioception produce imbalance and place the patient at risk for falls.

If multiple sensory systems are involved (e.g., vision is also impaired), sensory compensatory strategies are not likely to be successful.

Patients with proprioceptive losses demonstrate impairments in movement control and motor learning. They require increased use of other sensory systems, especially vision. Tapping, verbal cueing, and/or biofeedback can all be effective forms of augmented feedback. Proprioceptive loading through exercise, light tracking resistance, resistance bands or weights, and the use of a pool may heighten residual proprioceptive function and improve movement awareness.

Visual loss will interfere with movement and postural control. Blurred vision, especially at night or in low light situations, can occur after episodes of optic neuritis. When individuals with MS have to stand in an upright position in the dark, the likelihood of falls increases.[105] It is therefore important to instruct the patient to maintain adequate lighting at all times (e.g., use of a bright light at night) and reducing clutter to improve safety. Adding color contrast between items in the environment (e.g., stair markings) can also improve safety. Double vision is frequently the result of impaired coordination and weak eye muscles. It can be controlled by placing a patch over one eye and is an important strategy for improving reading, driving, or watching television. However, eye patching should not be used all the time, because it will prevent possible adaptation of the CNS. Eye patching also interferes with depth perception. The symptoms of visual blurring and double vision also fluctuate and can be heightened with fatigue, an increase in temperature, stress, and infection. Management of these symptoms is important to improve vision.[104] If low vision persists, the patient should be referred to a low-vision specialist or one of the national service organizations that provide help to individuals with vision impairments (*National Association for Visually Handicapped, National Federation of the Blind, American Foundation for the Blind*).

One of the most common early sensory symptoms of MS is decreased sensitivity to touch.[103] Patients with MS face an increased risk of developing pressure ulcers owing to the symptoms of MS, including loss of sensation, immobility, loss of bowel and bladder control, and a catabolic nutritional state.[104] Changes in skin turgor, static posturing, and prolonged pressure over bony prominences increase the likelihood of skin breakdown. Approximately 20% of patients with MS will develop a pressure ulcer during the course of the disease.[8] Patients may not feel the discomfort of a prolonged position or may be unable to shift position because of weakness or spasticity. In addition, spasticity and/or spasms may cause friction effects between the skin and supporting surfaces. Awareness, protection, and care of desensitized parts should be taught early in the rehabilitation process and consistently reinforced by all members of the team. It has been demonstrated that patient education programs result in 50% reductions in pressure sore incidence.[106] The patient/family/caregiver should be educated in the following principles of skin care:

- The skin should be kept clean and dry. Soiled skin should be cleansed and dried promptly.
- The skin should be inspected regularly (at least once a day) and carefully, with particular attention to persistent areas of redness and over bony prominences.
- Clothing should be breathable and comfortable (soft, not too loose or wrinkled, or too tight). Seams, buttons, and pockets should not press on the skin, particularly in weight-bearing areas.
- Regular pressure relief is essential. Patients should be instructed to change their position or be changed frequently, typically every 2 hours in bed and every 15 to 30 minutes when sitting in a wheelchair.[107]

Pressure-relieving devices (PRDs) may be necessary to protect insensitive areas and should be implemented as appropriate. These can include mattresses (water, gel, air, or alternating pressure) to distribute body weight and reduce shear and friction in bed. Sheepskins, air or foam cushions, cuffs, and/or boots may be necessary to protect body areas prone to breakdown (shoulder blades, elbows, ischial tuberosities, sacrum, trochanters, knees, malleoli, or heels). Cushions (foam; fluid or air pressure–relieving cushions) are necessary for patients who spend prolonged periods of time sitting in their wheelchair. When evaluating a PRD it is imperative that a pressure mapping system be used to determine its effectiveness and to ensure that the areas of high pressure are adequately protected.[107-109]

Prevention is the best strategy. Important measures for maintaining skin integrity and function include maintaining good nutrition and drinking plenty of fluids. Studies suggest that for patients with MS with pressure sores, there are increased requirements for specific nutrients; particularly zinc and iron supplementation should be considered.[110] The patient must be cautioned against activities that might traumatize the skin. Dragging, bumping, or scraping body parts during a transfer or bed mobility activities can injure the skin. Thermal injury can result from contact with hot water or hot objects. If nonblanchable skin redness develops (lasting longer than 30 minutes), patients should be instructed to stay off the area until the redness disappears. If the redness does not disappear within 24 hours, the individual should seek medical attention. Blisters, blue areas, or open sores indicate more serious injury and require immediate attention. This may include systemic antibiotic therapy for infection and wound management techniques (cleansing and débridement, topical antibiotic agents, and protective dressings).[8]

Management of Pain

Pain can be classified into four categories: pain directly from MS, pain secondary to other symptoms of MS, pain as a result of drug treatment for MS, and pain independent of MS. The management of pain depends on an accurate determination of its causes. Musculoskeletal strain or joint malalignment from chronically weakened muscles are important considerations and are responsive to physical therapy intervention. Patients may experience relief of pain with regular stretching or exercise, massage, and ultrasound. Postural retraining and correction of faulty movement patterns along with orthotic and/or adaptive seating devices can reduce malalignment and pain. Stabbing pain from Lhermitte's sign may be relieved with a soft cervical collar to limit neck flexion. Hydrotherapy or pool therapy using *lukewarm* water may have a beneficial effect on painful dysesthesias. Pressure stockings or gloves can also be used to relieve pain, converting the sensation of pain to one of pressure. Neutral warmth may be an additional factor in the pain relief experienced with stockings or gloves. Patients with chronic pain may benefit from referral to a total management approach for chronic pain, for example, the *multidisciplinary pain clinic* (see Chapter 25, Chronic Pain). Stress management techniques, relaxation training, biofeedback, and meditation are often helpful in reducing both anxiety and pain. The use of transcutaneous electrical nerve stimulation (TENS) to modulate pain in patients with MS has had conflicting results, with some patients experiencing improvement and some a worsening of symptoms.[9,10]

Exercise Training

Muscle weakness and decreased endurance are common findings in patients with MS. In addition, patients with MS often adopt a sedentary lifestyle and limit their physical activity. The benefits of exercise have been firmly established in terms of producing meaningful physiological and psychological changes, improving function while lessening disability, and enhancing quality of life.[111-128] In a Cochrane Database Systematic Review of Exercise Therapy for MS, researchers identified nine high-quality RCTs (260 participants).[128] Six trials compared exercise versus no exercise while three trials compared two types of exercise therapy. The researchers found strong evidence in favor of exercise therapy for improving muscle power, exercise tolerance, and mobility-related activities. Moderate evidence was found for improving emotional mood. There were no adverse effects on fatigue and perception of handicap. The researchers found no evidence that a specific exercise therapy program was more successful in improving level of activity and participation than another. Individuals with minimal to moderate impairments (i.e., EDSS scores between 1 and 6) demonstrate the best exercise tolerance. This speaks to the need to institute exercises early in the course of the disease. Exercise responses of the patient with MS are influenced by a host of factors that require careful attention during exercise, including fatigue, spasticity, incoordination, impaired balance, sensory loss (numbness), tremor, and heat intolerance. Depression may affect adherence to an exercise program. Therapists therefore need to provide constant reinforcement and a positive environment.

Individuals with MS will vary greatly in their responses to exercise. The focus and pace of therapy must be readjusted according to the patient's specific abilities and needs at that time. Patients with RRMS who are experiencing an exacerbation should not exercise until remission is evident. Exercise therapy can be reinstituted when the deterioration has stabilized and no new symptoms are appearing. Patients with PPMS can exercise within the limits of their capabilities as exercise may slow further deterioration and optimize remaining function.[129,130] Box 16.5 Evidence Summary presents a summary of selected research on exercise and MS.

Strength and Conditioning

Maximal muscle force during sustained isometric or isokinetic exercise is lower for persons with MS secondary to reduced ability to activate muscles (reduced force/unit muscle mass), reduced muscle metabolic responses, and muscle weakness secondary to muscle fiber atrophy, spasticity, and disuse.[129] Determining an appropriate exercise prescription to improve strength and endurance is challenging and needs to be carefully individualized for each patient. Prescription is based on four interrelated elements: frequency of exercise, intensity of exercise, type of exercise, and time or duration (the *FITT equation*). The following guidelines can be used:[130]

- Exercise sessions should be scheduled on alternate (non-endurance) days and during optimal times, such as in the morning, when body core temperatures tend to be lowest and before fatigue sets in. Patients with greater neurological involvement may require more frequent exercise (e.g., daily exercise time).
- Resistance training modes can include weight machines, free or pulley weights, latex resistance bands, or isokinetic machines.
- Circuit training, in which improved work capacity is developed through the use of various different stations that alternate work between UEs and LEs, distributes the load among muscles and may prove beneficial for reducing the likelihood of fatigue.
- Sessions should involve discontinuous work, carefully balancing exercise with adequate rest periods.
- Progression is generally slower than with healthy individuals.
- Precautions should be taken to prevent the deleterious effects of overwork. Exercising to the point of fatigue is contraindicated and can result in worsening of symptoms, most notably increased weakness.

Box 16.5 Evidence Summary Exercise and Multiple Sclerosis

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Andreasen et al[122] (2011)	Identified 21 studies	Systematic review of studies evaluating the effect of exercise on MS fatigue; studies included endurance training, resistance training, combined training, or other training modalities		Heterogeneous results; only a few studies evaluated MS fatigue as the primary outcome; many studies applied nonfatigued study populations; those studies that included fatigued patients with MS show positive results	Exercise has the potential to have a positive effect on MS fatigue; remains unclear whether any exercise modalities are superior to others; high-quality studies are needed regarding the different exercise interventions, using fatigue as a primary endpoint
Cakit et al[124] (2010)	45 subjects, in 2 exercise groups, 1 control group; relapsing-remitting or secondary progressive MS, mild-mod MS, no exacerbation, able to stand indep	RCT Exer group 1: PRT on bicycle ergometer and balance exer Exer group 2: home-based LE strengthening and balance exer Control group: home-based LE strengthening and balance exer Outcome measures: duration of exercise; TMW; TUG; DGI, FR, FES; 10-mWT, FSS, Beck Depression Inventory, SF-36	8 weeks, 2×/wk 15 repetitions of high resistance (40% TMW) 2 min followed by low resistance or rest 2 min	Exer group 1: significant improvement in all outcome measures Exer group 2: significant improvement in FES, TMW, and duration of exer Control group: no improvements	PRT results in improved balance, decreased fear of falling, and decreased depression; there were no injuries or increases in MS symptoms
Dalgas et al[123] (2010)	45 subjects with RRMS, EDSS, 3.0–5.5, able to walk > 100 m, age > 18	RCT, crossover design; 5 min warm-up followed by PRT (loads and volume increased every 2 weeks); control group participated in same intervention after 12 weeks Outcome measures: FSS, MDI, SF-36, muscle strength (MVC), functional capacity	12 weeks, 2×/wk; post-study follow-up period of 12 weeks	Significant improvements in strength, fatigue, and functional capacity score; significant changes in mental but not physical components of SF-36	Resistance training well tolerated; improved scores for strength, fatigue, mood, QOL, and ambulatory function; at follow-up no significant deterioration in scores
Rampello et al[125] (2007)	19 subjects with mild to mod MS, score of 6 or less on EDSS, no recent relapse	RTC, crossover design AT group: leg cycle ergometer (5 min warm-up; 30 min at 60% max work rate; 5 min cool-down) Control group: neurological rehab program (NR) Outcome measures: MFIS, MSQOL-54; 6-MWT; walking speed	3 training sessions per week for 8 weeks	With AT but not NR, walking distances and speeds, max work rate, peak O_2 uptake and max work rate significantly improved; no differences on fatigue	AT improves maximum exercise capacity and walking capacity; subjects who were most disabled tended to benefit from AT; there was a high rate of subject loss (4/19 in AT group)

Box 16.5 Evidence Summary Exercise and Multiple Sclerosis—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Rietberg et al[128] (2004)	Identified 9 studies (RCTs); 262 subjects with MS	Meta-analysis of 9 high-quality RCTs Inclusion criteria: exercise therapy for adults with MS (not currently experiencing an exacerbation) Outcome measures: activity limitation and QOL, or both	6 trials: exercise therapy versus no exercise therapy; 3 trials: compared 2 interventions of exercise therapy	Best evidence: Strong evidence in favor of exercise compared to no exercise, improvements in muscle power function, exercise tolerance functions, mobility-related activities noted; moderate evidence: for improving mood; no evidence: effect on fatigue and perception of handicap; no evidence: any specific exercise therapy better than others	No deleterious effects of exercise therapy described. Exercise therapy is beneficial for patients with MS not experiencing an exacerbation. Consensus is needed for core set of outcome measures. Better controls needed for type, intensity of training and for type of MS.
Surakka et al[112] (2004)	95 subjects with MS, mild-mod disability; EDSS scores between 1 and 5.5; exercise group = 46; non-exercise group = 48	RCT, 5 PRT and 5 AT sessions; aerobic exercises in pool (temp 82.4°F[28°C]), 65%–70% age-predicted HR_{max}; resistance training (RT) = circuit training UE and LE Ms, 50%–60% 1-RM; home exercise program (HEP): RT used elastic bands; aerobic training, walking; subjects kept daily diary Outcome measures: Ms torque (dynamometer); Fatigue (FI, FSS, AFI)		Significant decrease in motor fatigue in women ($n = 30$) but not men ($n = 17$) after 6 months of aerobic and strength exercise; exercise activity of women was 25% more than men	Long training period (6 months) may have masked disease progression, especially in men. Men more likely to have PPMS then RRMS.
Mostert and Kesselring[113] (2002)	26 subjects with MS, mild-mod disability, inpatient rehabilitation; EDSS scores between 2.5–6.5; MS-exercise group =13; MS–no intervention group = 13; healthy control group = 26	Randomized control trial Aerobic exercise training: leg cycle ergometry Outcome measures: max GXT; tests of lung function (FVC); spasticity LEs (mAS); EDSS Baecke Activity Questionnaire; SF-36 Health Survey; FSS	4 weeks, 5×/wk, 30 min sessions	MS training group increased aerobic threshold, improved health perception (vitality increased 46%, social interaction increased 36%); increased activity level (17%); tendency for less fatigue; lung function did not change	Aerobic training is safe and improves aerobic capacity; symptom exacerbation lower than expected (6%); compliance of MS training group was low (65%); stresses need for motivational setting; MS patients less fit than healthy controls; more disabled MS patients improved more than less impaired patients; small sample size.

Box 16.5 Evidence Summary Exercise and Multiple Sclerosis—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Sutherland et al[121] (2001)	22 subjects, with MS, mild-mod disability; EDSS of 5.0 or less; no-special-activity group = 11; exercise group = 11	RCT, exercise intervention: land-based weight training; water aerobics, water jogging Outcome measures: submax GXT; HRQOL	10 weeks, 3×/wk, 45 min sessions	Exercise group increased in physical fitness (not significant); reported increased energy and vigor, mood, better social and sexual functioning; less bodily pain and fatigue	Exercise improved psychological health and quality of life; use of water-based aerobics can be effective in patients with MS who have spasticity and coordination deficits; small sample size.
Snook and Motl[127] (2009)	Meta-analysis of 22 studies of 600 patients with MS	Search included published exercise training studies from 1960 to 2007; studies measured walking mobility, using instruments identified as acceptable walking mobility constructs and outcome measures for individuals with neurological disorders, before and after an intervention that included exercise training.	22 studies over 47 years	Computed effect sizes expressed as Cohen's *d*. Sixty-six effect sizes were retrieved and yielded a weighted mean effect size of g = 0.19 (95% confidence interval, 0.09–0.28). There were larger effects associated with supervised exercise training (g = 0.32), exercise programs that were less than 3 months in duration (g = 0.28), and mixed samples of RRMS and progressive MS (g = 0.52).	The cumulative evidence supports that exercise training is associated with a small improvement in walking mobility among individuals with MS.
Dodd et al[126] (2006)	Seven women and two men (mean age 45.6 years, SD 10.7) with MS	Cohort study Gymnasium-based progressive resistance strengthening program: 3 exercises for the legs (leg press, knee extension, seated heel raise) and 3 exercises for the arms (lat pull down, seated chest press, and seated row)	10 weeks, 2×/wk	Positive physical, psychological, and social benefits and decreases in fatigue. Key extrinsic factors for program completion were the leaders' encouragement and knowledge of exercise and the group aspect of the program	Progressive resistance strength training is a feasible fitness option for some people with MS. Choosing encouraging leaders with knowledge of exercise and exercising in a group may contribute to program success.

AFI = Ambulatory Fatigue Index (500-m walk test); AT = aerobic training; BMI = body mass index; DGI = Dynamic Gait Index; EDSS = Expanded Disability Status Scale (Kurtzke); exer = exercise; FES = Falls Efficacy Scale; FI = Fatigue Index; FSS = Fatigue Severity Scale; FR = functional reach; GXT = Graded Exercise Test; QOL = quality of life; LE = lower extremity; mAS = Modified Ashworth Scale; MDI = Major Depression Inventory; MHR = maximal heart rate; MFIS = Modified Fatigue Impact Scale; 6MWT = 6-Minute Walk Test; MVIC = maximal voluntary isometric contraction; MSQOL-54 = Multiple Sclerosis Quality of Life–54 questionnaire; MS = multipal sclerosis; POMS = Profile of Mood States; PPMS = primary-progressive multiple sclerosis; PRT = progressive resistance training; RCT = randomized controlled trial; RRMS = relapsing-remitting multiple sclerosis; SIP = Sickness Impact Profile; 1-RM = 1-repetition maximum contraction; TMW = tolerated maximum workload; TUG = Timed Up and Go Test; UE = upper extremity; VLDL = very-low-density lipoprotein; VO_{2max} = maximal oxygen uptake.

This may have additional adverse effects on the continuing motivation of the patient.
- Precautions should be taken to monitor the effects of fatigue. *Time to fatigue* varies greatly among individuals with MS and is *not* correlated with the level of physical impairment or disability.
- Precautions should be taken to manage core body temperature and prevent overheating.[131,132] Environmental temperatures should be carefully controlled. Air conditioning is a medical necessity in many climates. Additional cooling can be achieved through the use of fans, wet neck wraps, spray bottles for misting the skin with cool water, and immersion in cool water with aquatic exercises. Surface cooling devices have emerged as effective tools in managing body temperatures, controlling fatigue, and improving function. These include cooling suits or vests.[133-135]
- Precautions should be taken with certain impairments. Tactile and proprioceptive losses or incoordination and tremors may make the use of some equipment (e.g., free weights) unsafe. Visual feedback, when intact, should be used to monitor exercise performance. An alternative suggestion would be to use synchronized arm/leg ergometers to control limb movements.
- Precautions should be taken with cognitive and memory impairments. Individuals may require written or posted exercise instructions/diagrams including reminders of the number of repetitions, proper form, and correct use of equipment.
- Functional training activities (e.g., closed chain exercises) can be used to promote strength and functional endurance. Individuals with ataxia and balance problems may require the use of more stable postures (e.g., modified plantigrade, quadruped, or supported sitting).
- Group exercise classes can provide valuable motivation and social support. The therapist's primary role is one of educator and group leader. Successful management of group classes requires careful, individualized examination of group members to determine specific goals and exercises.
- Outcome measures can include isokinetic dynamometry, MMT (may be unreliable if spasticity is present), functional tests (e.g., sit-to-stand), fatigue (MFIS), and quality-of-life measures (HRQL).

Aerobic Conditioning

Individuals with MS demonstrate expected physiological responses to submaximal aerobic exercise; that is, heart rate (HR), blood pressure (BP), and oxygen uptake (VO_2) all increase in a linear fashion in response to increasing workloads. Respiratory responses (respiratory rate [RR] and minute ventilation) also increase.[129] However, HR and BP responses may be blunted if cardiovascular dysautonomia is present. A direct relationship exists between the duration and extent of disease and the likelihood of autonomic cardiovascular dysfunction. Patients with MS can also demonstrate respiratory muscle dysfunction (weakness, dyssynergia), contributing to reduced exercise tolerance.

Exercise tolerance and maximal aerobic power (VO_{2max}) are reduced in individuals with reduced cardiorespiratory fitness secondary to physical inactivity. Decreased physical work capacity, decreased vital capacity, increased HR at rest and in response to exercise, decreased muscular strength, increased fatigue, increased anxiety, and depression are common findings.

Determining an appropriate exercise prescription to improve cardiovascular conditioning needs to be carefully individualized for each patient. While predicting exercise capacity and cardiorespiratory fitness is challenging for individuals with MS, recent studies have shown that peak VO_2 and exercise capacity can be predicted through submaximal testing. [136,137] The following guidelines for *clinical exercise testing* can be used.[130]

- The preferred mode is either an upright or recumbent leg cycle ergometer. A recumbent device is indicated if sitting balance is impaired. Combination leg and arm ergometry or UE ergometry alone may be necessary in the presence of significant LE involvement. Toe clips and heel straps are recommended to control foot placement especially in patients with spasticity, tremor, or weakness.
- Performance measures include HR, ratings of perceived exertion (RPE), BP, and expired gas analysis (VO_2). Using the RPE scale, peripheral (muscles, joints) exertion is consistently rated as more stressful (higher) than central (cardiopulmonary) exertion.
- A continuous or discontinuous protocol (3- to 5-minute stages) can be used; the discontinuous protocol is indicated with symptomatic disease, especially fatigue.
- A submaximal test should be used. Most individuals with MS can achieve 70% to 85% of their age-predicted maximal heart rate (HR_{max}).
- Recommendations for increasing workloads for each stage are 12 to 25 watts for LE work and 8 to 12 watts for combined UE and LE work.
- Termination criteria include achievement of peak HR, peak VO_2, volitional fatigue, significant BP changes (systolic blood pressure [SBP] greater than 250 mm Hg or diastolic blood pressure [DPB] greater than 115 mm Hg or a hypotensive response), or a decrease in oxygen uptake with increasing work rate.
- Precautions should be taken to monitor for attenuated HR or BP responses during exercise. A category-ratio RPE scale can be used to estimate central and peripheral exertion.[84]
- Precautions should be taken to manage core body temperature and prevent overheating (e.g., use of a fan for cooling).

- Precautions should be taken to monitor the effects of fatigue.
- Precautions should be taken to prevent the deleterious effects of overwork.
- Precautions should be taken with certain medications that can affect results: amantadine hydrochloride (HCl) may temporarily reduce fatigue; baclofen and amitriptyline HCl may cause muscle weakness; prednisone can also cause muscle weakness along with reduced sweating and hypertension.
- Morning is the optimal time for testing.

Prescription is again based on the four interrelated elements of the FITT equation. Recommendations for exercise programming to improve aerobic conditioning include the following:[130]

- Recommended training frequency is 3 to 5 days/week, on alternate days. Daily exercise at lower levels of intensity is recommended for individuals with more limited exercise capacities (e.g., 3 to 5 metabolic equivalent [METs]).
- Training intensity should be limited to 60% to 85% HR_{peak} or 50% to 70% peak VO_2.
- Recommended duration is 30 minutes per session or, for more involved individuals, three 10-minute sessions per day.
- Type of exercise can include cycling, walking, swimming, or water aerobics.
- Circuit training may prove best for optimizing training.
- Individuals with balance problems or sensory loss will require non–weight-bearing activities.
- Exercise precautions: discussed in previous section.
- Outcome measures include graded exercise test results (GXT), HR (which may be difficult to monitor with dysautonomia; sensory loss in the fingers may make self-monitoring difficult), tests of lung function (forced vital capacity [FVC]), body composition, RPE, fatigue (FI, MFIS), functional status, and quality-of-life measures (HRQL).

Patient education is particularly important because the overall success of a fitness program is influenced by the individual's level of understanding of the basic principles of training, independence in self-monitoring, and skill in decision making relative to level of impairment and exercise modifications required, as well as lifestyle and general health and safety considerations.

Flexibility Exercises

Stretching and ROM exercises are necessary to ensure adequate joint motion and to counteract the effects of spasticity (Fig.16.3). Sedentary or inactive persons who are dependent on wheelchairs often develop tightness in hip flexors, adductors, hamstrings, and plantarflexors. Limited overhead ROM is seen with tightness in the pectoralis major/minor, and latissimus dorsi and is associated with a slumped, forward posture. Patients confined to bed typically present with tightness in hip/knee extensors, adductors, and plantarflexors. Stretching and ROM exercises should be performed daily. For adequate stretching, holding at end range should be a minimum of 30 to 60 seconds repeated for a minimum of 2 repetitions. The use of orthoses or dynamic splinting is an appropriate option for prevention and in some cases reversal of contractures.[138,139] Considering the gait deviations and difficulty with transfers/bed mobility that arise from limited ROM and spasticity, it is important to also include aggressive trunk ROM to allow for full function of the core musculature, most notably the quadratus lumborum (Fig. 16.4). More active patients may benefit from Tai Chi, which provides additional important benefits of relaxation and balance training. ROM measurement using goniometry is an appropriate outcome measure.

Figure 16.3 Side-lying hip flexor/rectus femoris stretch. This position allows the therapists to control the hip and ensure that excessive lumber lordosis is prevented while also modulating the amount of stretch between the iliopsoas and the rectus femoris.

Management of Fatigue

With approximately 75% of individuals with MS describing persistent or sporadic symptoms, fatigue is among the most debilitating. Fatigue is characterized by overwhelming sleepiness, excessive tiredness, and sense of weakness that comes on suddenly and severely. Aversion to activity for fear of bringing on fatigue is also common. The resultant lowered activity levels have important implications for diminished health status and deconditioning. Therapists are faced with a balancing act, on one hand prescribing exercise, while on the other hand avoiding overwork and the development of fatigue. Aerobic exercise training (previously discussed) and *energy effectiveness strategies (EES)* are central to any intervention plan to lessen fatigue.[13] During exercise prescription and physical therapy sessions, it is imperative that a skilled therapist recognize the difference between MS-related fatigue and the expected exercise-related fatigue. MS-related fatigue during exercise is

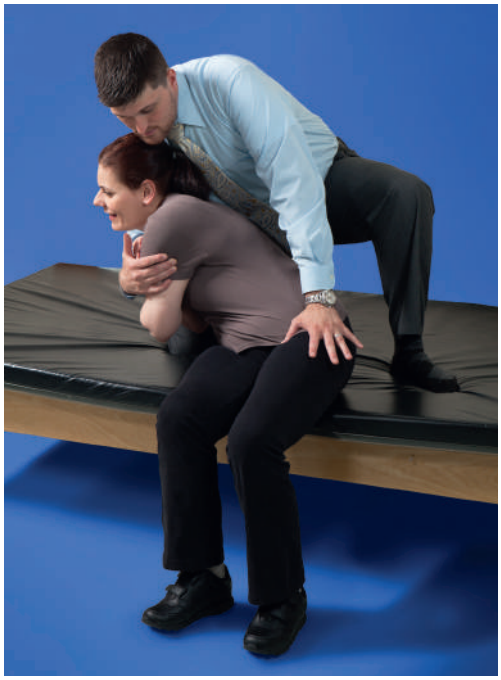

Figure 16.4 Seated trunk stretch. The pictured position allows the therapist to control the pelvis to ensure trunk stretching while maintaining control of the individual's trunk to apply the correct emphasis to the desired muscle groups.

often associated with thermal stress, which can be offset with adequate rest and the use of cooling and precooling treatments during exercise.[132-134]

Patients are instructed to keep an *activity diary* in which they record how they slept the night before, daily activities by hour, and how costly those activities were. For each activity, they can be asked to rate their level of fatigue (F), the value or importance of the activity (V), and satisfaction perceived with performance of the activity (S) by assigning a number between 1 and 10 with 1 being very low and 10 being very high. For example, the activity might be fixing lunch. Scores reported for this activity might be $F = 7$, $V = 3$, and $S = 2$. Aggravating factors associated with increasing fatigue (e.g., heat stress) and MS symptoms that appear or worsen during the day are also recorded. An *MS Daily Activity Diary* is presented in Appendix 16.C.[140]

Based on this information, therapists can initiate training sessions, teaching energy effectiveness strategies. **Energy conservation** refers to the adoption of strategies that reduce overall energy requirements of the task and overall level of fatigue. These can include modifying the task or modifying the environment to ensure successful completion of daily activities. For example, a motorized scooter or powered wheelchair can be considered for community or home mobility to help conserve energy and maintain independence. Other mobility equipment such as walkers, crutches, or orthotics can also be considered. Activities that are difficult or have high energy needs can be broken down into component parts, requiring accurate activity analysis. **Activity pacing** refers to the balancing of activity with rest periods interspersed throughout the day. For the patient with chronic fatigue, *rest–activity ratios* are developed, with periodic rest periods planned in advance. Time-outs with complete rest should be instituted if an activity becomes exhaustive. Overall levels of energy can be improved if patients learn to set priorities and limit their activities, saving their energy for those activities that are truly important to them (e.g., activities that are enjoyable and meaningful in terms of the individual's lifestyle). The occupational therapist addresses EES and can provide valuable suggestions in terms of planning, work simplification, and developing energy-efficient activities for self-care and home management. The vocational rehabilitation counselor can provide useful strategies for behavioral modification and vocational rehabilitation. Team efforts with the physical therapist and others are important for consistency and reinforcement. Weekly review of activities and recommended modifications is used to evaluate progress. The MFIS should be administered on a regular basis to monitor ongoing fatigue status (see Appendix 16.A). Finally, stress management techniques are important components of symptom management.

The occupational and physical therapist should complete a direct environmental examination of the home and/or job site (see Chapter 9, Examination of the Environment). A number of adaptations may be considered to improve efficiency and safety, including air-conditioning, home, or work modifications, or ergonomic equipment. The patient/family/caregivers should be educated as to the importance of these recommendations for improved function. Periodic review of equipment and environmental modifications is also recommended.

Proper communication between the occupational and physical therapist and the patient's physician can ensure that the correct doses of the pharmacological treatments are in place, as the therapist has the unique opportunity of observing the patient in various circumstances and activity levels.

Management of Spasticity

Although spasticity varies greatly from person to person, muscles that typically demonstrate strong tone include the antigravity muscles. For example, in the LEs, the quadriceps, hip adductors, and plantarflexors are often spastic while in the UEs the elbow, wrist, and finger flexors together with shoulder adductors are spastic. Individuals with MS typically demonstrate stronger spasticity in the LEs than the UEs. Spasticity is functionally limiting and contributes to the development of a number of secondary impairments such as contractures, postural deformity, and decubitus ulcers.

A variety of physical therapy interventions can be used, including cryotherapy, hydrotherapy, therapeutic exercise, stretching, positioning, or any combination thereof. The responses to these interventions must be

monitored closely and carefully balanced with pharmacological interventions. The therapist must closely monitor the effects of the antispasticity medications prescribed and optimize physical therapy interventions with the dosing cycle. For example, patients on baclofen will respond better to stretching techniques if they are applied in the middle of the dosing cycle rather than at the end or beginning. Physical therapists must also recognize contributing factors that affect tone and respond appropriately. For example, infection or fever that increases tone may require a referral to the physician. It is important to reduce or eliminate all factors that can aggravate spasticity (e.g., heat, humidity, stress).

Topical cold (ice packs or wraps) or hydrotherapy (cool bath) can temporarily reduce spasticity by decreasing tendon reflex excitability and clonus and by slowing conduction of impulses in nerves and muscles. The effects of cryotherapy are relatively short-lived, although some patients may experience enhanced ability to move that lasts for minutes or hours. It is important to remember that some patients, particularly those with intact sensation, may react to the unpleasant sensation of cold with *fight or flight* (autonomic nervous system) responses, such as increased HR, increased RR, or nausea. Cryotherapy is contraindicated in these patients.

Stretching and ROM exercises begun early in the course of the disease and continued daily can help patients maintain joint integrity and mobility in the presence of spasticity. Combining stretching with movements using rhythmic rotation (gentle rotation of the limb) or proprioceptive neuromuscular facilitation (PNF) stretching techniques (hold–relax active contraction [HRAC], contract–relax active contraction [CRAC]) is effective in gaining ROM.[141] See Chapter 10, Strategies to Improve Motor Function, for a discussion of these techniques. Maintained stretch, held for 30 minutes to 3 hours, also can be used to decrease stretch reflex activity. Maintained stretch can be achieved with prolonged positioning (e.g., tilt table standing with toe wedges), low-load weights applied using skin traction, or serial casts. Air splints also provide an effective mechanism to maintain limbs in lengthened, out of spasticity positions. Patients/family members/clients should be taught stretching exercises as part of a home exercise program (HEP). Fast, ballistic stretching movements are contraindicated, because spasticity is velocity sensitive. Stretching movements need to proceed slowly to gradually achieve the desired range.

Active exercises at slow or self-selected speeds should focus on expanding the available ROM. Emphasis on contracting the antagonist muscles can assist through mechanisms of reciprocal inhibition. Electrical stimulation of muscles antagonist to the spastic muscles can also be used to decrease spasticity. Movements that encourage abnormal postures should be discouraged. Patients with abnormal co-contraction may benefit from exercises focused on improving motor control (timing exercises) or biofeedback. Tai Chi, yoga, and aquatic exercises combined with cool water temperatures (less than 85°F [29.44°C]) can also be helpful in producing desired relaxation.[12]

Functional activities aimed at reducing tone should concentrate on trunk and proximal segments, because many patterns of hypertonus seem to be fixed from the action of the stronger proximal muscles. Extensor tone seems to predominate, so activities that stress LE flexion with trunk rotation are generally the most effective. For example, lower trunk rotation (LTR) in hook-lying can be effective in reducing proximal extensor tone. One very effective strategy is to position the patient in hook-lying with a therapy ball under the flexed legs and gently rock the ball back and forth. Moving from quadruped position to side-sitting can also be effective in reducing extensor tone in some patients as the activity combines LTR with prolonged inhibitory pressure on the quadriceps.[142]

For the patient with limited functional mobility (EDSS levels of 7.0 or above) positioning out of abnormal spastic postures is an important component of the management program. In general, prolonged or static positioning in any fixed posture can be deleterious to the patient with strong spasticity and should be avoided. For example, the patient who remains in bed all day with the LEs positioned in extension, adduction, and plantarflexion may be unable to flex enough at the hips and knees to sit in a wheelchair. Similarly, the feet will remain fixed in plantarflexion and cannot be positioned on the footpedals. A positioning schedule using varied positions (in bed, chair, or wheelchair) will help keep the patient from getting stuck in any one posture. Mechanical positioning devices (e.g., resting splints, toe spreader, finger spreader, ankle splint) are helpful in maintaining position and preserving joint structures.

Management of Coordination and Balance Deficits

Cerebellar deficits (ataxia, postural instability) are common in MS. Impairments in somatosensory, visual, and vestibular systems are also common and result in disordered proprioception. Spasms and muscle weakness can affect balance by changing the force and sequence of muscle contraction.[143] These combined effects result in difficulty in sustaining upright postures, walking, and other functional activities, leading to an increased risk of falls.

Interventions directed at promoting postural control should first focus on static control (holding) in weight-bearing, antigravity postures (e.g., sitting, quadruped, kneeling, modified plantigrade, and standing). Progression through a series of postures is used to gradually increase postural demands by varying the base of support (BOS), raising the center of mass (COM), and increasing the number of body segments (degrees of freedom) that must be controlled. Specific exercise techniques that can be used to promote stability include joint approximation applied through proximal joints (shoulders or hips) or spine, and rhythmic stabilization (PNF). Patients with significant ataxia will not be able to hold

steady and may benefit from the application of the technique of PNF dynamic reversals (slow reversals), progressing through decrements of range.[141] Dynamic postural control can be challenged by incorporating activities such as weight shifting and UE reaching (Fig. 16.5) or LE stepping. In sitting, a resisted PNF chop pattern that combines UE movements with trunk movements (flexion with rotation and extension with rotation) is an excellent activity. This can be progressed to more advanced dynamic activities with the patient sitting on a therapy (Swiss) ball as opposed to sitting on a hard flat surface (Fig. 16.6). Core musculature is engaged while the demands on ankle and knee musculature are minimized. This allows for a more focused core balance program that can be progressed to standing.[144,145]

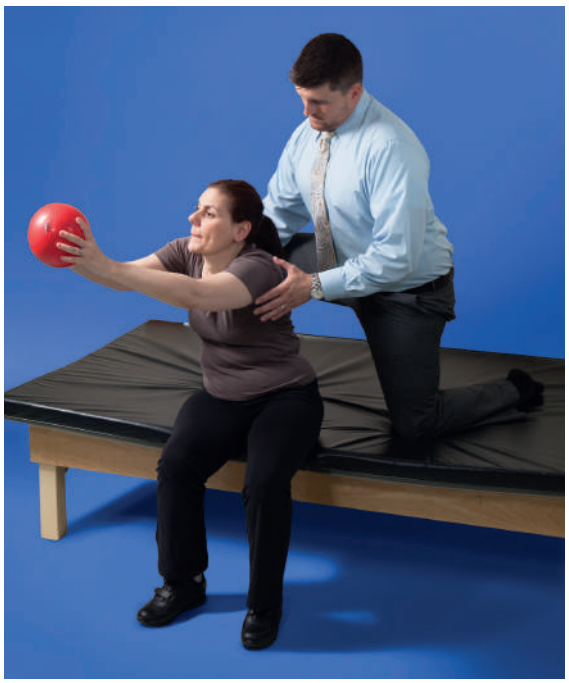

Figure 16.5 Dynamic postural control is promoted through weight shifting and upper trunk rotation to the right.

An important goal of therapy is to promote safe and functional balance. Effective training should involve a variety of everyday functional tasks that challenge balance. Figure 16.7 demonstrates a dynamic postural control activity of combined stepping and reaching. Figure 16.8 demonstrates sit-to-stand movement transitions. As training progresses, tasks are modified (e.g., wide base to narrow base to tandem stance, stable surface to moveable surface) to promote adaptation of skills. Sensory contexts are also varied to promote adaptive control in various different perceptual contexts (e.g., eyes open to eyes closed, firm surface to thick foam surface).[142] Patients with MS and central vestibular dysfunction may benefit from vestibular rehabilitation to improve impaired balance and disability due to dizziness or disequilibrium (Fig. 16.9). See Chapter 21, Vestibular Disorders, for additional discussion.[146]

The pool is an important therapeutic medium to practice static and dynamic postural control in both sitting and standing, as well as walking. Water provides graded resistance that slows down the patient's ataxic

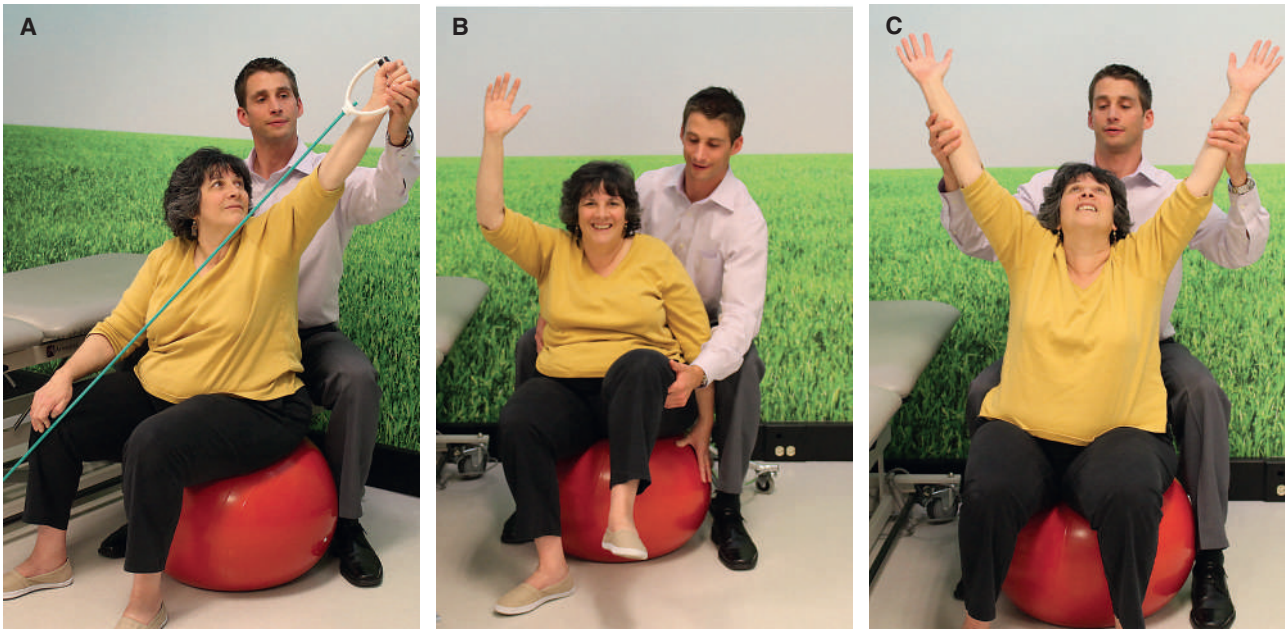

Figure 16.6 Sitting on the ball, the patient practices dynamic postural control activities: (a) unilateral resisted overhead reach, (b) reciprocal stepping and overhead arm swing, and (c) resisted bilateral symmetrical PNF D2 flexion patterns with extension.

movements, while the buoyancy aids in upright balance. Water aerobics have been shown to be effective in improving strength, decreasing muscular fatigability, increasing endurance, and improving quality of life in patients with MS.[120,147] When recommending aquatic exercise programs it is imperative to assess the individual's tolerance to heat. It is commonly recommended that persons with MS exercise in a pool that is 80° to 85°F (26.66° to 29.44°C).

Biofeedback training using augmented feedback can be used to improve balance function. Augmented visual feedback[148] and augmented proprioceptive feedback (e.g., whole body vibration platform training)[149] have been used to improve function in patients with MS. Training on a moveable force platform (e.g., SMART Balance Master® [NeuroCom International,

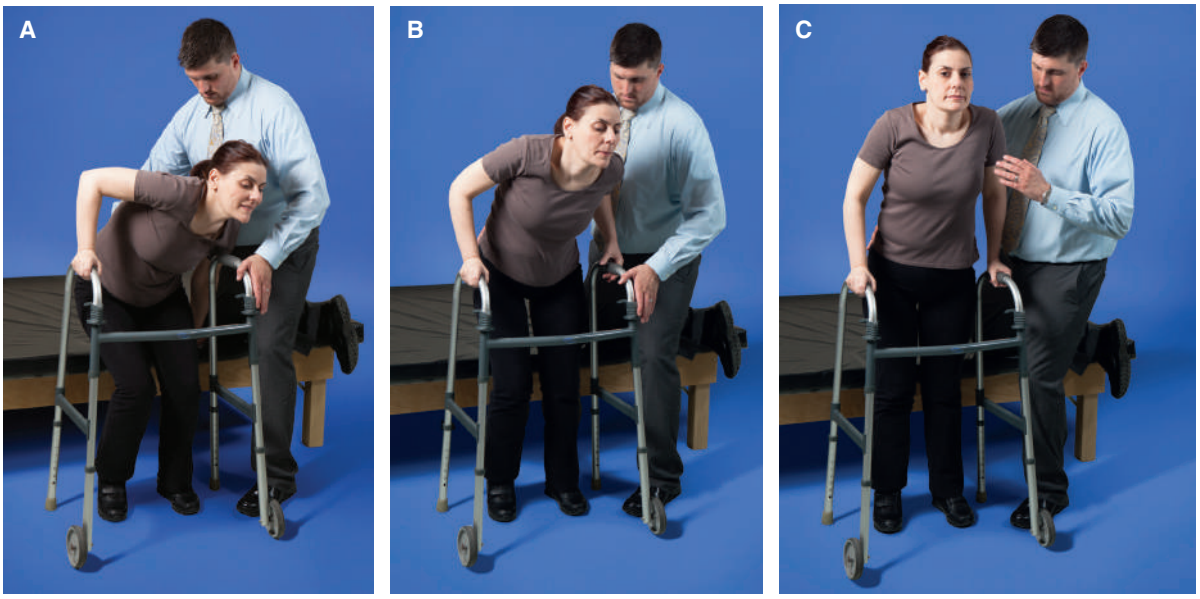

Figure 16.8 Sit-to-stand movement transition. The sit-to-stand transition is an important component of pre-gait/gait training, transfer training, and balance training.

Inc., Clackamas, OR 97015]) can also improve balance. The added biofeedback from visual and/or auditory feedback displays on force platform training machines is especially useful for patients with somatosensory deficits. The patient with ataxia needs to learn how to reduce excess postural sway (frequency and amplitude) and to control center of alignment position. Prolonged latencies (onset of responses) should be expected. Additionally, with advancements in technology, whole body vibration[150] and household video game platforms (i.e., Nintendo Wii) have become useful tools for balance training for individuals with neurological conditions.[151,152]

Control of ataxic limb movements (tremor and dysmetria) can be achieved through proprioceptive loading and light resistance. For example, the therapist can use PNF extremity patterns using the technique of dynamic reversals with light tracking resistance to modulate force output and reciprocal actions of muscles. Ataxic movements have sometimes been helped by the application of latex resistance bands or light weights to stabilize movements. Velcro® weight cuffs (wrist or ankle), weighted boots, or a weighted jacket or belt can reduce tremors of the limbs or trunk. The extra weight will also increase energy expenditure, and must therefore be carefully balanced against the increased fatigue they might cause. Weighted canes or walkers can be used to reduce ataxic UE movements that interfere with the use of an assistive device during ambulation. Weighted spoons or forks can be used to enhance eating. For patients with significant tremor, these devices may mean the difference between dependent and independent function. External devices (braces or splints) can be used to stabilize ataxic limbs but also have the undesirable effect of adding weight to limb movements. Air splints can also stabilize limb movements and should be considered, because they are lighter and less energy costly. A soft cervical collar can be used to stabilize head and neck tremors. All these strategies, however, should be viewed as temporary and compensatory. Once the devices are removed, ataxic movements will return or in some cases may actually temporarily worsen.

Unwanted movements are worse under conditions of stress, anxiety, and excitement. The increased arousal, the result of adrenalin pumping through the system, increases existing tremors while decreasing function. Stress management techniques are therefore an important component of the POC. In general, patients do better in a low-stimulus environment that allows full concentration on control of movements. They benefit from augmented feedback (verbal cueing of knowledge of results and knowledge of performance; biofeedback) and repetition to improve motor learning. The patient with MS is often restricted in practice by neuromuscular fatigue and neurological deficits that impair sensory feedback, attention, memory, and concentration. The successful therapist will need to carefully identify the patient's resources and abilities and capitalize on them to maximize motor learning.

Locomotor Training

Walking ability is frequently impaired. However, at least 65% of patients with MS are still walking after 20 years.[9] Early gait problems often include poor balance and heaviness of one or more limbs. Patients frequently report difficulty lifting their legs (hip flexor weakness). Weak dorsiflexors are also common, resulting in foot drop. Problems with foot clearance may result in a circumducted gait pattern, among other gait deviations. Later problems evolve owing to clonus, spasticity, sensory loss, and/or ataxia. Weakness generally extends to include the quadriceps and hip abductors. Quadriceps weakness typically results in hyperextension of the knee and forward flexion of the trunk with increased lumbar lordosis. Hip abductor weakness results in a Trendelenburg gait pattern with a strong lateral lean to the weak side.

A well-designed exercise program of tone management, stretching, and strengthening exercises can improve walking. Standing and walking activities should stress safety and maintaining a stable BOS; maximum weight-bearing through the LEs; and adequate weight transfer and forward progression with trunk, limb, and pelvic kinematics consistent with safe walking. Verbal and manual cueing can assist the patient in the correct mechanics of gait. A variety of functional activities should be practiced. These include walking forward and backward, side-stepping, and cross-stepping (Fig. 16.10). Braiding (a PNF activity that combines side-stepping and cross-stepping) is a complex, higher-level walking activity. Stair

Figure 16.10 Patient practices cross-stepping. Dynamic standing activities are an integral component of an exercise program geared toward improving gait/locomotion.

climbing, negotiating curbs and ramps, navigation around obstacles, and walking on varied surfaces should also be practiced for safety in community mobility. See Chapter 11, Locomotor Training, for further discussion. As previously mentioned, the pool is an important medium that can be used to assist training of the more involved patient with ataxia while reducing tone and fatigue.

Locomotor training (LT) using an antigravity treadmill or a treadmill training (TT) with body weight support (BWS) has been the focus of increasing attention in the literature and used extensively to improve gait in patients with spinal cord injury and stroke (see discussion in Chapter 10 and Evidence Summary Boxes in Chapter 15, Stroke, and Chapter 20, Traumatic Spinal Cord Injury). In studies involving persons with MS using LT and BWS, improvements in muscle strength, spasticity, endurance, balance, walking speed, and quality of life have been reported. Level of effort was reduced while detrimental effects on fatigue are not evident.[153-155] Robot-assisted treadmill training (RATT) with BWS has also been used and when compared to conventional BWS TT, patients in both groups experienced similar improvements in outcome measures.[156,157] When RATT was compared to conventional gait training, no difference in outcomes was found between the groups.[158] In summary, LT with BWS is an activity-dependent intervention that is feasible and safe and has the potential to result in significant improvements in function for patients with MS.

Orthotics and Assistive Devices

Patients with MS typically require orthotic devices as ambulation skills decline. Ankle-foot stability can be achieved by the addition of an ankle-foot orthosis (AFO). Improvements in energy efficiency and safety are also important outcomes. AFOs are prescribed for foot drop, poor knee control (especially hyperextension), minimal to moderate spasticity, and poor somatosensation. The most common type used is the standard polypropylene AFO, which is lightweight and has the added benefit of cosmesis (Fig. 16.11). An AFO with an articulated joint can be prescribed to provide more rigid control for the ankle with the addition of a plantarflexion stop. Functional electrical stimulation (FES) devices have become prevalent in treatment and compensation for foot drop with improvements in walking performance and satisfaction reported. Patients also experienced fewer falls and reduced fatigue.[159-161] In order to effectively use any orthotic or FES device for foot drop, an individual must have adequate hip flexion strength. Relative contraindications to the prescription of these devices include severe spasticity, foot edema, and weakness (nonfunctional grades of LE muscles, especially hip flexors). Although knee-ankle-foot orthoses (KAFOs) can provide additional stabilization control of the knee, they are rarely used because of the increased energy expenditure required.

Canes, forearm crutches, or a walker may be necessary to compensate for deficits in fatigue, strength, sensory loss (numbness), or balance (Fig. 16.12). For many patients acceptance of an assistive device involves full recognition of their disability. They need to be convinced that use of these devices is far safer than "wall walking" or "furniture walking." Devices also provide recognition to the community at large that patients are not staggering or losing their balance because they are "drunk," a

Figure 16.11 Patient is wearing an ankle-foot orthosis (AFO) to stabilize the ankle and prevent foot drop.

Figure 16.12 Locomotor training with a front-wheeled rolling walker.

frequent occurrence with many patients. The devices may be the difference between community participation or remaining homebound because of fear of falling. Patients should be encouraged to try out different devices to determine which works best for them. For example, the patient with significant fatigue levels may benefit from a large-wheeled walker with locking hand brakes and a seat that allows for frequent rests. Recent technological advancements have brought a new breed of mechanical upright walking devices that have integrated computer chips, sensors, and motors to aid an individual in ambulation. Cosmesis is an important factor in promoting acceptance. There are many innovations in assistive technology that make the choices easier. For example, designer canes now come in many different colors and styles, including clear Lucite. ABLEDATA (www.abledata.com) is a federally funded project that offers product information, resources, and links to manufacturers.[162]

As the disease progresses, many patients benefit from a wheeled mobility device (powered scooter or wheelchair). The course and progression of the disease and presenting symptoms should be taken into consideration when deciding on a device. For patients with adequate trunk stability, UE function, and appropriate visual, perceptual, and cognitive skills, a scooter provides needed mobility while conserving energy. Scooters also do not carry the same negative stigma as that of a wheelchair. Both three- and four-wheel scooters are available. Four-wheel scooters have superior outdoor and uneven terrain performance, but are not as easily transported. Features that should be recommended include a seat that rotates for easy mounting and dismounting, easy dismantling for loading into the car, and steering mechanisms that minimize the work of the UEs. One disadvantage of scooters is that seating cannot always be customized. They are often not designed for prolonged sitting or for patients with moderate to severe postural instability. Some new three-wheeled scooters are designed to turn in very small areas while others have a wide turning radius and may not be suitable for in-home use. The individual with MS must be adequately educated on the safety precautions of a scooter, because the trunk strength and stability requirements are significantly higher than those of a power wheelchair.

A wheelchair should be considered when postural demands necessitate increased support. A standard wheelchair requires additional energy expenditure and coordination for propulsion. When prescribing a manual wheelchair to an individual with MS it is important to include education on proper wheelchair propulsion for both preservation of shoulder strength and energy conservation. A power wheelchair should be considered when impairments prevent or limit manual propulsion or when fatigue is a major limiting factor in mobility (Fig. 16.13). However, they are more costly and require specialized transportation by a wheelchair-accessible van or bus. Most patients will navigate using a joystick. For patients with impaired hand strength and sensation, the joystick can be adjusted to increase sensitivity. Wheelchair seating should ensure proper alignment of the pelvis, trunk and head, and limbs while enhancing function. Common malalignments include posterior tilting of the pelvis (sacral sitting) with kyphosis, typically the result of spasticity in the hamstring muscles. This can be improved with the addition of a seat cushion. Postural alignment can also be assisted by the addition of contoured seating (custom built). A solid back support and adjustable lateral trunk supports may be needed to enhance postural alignment and upright sitting. Footrests should be positioned to ensure that the thighs are parallel to the floor. If extensor spasms are strong, they can actually propel the patient out of the chair. A strong lap belt that secures firmly around the pelvis is necessary for safety. For patients with strong adductor spasticity, a medial knee block (pommel) may be necessary. Heel loops and straps may be required to maintain foot position on the footrests. Patients who no longer demonstrate adequate trunk and head stability require an alternate seating design. A tilt-in-space wheelchair with head/neck support is a better option than a reclining wheelchair with high back and elevating leg rests. The former maintains the normal hip sitting angle; the latter produces extension of the hips and may feed into strong extensor spasticity. Elevating leg rests tend to stretch hamstring muscles and may cause posterior pelvic tilting when spasticity is present. The reclining wheelchair with elevating leg rests also creates greater environmental access problems. Motorized control of the seat back available in tilt-in-space wheelchairs will allow the patient to

Figure 16.13 An individual with MS using a power wheelchair with joystick control for mobility. The correct power wheelchair prescription can encourage proper alignment of the pelvis, trunk, head, and limbs.

make easy adjustments in position, thus preventing skin breakdown. See Chapter 32, The Prescriptive Wheelchair, for additional discussion.

Patients should be instructed in transfer and wheelchair mobility/management skills. A transfer board or hydraulic lift may be necessary as UE function deteriorates. Attention to good sitting posture and pressure-relief techniques is essential to maintain alignment and prevent skin breakdown. Patients should be encouraged to balance time in the wheelchair with other activities, such as walking or exercising, and should be extra diligent in stretching muscles that tend to contract as a result of prolonged sitting (e.g., hip and knee flexors).

One of the constraints the therapist will have to deal with is financial reimbursement for the changing mobility needs of the patient with chronic MS. Private or public insurance organizations require a statement of medical necessity for payment. Because symptoms are not static in MS but rather typically exacerbate or remit, the therapist needs to provide clear and convincing documentation of need, stressing improved function and safety. Many third-party payers will not reimburse for new wheelchairs prescribed within specified time intervals or may be hesitant to finance expensive specialty wheelchairs such as the tilt-in-space chair or a second lightweight chair for traveling. The therapist will need to provide careful documentation of potential adverse outcomes to justify the cost of the new chair. For example, a likely deleterious outcome for a patient who is denied reimbursement for a tilt-in-space chair may be skin breakdown. The costs of nursing and surgical care for decubitus ulcers can then be compared to the cost of the new wheelchair, which can be justified as a preventive measure. It is equally important to anticipate future needs as they relate to rate of disease progression when ordering equipment.

Functional Training

Functional training should focus on problem solving and the development of appropriate decision making skills required to meet the challenges of being disabled. Skills should be adapted and practiced to ensure safe performance in both the home and community environments. Training in functional mobility skills (e.g., bed mobility, transfers, locomotion) is typically directed by the physical therapist whereas ADL (e.g., dressing, personal hygiene, bathing, toileting, grooming, and feeding) and IADL (e.g., cooking, laundry, and bed making) training is directed by the occupational therapist and training in communication skills by the speech-language pathologist. Close communication and coordination among team members is necessary to ensure that training methods are consistently applied and successful. Full participation of the patient in all phases of planning and training will increase personal involvement while decreasing dependency and passivity.

The majority of patients with MS will use multiple adaptive devices. This requires careful attention to appropriate prescription of devices and environmental modifications to assist the patient in conserving energy and maintaining function. Adaptive equipment can include bed or bathroom grab bars, overhead trapeze, raised seats, transfer board, or hydraulic lift. Appropriate positional and functional splints to facilitate writing or typing and plates and cups with lips to minimize spills are often helpful in assisting with hand function. Long-handled shoehorns, reachers, button hooks, sock aids, or Velcro® closures can assist in dressing. Effective communication may require built-up writing utensils or a universal cuff for written communication or more sophisticated computerized devices. Patients with severe speech problems may require voice amplification devices, electronic aids, or computer-assisted alternative communication systems. The team must recognize when a device is indicated, and assist the patient in acceptance and in learning how to use the device *before* significant deterioration of function occurs.

Management of Speech and Swallowing

Impairments in communication and swallowing have been identified in individuals with MS.[163] The scientific literature reports that 44% of MS patients experience impairments of speech and voice in the early onset of their disease, and as many as 35% to 43% of MS patients can acquire voice, chewing, and swallowing disorders.[164] Respiratory deconditioning, characterized by reduced diaphragmatic support and shortening of the intercostal muscles, contributes to speech disorders and increases the likelihood of respiratory infections. Thus, collaborating with a speech-language pathologist to develop a *resistive breathing training* (RBT) program paired with activities to improve trunk stability, head control, and sitting balance is an important component of the POC for patients with MS. Improved respiration can be facilitated through the implementation of prolonged phonation exercises, resistive breathing exercises, and incentive spirometry. The therapist should focus on diaphragmatic and segmental chest expansion, expiratory training, and volitional and effortful coughing.[165]

When dysphagia or difficulty in swallowing occurs, physical therapists should work closely with speech-language pathologists to preserve safety of swallowing. Often a detailed examination is needed to investigate the deceptively complex swallowing mechanism. Diagnostic methods include *Videofluoroscopic Swallowing Studies (VFSS)* and *Flexible Endoscopic Evaluation of Swallowing* (FEES).[166] The role of the physical therapist is important in assisting with improving sitting position, body posture, and head control. An upright body posture with a slightly forward and downward-pointing chin position can be helpful in achieving a safe swallow and preventing aspiration.[167] Application of transcutaneous neuromuscular electric stimulation (NMES) to the submental muscles (suprahyoid triangle) to facilitate muscle reeducation was cleared by the FDA in late 2002, after the submission of data from over 800 patients (adults and children). NMES of the submental muscles paired with selected oral–motor exercises and swallowing maneuvers

(e.g., Mendelsohn maneuver, effortful swallow, super-supraglottic swallow) can improve the strength, ROM, and coordination of the swallowing musculature.[165]

Thermal-tactile stimulation (TTS) is a sensory technique whereby stimulation is provided to the anterior faucial pillars to improve swallowing reflexes and the pharyngeal phase of swallowing. Anecdotally, the use of cold and icy beverages such as a shakes, fruit slushes, and ice chips provide heightened sensory input, which can improve the initiation of swallowing for many patients. Some patients also benefit from alternating small (teaspoon sized) sips of liquids with their food during mealtime. Most patients should be discouraged to engage in consecutive swallowing because it increases demand on the respiratory system and decreases airway protection. Resistive sucking through a straw can also be helpful. Thick liquids such as honey-thick and nectar-thick liquids can provide some resistance to facilitate muscle strengthening.[168] Moist foods (with sauces, broth, water, or milk) are easier to manage than dry ones. Semisolid and pureed foods are easier than regular solids. Foods that irritate the throat (e.g., vinegar) and crumbly or stringy foods (e.g., cake, cookies, potato chips, celery, cheeses) should be avoided. Patients also benefit when instructed to focus their effort on eating and never attempting to talk during active eating (mastication). Maintaining a quiet and peaceful environment during meals is helpful in improving attention and focus. Fatigue can also affect food intake. Many patients with MS benefit from reducing the size of their meals and eating smaller, more nutrient-dense meals throughout the day. Percutaneous endoscopic gastrostomy (PEG) feeding tubes and/or nasogastric tubes may become medically necessary for individuals with severe dysphagia.[169] For overall safety, it is important that family members, caregivers, and health care providers alike are educated in the use of the Heimlich maneuver in the event of an emergency.[170]

Cognitive Training

Cognitive impairments can present major difficulties for the patient and for the rehabilitation team in general. Referral to a neuropsychologist may be indicated to determine the patient's strengths and weaknesses and to assist in the adaptive process. Compensatory strategies for memory deficits can be helpful. These include the use of memory aids, timing devices, and environmental strategies. Memory can be assisted by using a memory notebook to log daily events and reminders. With the increasing availability of mobile technologies, mobile devices have proven helpful for individuals with cognitive impairment related to MS. Trials have shown that use of a personal digital assistant (PDA) device significantly improves functional performance of everyday tasks. Patients who have incorporated mobile devices into their daily routines note improvement in organization and self-efficacy that positively affected their daily lives.[171] A pill dispenser can assist the patient in maintaining a correct medication schedule. Cueing devices such as an alarm clock, bell timer, or watch alarm can help patients remember when to do certain tasks (e.g., taking medications, performing pressure relief). Structuring and labeling the environment is also an effective strategy to assist memory (e.g., labeled drawers, cabinets). Directions for functional tasks (e.g., transfers, self-stretching techniques) should be carefully written down for both patients and caregivers. Complex tasks can be broken down with clear written directions provided for each step. Directions can be posted in different areas of the home (e.g., steps to follow for toilet or tub transfer posted in the bathroom). Additional cognitive strategies that may be helpful include mental rehearsal, requesting assistance, maximizing alertness, avoidance of difficult situations, and mental exercises. Poor follow-through should be expected among patients with severe cognitive deficits, because often there is very little insight. In this situation, the efforts of family and caregivers must be fully maximized.[17]

Cognitive-behavioral therapy (CBT) for patients with MS can yield significant improvement in the ability to deal with distress, debilitating symptoms, impairment and disease exacerbation, and progression.[172] As with healthy individuals, regular physical activity can have a positive effect on cognitive function, self-efficacy, and quality of life.[173,174] A computer-based home training program used in conjunction with other treatments has been shown to improve function in patients with MS.[175]

PSYCHOSOCIAL ISSUES

Individuals with MS and their families experience a variety of losses such as loss of social functioning, interpersonal relationships, employment status, independence, and functional skills. Disabilities emerge as the disease progresses over time. Various different psychosocial adaptations can be seen, including anger, denial, depression, and so forth. The unique feature of a relapsing-remitting disease course is that it requires continual readjustment every time a new set of symptoms appears. Patients who appear well adjusted at one stage may regress as the disease worsens. The uncertainty of MS produces significant cognitive and emotional stress. Patients often feel out of control and unsure of themselves. Living with MS requires not only initial acceptance, but also a tremendous flexibility to deal with this lack of closure. Patients also experience the cumulative effects of smaller, everyday stresses that are associated with fluctuating symptoms, inability to perform ADL, dependency on others, architectural barriers, and so forth. Many factors play a role in determining how an individual reacts to MS. These include the overall effect of the disease on daily life functioning, previous coping skills, perceived self-efficacy, extent of social support, and spiritual well-being. They may experience attitudes of "wait and see" or "nothing can be done." This may explain why

many individuals with MS do not take medications to help control their MS despite medical guidelines recommending disease-modifying drugs. The longer they are influenced by these attitudes, the less likely they are to seek help. Learned helplessness, low self-efficacy, and lack of environmental mastery have been identified as major factors contributing to depression and fatigue.[20]

As mentioned, depression does not necessarily correlate to the severity of the disease. For example, a person with mild disease can be severely depressed, whereas the person with severe disability is not. The therapist must be alert to the signs of depression and intervene as appropriate. Chapter 26, Psychosocial Disorders, presents a complete discussion of this topic.

Despite the negative psychosocial effects of the disease, studies indicate that while initial diagnosis was met with negative reactions, over time positive changes in terms of values and outlook often occur. Interventions that target reexamination of the individual's role and identity result in an increased appreciation for life and can assist individuals with MS in better managing the disease and enjoying their lives.[176] *Self-efficacy* is the belief that an individual will be able to deal with particular situations that may contain novel, unpredictable, and stressful elements. Strategies that enhance self-efficacy and self-management (elements of CBT) empower the patient with MS.[177] Additional interventions include education, involvement in goal-setting and treatment planning, wellness forums, and support or psychotherapy groups. The use of stress reduction techniques (e.g., relaxation techniques, meditation, and exercise) can also be helpful in promoting effective coping. Family and multidisciplinary support are key elements in effective psychosocial management.[178,179]

PATIENT AND FAMILY/ CAREGIVER EDUCATION

The primary roles of the clinician can be categorized as caring professional, expert teacher, and competent practitioner. A positive, affirming attitude can effectively influence patients' attitudes and assist them to view rehabilitation from a more positive perspective. The development of a strong collaborative relationship with the patient and family/caregivers in which there is respect, compassion, and effective communication is key to successful rehabilitation outcomes.[177] The overall focus should be on the maintenance of *hope* and *encouragement* tempered with *realism*.

As an educator, the therapist has an important role in assisting the patient and family/caregivers in providing information on the following:

- The disease process, clinical manifestations, and their significance in terms of management
- Prevention of secondary complications, indirect impairments, and activity limitations
- The rehabilitation process, the POC, and its specific interventions
- The HEP, including interventions that can be carried out independently
- Monitoring the effects and possible adverse reactions of medications
- Use of assistive devices and adaptive equipment
- General health and stress management techniques
- Community resources

Prompt referral to community resources including a support group can provide a necessary stabilizing base for patients and their families/caregivers. Within this environment individuals can gain accurate and useful information about the disease, discuss common problems and methods of coping, and share anxieties and resources. Thus, it provides a valuable forum to assist in the continual adjustment process. The National Multiple Sclerosis Society (www.nationalmssociety.org) provides education, emotional support, and a variety of programs and services to individuals with MS and their families through their local chapters.[180] Web-based resources are provided in Appendix 16.D.

A significant number of patients with MS (one out of every two patients) will require the assistance of another person at some point in the course of their disease. This places an extra burden on family members and on the financial resources of the patient if outside caregivers must be utilized. The majority of caregivers experience moderate levels of stress associated with their caregiving duties. As the level and duration of physical care increases, caregivers can experience a variety of signs and symptoms, including physical (e.g., fatigue, headache, sleep disturbances, appetite changes), psychological (e.g., anxiety, depression, frustration), social (e.g., family conflicts, decreasing social experiences or "lack of life"), and spiritual changes (e.g., hopeless and meaningless life and work).[181] This can also put stress on relationships, as the caregiver is often a spouse and the dependency and the degree of support needed to perform certain tasks can be a source of tension.[182] The therapist will need to be sensitive to these changes and to conflicts, problems, and tensions as they develop. Considerable time and energy will be devoted to counseling and educating caregivers and coordinating home management. Attention should also be paid to the children of patients with MS, because studies have indicated that parental MS has a negative impact on children's psychological well-being. This is due, in part, to lack of understanding about the disease, and education may help ameliorate some of the negative effects.[183]

SUMMARY

Timely referral to neurorehabilitation services is the key to successful management of activity limitations, disability, and quality-of-life issues in patients with MS. Too often services are not begun until the individual becomes severely disabled. A comprehensive POC that addresses the needs of the whole patient and emphasizes meaningful functional activities, patient education, and self-management is ideal for such a complex neurodegenerative disorder. Activities that prove attainable and safe ensure patient success and build self-efficacy. Many patients with MS report that they lack the knowledge and skills needed to exercise safely. Promoting self-efficacy, self-management, and mastery can be achieved through supervised programs that focus on regular exercise, activity pacing, energy conservation, and overall healthy behaviors. Comprehensive efforts of the interdisciplinary team are needed to provide the coordinated and continuing care required with anticipated inpatient, outpatient, and home/community episodes of care.

Acknowledgment

The authors wish to thank Marissa A. Barrera, MS, MPhil, MSCS, CCC-SLP for her contributions to this chapter.

Questions for Review

1. What are the pathophysiological processes involved in MS? What are the primary areas of CNS involvement?
2. Differentiate among the various disease courses (clinical subtypes) of MS.
3. How is the diagnosis of MS established? What tests and measures are used to confirm the diagnosis?
4. What is the role of disease-modifying drugs used in the medical management of MS? What are their indications and potential adverse effects?
5. Discuss the Expanded Disability Status Scale (EDSS) for patients with MS and indications for use.
6. Discuss the guidelines for an effective exercise prescription for the patient with MS to improve strength and conditioning.
7. Discuss the guidelines for an effective exercise prescription for the patient with MS to improve aerobic performance.
8. Discuss the problem of fatigue in MS and how it influences the design of an exercise program.
9. What strategies can be used to assist in the psychosocial adjustment of the patient with relapsing-remitting MS?

CASE STUDY

HISTORY

The patient is a 27-year-old graduate student who was admitted to an acute care facility with a chief complaint of double vision for 2 weeks. She reported that both lower extremities (LEs) seemed weaker recently. Four months earlier, she had noticed persistent tingling of her fingers on the left hand and some numbness on the left side of her face.

Neurological examination showed a scotoma in the upper field of the left eye, weakness of the left medial rectus muscle, horizontal nystagmus on left lateral gaze, and mild weakness of the left central facial muscles. All other muscles had normal strength. The deep tendon reflexes were normal on the right and brisk on the left, and there was a left extensor plantar response. The sensory system was unremarkable. A diagnosis of suspected MS was made. The patient was discharged a few days later, seemingly improved after corticosteroid treatment.

The patient was readmitted to a neurological service 10 months later because she noticed increased difficulty in walking and her speech had become thickened.

NEUROLOGIST REPORT

Patient presents with wide-based ataxic gait, minor slurring of speech, bilateral tremor in the finger-to-nose test, and dysdiadochokinesia. CT scan is within normal limits. MRI scan reveals numerous white areas indicative of lesions. Lumbar puncture shows 56 mg of protein with increased level of gamma-globulin. All other CSF findings are normal. Treatment with high doses of intravenous

corticosteroids seemed to improve the neurological symptoms. Patient was discharged home with a referral for outpatient rehabilitation.

Two months later, the patient's symptoms worsened and she is now admitted for intensive rehabilitation.

MEDICATIONS

Prednisone 20 mg po qid
Maalox 30 mL po qid
Valium 10 mg qid

SOCIAL HISTORY

Patient has been living on her own for several years until her recent illness. She has taken a medical leave from graduate school and had returned home to live with her parents. They are both supportive and would like some advice as to how to modify their two-story home. There are five entry stairs with a handrail on both sides. There is a first floor bathroom, and they plan to convert the first floor study into a bedroom. Her parents are both in their early 60s, in good health, and very anxious about their daughter's rapidly deteriorating condition.

PHYSICAL THERAPY EXAMINATION FINDINGS

Mental Status

Alert, oriented
Memory: minimal impairment
At times lacks insight, seems unaware of the seriousness of her condition
Euphoric at times; other times she is depressed and cries easily

Communication

Speech is dysarthric, difficult to understand at times

Vision

Transient double vision
Gaze-evoked nystagmus to both left and right
Ocular dysmetria
Upper field defect of left eye

Endurance/Fatigue

Moderate impairment
Tolerance to activity is approximately 10 minutes before rest is required

Skin

WNL except for small bruise on right lateral malleolus

ROM

WNL except for 0° right dorsiflexion; 0° to 5° left dorsiflexion

Tone

Moderate extensor spasticity (2 on the modified Ashworth Scale) in both lower extremities (BLEs), left greater than right
Occasional extensor spasms, which are a major safety risk when they occur during transfers

Sensation

Paresthesias in BLEs with moderate proprioceptive losses, ankle joints greater than proximal joints
Both upper extremities (BUEs): mild decrease in light touch, left greater than right

Strength

Moderate weakness in BLEs; generally functional muscle grades (able to move against gravity), with the greatest weakness noted at the hips
Standard MMT positions not used owing to spasticity
BUEs 3+/5 (fair+) to 4/5 (good) strength

Coordination

BUEs: Intention tremors with mild limb ataxia; voluntary movements are hypermetric
RAM are moderately impaired
BLEs: Movements restricted by spasticity and spasms; unable to test

Balance

Sitting balance:

- *Static:* With eyes open (EO), able to maintain position independently up to 5 minutes with minimal postural tremor; with eyes closed (EC), truncal ataxia is pronounced

- *Dynamic:* With EO, able to weight shift to left and right to about 40% of limits of stability (LOS); with EC, experiences loss of balance (LOB) with minimal weight shifts

Standing balance:

- *Static:* Able to maintain standing position in parallel bars with min assist × 1 for up to 3 minutes; during standing, patient is unable to maintain centered alignment; demonstrates moderate postural tremor; with EC, sway is increased dramatically and patient quickly loses her balance
- Tends to keep her hips and knees stiff in extension/hyperextension
- *Dynamic:* Unable to weight shift or step without bilateral handhold

Functional

Functional Independence Measure (FIM):

- Eating: FIM 6; requires adaptive equipment
- Grooming: FIM 6; requires adaptive equipment
- Bathing: FIM 5; requires setup and adaptive equipment
- Dressing—upper and lower: FIM 4; minimal assist
- Toileting: FIM 4; minimal assist for balance
- Sphincter control—bladder FIM 6; bowel FIM 6
- Transfers—bed, chair, wheelchair: FIM 4, minimal contact assist for stand pivot transfers
- Transfers—toilet and tub: FIM 4; minimal contact assist
- Locomotion—walk: FIM 4; minimal contact assist, uses walker
- Locomotion—stairs: FIM 2; less than 4 to 6 stairs, maximal assist
- Locomotion—wheelchair: FIM 5; supervision, uses manual wheelchair for distances up to 150 ft; posture in wheelchair: sacral sitting
- Requires a lap belt due to extensor spasms, which can cause her to fling out of the chair
- Communication—expression: FIM 6; requires extra time, mild dysarthria
- Communication—comprehension: FIM 6; complete understanding, requires extra time for processing
- Social interaction: FIM 7
- Problem solving: FIM 6; requires extra time, slight difficulty initiating decisions
- Memory: FIM 6; slight difficulty remembering daily routines and executing requests without need for repetition

Expanded Disability Status Scale (EDSS) score: 6.5

PATIENT'S GOALS

She would like to regain ambulation skills and independent living status. She recognizes the need to live with her parents for the time being but sees this as only temporary.

GUIDING QUESTIONS

1. Develop a problem list: identify/categorize this patient's problems in terms of direct impairments, indirect impairments, functional limitations, and disability.
2. Identify two outcomes (the remediation of functional limitations and disability) and two goals (remediation of impairments) for this patient.
3. Formulate four treatment interventions that could be used at the start of therapy to achieve the stated outcomes and goals. Provide a brief rationale for each.
4. What strategies can be used to develop self-management skills and promote self-efficacy and quality of life?

Modified Fatigue Impact Scale (MFIS)

appendix **16.A**

Fatigue is a feeling of physical tiredness and lack of energy that many people experience from time to time. But people who have medical conditions like MS experience stronger feelings of fatigue more often and with greater impact than others.

Following is a list of statements that describe the effects of fatigue. Please read each statement carefully, then *circle the one number* that best indicates how often fatigue has affected you in this way during the *past 4 weeks.* (If you need help in marking your responses, *tell the interviewer the number* of the best response.) *Please answer every question.* If you are not sure which answer to select, choose the one answer that comes closest to describing you. Ask the interviewer to explain any words or phrases that you do not understand.

Name: _____ Date: _____ / _____ / _____

ID#: _____ Test: 1 2 3 4

Because of my fatigue during the past 4 weeks. . .

	Never	Rarely	Sometimes	Often	Almost always
1. I have been less alert.	0	1	2	3	4
2. I have had difficulty paying attention for long periods of time.	0	1	2	3	4
3. I have been unable to think clearly.	0	1	2	3	4
4. I have been clumsy and uncoordinated.	0	1	2	3	4
5. I have been forgetful.	0	1	2	3	4
6. I have had to pace myself in my physical activities.	0	1	2	3	4
7. I have been less motivated to do anything that requires physical effort.	0	1	2	3	4
8. I have been less motivated to participate in social activities.	0	1	2	3	4
9. I have been limited in my ability to do things away from home.	0	1	2	3	4
10. I have trouble maintaining physical effort for long periods.	0	1	2	3	4
11. I have had difficulty making decisions.	0	1	2	3	4
12. I have been less motivated to do anything that requires thinking.	0	1	2	3	4
13. My muscles have felt weak.	0	1	2	3	4
14. I have been physically uncomfortable.	0	1	2	3	4
15. I have had trouble finishing tasks that require thinking.	0	1	2	3	4
16. I have had difficulty organizing my thoughts when doing things at home or at work.	0	1	2	3	4
17. I have been less able to complete tasks that require physical effort.	0	1	2	3	4
18. My thinking has been slowed down.	0	1	2	3	4

	Never	Rarely	Sometimes	Often	Almost always
19. I have had trouble concentrating.	0	1	2	3	4
20. I have limited my physical activities.	0	1	2	3	4
21. I have needed to rest more often or for longer periods.	0	1	2	3	4

Instructions for Scoring the MFIS

Items on the MFIS can be aggregated into three subscales (physical, cognitive, and psychosocial), as well as into a total MFIS score. All items are scaled so that higher scores indicate a greater impact of fatigue on a person's activities.

Physical Subscale

This scale can range from 0 to 36. It is computed by adding raw scores on the following items: 4 + 6 + 7 + 10 + 13 + 14 + 17 + 20 + 21.

Cognitive Subscale

This scale can range from 0 to 40. It is computed by adding raw scores on the following items: 1 + 2 + 3 + 5 + 11 + 12 + 15 + 16 + 18 + 19.

Psychosocial Subscale

This scale can range from 0 to 8. It is computed by adding raw scores on the following items: 8 + 9.

Total MFIS Score

The total MFIS score can range from 0 to 84. It is computed by adding scores on the physical, cognitive, and psychosocial subscales.

From Multiple Sclerosis Council for Clinical Practice Guidelines,[140] with permission.

An Expanded Disability Status Scale (EDSS) for Patients with Multiple Sclerosis

appendix
16.B

FUNCTIONAL SYSTEMS

Pyramidal Functions

0. Normal.
1. Abnormal signs without disability.
2. Minimal disability.
3. Mild or moderate paraparesis or hemiparesis; severe monoparesis.
4. Marked paraparesis or hemiparesis; moderate quadriparesis; or monoplegia.
5. Paraplegia, hemiplegia, or marked quadriparesis.
6. Quadriplegia.
V. Unknown.

Cerebellar Functions

0. Normal.
1. Abnormal signs without disability.
2. Mild ataxia.
3. Moderate truncal or limb ataxia.
4. Severe ataxia, all limbs.
5. Unable to perform coordinated movements due to ataxia.
V. Unknown.
X. Is used throughout after each number when weakness (grade 3 or more on pyramidal) interferes with testing.

Brainstem Functions

0. Normal.
1. Signs only.
2. Moderate nystagmus or other mild disability.
3. Severe nystagmus, marked extraocular weakness, or moderate disability of other cranial nerves.
4. Marked dysarthria or other marked disability.
5. Inability to swallow or speak.
V. Unknown.

Sensory Functions (revised 1982)

0. Normal.
1. Vibration or figure-writing decrease only, in one or two limbs.
2. Mild decrease in touch or pain or position sense, and/or moderate decrease in vibration in one or two limbs; or vibratory decrease alone in three or four limbs.
3. Moderate decrease in touch or pain or position sense, and/or essentially lost vibration in one or two limbs; or mild decrease in touch or pain and/or moderate decrease in all proprioceptive tests in three or four limbs.
4. Marked decrease in touch or pain or loss of proprioception, alone or combined, in one or two limbs; or moderate decrease in touch or pain and/or severe proprioceptive decrease in more than two limbs.
5. Loss (essentially) of sensation in one or two limbs; or moderate decrease in touch or pain and/or loss of proprioception for most of the body below the head.
6. Sensation essentially lost below the head.
V. Unknown.

Bowel and Bladder Functions (revised 1982)

0. Normal.
1. Mild urinary hesitancy, urgency, or retention.
2. Moderate hesitancy, urgency, retention of bowel or bladder, or rare urinary incontinence.
3. Frequent urinary incontinence.
4. In need of almost constant catheterization.
5. Loss of bladder function.
6. Loss of bowel and bladder function.
V. Unknown.

Visual (or Optic) Functions

0. Normal.
1. Scotoma with visual acuity (corrected) better than 20/30.
2. Worse eye with scotoma with maximal visual acuity (corrected) of 20/30 to 20/59.
3. Worse eye with large scotoma, or moderate decrease in fields, but with maximal visual acuity (corrected) of 20/60 to 20/99.
4. Worse eye with marked decrease of fields and maximal visual acuity (corrected) of 20/100 to 20/200; grade 3 plus maximal acuity of better eye of 20/60 or less.
5. Worse eye with maximal visual acuity (corrected) less than 20/200; grade 4 plus maximal acuity of better eye of 20/60 or less.
6. Grade 5 plus maximal visual acuity of better eye of 20/60 or less.
V. Unknown.
X. Is added to grades 0 to 6 for presence of temporal pallor.

Cerebral (or Mental) Functions

0. Normal.
1. Mood alteration only (does not affect DSS score).
2. Mild decrease in mentation.
3. Moderate decrease in mentation.
4. Marked decrease in mentation; chronic brain syndrome: moderate.
5. Dementia or chronic brain syndrome: severe or incompetent.
V. Unknown.

Other Functions

0. None.
1. Any other neurological findings attributed to MS (specify).
V. Unknown.

EXPANDED DISABILITY STATUS SCALE (EDSS)

0 = Normal neurological examination (all grade 0 in functional systems [FS]; cerebral grade 1 acceptable).

1.0 = No disability, minimal signs in one FS (i.e., grade 1 excluding cerebral grade 1).

1.5 = No disability, minimal signs in more than one FS (more than one grade 1 excluding cerebral grade 1).

2.0 = Minimal disability in one FS (one FS grade 2, others 0 or 1).

2.5 = Minimal disability in two FS (two FS grade 2, others 0 or 1).

3.0 = Moderate disability in one FS (one FS grade 3, others 0 or 1), or mild disability in three or four FS (three/four FS grade 2, others 0 or 1) though fully ambulatory.

3.5 = Fully ambulatory but with moderate disability in one FS (one grade 3) and one or two FS grade 2; or two FS grade 3; or five FS grade 2 (others 0 or 1).

4.0 = Fully ambulatory without aid, self-sufficient, up and about some 12 hours a day despite relatively severe disability consisting of one FS grade 4 (others 0 or 1), or combinations of lesser grades exceeding limits of previous steps. Able to walk without aid or rest some 500 meters.

4.5 = Fully ambulatory without aid, up and about much of the day, able to work a full day, may otherwise have some limitation of full activity or require minimal assistance; characterized by relatively severe disability, usually consisting of one FS grade 4 (others 0 or 1) or combinations of lesser grades exceeding limits of previous steps. Able to walk without aid or rest for some 300 meters.

5.0 = Ambulatory without aid or rest for about 200 meters; disability severe enough to impair full daily activities (e.g., to work full day without special provisions). (Usual FS equivalents are one grade 5 alone, others 0 or 1; or combinations of lesser grades usually exceeding specifications for step 4.0.)

5.5 = Ambulatory without aid or rest for about 100 meters; disability severe enough to preclude full daily activities. (Usual FS equivalents are one grade 5 alone, others 0 or 1; or combinations of lesser grades usually exceeding those for step 4.0.)

6.0 = Intermittent or unilateral constant assistance (cane, crutch, or brace) required to walk about 100 meters with or without resting. (Usual FS equivalents are combinations with more than two FS grade 3+.)

6.5 = Constant bilateral assistance (canes, crutches, or braces) required to walk about 20 meters without resting. (Usual FS equivalents are combinations with more than two FS grade 3+.)

7.0 = Unable to walk beyond about 5 meters even with aid, essentially restricted to wheelchair; wheels self in standard-wheelchair and transfers alone; up and about in wheelchair some 12 hours a day. (Usual FS equivalents are combinations with more than one FS grade 4+; very rarely, pyramidal grade 5 alone.)

7.5 = Unable to take more than a few steps; restricted to wheelchair; may need aid in transfer, wheels self but cannot carry on in standard wheelchair a full day; may require motorized wheelchair. (Usual FS equivalents are combinations with more than one FS grade 4+.)

8.0 = Essentially restricted to bed or chair or ambulated in wheelchair, but may be out of bed itself much of the day; retains many self-care functions; generally has effective uses of arms. (Usual FS equivalents are combinations, generally grade 4+ in several systems.)

8.5 = Essentially restricted to bed much of the day; has some effective use of arm(s); retains some self-care functions. (Usual FS equivalents are combinations, generally 4+ in several systems.)

9.0 = Helpless bed patient; can communicate and eat. (Usual FS equivalents are combinations, mostly grade 4+.)

9.5 = Totally helpless bed patient; unable to communicate effectively or eat/swallow. (Usual FS equivalents are combinations, almost all grade 4+.)

10.0 = Death due to MS.

From Kurtzke,[93] with permission.

Multiple Sclerosis Daily Activity Diary

appendix 16.C

INSTRUCTIONS

1. At the top of the day's diary, describe how you slept the night before.
2. Assign a number value from **1 to 10** (1 being very low and 10 being very high) for:
- Your level of fatigue (**F**)
- The value or importance of the activity you are doing (**V**)
- The satisfaction you feel with your performance of the activity (**S**)

You can compute the "value" of an activity by comparing it to other activities you would like to do during the course of the day.

For example:
1 PM: F = 7 V = 3 S = 2 Activity: Fixing lunch standing 15 minutes (hot);
Comment: Blurred vision

3. Always describe the physical work done in the **Activity** section (e.g., stood to shower 10 minutes, went up 20 stairs, walked 200 feet).
4. Note the **external temperature** of the environment under Activity.
5. List under **Comment** all MS symptoms as they appear or worsen during the day, including cognitive problems, visual problems, weakness, dizziness, dragging foot, pain, numbness, burning, and so forth.
6. Make notes **every hour.**

Name: _____ Date: _____

Describe sleep last night: _____

Time	F	V	S	Activity	Comment
6:00 AM					
7:00					
8:00					
9:00					
10:00					
11:00					
12:00 PM					
1:00					
2:00					
3:00					
4:00					
5:00					
6:00					
7:00					
8:00					
9:00					
10:00					
11:00

Amyotrophic Lateral Sclerosis

Vanina Dal Bello-Haas, PT, PhD

Chapter 17

LEARNING OBJECTIVES

1. Describe the epidemiology, risk factors, etiology, pathogenesis, diagnosis, and general prognosis of amyotrophic lateral sclerosis (ALS).
2. Compare and contrast the El Escorial diagnostic criteria for ALS.
3. Differentiate among impairments related to lower motor neuron pathology, upper motor neuron pathology, and bulbar impairments.
4. Discuss the medical and health care management of individuals with ALS.
5. Outline a framework for rehabilitation for individuals with ALS.
6. Describe the components of the physical therapy examination for individuals with ALS.
7. Describe the role of the physical therapist in the management of an individual with ALS and the factors that influence intervention options.
8. Compare and contrast overwork damage and disuse atrophy as it relates to ALS.
9. Summarize the literature related to exercise and ALS.
10. Describe considerations that must be taken into account when designing an exercise program for the individual with ALS.
11. Discuss problems commonly seen in individuals with ALS and the physical therapy interventions for these common problems.
12. Determine the anticipated goals and expected outcomes for an individual with ALS based on physical therapist examination findings.
13. Design an intervention program for the individual with ALS based on the physical therapist examination findings.

SUMMARY *795*

Motor neuron diseases (MND) include a heterogeneous spectrum of inherited and sporadic (no family history) clinical disorders of the upper motor neurons (UMNs), lower motor neurons (LMNs), or a combination of both[1] (Table 17.1). **Amyotrophic lateral sclerosis** (ALS),* commonly known as Lou Gehrig's disease, is the most common and devastatingly fatal MND among adults. ALS is characterized by the degeneration and loss of motor neurons in the spinal cord, brainstem, and brain, resulting in a variety of UMN and LMN clinical signs and symptoms.[2]

EPIDEMIOLOGY

It is estimated that 30,000 individuals in the United States have ALS at any one time and 15 cases are diagnosed every day. Except in a very few high-incidence areas, such as Guam and the Kii Peninsula of Japan (geographical foci, Western Pacific form of ALS), the overall incidence of ALS has been reported to be in the range of 0.4 to 2.4 cases per 100,000, with the incidence increasing with each decade of life, until at least the seventh decade. The prevalence of ALS has been reported to be 4 to 10 cases per 100,000.[3-7]

Although ALS can occur at any age, the average age at onset is the mid-to-late 50s.[4,5,7,8] Most studies have found that the disease affects men slightly more than women, with an approximate ratio of 1.7:1;[3,5,6] however, after age 65, this gender-related incidence is less pronounced.[3] In about 5% to 10% of individuals the disease is inherited as an autosomal dominant trait *(familial ALS [FALS]),*[3,9,10] although rare cases of juvenile-onset ALS are inherited in an autosomal recessive pattern.[11] Of the hereditary adult ALS cases, approximately 20% are a result of one of more than 100 mutations in superoxide dismutase 1 (SOD1),[12,13] a gene that encodes the copper-zinc superoxide dismutase enzyme. The very large majority of adult individuals with ALS have no family history of the disease *(sporadic ALS),* although a very small percentage of individuals with sporadic ALS do have a mutation in *SOD1*.[14,15]

Approximately 70% to 80% of individuals develop *limb-onset ALS,* with initial involvement in the extremities; 20% to 30% develop *bulbar-onset ALS,* with initial involvement in the bulbar muscles.[6,16,17] Bulbar-onset ALS is more common in middle-aged women, and initial symptoms may include difficulty speaking, chewing, or swallowing.[2,6]

Table 17.1 Motor Neuron Disorders

Subtype	Nervous System Pathology
Amyotrophic lateral sclerosis	Degeneration of the corticospinal tracts, neurons in the motor cortex and brainstem, and anterior horn cells in the spinal cord
Primary lateral sclerosis	Degeneration of upper motor neurons
Progressive bulbar palsy	Degeneration of motor neurons of cranial nerves IX to XII
Progressive muscular atrophy	Loss or chromatolysis of motor neurons of the spinal cord and brainstem

Adapted in part from Rowland.[1]

ETIOLOGY

Epidemiologic evidence has identified several known and possible risk factors for ALS (Fig. 17.1). However, other than the small percentage of hereditary (FALS) cases, etiology for the most part is unknown. It is thought that no one single mechanism but rather multiple or cumulative mechanisms, including oxidative stress, exogenous neurotoxicity, excitotoxicity, impaired axonal transportation, protein aggregation, **apoptosis** (programmed cell death), and lifestyle factors, may be responsible for neuron degeneration in ALS:[13]

1. *Superoxide dismutases* are a group of enzymes that eliminate oxygen free radicals that, although products of normal cell metabolism, have been implicated in neurodegeneration. There are three isoforms of SOD in humans: *cytosolic copper-zinc superoxide dismutase (CuZnSOD), mitochondrial manganese superoxide dismutase (MnSOD),* and *extracellular superoxide dismutase (ECSOD).* SOD1, a gene on chromosome 21, encodes CuZnSOD. Genetic studies of individuals with adult-onset FALS have determined that about 20% of these individuals have mutations in SOD1; however, the primary gene defect is unknown. When the SOD enzyme activity is decreased, as has been observed in individuals with FALS with SOD1 mutations, free radicals may accumulate causing damage.[13,18,19] Most mutations identified in FALS show modest loss in enzyme activity,[20] suggesting the mutant SOD-1 protein may have toxic properties that cause motor neurons to die. However, the mechanism has yet to be determined.[13]
2. *Glutamate,* an excitatory neurotransmitter, has also been implicated in neurodegeneration. Excess glutamate triggers a cascade of events leading to cell death.[13] Increased levels of glutamate in the cerebrospinal fluid (CSF), plasma, and in postmortem tissue of individuals with ALS have been reported.[21,22] A deficiency in excitatory amino acid transporters 2 (EAAT2), a specific glutamate transporter protein, in the motor cortex and spinal cord of postmortem ALS tissue was reported and lends support to the theory of excitotoxicity causing neurodegeneration.[23,24]

*The term MND is used to describe the disease in the United Kingdom, whereas the term ALS is used in North America and Europe. In Europe, ALS is also called Charcot's disease.

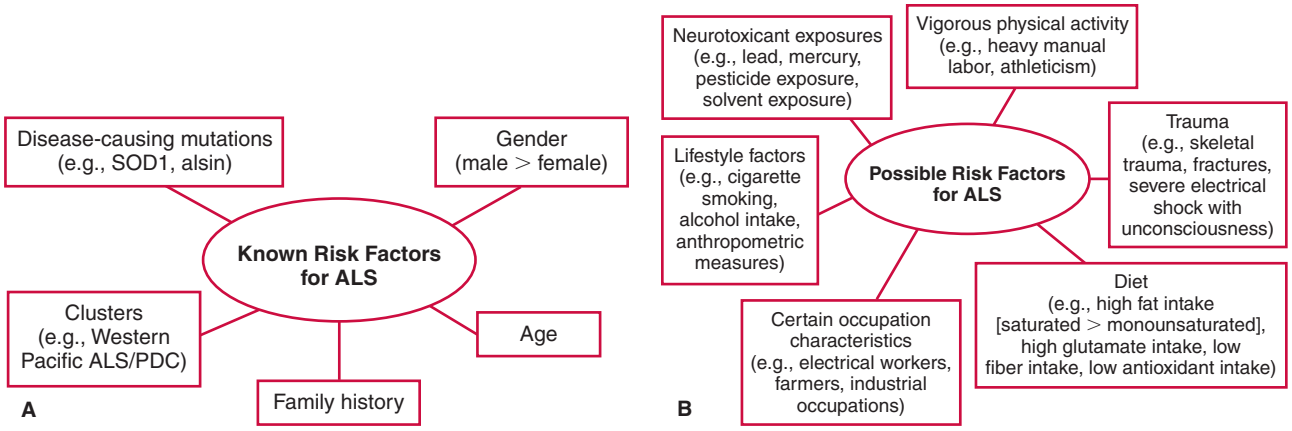

Figure 17.1 **(A)** Known risk factors for ALS. **(B)** Possible risk factors for ALS. ALS/PDC = amyotrophic lateral sclerosis and parkinsonism dementia complex.

3. Clumping of neurofilament proteins into spheroids in the cell body and proximal axon is one of the histopathological characteristics of ALS.[13,25,26] Whether or not abnormal accumulation is secondary to the pathology or contributes to motor neuron degeneration has yet to be determined.[13]
4. Several studies have implicated an autoimmune reaction in the etiology of ALS.[7,27-29] For example, serum factors toxic to anterior horn motor neurons in individuals with ALS have been reported,[27] and antibodies to calcium channels have been identified in individuals with ALS.[29]
5. It has been hypothesized that a lack of neurotrophic factors could contribute to the development of ALS and other neurodegenerative disorders.[30] In vivo experiments and experiments with isolated motor neurons in cell culture have shown that neurotrophic factors are important in motor neuron survival.[31,32] However, factor deficits in ALS have not been conclusive. For example, a postmortem study found decreased amounts of ciliary neurotrophic factor (CNTF) in the ventral horn of the spinal cord, but not in the motor cortex; nerve growth factors were decreased in the motor cortex, but increased in the lateral column of the spinal cord.[33]
6. Other potential theories thought to contribute to neurodegeneration in ALS, which have anecdotal, limited, or indirect evidence, include exogenous or environmental factors,[34] apoptosis,[35] and viral infections.[36]

PATHOPHYSIOLOGY

Amyotrophic lateral sclerosis is characterized by a progressive degeneration and loss of motor neurons in the spinal cord, brainstem, and motor cortex (Fig. 17.2). UMNs in the cortex are affected, as are the corticospinal tracts. Brainstem nuclei for cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), X (vagus), and XII (hypoglossal) and anterior horn cells in the spinal cord are also involved.[2] Brainstem nuclei for cranial nerves controlling external ocular muscles (III: oculomotor, IV: trochlear, and VI: abducens) are usually spared; if degeneration occurs, it does so late in the course of the disease.[37] Motor neurons of the *Onufrowicz nucleus (Onuf's nucleus),* located in the ventral margin of the anterior horn in the second sacral spinal level, are also generally spared; if they are affected, it is to a very limited extent.[38,39] These neurons control striated muscles in the pelvic floor, including anal and external urethral sphincters.[40]

The sensory system and spinocerebellar tracts are also generally spared in ALS. Some studies suggest that sensory neurons may be involved in ALS, but to a much lesser extent than the motor neurons. Morphological studies have found that peripheral sensory nerves exhibit axonal atrophy, demyelination, and degeneration,[41,42]

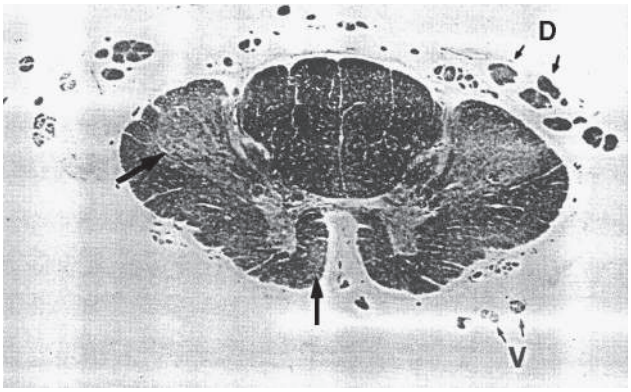

Figure 17.2 Luxol Fast B stained cross section of spinal cord at the high cervical level from a patient with classical ALS. Marked pallor, secondary to degeneration of the lateral and anterior corticospinal tracts, can be seen (large arrows). The ventral roots (V, small arrows) are atrophied, especially compared to the dorsal roots (D, small arrows). *(From King, PH, and Mitsumoto, H: Neuropathology of amyotrophic lateral sclerosis. In Belsh, JM, and Schiffman, PL [eds]: Amyotrophic Lateral Sclerosis: Diagnosis and Management for the Clinician. Blackwell Publishing, Oxford, UK, 1996, p 205, with permission.)*

and dorsal root ganglia cells at autopsy reveal loss of large ganglion cells.[43] Degeneration of Clarke's neurons and of the spinocerebellar tracts has also been reported.[44-46] Degeneration of the spinocerebellar tracts is a well-recognized pathological feature of FALS and has been described in sporadic ALS, although it is rare.[44] Posterior column degeneration is more common in FALS, but is rare in sporadic ALS.[47]

As motor neurons degenerate, they can no longer control the muscle fibers they innervate. Healthy, intact surrounding axons can sprout and reinnervate the partially denervated muscle[48] (Fig. 17.3), in essence assuming the role of the degenerated motor neuron and preserving strength and function early in the disease; however, the surviving motor units undergo enlargement.[49,50] Reinnervation can compensate for the progressive degeneration until motor unit loss is about 50%,[49,50] and electromyography (EMG) studies have found evidence of motor unit reinnervation in individuals with ALS.[51,52] As the disease progresses, reinnervation cannot compensate for the rate of degeneration,[51] and a variety of impairments develop (Table 17.2).

The progression of ALS is thought to spread in a *contiguous* manner, e.g., within spinal cord segments (cervical segments to cervical segments), before developing rostral or caudal symptoms.[17,53] Thus, signs and symptoms spread locally within a region (e.g., bulbar, cervical, thoracic, lumbosacral) before moving to other regions. Caudal-to-rostral spread within the spinal cord and spread from the cervical to bulbar region appears to occur faster than rostral-to-caudal spread within the spinal cord.[17,53]

CLINICAL MANIFESTATIONS

Clinical manifestations of ALS vary depending on the localization and extent of motor neuron loss, the degree and combination of LMN and UMN loss, pattern of onset and progression, body region(s) affected, and stage of the disease. At onset, signs or symptoms are usually asymmetrical and focal.[2] Progression of the disease leads to increasing numbers and severity of impairments.

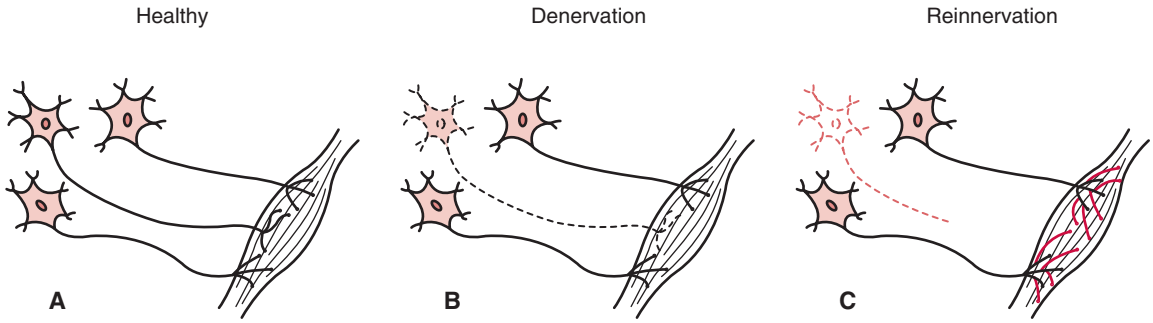

Figure 17.3 Sprouting: **(A)** normal motor neurons; **(B)** denervation; **(C)** reinnervation.

Table 17.2 Common Impairments Associated with Amyotrophic Lateral Sclerosis

Pathology/System Affected	Clinical Manifestations/Impairments
LMN pathology	Muscle weakness, hyporeflexia, hypotonicity, atrophy, muscle cramps, fasciculations
UMN pathology	Spasticity, pathological reflexes, hyperreflexia, muscle weakness
Bulbar	Bulbar muscle weakness, dysphagia, dysarthria, sialorrhea, pseudobulbar affect
Respiratory	Respiratory muscle weakness (inspiratory and expiratory), dyspnea, exertional dyspnea, nocturnal respiratory difficulty, orthopnea, hypoventilation, secretion retention, ineffective cough
ALS-FTD, ALSci, ALSbi	Frontotemporal dementia–related impairments (e.g., loss of insight, emotional blunting), cognitive impairments (e.g., attention deficits, deficits in cognitive flexibility), behavioral impairments (e.g., irritability, social disinhibition)
Other	*Rare impairments:* sensory impairments, bowel and bladder dysfunction, ocular palsy *Indirect and composite impairments:* Fatigue, weight loss, cachexia, decreased range of motion, tendon shortening, joint contracture, joint subluxation, adhesive capsulitis, pain, balance and postural control impairments, gait disturbances, deconditioning, depression, anxiety

Adapted in part from Swash.[2]

ALS = amyotrophic lateral sclerosis; ALSbi = ALS with behavioral impairment; ALSci = ALS with cognitive impairment; ALS-FTD = ALS with frontotemporal dementia; LMN = lower motor neuron; UMN = upper motor neuron.

Impairments Related to LMN Pathology

The most frequent presenting impairment, occurring in the majority of patients, is focal, asymmetrical muscle weakness beginning in the lower extremity (LE) or upper extremity (UE), or weakness of the bulbar muscles.[3,7] Muscle weakness is considered the cardinal sign of ALS and may be caused by LMN or UMN loss. The weakness associated with LMN loss causes more significant dysfunction than the weakness from UMN loss.[54] Initial muscle weakness usually occurs in isolated muscles, most often distally, and is followed by progressive weakness and activity limitations.[2,54] For example, at onset an individual may notice difficulty with fine motor movements, such as buttoning, pinching, or writing, or may notice foot "slapping" or increased frequency of tripping while walking. Individuals with bulbar onset may notice changes in their voice, difficulty moving the tongue, or decreased ability to move the lips or open or close the mouth.

In people with ALS, cervical extensor weakness is typical.[2,54] Individuals may initially notice neck stiffness, feel "heavy-headed" after reading or writing, or may have difficulties stabilizing the head with unanticipated movements, such as in an accelerating car. As weakness progresses, the head may begin to fall forward, and in more advanced stages the neck becomes completely flexed with the head dropped forward, causing cervical pain and impairments in ambulation and feeding (Fig. 17.4).

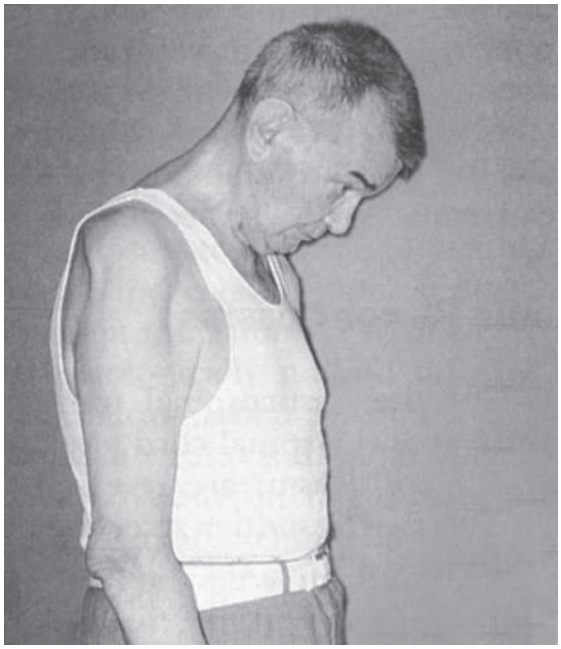

Figure 17.4 Marked head droop in a 65-year-old man with ALS who first developed progressive weakness in both upper extremities. *(From Mitsumoto, H, Chad, DA, and Pioro, EK: Clinical features: Signs and symptoms. In Mitsumoto, H, Chad, DA, and Pioro, EK (eds): Amyotrophic Lateral Sclerosis. F.A. Davis, Philadelphia, 1998, p 47, with permission.)*

Muscle weakness leads to secondary impairments, including decreased range of motion (ROM), predisposing the patient to joint subluxation (e.g., shoulder), tendon shortening (e.g., Achilles), joint contractures (commonly claw-hand deformity), and adhesive capsulitis. Weakness also results in ambulation difficulties, deconditioning, and impaired postural control and balance. Foot drop, secondary to distal weakness, and instability, secondary to proximal weakness, are common. The pattern and progression of LE weakness are characterized by greater losses of muscle force in distal muscles compared to proximal muscles.[55,56] A retrospective study found that decreases in walking ability from independent walking, to walking in the community with assistance, to walking only at home, to being unable to walk were precipitated by relatively small changes in muscle force.[56] Falls are also common, reported to occur in 46% of individuals with ALS.[57]

Several factors affect fatigue levels in patients with ALS. As motor neurons die, the remaining neurons or sprouted neurons are overburdened. Weak muscles must work at a higher percentage of their maximal strength to perform the same activity. This hastens muscle fatigue.[58] Fatigue may also be related to sleep disturbances, respiratory impairments, hypoxia, and depression. Sanjak et al[59] demonstrated that individuals with ALS have abnormal physiological and metabolic responses to single bouts of exercise. Sharma et al[60] found that in individuals with ALS, tetanic and maximal voluntary force during sustained contraction were decreased compared to controls. No impairment was found in the muscular membrane or neuromuscular transmission, suggesting that muscle fatigue in ALS, in part, is due to impaired contraction activation.[60]

As muscle fibers progressively denervate, their volume decreases resulting in atrophy. *Fasciculations*, random spontaneous twitching of muscle fibers often seen through the skin, are common in individuals with ALS, although they are rarely an initial symptom. The etiology of fasciculations remains unclear and is thought to be related to hyperexcitability of motor axons.[54]

Other LMN signs include hyporeflexia, decreased or absent reflexes, decreased muscle tone or flaccidity, and muscle cramping.[2,54] The etiology of muscle cramping is not well understood and is also thought to be related to hyperexcitability of motor axons. In individuals with ALS, muscle cramps can occur in uncommon sites such as the tongue, jaw, neck, or abdomen, as well as in the UEs, hands, and calf or thigh.[2]

Sensory pathways are spared for the most part in people with ALS; however, some patients may complain of ill-defined paresthesia or pain in the limbs. Pain can occur, especially when muscle weakness and spasticity lead to immobility, adhesive capsulitis, or contractures. Cramps and spasticity are other sources of pain, as is increased pressure on the skin, bones, and joints owing to immobility.[2,54]

Impairments Related to UMN Pathology

UMN loss is characterized by spasticity, hyperflexia, clonus, and pathological reflexes, such as a Babinski or Hoffmann sign, and may also cause muscle weakness. As the disease progresses, UMN signs may decrease.[2,54]

Spasticity can eventually lead to contractures and deformities, as well as cause dyssynergic movement patterns, abnormal timing, loss of dexterity, and fatigue, all of which affect motor control and function.[61,62] For example, difficulties with the swing phase of gait secondary to distal spasticity and decreased balance owing to generalized spasticity are often seen in individuals with ALS.

Impairments Related to Bulbar Pathology

As bulbar UMNs and LMNs degenerate, *spastic bulbar palsy* or *flaccid bulbar palsy* (respectively) develops. In individuals with ALS a mixed palsy, which includes both flaccid and spastic components, is common.[54]

Dysarthria, impaired speech, can occur with either spastic or flaccid palsy, owing to weakness of the tongue and muscles of the lip, jaw, larynx, and pharynx. Initial symptoms include the inability to project the voice (e.g., shouting, singing) and problems with enunciation. With spastic dysarthria, the voice sounds forced, as more effort is needed to move air through the upper airway; whereas in flaccid dysarthria, the voice sounds hoarse or breathy. With pharyngeal weakness, air in the mouth leaks into the nose during enunciation, resulting in a nasal tone. As the disease progresses, speech becomes more difficult and unintelligible, and eventually the individual becomes **anarthric**.[2,54]

Dysphagia, impaired chewing or swallowing, can also occur with either spastic or flaccid palsy. Manipulating food inside the mouth or moving food into the esophagus is difficult, and swallowing is impaired. With flaccid bulbar palsy, liquids may regurgitate into the nose because of pharyngeal weakness and the cough reflex may be weak or absent, greatly increasing the risk of aspiration. Individuals with spastic bulbar palsy will have uncoordinated closure of the epiglottis, which may allow liquids or solids to pass to the larynx.[2,54] Choking and slowed eating pattern are associated with dysphagia, placing the patient at risk for less than optimal fluid and caloric intake that results in weight loss and potentially cachexia.[54]

Individuals with ALS frequently experience **sialorrhea**, excessive saliva and drooling, because of an absence of automatic, spontaneous swallowing to clear excessive saliva, or because the lower facial muscles are too weak to close the lips tightly to prevent leakage.[54] Individuals with bulbar onset will experience this symptom relatively early. Initially, the individual may begin to notice drooling at night (e.g., the pillow is wet in the morning); this eventually leads to needing to use a tissue repeatedly to wipe away the saliva.

Pseudobulbar affect is a term used to describe poor or pathological emotional control.[63] Spontaneous crying or laughter occurs in the absence of emotional triggers or emotional responses are exaggerated and not related to the context.[63] This symptom is commonly seen in individuals with spastic bulbar palsy,[2,54] and can occur in as many as 50% of individuals.[64]

Respiratory Impairments

Respiratory impairments in people with ALS are related to loss of respiratory muscle strength and a decrease in vital capacity (VC). A VC reduced to 50% of predicted is often associated with respiratory symptoms.[65] Early signs and symptoms of respiratory muscle weakness may include fatigue, dyspnea on exertion, difficulty sleeping in supine, frequent awakening at night, recurrent sighing, excessive daytime sleepiness, and morning headaches due to hypoxia.[66,67] Patients experiencing a gradual increase in respiratory muscle weakness will not complain of respiratory symptoms because they tend to decrease their overall level of physical activity owing to muscle weakness in the extremities.[68] Although the decline of respiratory muscle strength differs among individuals, for the most part it tends to progress at a linear rate.[69] As weakness progresses, truncated speech, orthopnea, dyspnea at rest, paradoxical breathing, accessory muscle use, and a weak cough are typically evident. A VC of less than 25% to 30% of predicted indicates significant risk of impending respiratory failure or death.[65] If an individual does not receive ventilatory support, eventual CO_2 retention will lead to acidosis, coma, and respiratory failure.[68]

Cognitive Impairments

Although once considered rare outside the western Pacific region, cognitive impairments ranging from mild deficits[70] to severe *frontotemporal dementia (FTD)*[71] are now considered part of the ALS disease spectrum.[72] A large prospective study found that 35.6% of patients with ALS showed clinically significant cognitive impairment.[73] ALS-associated FTD has been characterized by cognitive decline; executive functioning impairments; difficulties with planning, organization, and concept abstraction; and personality and behavior changes.[71,74-76] Individuals with ALS, without FTD, have been reported to have a variety of cognitive impairments, including difficulties with verbal fluency, language comprehension, memory, abstract reasoning, and generalized impairments in intellectual function.[73,76-78] Studies have found that patients with bulbar-onset ALS are more likely to have cognitive impairments than patients with limb-onset disease.[76,77]

Rare Impairments

Sensory pathways are spared, for the most part, in people with ALS. Some individuals may complain of vague, ill-defined sensory symptoms of paresthesia or focal pain in the limbs.[54] External ocular muscles are usually spared in people with ALS; if degeneration occurs, it does so late in the course of the disease.[37] Patients who have

been maintained on ventilators for long periods of time may develop the inability to voluntarily close the eyes or *ophthalmoplegia,* complete ocular paralysis.[37]

Motor neurons controlling the anal and vesicourethral sphincter muscles and muscles of the pelvic floor are generally spared. Urinary symptoms, such as urgency, obstructive micturition, or both, have been reported, suggesting that supranuclear control over sympathetic, parasympathetic, and somatic neurons may be abnormal in ALS.[54]

DIAGNOSIS

With the exception of one genetic test, no definitive diagnostic test or diagnostic biological marker exists for ALS. For individuals with a clinical presentation of ALS, laboratory studies, EMG, nerve conduction velocity (NCV) studies, muscle and nerve biopsies, and neuroimaging studies are used to support the diagnosis of ALS and to exclude other diagnoses.

The diagnosis of ALS requires the *presence* of (1) LMN signs by clinical, electrophysiological, or neuropathological examination; (2) UMN signs by clinical examination; and (3) progression of the disease within a region or to other regions by clinical examination or via the medical history. The *absence* of (1) electrophysiological and pathological evidence of other diseases that may explain the UMN and LMN signs; and (2) neuroimaging evidence of other disease processes that may explain the observed clinical and electrophysiological signs are also evaluated.[79]

Because of the variability in clinical findings in the early stages of ALS and the lack of absolute biological diagnostic markers, the *World Federation of Neurology Research Group on Motor Neuron Diseases* established the *El Escorial criteria* in 1994, and these were revised in 1998.[79] These widely accepted criteria are considered standard for the diagnosis of ALS for clinical practice, therapeutic trials, and other research purposes. In the absence of pathological evidence, the diagnosis of ALS is classified into *clinically definite, clinically probable, clinically probable with laboratory support,* and *clinically possible* categories (Fig. 17.5).[79] A diagnosis of *clinically definite ALS* is defined as both UMN and LMN findings in at least three of four regions (bulbar, cervical, thoracic, or lumbosacral) or UMN and LMN signs in the bulbar region and at least two spinal regions. *Clinically probable* ALS is defined as UMN and LMN signs in two regions, with at least one UMN finding rostral to the LMN findings. *Clinically probable, laboratory-supported* ALS is defined as UMN and LMN clinical signs in one region only, or UMN signs alone present in one region and LMN signs defined by EMG criteria present in at least two regions. The EMG criteria include signs of active denervation, such as fibrillation potentials and positive sharp waves; and signs of chronic denervation, such as large motor unit potentials (increased duration, increased proportion of polyphasic potentials, increased amplitude) and unstable motor unit potentials. *Clinically*

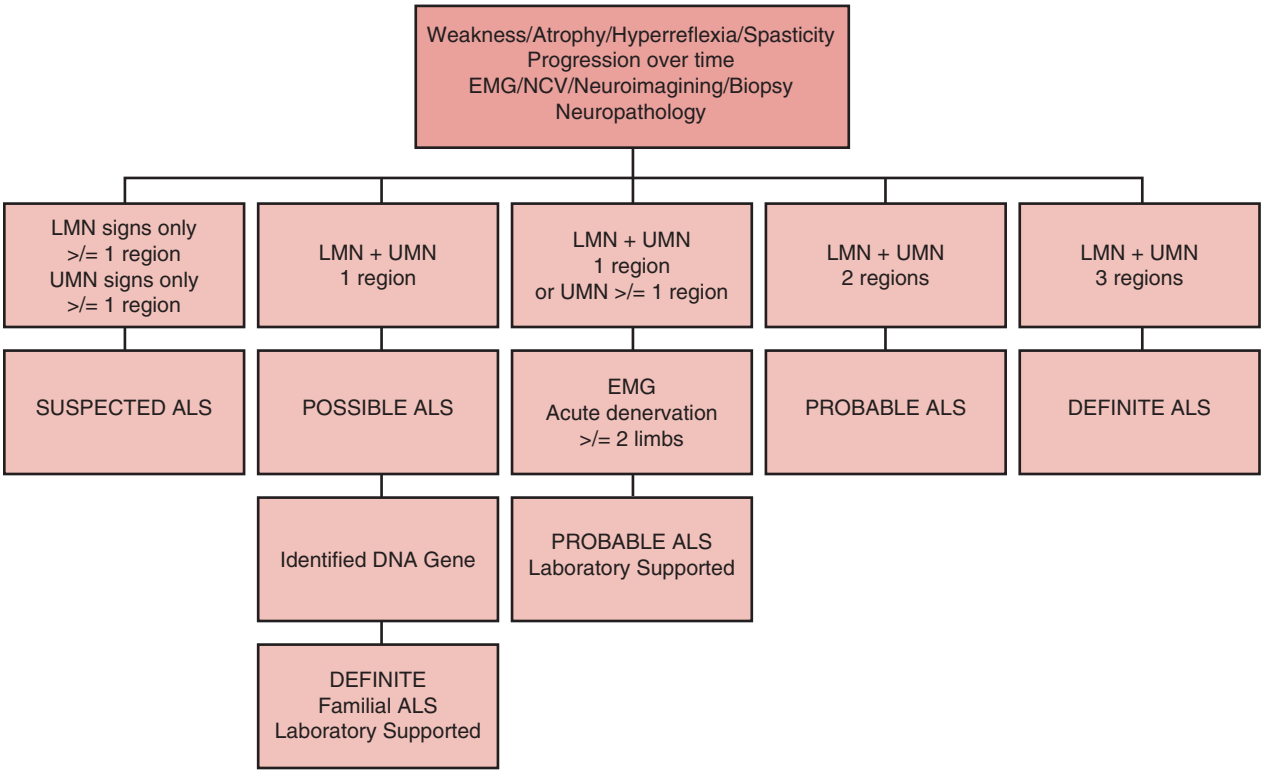

Figure 17.5 El Escorial Criteria for the Diagnosis of ALS. *(Note: The Suspected ALS category was removed when the El Escorial criteria were revised.)*

possible ALS is defined as UMN and LMN signs found together in only one region, or UMN signs found alone in two or more regions, or LMN signs found rostral to UMN signs and the inability to establish a diagnosis of clinically probable, laboratory-supported ALS.[79]

DISEASE COURSE

ALS has a progressive and deteriorating disease trajectory, and the progression from pathology to impairments to activity limitations to participation restrictions is inevitable. Although the disease course varies among individuals, with time from onset to death ranging from several months to 20 years, studies have found the average duration of ALS to be between 27 and 43 months, and the median duration to be between 23 and 52 months.[3,5,7,80,81] Five-year and ten-year survival rates range from 9% to 40% and 8% to 16%, respectively.[7,80,82,83] A 50% survival probability after the first symptom of ALS appears is slightly greater than 3 years, unless mechanical ventilation is used to sustain breathing.[6] In most patients, death occurs within 3 to 5 years after diagnosis and usually results from respiratory failure.[5]

PROGNOSIS

Age at time of onset has the strongest relationship to prognosis. Studies have found that patients less than 35 to 40 years of age at onset had better 5-year survival rates than older individuals.[5,6,81,84,85] Individuals with limb-onset ALS have a better prognosis than those with bulbar-onset ALS; 5-year survival rates were reported to be 37% and 44%, compared to survival rates of 9% and 16% for patients with bulbar-onset ALS.[84,85] Less severe involvement at the time of diagnosis, a longer interval between onset and diagnosis, and no symptoms of dyspnea at onset are other factors associated with a better prognosis.[5,6,86]

A study of 144 individuals with ALS found that those individuals with psychological well-being had significantly longer survival times compared to those with psychological distress. Mortality rates were found to be 6.8 times greater in those experiencing psychological distress, and the relationship was independent of age, disease severity, and length of time from diagnosis.[87] These findings were confirmed in a later study that found degree of physical disability, disease progression, and survival could be predicted by the patient's psychological status.[88]

MANAGEMENT

Patients with ALS may receive care in a variety of health care settings. Care via specialized centers or clinics that provide a comprehensive and multidisciplinary approach is considered the most advantageous owing to the progressive nature of the disease and continually changing patient status (Fig. 17.6). A study comparing a cohort of patients attending a multidisciplinary clinic versus

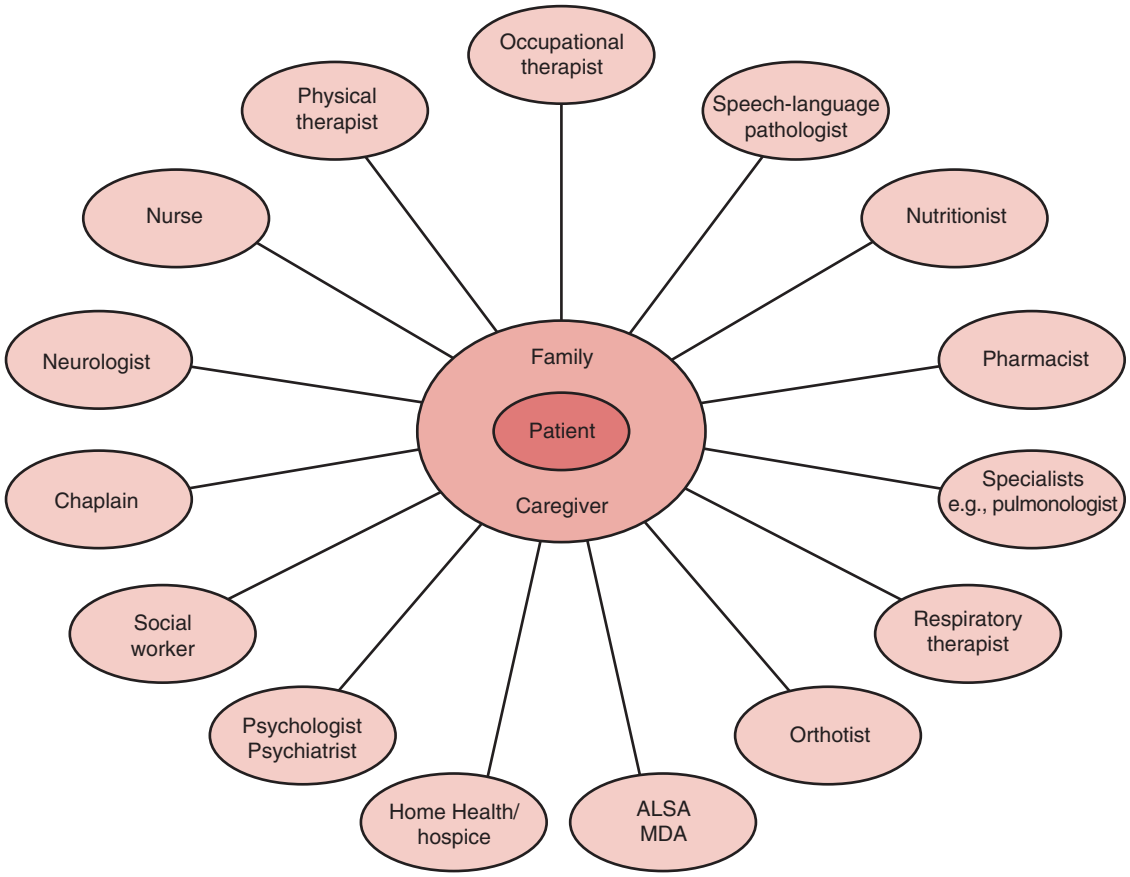

Figure 17.6 Multidisciplinary approach to the care of the individual with ALS. ALSA = Amyotrophic Lateral Sclerosis Foundation; MDA = Muscular Dystrophy Association.

those attending a general neurology practice found the median survival of the ALS clinic cohort was 7.5 months longer than for patients in the general neurology cohort. The findings indicated that attendance at the ALS clinic was an independent covariate of survival, suggesting that active and aggressive management enhances survival.[89]

The *Amyotrophic Lateral Sclerosis Association (ALSA)* and the *Muscular Dystrophy Association (MDA)*, nonprofit voluntary health agencies, have developed standards for ALS clinics and centers. Clinics and centers that meet ALSA's standards and pass a rigorous application and site visit are certified as ALSA Centers. MDA centers that conduct ALS research and have staff with expertise in dealing with ALS earn special designations as MDA ALS Research and Clinical Centers.

Disease-Modifying Agents

Currently, there is no cure for ALS, although a number of clinical drug trials are ongoing. In 1995, the Food and Drug Administration approved riluzole (Rilutek), a glutamate inhibitor, for the treatment of ALS. The standard dose of riluzole is one 50 mg tablet two times a day, and side effects include liver toxicity (which requires discontinuation), asthenia, nausea, vomiting, and dizziness. Evidence suggests the effects of riluzole to be modest, extending survival for 2 to 3 months.[90,91]

Symptomatic Management

Disease-modifying agents currently available are not curative and may extend survival for a very short time. Because the pathological process cannot be reversed and is progressive in nature, the context of medical management for individuals with ALS may be considered palliative. As defined by the World Health Organization, palliative care is "an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual."[92, p. 1]

Although there is no cure for ALS, it is still considered a "treatable disease" and rehabilitation plays an integral role in the overall comprehensive care of the patient. Medical management is symptomatic and individualized and involves supportive care to address impairments as they arise. Medical management may include the prescription of anti-cramping and antispasticity agents, drying agents for sialorrhea, and antidepressants; recommendations and referrals for *percutaneous endoscopic gastrostomy* tubes and ventilatory support (noninvasive ventilation, tracheostomy); and discussion of advanced care directives.[2,54,93]

In 1999 a multidisciplinary task force was established to develop consensus-based recommendations for the management of people with ALS and these recommendations were recently updated.[94,95] Research and clinical evidence related to the care of individuals with ALS in several keys areas were examined: (1) informing the patient and family about the diagnosis and prognosis; (2) management of communication problems, insomnia, anxiety, depression, spasticity, fatigue, cramps, *sialorrhea,* and *pseudobulbar affect;* (3) nutrition management and percutaneous endoscopic gastrostomy (PEG) decisions; (4) management of respiratory insufficiency and ventilation decisions; (5) diagnosis and management of cognitive and behavioral impairments; (6) drug therapies; and (7) multidisciplinary management and palliative care. Clinical decision making algorithms (practice parameters) for the management of nutrition and respiratory signs and symptoms are presented in Figures 17.7 and 17.8. Full guidelines for other recommendations and information regarding definitions of the levels of recommendations and classifications of evidence can be found at the *American Academy of Neurology* website (www.aan.com).

Management of Sialorrhea and Pseudobulbar Affect

Management of *sialorrhea* in people with ALS and other diseases is often directed toward prescription of anticholinergic medications that decrease saliva production. Examples include glycopyrrolate (Robinul), benztropine (Cogentin), transdermal hyoscine (scopolamine), atropine, and trihexyphenidyl hydrochloride (Artane).[93] For patients with associated thick mucus production, beta-blockers such as propranolol (Inderal) or metoprolol (Toprol) are often prescribed. Botulinum type injections into the parotid and submandibular glands and low-dose radiation have been found to be effective for individuals with ALS with medically refractory sialorrhea.[96] Use of mechanical suction to remove oropharyngeal secretions and nonpharmacological treatments that are used for clearing respiratory secretions (see section below titled Management of Respiratory Impairments) may also be useful.

For patients with pseudobulbar affect, tricyclic antidepressants, such as amitriptyline (Elavil), or selective serotonin reuptake inhibitors (SSRIs), such as fluvoxamine (Luvox), are often prescribed.[93] Research has found that a fixed-dose combination of dextromethorphan/quinidine reduced the severity and frequency of crying and laughing behaviors. However, side effects, including somnolence, dizziness, and nausea, were common.[96]

Management of Dysphagia

Early, mild **dysphagia** is addressed by a nutritionist or registered dietitian together with a speech-language pathologist (SLP). Speech-language pathologists conduct swallowing examinations such as video fluoroscopy to determine the degree and nature of the swallowing impairment and to assist in formulating a plan of care (POC). Nutritionists provide counseling and diet management throughout the course of the disease.

Nutrition status has been identified as a prognostic factor for survival and disease complications.[96] A study of 1,600 hospitalized patients with ALS found the most

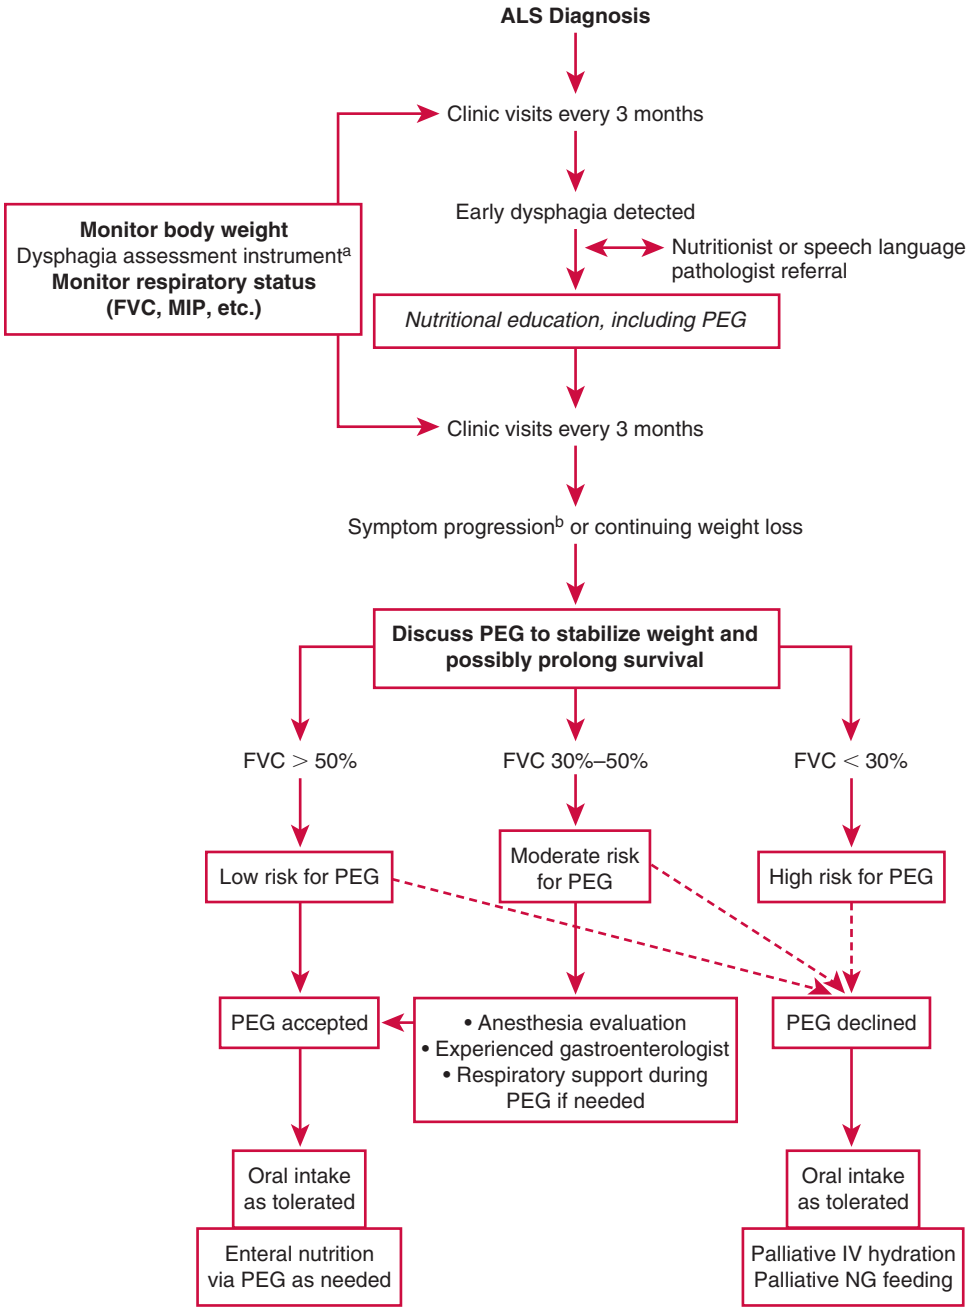

Figure 17.7 Algorithm for nutrition management. Note that **bolded text represents evidence-based information;** *text in italics denotes consensus-based information.*[a]
For example, Questions #1 to 3 (bulbar questions) from the Amyotrophic Lateral Sclerosis Functional Rating Scale—Revised (ALSFRS-R), or other instrument.[b]
For example, prolonged mealtime, ending meal prematurely because of fatigue, accelerated weight loss due to poor caloric intake, family concern about feeding difficulties.
FVC = forced vital capacity (supine or erect); IV = intravenous; MIP = maximum inspiratory pressure; NG = nasogastric; PEG = percutaneous endoscopic gastrostomy. *(From Miller, RG, et al (ALS Practice Parameters Task Force): The care of the patient with amyotrophic lateral sclerosis (an evidence-based review). Report of the quality Standards Subcommittee of the American Academy of Neurology. Neurology 52(7):1311, 1999, p 1316, with permission.)*

common concurrent diagnosis was dehydration and malnutrition, present in 36% of patients.[97] Regardless of whether poor nutritional status results from dysphagia, hypermetabolism, or inability to eat due to UE muscle weakness, research findings emphasize the need for careful attention to nutritional and hydration status, in particular with individuals with impaired oral intake or arm or hand weakness limiting self-feeding.

Initial treatment of dysphagia is directed toward (1) dietary modifications, such as adapting foods and

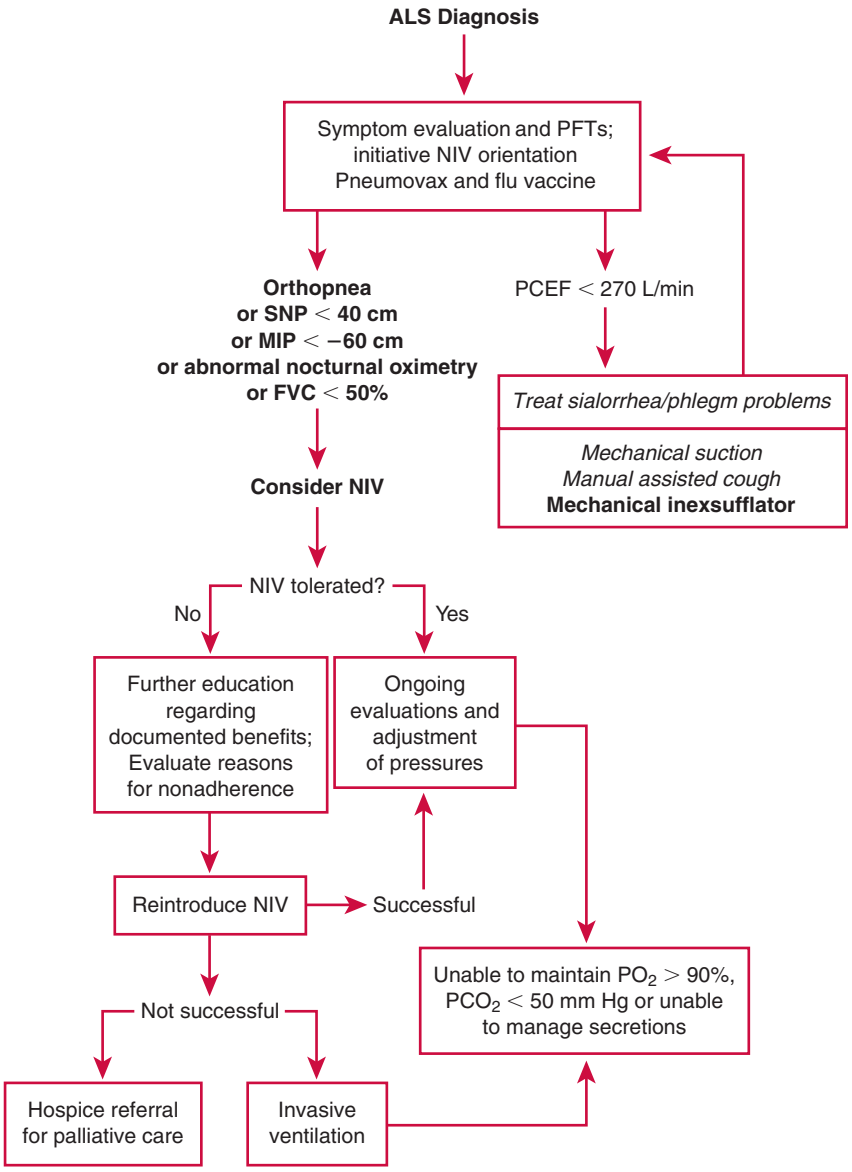

Figure 17.8 Algorithm for respiratory management. Note that **bolded text represents evidence-based information;** *text in italics denotes consensus-based information.* FVC = forced vital capacity (supine or erect); MIP = maximal inspiratory pressure; NIV = noninvasive ventilation; PCEF = peak cough expiratory flow; PFT = pulmonary function tests; SNP = sniff nasal pressure. *(From Miller, RG, et al (ALS Practice Parameters Task Force): The care of the patient with amyotrophic lateral sclerosis (an evidence-based review). Report of the quality Standards Subcommittee of the American Academy of Neurology. Neurology 52(7):1311, 1999, p 1317, with permission.)*

fluid consistencies for easier and safer swallowing; (2) patient education regarding dietary strategies for maximizing calories and nutrients and maintaining adequate hydration; and (3) adaptations to promote swallowing such as tucking the chin down during swallowing or performing a clearing cough after each swallow.[98]

As dysphagia progresses, the time required to consume a meal gradually increases owing to fatigue, increased difficulty chewing, and frequent choking. It is not uncommon for these eating difficulties to cause an accelerated weight loss. In these circumstances a PEG may be recommended. A PEG is a type of gastrostomy tube inserted via endoscopic surgery that creates a permanent opening into the stomach for the introduction of food. A PEG is useful for stabilizing body weight/mass.[94] Although there is no firm evidence, for optimal safety and efficacy the PEG procedure should be offered to the patient and completed before the individual's VC falls below 50% of predicted at the time of the procedure.[99] Studies have found that PEG insertion may prolong survival. Patients with PEG were found to live 1 to 4 months longer than those individuals who refused PEG or were deemed ineligible for the procedure. Survival was greatest for patients with a VC greater than 50% predicted at the time of the procedure.[100,101] It is important for physical therapists to be aware that a PEG does not prevent the risk of aspiration.[102,103]

Management of Respiratory Impairments

Respiratory impairments place the patient at risk for respiratory tract infections. Important management considerations include (1) pneumococcal and yearly influenza vaccinations;[68] (2) prevention of aspiration; and (3) effective oral and pulmonary secretion management. Supplemental oxygen must be used with caution because it can suppress respiratory drive, exacerbate hypoventilation, and ultimately lead to hypercarbia and respiratory arrest. Typically, supplemental oxygen is recommended only for individuals with concomitant pulmonary disease

or as a comfort measure for patients who decline ventilatory support.[68]

When VC decreases to 50% of predicted, positive-pressure noninvasive ventilation (NIV) is recommended.[68,99] Noninvasive ventilation has been shown to decrease symptoms of hypoventilation and increase survival time by several months.[104-107] In addition, improvement in cognition has been noted after NIV initiation.[89] When NIV can no longer be tolerated or it is no longer effective, a decision must be made between invasion ventilation (IV) with tracheostomy via surgical intervention or hospice care to address late-stage respiratory symptoms. Owing to the emotional, social, and financial burden of IV, patients and families must be carefully informed of the multiple costs and benefits of the intervention. No controlled studies of specific strategies for ventilation withdrawal have been published, although case studies provide practical advice.[94] Conditions for withdrawal of ventilation are discussed before, or at the time of, instituting IV because the patient may become unable to communicate his or her wishes as the disease progresses.[68,99]

Manually assisted coughing techniques and use of a mechanical insufflation–exsufflation (MI-E) device are used to facilitate clearance of respiratory and oral secretions[94] (Fig. 17.9). The MI-E device is designed to inflate the lung with positive pressure and assist cough with negative pressure through the flip of a switch. A positive-pressure breath of 30 to 50 cm H_2O over a 1- to 3-second period via an oral–nasal mask or tracheal airway is provided. The airway pressure is then reversed abruptly to –30 to –50 cm H_2O and maintained for 2 to 3 seconds. A peak expiratory "cough" flow within normal range is achieved, thereby assisting with the clearance of secretions.[108]

Management of Dysarthria

Dysarthria impairments are managed primarily by a speech-language pathologist. Initial speech changes are usually managed with intelligibility strategies, such as having the individual exaggerate articulation or decrease the rate of speech; and environmental modifications, such as decreasing background noise. As the severity of dysarthria progresses, management will focus on decreasing the patient's dependence on speech as the primary method of communication. Interventions first include "low-tech" devices, such as using a writing board or pad and pen for patients with adequate hand function or using an alphabet board. A progression is then made to more "high-tech" devices, such as computers with voice synthesizers or single-switch, scanning computerized communication systems.[109,110]

A *palatal lift prosthesis* may be prescribed for individuals with good articulation but who have a breathy voice quality or decreased loudness because of excessive air loss through the nose. The device, a dental appliance designed to attach to the existing teeth and to elevate the soft palate, is custom-made by a prosthodontist. It allows the soft palate to close around the surrounding structures such as the pharynx, making verbal communication more understandable by reducing or eliminating hypernasal speech. The device also lowers the hard palate, which reduces tongue movement allowing speech to be less fatiguing.[110] Findings from a retrospective study of 25 patients with ALS treated with a palatal lift indicated 21 patients showed improvement in their dysarthria, specifically in reduction of hypernasality, with 19 patients benefiting at least moderately for 6 months.[111]

Figure 17.9 Mechanical insufflation-exsufflation (MI-E) device. *(Courtesy of JH Emerson Co., Cambridge, MA 02140.)*

Management of Muscle Cramps, Spasticity, Fasciculations, and Pain

Anticonvulsant medication such as phenytoin (Dilantin) and carbamazepine (Atretol, Tegretol) may be prescribed for muscle cramps, if they are not relieved with a program of muscle stretching and adequate hydration and nutrition. Both of these medications can cause gastrointestinal upset and rash, and carbamazepine can cause sedation. Benzodiazepines, such as diazepam (Valium), clonazepam (Klonopin), or lorazepam (Ativan), can also be prescribed for muscle cramps, and side effects may include sedation, dizziness, respiratory depression, and increased weakness. Benzodiazepines, especially diazepam, may be prescribed for spasticity, although baclofen (Lioresal) and tizanidine (Zanaflex) are more commonly used. Side effects include weakness, fatigue, sedation, and hypotension.[54,111]

Patients with brisk, widespread fasciculations are generally instructed to avoid or minimize caffeine and nicotine. Lorazepam (Ativan) may be prescribed to decrease the intensity of the fasciculations.[54] Depending on the etiology of pain, a variety of management strategies may be utilized. Mild pain or pain associated with joint discomfort is usually addressed with analgesics, such as acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). For more severe

refractory pain, narcotics such as codeine, hydrocodone, or methadone may be prescribed. In the terminal stages of ALS, morphine may be administered to provide analgesia, sedation, and relief from respiratory distress.[54,111]

Management of Anxiety and Depression

Anxiety and depression can greatly affect a patient's and his or her family's quality of life, as well as the ability to cope with and adapt to the progressive changes and losses of the disease. Thus, pharmacotherapy and psychological counseling are important management strategies for addressing the anxiety and depression that can develop. Individuals with depression may be prescribed an SSRI, such as fluoxetine (Prozac) or sertraline (Zoloft). It is important to note that antidepressant effects may not occur for several weeks after initiation of the medications, and side effects may include agitation and insomnia. If the patient presents with depression and insomnia or agitation, a tricyclic antidepressant, such as amitriptyline (Elavil) or imipramine (Tofranil), is preferred.[54,93]

Benzodiazepines, such as chlordiazepoxide (Librium), clorazepate, diazepam, and flurazepam (Dalmane), may be prescribed for anxiety or for patients with depression and insomnia. For patients whose respiratory status is affected, a non-benzodiazepine anxiolytic, such as buspirone (BuSpar), is preferred.[54,93,111]

FRAMEWORK FOR REHABILITATION

As previously described, the course of ALS cannot be altered and eventually the individual will become dependent in essentially all aspects of mobility and self-care. However, appropriate rehabilitation programs should be designed and implemented to allow the individual to maintain his or her independence and function for as long as possible, within the context of his or her goals and resources, throughout the disease and across health care settings. Because of the progressive nature of ALS, it is imperative that the physical therapist not only addresses an individual's current problems, but also plans ahead for future problems.[112,113]

A large body of evidence to help guide physical therapy decision making is currently unavailable. As identified earlier, ALS has a progressive and deteriorating disease trajectory, with inevitable progression to disability. However, there is great variability among individuals across the disease trajectory. Staging ALS into *early, middle* (early-middle and late-middle), and *late* stages based on impairments, activity limitations, and participation restrictions may assist the therapist in designing appropriate and realistic interventions throughout the disease process, as well as anticipate the evolving needs of individual patients[113] (Fig. 17.10).

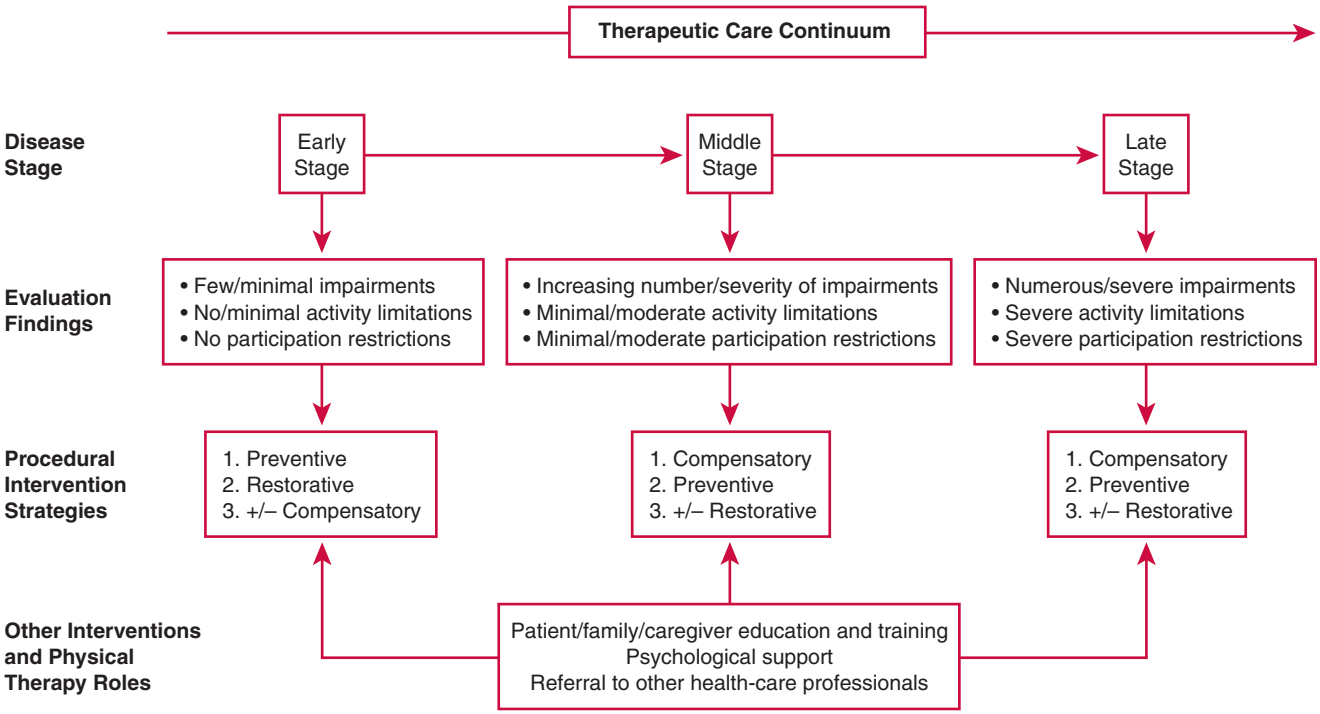

Figure 17.10 Framework for rehabilitation for individuals with ALS. *(From Dal Bello-Haas, V: A framework for rehabilitation in degenerative diseases: Planning care and maximizing quality of life. Neurology Report (now JNPT) 26(3):115, 2002, p 116, with permission.)*

In the *early* stage of the disease, ALS will manifest as a variety of signs and symptoms recognized by the patient as abnormal. The resultant impairments may or may not cause minor activity limitations and no participation restrictions are present. In the *middle* stage of ALS, the patient experiences increasing signs and symptoms, and develops an increase in the number of impairments and the severity of impairments. Minimal to moderate activity limitations will be noted and participation restrictions will develop. In the *late* stage of ALS, disease progression leads to numerous and increasingly more severe impairments. The patient becomes increasingly more functionally limited owing to lack of voluntary motor control and numerous participation restrictions ensue. The patient becomes dependent in essentially all aspects of mobility and self-care, and may require mechanical ventilation to address respiratory compromise, if not already ventilated.[113]

Within this framework, impairments, activity limitations, and participation restrictions are managed through restorative, compensatory, or preventative physical therapy interventions. These interventions should be tailored to the stage of the disease, keeping in mind individual variability throughout disease course (e.g., presence of cognitive impairments or respiratory signs and symptoms) and disease progression (e.g., slowly progressing versus fast progressing), and grounded in evidence-based research whenever possible. The patient's goals are paramount, and psychosocial factors that may influence the patient's decision making, such as acceptance of the diagnosis, and social and financial resources must be considered.[113]

PHYSICAL THERAPY EXAMINATION

At any one time, a variety of body regions can be affected by ALS and in various combinations. Impairments may occur as a direct result of the pathology (*direct impairment*), as sequelae to the pathology (*indirect impairment*), or may be the result of multiple underlying origins *(composite impairments).* Therefore, a careful and comprehensive examination is required to determine the extent of involvement and the impact of involvement on activity limitations and participation restrictions. Reexamination at regular intervals is necessary to determine the extent and rate of progression of the disease. However, at times it may be difficult to differentiate between the progressive course of the disease and the lack of impact of the interventions. In considering the tests and measures to include in a reexamination, the physical therapist needs to weigh the benefits against the psychological impact of repeating tests and measures when the patient is progressively deteriorating. This is especially true in the late-middle and late stage of the disease. It is important for the physical therapist to reexamine, monitor, and evaluate changes, because some medical decision making may be based on the physical therapist's findings, for example, the patient's percent predicted VC and the timing of PEG placement.

The patient's goals and individual psychosocial factors, rate of disease progression, extent and area of involvement, stage of the disease, and respiratory and bulbar involvement that may affect the patient's ability to participate all need to be taken into account when structuring the initial examination. The types of data generated from the patient history and interview are presented in Chapter 1, Clinical Decision Making. When collecting these data, determining what is important, relevant, and valued by the individual patient is key. By understanding what is most meaningful to a patient, the physical therapist can narrow the gap between a patient's expectations and hopes and actual experiences through realistic and appropriate interventions. For example, a young mother with ALS may inform the physical therapist her priority is caring for her children rather than maintaining employment. Thus, the initial examination would be structured around abilities and activities related to home, rather than work.

Many of the tests and measures described in this text are generally appropriate components of a comprehensive examination for an individual with ALS. However, selection is always based on specific patient need. The tests and measures frequently applicable to patients with ALS include examination of sensory function, muscle performance, motor function, coordination and balance, gait, functional status, the environment, respiratory function, and cognitive function (see Chapters 3, 5, 6, 7, 8, 9, 12, and 27). The following section presents areas that typically warrant emphasis during the examination.

Cognition

No ALS-specific cognitive test or measure exists. If dementia or cognitive impairments are suspected, executive function, language comprehension, memory, and abstract reasoning should be examined. The *Mini-Mental State Examination*[114] has been used in clinical studies, although it may not be sensitive to frontotemporal function impairments. Referral for a neuropsychological evaluation may also be indicated to identify specific cognitive impairments.

Psychosocial Function

As depression and anxiety are common in individuals with ALS, screening is important and referral to a psychologist or psychiatrist for further evaluation may be indicated. The *Beck's Depression Inventory,*[115] the *Center of Epidemiologic Study Depression Scale,*[116] the *Hospital Anxiety and Depression Scale* (HADS),[117] and the *State-Trait Anxiety Inventory*[118] have been used in clinical studies.

Pain

Pain is common in individuals with ALS and should be examined subjectively and objectively, using a *Visual*

Analogue Scale (VAS) for example. Pain is not necessarily a direct impairment of ALS, but rather an indirect (decreased ROM, adhesive capsulitis) or a composite impairment (joint malalignment secondary to spasticity and faulty posture). Further examination of underlying causes of pain is often required.

Joint Integrity, Range of Motion, and Muscle Length

Functional ROM, active, active-assisted, and passive range ROM, muscle length, and soft tissue flexibility and extensibility should be examined using standard methods.

Muscle Performance

Specific deficits of muscle strength, power and endurance, and muscle performance during functional activities should be determined. Specific deficits can be measured with manual muscle testing (MMT), isokinetic muscle strength testing, or handheld dynamometry. In clinical trials, muscle strength has been examined as *maximum voluntary isometric contraction* (MVIC) using a strain gauge tensiometer system.[119] This method eliminates muscle length and velocity as factors in testing and produces reliable, valid, interval data.[119-122] MVIC is considered the most direct technique for investigating motor unit loss, and has been used extensively for examining muscle strength in individuals with ALS for the past 10 years. Its range and sensitivity have been validated by several natural history studies.[5,17,123] However, MVIC testing requires specialized equipment and training in its use.

Test reliability of MMT and MVIC scores among uniformly trained physical therapists at several institutions has been examined. Reproducibility between MMT and MVIC was found to be equivalent. Sensitivity to detect progressive muscle strength changes in individuals with ALS favored MMT. However, 6 muscles were tested with MVIC and 34 muscles were tested with MMT; thus, the difference in detecting change was largely accounted for by the number of muscles sampled by MMT versus MVIC.[124]

Motor Function

Impairments in dexterity, coordination of large movement patterns, as well as gross and fine motor control may be evident owing to spasticity and muscle weakness. Hand function and initiation, modification, and control of movement patterns should be examined.

Tone and Reflexes

Muscle tone may be examined using the *Modified Ashworth Scale.*[125] Deep tendon and pathological reflexes should be tested to distinguish between UMN and LMN involvement.

Cranial Nerve Integrity

The cranial nerves commonly affected by ALS include V, VII, IX, X, and XII. Cranial nerves should be tested to determine the extent of bulbar involvement. Screening for oral motor function, phonation, and speech production can be accomplished through the interview and observation. Referral to a speech-language pathologist is recommended.

Sensation

If the patient complains of sensory symptoms or if sensory involvement is suspected, sensory testing should be completed.

Postural Alignment, Control, and Balance

Static and dynamic postural alignment and body mechanics during self-care, functional mobility skills, functional activities, and work conditions and activities should be examined. Postural stability, reactive control, anticipatory control, and adaptive postural control should also be determined. No ALS-specific balance test or measure exists. A variety of balance status measures, originally designed for use with other patient populations, including the *Tinetti Performance Oriented Mobility Assessment* (POMA),[126] the *Berg Balance Scale*,[127] the *Timed Up and Go Test* (TUG),[128] and the *Functional Reach Test*,[129] can be used. Low total *Tinetti Balance Test* scores, indicating impaired balance, were found to be moderately to strongly related to LE muscle weakness and disability in individuals with ALS.[130,131] Kloos et al[130] suggest that the POMA is a reliable measure for individuals in the early or early-middle stages of ALS. A study of 31 individuals with ALS who underwent monthly TUG, Amyotrophic Lateral Sclerosis Functional Rating Scale—Revised (ALSFRS-R), forced vital capacity (FVC), MMT, and quality-of-life assessments for 6 months found that the TUG was significantly associated with the chance of falling.[132]

Gait

No ALS-specific gait test or measure exists. Documentation of gait within a particular time period (e.g., within 15 seconds) or over a certain distance (e.g., 10 feet [3 meters]) has been measured in clinical trials. Gait stability, safety, and endurance should be examined. Energy expenditure, alignment, fit, practicality, safety, and ease of use of orthotic and assistive devices should also be examined at regular intervals.

Respiratory Function

Determination of respiratory status and function includes examination of respiratory symptoms and muscle function, breathing pattern, chest expansion, respiratory sounds, cough effectiveness, and VC or forced vital capacity (FVC) using a handheld spirometer. Supine FVC may be a better indicator of diaphragm weakness than erect FVC, and maximal inspiratory pressure (MIP) may also be useful in respiratory function monitoring because it can detect early respiratory insufficiency.[94] Sniff nasal pressure (SNP) may be effective in detecting

hypercapnia, and peak cough expiratory flow (PCEF) is the most widely used measure of cough effectiveness.[94] Aerobic capacity and cardiovascular–pulmonary endurance may be tested in the early stages of ALS using standardized, modified protocols to evaluate and monitor responses to aerobic conditioning.

Integument

In general, even in the late stage of ALS skin integrity is rarely a problem. Skin inspection should be used to examine contact points between the body and assistive, adaptive, orthotic, protective, and supportive devices, mobility devices, and the sleeping surface. Such inspection is especially important when the patient's mobility becomes increasingly more dependent. If present, swelling should also be examined and monitored. Swelling of the distal limb may develop owing to lack of muscle pumping action in a weakened extremity.

Functional Status

Functional mobility skills, safety, and energy expenditure are important considerations. Basic and instrumental activities of daily living and the need for adaptive equipment should be examined. The *Functional Independence Measure* (FIM)[133] has been used to document functional status in clinical trials.

The *Schwab and England Activities of Daily Living Scale*[134] is an 11-point global measure of functioning that asks the rater to report activities of daily living (ADL) function from 100% (normal) to 0% (vegetative functions only), and has been used to examine function in individuals with ALS (Appendix 17.A). The ALS Ciliary Neurotrophic Factor (CNTF) Treatment Study Group found the scale to have excellent test-retest reliability, to correlate well with qualitative and quantitative changes in function, and to be sensitive to changes over time.[135]

Environmental Barriers

The patient's home and work environments should be examined for current and potential barriers, access, and safety.

Fatigue

Fatigue is very common in individuals with ALS. No ALS-specific measures exist; the *Fatigue Severity Scale*[136] has been used in clinical trials.

DISEASE-SPECIFIC AND QUALITY-OF-LIFE MEASURES

Disease-Specific Measures

The *ALS Functional Rating Scale* (ALSFRS)[135] and the revised version, ALSFRS-R[137] (Appendix 17.B) examine the functional status of patients with ALS. The patient is asked to rate his or her function using a scale from 4 (normal function) to 0 (unable to attempt the task). The original scale, the ALSFRS, correlated positively with objective measures of UE and LE strength and was found to be valid and reliable for measuring the decline in function that results from loss of muscular strength.[135] The ALSFRS-R was expanded to include additional respiratory items, and was found to have internal consistency and construct validity, and to have retained the properties of the original scale.[137] Telephone administration of the ALSFRS-R has also been found to be reliable.[138] Other disease-specific scales include the *Appel ALS Scale* (AALS),[139] the *ALS Severity Scale* (ALSSS),[140] and the *Norris Scale.*[141]

Quality-of-Life Measures

Quality of life in individuals with ALS has been examined with generic measures, such as the SF-36,[142] the *Schedule for Evaluation of Individual Quality of Life—Direct Weighting* (SEIQoL-DW),[143] and the *Sickness Impact Profile* (SIP).[144]

The *Amyotrophic Lateral Sclerosis Assessment Questionnaire* (ALSAQ-40),[145] an ALS-specific quality of life measure, contains 40 items that represent five distinct areas of health: mobility (10 items), ADL (10 items), eating and drinking (3 items), communication (7 items), and emotional functioning (10 items). The questions refer to the patient's condition during the past 2 weeks and responses are given on a five-point Likert scale. The ALSAQ-40 measures health status in each domain using a summary score from 0 (best health status) to 100 (worst health status). The validity and reliability of this instrument have been examined and reported.[145,146] The *ALSAQ-40* has been shortened to 11 items and also appears to be valid and reliable.[147]

PHYSICAL THERAPY INTERVENTIONS

The role of the physical therapist in management of individuals with ALS and the extent of interventions provided vary depending on whether or not the therapist is working as a member of a team specialized in ALS care or as an independent or clinic-based therapist. Additional variables include the availability of other health care professionals in the practice setting and the reason the individual is seeking physical therapy (e.g., specific ALS-related problem versus a co-morbidity problem such as arthritis).

Restorative intervention is directed toward remediating or improving impairments and activity limitations. In the early and middle stages of ALS, restorative interventions are temporary at best because disease progression is expected and permanent loss of function and disability is likely. Restorative interventions in the late stage of ALS are for the most part directed solely toward remediation of impairments that result from other systems pathology (e.g., pressure sores, edema, pneumonia, atelectasis, adhesive capsulitis).

Compensatory intervention is directed toward modifying activities, tasks, or the environment to minimize

activity limitations and participation restrictions. In the early and middle stages of ALS, tasks or activities may be adapted to achieve function. As the disease progresses, increasing environmental adaptations will be necessary to maintain and promote function.[113]

In the early and early-middle stages of ALS, **preventative intervention** is directed toward minimizing potential impairments such as loss of ROM, aerobic capacity, or strength, preventing pneumonia or atelectasis, and activity limitations. Beginning an early prevention program may alter impairments and maintain physical function temporarily, and may also improve well-being and decrease fatigue, as well as the secondary effects of immobility. In the late-middle and late stages, the pathology is more advanced and mobility becomes progressively restricted. In these stages, it may be extremely difficult or impossible to prevent impairments and activity limitations that are directly related to the nervous system pathology. Thus, the role of prevention is *tertiary,* in order to mitigate the effects of the pathology that lead to impairments in other systems (e.g., educating caregivers about a passive ROM exercise program to prevent adhesive capsulitis in the shoulder).[113] In general, the role of the physical therapist includes the following:

- Promoting independence and maximizing function throughout the stages of the disease, through restorative and compensatory interventions that address impairments, activity limitations, and participation restrictions
- Promoting health and wellness in the early and early-middle stages of the disease through restorative and preventative interventions
- Providing alternative means of carrying out functional activities with adaptive equipment and alternate methods for performing tasks and activities through compensatory interventions as the disease progresses
- Minimizing or preventing complications through preventative interventions throughout the course of the disease
- Providing education, psychological support, and recommendations for equipment and community resources to assist in adapting to the disease progression[113]

Owing to the individual variability of the disease onset, disease course, and disease progression, patients with ALS will present with unique and different sets of problems; thus, interventions will vary. As described earlier, interventions are directed mainly toward addressing activity limitations and participation restrictions, because often the impairments causing the limitations and restrictions cannot be altered. However, in the early and early-middle stages of ALS, it may be possible to direct treatment toward the underlying CNS impairments, and perhaps postpone the onset of particular activity limitations. For example, a study of patients in the early stages of ALS (FVC ≥90% predicted and ALSFRS ≥30) who engaged in moderate load, moderate resistance exercises were found to have higher ALSFRS scores and SF-36 Physical Function scores compared to a matched control group who performed stretching exercises.[148] Patients and therapists must understand that any beneficial effects of an early prevention program will be short term and will not have an impact on the overall course of the disease. Much more research into the effectiveness of interventions for individuals with ALS is needed.

In developing a POC, in addition to the patient's goals, the therapist must also consider the rate of disease progression, the extent and area of involvement, stage of the disease, respiratory and bulbar factors that may affect participation, timing of the intervention, patient acceptance and motivation, life support choices, availability of psychosocial support, and resources.

Some patients may view the need to use adaptive equipment, such as an ambulatory assistive device or wheelchair, as a definitive marker for disease progression and impending death. This may cause the patient to be hesitant to accept the recommended aid or device as a means of maintaining some aspect of control over the disease. The physical therapist will be required to maintain a balance between being realistic about what can be achieved and providing a sense of hope, not helplessness, when discussing intervention options. An overview of ALS disease stages and general intervention strategies is presented in Table 17.3. Common impairments and activity limitations associated with ALS and their respective interventions are described below.

Cervical Muscle Weakness

Progressive cervical extensor weakness will cause the head to fall forward, resulting in overstretching of the posterior musculature and soft tissues. This may cause bouts of acute pain or develop into anterior muscle tightness or a chronic cervical syndrome. Some patients will compensate for the forward head position by increasing lordosis, as they attempt to maintain their posture during ambulation.

For mild to moderate cervical weakness, a soft foam collar may be worn during specific activities. Soft collars are comfortable and usually well tolerated. However, wear-induced compressibility requires that they be replaced frequently. For moderate to severe weakness, a semirigid or rigid collar is prescribed. These are usually made of padded rigid plastic or leather and provide very firm support. Patients may find the collars very warm; may experience discomfort at points of body contact, such as the chin, mandible, sternum, or over clavicles; may feel pressure on the trachea; and may feel confined. Several types of collars are presented in Figures 17.11 and 17.12, and the pros and cons of individual collar types are summarized in Table 17.4.

Table 17.3 Amyotrophic Lateral Sclerosis Disease Stages and Common Intervention Strategies: Framework for Rehabilitation for Individuals with ALS

Stage	Common Impairments and Activity Limitations	Interventions
Early	Mild to moderate weakness in specific muscle groups Difficulty with ADL and mobility toward the end of this stage	**Restorative/Preventative** • Strengthening exercises*[147,178,179] • Endurance exercises[180] • Active ROM,[181] active-assisted ROM, stretching exercises **Compensatory** • Determine potential need for adaptive or assistive devices • Determine potential need for ergonomic modifications of home/workplace • Energy conservation • Educate the patient about the disease process, energy conservation, and support groups
Middle	Progressive decrease in mobility throughout stage Wheelchair needed for long distances; increased wheelchair use toward end of stage Severe muscle weakness in some groups; mild to moderate weakness in other groups Progressive decrease in ADL skills throughout stage Pain	**Compensatory** • Support weak muscles (assistive and supportive devices, adaptive equipment, slings, orthoses) • Modifications to workplace/home (e.g., install ramp, move bedroom to first floor) • Wheelchair prescription • Education of caregivers regarding functional training **Preventative** • Active,[181] active-assistive, and passive ROM, stretching exercises • Strengthening exercises[147,178,179] (early middle) • Endurance exercises[180] (early middle) • Determine need for pressure-relieving devices (e.g., pressure distributing mattress)
Late	Wheelchair dependent or restricted to bed Complete dependence with ADL Severe weakness of UE, LE, neck and trunk muscles Dysarthria, dysphagia Respiratory compromise Pain	**Preventative** • Passive ROM • Pulmonary care* • Hospital bed and pressure-relieving devices • Skin care, hygiene* **Compensatory** • Caregiver education regarding transfers, positioning, turning, skin care • Mechanical lift

Adapted from Dal Bello-Haas,[113 p 123] with permission.
*May be restorative.
ADL = activities of daily living; LE = lower extremity; ROM = range of motion; UE = upper extremity.

Some patients with combined cervical and upper thoracic weakness may benefit from a cervical-thoracic orthosis, or a Sternal Occipital Mandibular Immobilizer (SOMI). These devices provide greater support, but are more expensive and heavy and may be difficult to don and doff. For severe or intractable neck weakness, referral to an orthotist for a custom-made device may be necessary.

In addition to wearing collars, individuals with cervical weakness may also benefit from taking frequent rest periods; supportive seating, such as high-back chairs or recliners; tilt-in-space or reclining wheelchairs; elevating reading material; and education about good arm support for prolonged sitting, proper use of head rest when riding in a car, and ergonomic changes for work stations. It is important to note that when trunk weakness accompanies neck weakness, positioning for head support becomes more challenging.

Dysarthria and Dysphagia

In collaboration with the SLP and nutritionist, the physical therapist can play a role in managing dysarthria and dysphagia by addressing the patient's head and trunk control and position in sitting. In addition, the physical therapist can reinforce the use of strategies for eating and swallowing (e.g., chin tuck), the use of prescribed communication devices, and the need for food consistency modifications. Because patients are at

Figure 17.11 The Headmaster Collar. *(Courtesy of Symmetric Designs, Salt Spring Island, BC, Canada, V8K 1C9.)*

risk for aspiration, education of the patient, family, and caregiver is imperative (see section below titled Respiratory Muscle Weakness).

UE Muscle Weakness

Weakness of the UEs greatly affects the patient's ability to carry out ADL. There is a large variety of adaptive equipment available that may help the patient prolong function for as long as possible (see section below titled Activities of Daily Living).

Patients with a painful shoulder due to subluxation may benefit from a sling, similar to those used with patients following stroke with decreased tone, although subluxation cannot be corrected completely. Splinting of the wrist or hand may be indicated to prevent contractures or to improve the patient's function, such as the ability to grasp.

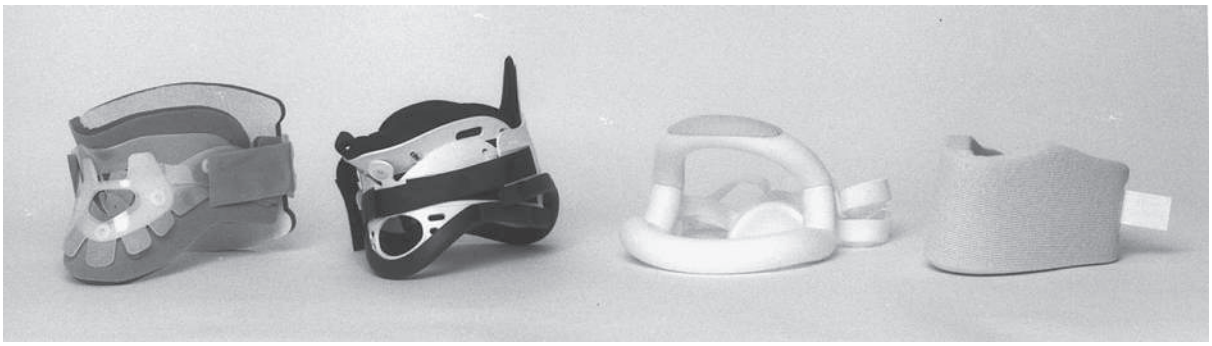

Figure 17.12 Types of collars. From left to right: Aspen Collar, Miami-J Collar, Executive Collar, and Soft Collar.

Table 17.4 Types of Semirigid and Rigid Cervical Collars

Type	Examples	Advantages	Disadvantages
Collars without anterior neck access	Philadelphia® Collar[a]	Offers good support	Patient may feel confined May cause pressure on trachea Patient may experience difficulty breathing or swallowing Can be uncomfortably warm
Collars with anterior neck access (for tracheostomy)	Miami-J® Collar[b] Aspen Collar[c] Malibu Collar[d]	Padding absorbs and wicks moisture away from skin Suitable for individuals with cervical weakness in all 3 planes	Patient may feel confined May be uncomfortably warm More expensive
	Canadian Collar[e] Headmaster Collar[e]	Open design allows for circulation of air Lightweight No pressure on trachea Some patients consider collar more cosmetically appealing	May put pressure on chin and sternum Some models more expensive Some models require custom cutting Not adequate if rotation and lateral flexion weakness is also present

Shoulder Pain

Individuals with ALS may develop shoulder pain and present with capsular patterns of restriction. Pain may be caused by several factors: abnormal scapulohumeral rhythm secondary to spasticity or weakness causing imbalance that may lead to impingement; overuse of strong muscles; muscle strain; faulty resting position; glenohumeral subluxation secondary to weakness; or a fall. Depending on the cause of the shoulder pain, interventions may include modalities, ROM exercises, passive stretching, joint mobilizations, and education about proper joint support and protection.

A 20% incidence of adhesive capsulitis in individuals with ALS has been found. Recommendations for managing the pain and decreased ROM included a protocol of an intra-articular analgesic and anti-inflammatory cocktail injection, followed by a course of aggressive ROM exercises. Some patients reported an acute resolution of pain, whereas others reported improvements over 2 to 3 weeks.[149]

Respiratory Muscle Weakness

Education is extremely important. Patients and caregivers must be taught how to balance activity and rest and educated about energy conservation techniques. Patients and caregivers should also be educated about signs and symptoms of aspiration; positioning to avoid aspiration, such as upper cervical spine flexion during eating; causes and signs of respiratory infection; and strategies for managing oral secretions (use of oral suction device) or choking episodes (Heimlich maneuver). Specific breathing exercises and positioning to optimize ventilation/perfusion matching may also be incorporated, although their effectiveness in ALS has not been determined. A small sample size double-blind study randomly assigned 9 people with ALS to an inspiratory muscle training (IMT) group. Subjects completed daily IMT training sessions (10 minutes per session) three times per day. After 12 weeks of training, subjects in the IMT group demonstrated trends toward improvement in FVC, VC, MIP, and SNP, compared to a control group who completed sham training (n = 10), and gains in inspiratory muscle strength were partially reversed after an 8-week period of training cessation.[150]

Airway clearance techniques may be necessary when conditions that cause secretion retention, such as pneumonia or atelectasis, arise. To compensate for a weakened cough, the patient and caregiver may be instructed in the use of manually assisted coughing techniques or MI-E. Again, the effectiveness of these techniques or device has not been demonstrated in ALS, but case reports have described the benefits from regular use of a mechanical insufflation device.[151,152] Studies of cough flows and pressures during cough augmentation have found that manual assistance increased flow 11% in those with bulbar ALS and 13% in those with nonbulbar ALS. MI-E increased flow by 26% in those with bulbar ALS and 28% in those with nonbulbar ALS. The greatest improvements were in patients with the weakest coughs.[153]

High-frequency chest wall oscillation (HF-CWO) has garnered some interest in terms of its applicability to the ALS population. HF-CWO is an external noninvasive modality that transmits high-frequency oscillatory pressures through the chest wall, thereby mobilizing secretions from the small peripheral airways and enhancing secretion clearance and gas exchange. HF-CWO has been effectively used in patient populations in which secretion retention and hypersecretion are issues (e.g., cystic fibrosis).[154,155] A study comparing 19 people with ALS who used HF-CWO to 16 who were not treated found that after 6 months, those using the device had significantly less breathlessness. In addition, those users with an FVC between 40% and 70% predicted had significantly less mean decrease in FVC and less breathlessness and fatigue.[156]

LE Muscle Weakness and Gait Impairments

Orthoses may be recommended to improve function by offering support to weakened muscles and the joints they surround, decrease the stress on remaining functioning or compensatory muscles, conserve energy, or minimize local or general muscle fatigue. Controlling knee impairments can often be achieved through an ankle-foot orthosis (AFO); as such, addressing the ankle should be considered first. It is also important to consider the weight of the orthosis as individuals with ALS will have energy expenditure issues, and it may be more fatiguing for the patient to ambulate with a heavy orthosis than to ambulate without the impairment being corrected. For this reason, a knee-ankle-foot orthosis (KAFO) is not recommended.

Deciding between a commercially manufactured versus a custom-made orthosis is certainly dependent on the patient's resources, but the rate of disease progression should also be considered. For an individual with rapidly progressive ALS and who is likely to use the orthosis for a limited time, a commercially manufactured orthosis may suffice. Solid AFOs are a good choice for patients who have medial/lateral instability of the ankle with quadriceps weakness. The fixed ankle position, combined with the quadriceps weakness, may make it difficult for sit-to-stand transfers, climbing stairs, and negotiating inclines. Hinged AFOs allow dorsiflexion and may be appropriate for the patient with adequate knee extensor strength with mild ankle strength loss.

The type of ambulatory assistive device prescribed is dependent on the degree of proximal muscle strength or instability; function of the UEs; the pattern, extent, and rate of disease progression; acceptance by the patient; and financial constraints. Again, weight of the device is an important factor to consider in decision making, while also taking into account which device will ensure optimal function and safety. Wheeled walkers, which do

not require the patient to lift the device, are usually recommended. In general, individuals with ALS are rarely prescribed crutches. If crutches are warranted, Loftstrand (Canadian) crutches are preferred.

Activities of Daily Living

A large variety of adaptive equipment is available to assist individuals with muscle weakness perform everyday tasks. However, the benefits and effectiveness of adaptive equipment for people with ALS have not been evaluated systematically. No one type of device is suitable for every patient or for every stage of the disease. Reimbursement for the equipment is variable and although a piece of adaptive equipment can help the patient maintain independence, limited financial resources may prevent recommending or purchasing the item. For example, in the early stages of ALS a universal cuff with a pocket for writing or feeding utensils may be beneficial. As the disease progresses and proximal shoulder weakness increases, a mobile arm support may be incorporated to allow the patient to maintain independence in eating. In the late stage of ALS when the patient is dependent on the caregiver for eating, a long straw and straw holder may be recommended to assist the caregiver with the activity. Examples of adaptive equipment that may be beneficial for performing ADL are presented in Table 17.5.

Decreased Mobility

Patients with LE weakness may have difficulty with sit-to-stand or car transfers. Simple interventions include placing a firm cushion 2 to 3 in (5 to 7.6 cm) thick under the buttocks in the chair or elevating the chair by placing the legs in prefabricated blocks (Fig. 17.13). Self-powered lifting cushions are relatively inexpensive and portable, but the individual needs adequate trunk control and balance in order to use the device safely (Fig. 17.14). Upholstered reclining chairs with powered seat lifts may also be recommended, but are more expensive. All these interventions increase the biomechanical advantage and make it easier for the patient to rise from a sitting position.

Figure 17.13 Prefabricated blocks. *(Courtesy of Homecraft AbilityOne, Kirkby-in-Ashfield, Nottinghamshire, England NG17 7ET.)*

Caregivers will need to be educated regarding assisting the patient with transitional movements. Transfer boards may be used for transfers once the individual is unable to stand, either alone if the person has adequate arm strength and good sitting balance, or the caregiver can be instructed in how to assist the patient. Other useful devices to assist the patient's mobility are transfer belts and swivel cushions or seats. Transfer belts ease the burden of the transfer for the caregiver and prevent potential pulling on the patient's UEs. Swivel cushions are lightweight, cushioned seats that swivel in both directions and make getting in and out of a car easier (Fig. 17.15).

Once an individual cannot perform transfers, even with the assistance of a caregiver, a hydraulic or mechanical lift is required. Commonly recommended lifts devices include the Easy Pivot™ (Rand-Scot Inc., Fort Collins, CO 80524), and the Hoyer Lift® (Sunrise Medical, Longmont, CO 80503). Use of an electric hospital bed may facilitate bed mobility and transfers both for the patient and caregiver, and, depending on resources,

Table 17.5 Common Types of Adaptive Equipment

Feeding and eating	Foam tubing to increase the size of utensil handles; utensils and cups with modified handles or holders; long-levered jar opener; plate guard; serrated or rocker knife; wrist splint/adapted cuff (for holding tools and instruments); mobile arm support; Dycem®
Self-care and bathing	Bathing benches; bath tub seats; shower commode; handheld shower head; grab bars; raised toilet seat; long handled sponge; electric toothbrush or shaver; strap-fitted hairbrushes
Dressing	Zipper pulls or hooks; button hooks; long-handled shoehorn; Velcro® clothing closures; elastic shoelaces
Writing and reading	Foam tubing to increase the size of the pen or pencil; triangular pencil grip; pen holders; book holders; automatic page turner; adjustable angle table
Other	Key holders; doorknob adapters; lamp extension switch; personal alarm system; switch-operated environmental controls; speaker phone with automatic dialing; telephone holder; use of telecommunication devices for the deaf (TDD)

home modifications and automobile adaptations may also be considered.

Chair glides or stairway lifts can be suggested for those individuals who live in multilevel homes, but who cannot or should not climb stairs (see Chapter 9, Examination of the Environment). These lifts are measured and custom-made for individual staircases and are very expensive. Insurance companies usually do not reimburse for stairway lifts, but some medical supply companies offer "rent-to-own" options. In addition, local ALSA or MDA chapters may have lifts that have been recycled.

At some time point as the disease progresses, the extent of muscle weakness or the energy requirements for ambulation will necessitate wheelchair use for mobility. In the early or early-middle stage of ALS a manual wheelchair, preferably lightweight, may be used for traveling long distances as an energy conservation technique. This wheelchair should be rented on a short-term basis or loaned from a local ALSA or MDA chapter or other source, because most insurance companies will reimburse for only one wheelchair purchase. As the disease progresses, a power wheelchair system tailored to the patient's current needs and potential future needs will be necessary. Numerous customized wheelchair features and options are available that can assist the individual in maintaining a maximum level of independence and comfort. A referral to a wheelchair and seating clinic may be the best option owing to the numerous, specialized, and evolving needs of the individual with ALS.

Trail et al[157] surveyed 42 patients with ALS and moderate disability, as documented on the AALS, about the wheelchair features they found most beneficial. Sixty-one percent of patients reported that their wheelchairs allowed them to maintain their previous activity levels. In order of priority, manual wheelchair users cited a lightweight frame, small turning radius, high reclining back and supports for the head, trunk, and extremities as most desirable; undesirable features included low, sling, nonreclining back; nonmotorized; static, nonadjustable leg rests; heaviness or large size; and nonremovable armrests. Desirable features for patients who used powered wheelchairs included independent mobility, maneuverability, overall comfort and tilt-in-space/recline features; undesirable features included low, nonreclining back, heaviness or large size, uncomfortable seat, nonadjustable leg rests, and general discomfort.[157]

Although power scooters may be suitable for a patient with adequate UE and trunk strength in the earlier stages of ALS, the vehicle becomes limiting as the disease progresses and should not be prescribed. If the patient has already been reimbursed for a scooter, most insurance companies will not pay for a power wheelchair, because the scooter is considered a power mobility device. If a scooter is to be recommended at all, the patient should rent or borrow the device for short-term use.

Muscle Cramps and Spasticity

Muscle cramps may be alleviated with massage and a stretching program. Cold can temporarily decrease

spasticity. Physical therapists can perform and instruct caregivers in slow prolonged stretches and passive ROM exercises to address spasticity. In addition, postural and positioning techniques can be incorporated to decrease spasticity and splinting may be necessary to prevent contractures. A published Cochrane review identified one randomized, controlled study that found patients with ALS who engaged in a 15-minute, twice-daily, moderate-intensity exercise had decreased spasticity, as measured by the *Modified Ashworth Scale,* compared to a control group who engaged in usual daily activities.[158]

Psychosocial Issues

A diagnosis of ALS is devastating for both the patient and family-caregiver unit. Because of the progressive nature of the disease, impairments readily lead to activity limitations and participation restrictions, which may affect quality of life. The emotional responses of the person experiencing the disease, family members, and individuals caring for the patient are multifaceted and may fluctuate throughout the stages of the disease. Much is lost when living with a terminal, progressive disease: physical health and abilities, body image, work and family roles, identity, family and social networks, lifestyle, independence, control, hope, meaning, and the anticipated future.[159,160] The physical therapist must be able to recognize the patient's ability to cope and adapt, and his or her psychological reactions, level of acceptance, and willingness and ability to integrate therapeutic recommendations. It is also imperative that the physical therapist be able to differentiate between normal reactionary grief to losses or a change in physical function and the presence of clinical anxiety and depression, and refer the patient to the appropriate health care team member, when necessary.[161]

When pervasive, anxiety and depressive symptoms need to be treated aggressively with pyschopharmacological medications, because left untreated these psychosocial impairments can adversely affect an individual's ability to adapt, cope, and participate in the POC. Depression may also lead to suicide. In addition, anxiety and depression may also be prevalent among family members or caregivers.[161]

EXERCISE AND ALS

Despite the high incidence of muscle weakness in individuals with ALS, the effects of exercise programs have not been extensively studied and, thus, are not well understood. Often physical therapy programs involve ROM and stretching exercises only. Despite the lack of research evidence, some discourage exercise programs because of fear of overuse weakness and believe that no exercise other than everyday activities is indicated.

Studies of individuals with other neuromuscular diseases such as poliomyelitis, Duchenne's muscular dystrophy, myotonic dystrophy, hereditary motor and sensory neuropathy, spinal muscular atrophy, and limb-girdle, Becker, and fascioscapulohumeral dystrophy have found that exercise programs are beneficial and do not produce overuse weakness.[162-169] The research evidence[162-169] from these patient populations suggests the following:

- Overuse weakness does not occur in muscles with an MMT grade of 3 (fair) or greater out of 5 (normal).
- Moderate resistance exercises can increase strength in muscles with an MMT grade of 3 or greater out of 5.
- Strength gains are proportional to initial muscle strength.
- Heavy eccentric exercise should be avoided.
- Exercise may produce functional benefits.
- Psychological benefits have yet to be determined.

When prescribed appropriately, exercise may be beneficial, especially in the early stages of the disease. Exercise may not improve the strength of muscles already weakened by ALS, certainly not those below grade 3. However, general active ROM and stretching of affected joints, resistive strengthening exercises of unaffected muscles with low to moderate weights, and aerobic activities, such as swimming, walking, and bicycling, at submaximal levels, may be prescribed.

When designing a strengthening exercise program for a patient with ALS, the physical therapist must take into consideration the balance between overuse fatigue and disuse atrophy. Evidence from patients with other neuromuscular diseases suggests that highly repetitive or heavy resistance exercise can cause prolonged loss of muscle strength in weakened, denervated muscle.[170,171] Some animal studies have found that neuromuscular activity has inhibitory effects on sprouting in partially denervated muscle,[172-174] whereas other studies have reported no effect[175,176] or that activity can promote sprouting or reinnervation.[177,178]

On the other hand, a marked reduction in activity level secondary to ALS can lead to cardiovascular deconditioning and disuse weakness beyond the amount caused by the disease itself. Therefore, the type and intensity of the exercise program should be carefully monitored and adjusted by the physical therapist in order to prevent excessive fatigue, while at the same time promoting optimal use of intact muscle groups. Patients should be advised not to carry out any activities to the point of extreme fatigue, and should keep track of *symptoms of overuse*, such as the inability to perform daily activities following exercise due to exhaustion or pain, increased fasciculations, or increased muscle cramping. They may also be advised to exercise for several brief periods throughout the day, with sufficient rest in between.

Disuse Atrophy

Reduced physical activity, particularly if prolonged, reduces function of the neuromuscular system, in addition to the skeletal and other organ systems. With insufficient activity, disuse atrophy develops when muscle

contractions are less than 20% of the total tension a muscle is capable of producing. As contractile proteins are lost, the muscle weakness progresses at a rate of 3% per day.[179] Strength loss through inactivity and disuse can significantly debilitate individuals with ALS, making them highly susceptible to deconditioning, and muscle and joint tightness leading to contractures and pain.

Overuse Fatigue

The potential for inducing overwork damage in individuals with ALS through excessive exercise is a common concern. Sanjak et al[59] found that individuals with ALS demonstrate abnormal physiological and metabolic responses to single bouts of exercise. Oxygen consumption during submaximal exercise was increased in individuals with ALS compared to controls, and VO_{2max} and work capacity were decreased. In addition, it was found that several metabolic substrates of plasma and muscle compartments did not increase to the same level as untrained control subjects, indicating that the availability of substrate for energy production is affected.[59]

In individuals with ALS, the safe range for therapeutic exercise narrows, and the degree to which the range narrows is dependent on the extent of disease involvement and the rate of disease progression. A weak or denervated muscle is more susceptible to overwork damage because it is already functioning close to its maximal limits. Activities of daily living alone may cause impaired muscles to act as though in training and exercise that would improve normal muscles may actually cause overwork damage in impaired muscles. The remaining motor units will respond to training, and these motor units must work harder to handle a given amount of exercise stress.[179] Thus, special attention must be paid to developing an exercise program for patients with ALS, and physical therapists should prescribe exercise training at moderate to low intensities.

The literature related to exercise in individuals with ALS is limited. Two early case studies demonstrated positive effects of specific strengthening and endurance exercises.[180,181] More recently, the effects of exercise in individuals with ALS have been evaluated with larger samples. Both of these studies found significantly less decline in function scores and other outcome measures[182,183] in the exercise group. Two animal studies found that endurance exercise training at moderate intensities slowed disease progression;[184,185] a third study found that high-endurance exercise training had detrimental effects on male mice only.[186] The evidence related to exercise and ALS is presented in Box 17.1 Evidence Summary (human studies) and Box 17.2 Evidence Summary (animal studies).[187-188]

PATIENT/CLIENT-RELATED INSTRUCTION

A diagnosis of ALS is devastating for individuals and their families. They are faced with continual, multiple changes and losses, and eventual death. Assisting the individual and his or her family and caregivers to come to terms with the impact of the disease is an important role for the physical therapist, and providing psychological support and opportunities for expression of feelings,

Box 17.1 Evidence Summary Exercise and ALS: The Evidence from Human Studies

Reference	Subject(s)	Methods	Duration	Results
Sanjak et al[181] (1987)	46-year-old man	Case study Air-Dyne bicycle ergometer Prospective, controlled single blind	6 weeks	Isokinetic strength and cardiopulmonary responses to exercise improved in the UEs, but not in the LEs

frustrations, and concerns is imperative. Collaborating with and educating the patient, family, and caregivers in an open and encouraging environment may empower patients in their efforts to cope with their disease, foster a sense of purpose and self-efficacy, and enhance the overall effectiveness of the intervention by increasing adherence with recommendations.[113]

Patient and family/caregiver education is integral throughout the stages of the disease. The scope of education can include, but is not limited to, the following:

- Providing accurate, factual information about the disease process and clinical manifestations, and their significance in terms of management. Give only as

much information as the patient, family, and caregivers need; information should be provided in a manner appropriate to their understanding.
- Instructing patients, family members, and caregivers regarding interventions that can be carried out independently such as monitoring the effects and side effects of medications, use of assistive devices and adaptive equipment, and preventing secondary complications.
- Advising the patient about methods to promote general health. Instruction regarding energy conservation, balancing rest and activity, and relaxation techniques may be beneficial in assisting the patient to cope with the daily constraints of the disease.
- Counseling regarding care and life decisions, if the patient asks about these issues.
- Referring patients to support groups or psychological counseling.
- Providing information on health and available social and support services.[113]

The ALSA and the MDA are two national voluntary organizations that provide many functions and programs for individuals with ALS and their families and caregivers, including the provision of written and video educational materials, local education programs, patient and caregiver support groups, equipment loan programs, respite programs, transportation programs, advocacy programs, and ALS Awareness Programs. Patients and families can contact the ALSA and MDA for information and can explore available resources on the websites:

Amyotrophic Lateral Sclerosis Association (Operations)
27001 Agoura Road, Suite 150
Calabasas Hills, CA 91301-5104
818-880-9007
www.alsa.org
The Muscular Dystrophy Association
3300 East Sunrise Drive
Tucson, AZ 85718-3208
800-572-1717
www.mdausa.org

In addition, there are numerous international organizations whose websites provide a variety of resources, including information about ALS, information about clinical trials, evidence-based reviews, evidence-based practice guidelines, and publications about living with ALS (see Appendix 17.C for Web-based resources).

SUMMARY

Amyotrophic lateral sclerosis, the most common and devastatingly fatal motor neuron disease among adults, causes a progressive increase in the number and severity of impairments, activity limitations, and participation restrictions. Other than a small percentage of cases, etiology for the most part is unknown, and it is hypothesized that multiple mechanisms may be responsible for the disease. Although there is no cure for ALS and its course cannot be altered, it should be considered a "treatable disease." Medical management is primarily symptomatic, and a team approach to care is considered optimal. Rehabilitation management is focused on maximizing function and promoting independence to the highest level possible, and ensuring optimal quality of life throughout the course of the disease and across health care settings.

The physical therapist plays an integral role in designing and implementing therapeutic interventions for individuals with ALS that will allow them to maintain independence and function for as long as possible. The selection of interventions, grounded in evidence-based research whenever possible, is based on the stage and progression of the disease and may be restorative, compensatory, or preventative. These interventions should take into consideration the individual's goals and psychosocial factors that may affect decision making, such as the individual's acceptance of the diagnosis and the individual's social and financial resources. Because of the progressive nature of the ALS, the physical therapist must not only address the patient's current problems, but also plan for the patient's future needs.

Acknowledgments

Special thanks to Ashley Chapman, Tasha Kravchenko, and Gabi Watson for their assistance with the editorial and administrative aspects of the manuscript, and sincerest thanks to Peggy Ingels-Allred for her thoughtful and critical review of earlier editions of this chapter.

Questions for Review

1. Describe the clinical manifestations of ALS. Differentiate among impairments associated with upper and lower motor neuron pathology, bulbar pathology, and respiratory system pathology. What cognitive, rare, indirect, and composite impairments might you see in an individual with ALS?
2. What examination procedures are used to help support the diagnosis of ALS?
3. Identify and define the major classifications of ALS included in the El Escorial criteria developed by the World Federation of Neurology Research Group on Motor Neuron Diseases.
4. Describe the disease course of ALS. What factors have shown a relationship to prognosis?
5. Considering the variety of impairments associated with ALS, what factors does a physical therapist need to consider when deciding on which tests and measures should be included in a comprehensive examination?
6. Differentiate among *restorative, compensatory,* and *preventive* interventions.
7. When designing an exercise program for a patient with ALS, what factors need to be taken into consideration?
8. What information should be considered and included when developing a plan for patient and family education following the diagnosis of ALS?

CASE STUDY

The patient is a right-handed 36-year old male recently diagnosed with amyotrophic lateral sclerosis (ALS). Seven months ago, the patient experienced cramping in his left calf and a few months later noted that his left foot slapped and that he "caught his toes" and tripped while playing basketball or walking on the golf course. He also noticed painless twitching of the muscles in his right hand, forearm, and upper arm and reported difficulty fastening the snaps on his youngest son's pajamas.

PAST MEDICAL HISTORY

No significant past medical history.

SOCIAL HISTORY

The patient has been married for 10 years. He has a 3-year-old and a 9-month-old son, and his wife is pregnant with their third child. He lives in a two-story house with 4 steps up to the front door (no railing), 12 stairs between levels (bilateral railing), and 10 stairs to the basement with a railing on the right.

He stopped playing basketball and baseball because he is embarrassed about the frequent tripping, but continues to play golf on the weekend. He uses a golf cart because he is unable to keep up with his friends on the golf course. He would like to be more active.

OCCUPATION

He is a manager at a computer graphics business and reports his voice becomes hoarse on occasion after long presentations. He reports significant fatigue if he works on the computer for long periods of time or if he has to stand for long periods for presentations. He attributes this to "getting older."

DIAGNOSTIC TESTS

Electromyographic studies showed (1) low compound motor action potentials in all extremities; (2) normal sensory nerve conduction; (3) fibrillations and fasciculations in all extremities; and (4) widespread neurogenic changes in motor unit action potentials, abnormal recruitment patterns in the distal leg musculature, and mild to moderate changes in the upper extremities.

PHYSICAL EXAMINATION FINDINGS

- Observation: Marked wasting of the interossei regions bilaterally.
- Speech: No abnormalities noted.
- ROM: Within normal limits (WNL) for all joints, except the thumbs and the L ankle. Patient was only able to oppose thumbs to the third digits. He lacks 5° of L dorsiflexion.

- Strength: Bilateral LE strength graded as 5/5, except for the hip flexor group (R = 4/5; L = 4+/5) and the L ankle dorsiflexors (3–/5). Shoulder muscle strength graded as 4+/5 (R) and 4/5 (L); elbow muscle strength graded as 4/4 (R) and 4+/5 (L).
- Hand strength: R = 12 lb; L = 24 lb (handheld dynamometer).
- Pinch strength: R-tripod = 2 lb; lateral = 3 lb; L-tripod = 5 lb; lateral = 3 lb (see below for normative data on grip and pinch strength). *Note:* Tripod pinch is a component of manual dexterity that involves opposition of the thumb and the first two fingers as a "tripod." Pinch strength measures are obtained using a pinch gauge.
- Manual coordination: Purdue Pegboard Testing, R—6 peg holes in 30 seconds; L—3 peg holes in 30 seconds.
- Tone: 1 for both UEs and 1+ for both LEs (Modified Ashworth spasticity scores).
- Reflexes: A clonic jaw reflex is evident; hyperreflexia in both UEs; hyporeflexia in both LEs; positive Babinski reflex bilaterally.
- Gait: Independent of assistive devices; positive for L foot drop and hip hiking; 15-ft walk test = 3.6 seconds.
- Balance (standing): Unilateral stance/eyes open, R = 25 seconds; L = 6 seconds.
- Respiratory: Forced vital capacity (FVC) and maximum inspiratory pressure (MIP) are within normal limits.
- Functional status: The patient rated himself at 90% on the Schwab and England Rating Scale (see Appendix 17.A). ALSFRS-R scores (see Appendix 17.B):

ALSFRS-R Scores

Item	Score
Speech	4
Salivation	3
Swallowing	3
Handwriting (pre-ALS dominant hand)	3
Cutting food and handling utensils (patients without gastrostomy)	3
Dressing and hygiene	3
Turning in bed; adjusting bed clothes	4
Walking	3
Climbing stairs	3
Dyspnea	3
Orthopnea	4
Respiratory insufficiency	4

Grip and Pinch Strength Values (Pounds) for Men 35 to 39 (n = 25)

	Hand	Mean	SD	SE	Low	High
Grip	R	119.7	24.0	4.8	76	176
	L	112.9	21.7	4.4	73	157
Tip	R	18.0	3.6	.73	12	27
	L	17.7	3.8	.76	10	24
Palmar	R	26.1	3.2	.65	21	32
	L	25.6	3.9	.77	18	32
Lateral (Key)	R	26.2	4.1	.83	19	36
	L	25.9	5.4	1.17	14	40

GUIDING QUESTIONS

1. What El Escorial diagnostic criteria would you anticipate documented in the patient's medical record?
2. Identify the patient's problems in terms of direct, indirect, and composite impairments.
3. What impact do the impairments have on the patient's ability to function (i.e., activity limitations)?
4. What additional tests and measurements should be conducted; what consultations should be recommended?
5. At present, what are the key areas of patient education that should be addressed initially?
6. Identify the general elements of a physical therapy plan of care for the patient.

Schwab and England Activities of Daily Living Scale

appendix 17.A

100% =	Completely independent; able to do all chores without slowness, difficulty, or impairment; essentially normal; unaware of any difficulty
90% =	Completely independent; able to do all chores with some degree of slowness, difficulty, and impairment; may take twice as long as usual; beginning to be aware of difficulty
80% =	Completely independent in most chores; takes twice as long as normal; conscious of difficulty and slowness
70% =	Not completely independent; more difficulty with some chores; takes three to four times as long as normal in some; must spend a large part of the day with some chores
60% =	Some dependency; can do most chores, but exceedingly slowly and with considerable effort and errors; some chores impossible
50% =	More dependent; needs help with half the chores, slower, and so forth; difficulty with everything
40% =	Very dependent; can assist with all chores but does few alone
30% =	With effort, now and then does a few chores alone or begins alone; much help needed
20% =	Does nothing alone; can be a slight help with some chores; severe invalid
10% =	Totally dependent and helpless; complete invalid
0% =	Vegetative functions such as swallowing, bladder, and bowels are not functioning; bedridden

From Schwab and England,[134] with permission.

appendix
17.B Amyotrophic Lateral Sclerosis Functional Rating Scale—Revised*

1. Speech

4 Normal speech processes.
3 Detectable speech disturbance.
2 Intelligible with repeating.
1 Speech combined with nonvocal communication.
0 Loss of useful speech.

2. Salivation

4 Normal.
3 Slight but definite excess of saliva in mouth; may have nighttime drooling.
2 Moderately excessive saliva; may have minimal drooling.
1 Marked excess of saliva with some drooling.
0 Marked drooling; requires constant tissue or handkerchief.

3. Swallowing

4 Normal eating habits.
3 Early eating problems—occasional choking.
2 Dietary consistency changes.
1 Needs supplemental tube feeding.
0 NPO (exclusively parenteral or enteral feeding).

4. Handwriting

4 Normal.
3 Slow or sloppy; all words are legible.
2 Not all words are legible.
1 Able to grip pen but unable to write.
0 Unable to grip pen.

5a. Cutting Food and Handling Utensils (Patients without Gastrostomy)

4 Normal.
3 Somewhat slow and clumsy, but no help needed.
2 Can cut most foods, although clumsy and slow; some help needed.
1 Food must be cut by someone, but can still feed slowly.
0 Needs to be fed.

OR

5b. Cutting Food and Handling Utensils (Alternate Scale for Patients with Gastrostomy)

4 Normal.
3 Clumsy but able to perform all manipulations independently.
2 Some help needed with closures and fasteners.
1 Provides minimal assistance to caregiver.
0 Unable to perform any aspect of task.

6. Dressing and Hygiene

4 Normal function.
3 Independent and complete self-care with effort or decreased efficiency.
2 Intermittent assistance or substitute methods.
1 Needs attendant for self.
0 Total dependence.

7. Turning in Bed and Adjusting Bed Clothes

4 Normal.
3 Somewhat slow and clumsy, but no help needed.
2 Can turn alone or adjust sheets, but with great difficulty.
1 Can initiate, but not turn or adjust sheets alone.
0 Helpless.

8. Walking

4 Normal.
3 Early ambulation difficulties.
2 Walks with assistance.
1 Nonambulatory functional movement only.
0 No purposeful leg movement.

9. Climbing Stairs

4 Normal.
3 Slow.
2 Mild unsteadiness or fatigue.
1 Needs assistance.
0 Cannot do.

10. Dyspnea

4 None.
3 Occurs when walking.
2 Occurs with one or more of the following: eating, bathing, dressing (ADL).
1 Occurs at rest, difficulty breathing when either sitting or lying.
0 Significant difficulty, considering using mechanical respiratory support.

11. Orthopnea

4 None.
3 Some difficulty sleeping at night due to shortness of breath, does not routinely use more than two pillows.
2 Needs extra pillows in order to sleep (more than two).
1 Can only sleep sitting up.
0 Unable to sleep.

[a] Original ALSFRS consists of items 1 through 9 and the original item 10 below:

10. Breathing

4 Normal.
3 Shortness of breath with minimal exertion (e.g., walking, talking).
2 Shortness of breath at rest.
1 Intermittent (e.g., nocturnal) ventilatory assistance.
0 Ventilator dependent.

BiPAP = bidirectional positive airway pressure; NPO = *non per os*, nothing by mouth.

12. Respiratory Insufficiency

4 None.
3 Intermittent use of BiPAP.
2 Continuous use of BiPAP during the night.
1 Continuous use of BiPAP during the night and day.
0 Invasive mechanical ventilation by intubation or tracheostomy.

From Cedarbaum, JM, et al,[137] with permission.

Parkinson's Disease

Susan B. O'Sullivan, PT, EdD
Edward W. Bezkor, PT, DPT, OCS, MTC

Chapter 18

LEARNING OBJECTIVES

1. Describe the etiology, pathophysiology, clinical manifestations, and sequelae of Parkinson's disease.
2. Identify and describe the examination procedures used to evaluate patients with Parkinson's disease to establish a diagnosis, prognosis, and plan of care.
3. Describe the role of the physical therapist in assisting a patient with Parkinson's disease in terms of direct interventions and patient and family/caregiver-related instruction to maximize function.
4. Describe appropriate elements of the exercise prescription for patients with Parkinson's disease.
5. Identify the neuropsychological effects and social impact of Parkinson's disease and describe appropriate interventions to maximize quality of life.
6. Analyze and interpret patient data, formulate realistic goals and outcomes, and develop a plan of care when presented with a clinical case study.

SUMMARY *844*

Parkinson's disease (PD) is a progressive disorder of the central nervous system (CNS) with both motor and nonmotor symptoms. Motor symptoms include the *cardinal features* of **rigidity**, **bradykinesia**, **tremor**, and, in later stages, postural instability. Nonmotor symptoms may precede the onset of motor symptoms by years. Early symptoms can include loss of sense of smell, constipation, rapid eye movement (REM) sleep behavior disorder, mood disorders, and orthostatic hypotension. Other nonmotor symptoms include altered bladder function, excessive saliva, integumentary changes, difficulty speaking and swallowing, and cognitive problems (slowed thinking, confusion, and in some cases dementia). Onset is insidious with a slow rate of progression. Disruptions in daily functions, roles, and activities, as well as depression, are common in individuals with PD.

INCIDENCE

PD is a common disease that affects an estimated 1 million Americans and an estimated 7 to 10 million people worldwide. More than 2% of people older than 65 years of age have PD, second only to Alzheimer's disease among neurodegenerative disorders. The prevalence of the disease is expected to increase substantially in the coming years due to the aging of the population. The average age of onset is 50 to 60 years. Only 4% to 10% of patients are diagnosed with early-onset PD (less than

40 years of age). Young-onset PD is classified as beginning between 21 and 40 years of age, and juvenile-onset PD affects individuals less than 21 years of age. Men are affected 1.2 to 1.5 times more frequently than women.[1,2]

ETIOLOGY

The term **parkinsonism** is a generic term used to describe a group of disorders with primary disturbances in the dopamine systems of basal ganglia (BG). Both genetic and environmental influences have been identified. Parkinson's disease, or idiopathic parkinsonism, is the most common form, affecting approximately 78% of patients. *Secondary parkinsonism* results from a number of different identifiable causes, including viruses, toxins, drugs, tumors, and so forth (Box 18.1). The term *parkinsonism-plus syndromes* refers to those conditions that mimic PD in some respects, but the symptoms are caused by other neurodegenerative disorders.[3]

Parkinson's Disease

Parkinson's disease was first described as "the shaking palsy" by James Parkinson in 1817[4] and refers to those cases where the etiology is idiopathic (unknown) or genetically determined. Two distinct clinical subgroups have been identified. One group includes individuals whose dominant symptoms include postural instability and gait disturbances (*postural instability gait disturbed [PIGD]*). Another group includes individuals with tremor as the main feature (*tremor predominant*). Patients who are tremor predominant typically demonstrate few problems with bradykinesia or postural instability.[3]

Genetic forms of PD represent less than 10% of cases overall. In a small number of families, several gene mutations have been identified (e.g., PARK1, PINK1, LRRK2, DJ-1, and glucocerebrosidase, among others).[1] Genes have been grouped into two categories: (1) causal genes, which actually produce the disease; and (2) associated genes that do not cause PD but increase the risk of developing it.

Secondary Parkinsonism

Postencephalitic Parkinsonism

The influenza epidemics of encephalitis lethargica that occurred from 1917 to 1926 affected large numbers of individuals. The onset of parkinsonian symptoms typically occurred after many years, giving rise to the theory that a slow virus infected the brain. In the absence of a recent outbreak, this type of parkinsonism is no longer seen. Moving case histories are portrayed in the book *Awakenings* by Oliver Sacks.[5]

Toxic Parkinsonism

Parkinsonian symptoms occur in individuals exposed to certain environmental toxins, including pesticides (e.g., permethrin, beta-HCH, paraquat, maneb, Agent Orange) and industrial chemicals (e.g., manganese, carbon disulfide, carbon monoxide, cyanide, methanol). The most common of these toxins is manganese, which represents a serious occupational hazard to many miners from prolonged exposure.[6,7] Severe and permanent parkinsonism has been inadvertently produced in individuals who injected a synthetic heroin containing the chemical MPTP (1-methyl-4-phenyl-1,2,3,6- tetra/hydropyridine).[8] It is important to note that simple exposure is never enough to cause the disease.

Box 18.1 Classification of Parkinsonism

Idiopathic Parkinson's Disease

Late-onset (>40 years; generally sporadic)
Early-onset (<40 years; often familial)
- Young-onset (>21 years)
- Juvenile (<21 years)

Parkinsonism Due to Identifiable Causes

Virus (e.g., encephalitis lethargica)
Toxins (e.g., carbon monoxide, manganese, methylphenyltetrahydropyridine [MPTP])
Drugs (e.g., phenothiazines, reserpine, butyrophenones, metoclopramide)
Vascular disease (multi-infarct)
Tumors of basal ganglia
Normal pressure hydrocephalus
Hemiparkinsonism, hemiatrophy
Metabolic
- Wilson's disease
- Hepatocerebral degeneration
- Hallervorden-Spatz disease
- Hypoparathyroidism

Parkinsonism in Other Neurodegenerative Disorders

Progressive supranuclear palsy
Cortical–basal ganglionic degeneration
Disorders with cerebellar/autonomic/pyramidal manifestation:
- Multiple-system atrophy
- Striatonigral degeneration
- Shy-Drager syndrome
- Olivopontocerebellar atrophy
- Machado-Joseph disease

Disorders with prominent and often early dementia:
- Diffuse cortical Lewy body disease
- Alzheimer's disease with parkinsonism

Parkinsonism–dementia–ALS complex of Guam
- Pallidopontonigral degeneration/disinhibition–dementia–parkinsonism–amyotrophy complex

From Pal, P, et al: Cardinal features of early Parkinson's disease. In Factor, S, and Weiner, W (eds): Parkinson's Disease—Diagnosis and Clinical Management. Demos Medical Publishing, New York, 2002, p 42, with permission.

Drug-Induced Parkinsonism (DIP)

A variety of drugs can produce extrapyramidal dysfunction that mimics the signs of PD. These drugs are thought to interfere with dopaminergic mechanisms either presynaptically or postsynaptically. They include (1) *neuroleptic drugs* such as chlorpromazine (Thorazine), haloperidol (Haldol), thioridazine (Mellaril), and thiothixene (Navane); (2) *antidepressant drugs* such as amitriptyline (Triavil), amoxapine (Asendin), and trazodone (Desyrel); and (3) *antihypertensive drugs* such as methyldopa (Aldomet) and reserpine. High doses of these medications are particularly problematic in the elderly. Withdrawal of these agents usually reverses the symptoms within a few weeks, although in some cases the effects can persist and may be related to subclinical PD.[9]

Parkinsonism can be caused in rare cases by metabolic conditions, including disorders of calcium metabolism that result in BG calcification. These include hypothyroidism, hyperparathyroidism, hypoparathyroidism, and Wilson's disease.[9]

Parkinson-Plus Syndromes

A group of neurodegenerative diseases can affect the substantia nigra and produce parkinsonian symptoms along with other neurological signs. These diseases include striatonigral degeneration (SND), Shy-Drager syndrome, progressive supranuclear palsy (PSPO), olivopontocerebellar atrophy (OPCA), and cortical–basal ganglionic degeneration (CBGD). In addition, parkinsonian symptoms can be exhibited in patients with multi-infarct vascular disease, Alzheimer's disease, diffuse Lewy body disease (DLBD), normal pressure hydrocephalus (NPH), Creutzfeldt-Jakob disease (CJD), Wilson's disease (WD), and juvenile Huntington's disease. Many of these conditions are rare and affect relatively small numbers of individuals. Early in their course, these diseases may present with rigidity and bradykinesia indistinguishable from PD. However, other diagnostic symptoms eventually appear (e.g., cognitive impairment in Alzheimer's disease). Another diagnostic feature is that Parkinson-plus syndromes typically do not show measurable improvement from the administration of anti-Parkinson medications such as levodopa (L-dopa) therapy (termed the *apomorphine test*). [9]

PATHOPHYSIOLOGY

The BG is a network of subcortical nuclei consisting of the *caudate nucleus*, the *putamen*, the *globus pallidus*, and the *subthalamic nucleus* along with the *substantia nigra.* The caudate and the putamen together are called the *striatum* (Fig. 18.1). The BG engages in a number of parallel circuits or loops, only a few of which are motor. The *direct motor loop* through the BG consists of signals transmitted from the cortex to putamen to globus pallidus, to ventrolateral (VL) nucleus of the thalamus, and back to cortex (supplementary motor area [SMA]) (Fig. 18.2). This VL-SMA connection is excitatory and facilitates discharge of cells in the SMA. The BG thus serves to activate the cortex via a positive-feedback loop and assists in the initiation of voluntary movement. Inhibition of the thalamus by the BG is thought to underlie the hypokinesia seen in PD. An *indirect loop* through the BG involves the subthalamic nucleus, the globus pallidus interna, and substantia nigra pars reticulata to the superior colliculus and midbrain tegmentum (Fig. 18.3). This indirect loop serves to decrease thalamocortical activation. The BG projection to the superior colliculus assists in regulation of saccadic eye movements. The BG projection to the reticular formation assists in the regulation of trunk and limb musculature (via extrapyramidal pathways), sleep and wakefulness, and arousal. Other circuits in the BG are involved with memory and cognitive functions.[10]

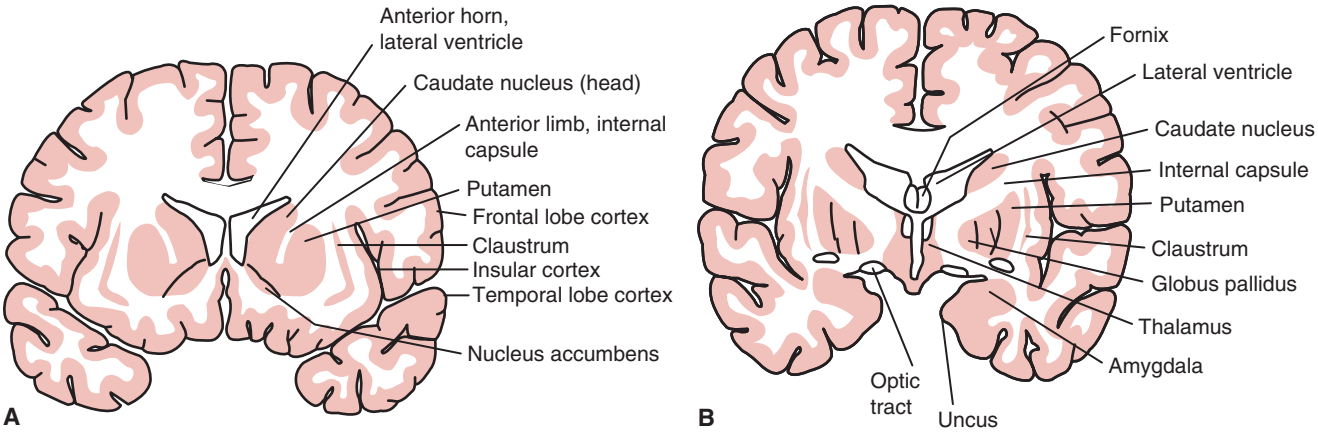

Figure 18.1 The major structures of the basal ganglia. **(A)** Coronal section through the rostral part of the frontal lobe showing the relation of the caudate nucleus, putamen, and nucleus accumbens to the surrounding telencephalic structures. **(B)** Coronal section through the caudal part of the front lobe showing the location of the lentiform nucleus later to, and the body of the caudate nucleus dorsal to, the diencephalon.

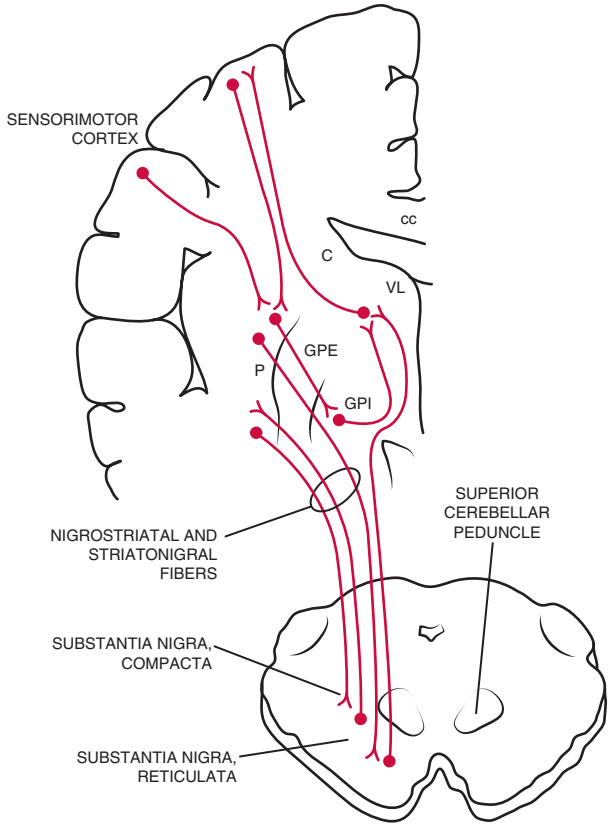

Figure 18.2 The direct loop through the putamen and the connections of the striatum with the substantia nigra pars compacta. The striatonigral fibers represented in this diagram arise in the putamen. However, most striatonigral fibers arise from the caudate. C = caudate nucleus; cc = corpus callosum; GPe = globus pallidus pars externa; GPi = glogus pallidus pars interna; P = putamen; VL = ventral lateral nucleus of the thalamus. *(From Gilman, S and Newman S, 2003,[10, p. 151] with permission.)*

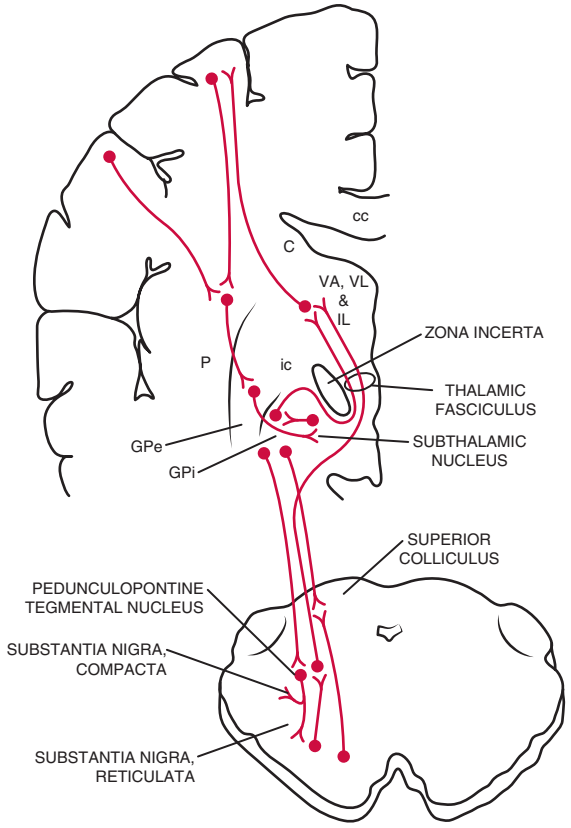

Figure 18.3 The indirect loop through the subthalamic nucleus; also represented are the efferents from the globus pallidus interna and substantia nigra pars reticulata to the superior colliculus and midbrain tegmentum. C = caudate nucleus; GPe = globus pallidus pars externa; GPi = globus pallidus pars interna; ic = internal capsule; IL = intralaminar nuclei of the thalamus; P = putamen; VA = ventral anterior nucleus of the thalamus; VL = ventral lateral nucleus of the thalamus. *(From Gilman and Newman, 2003,[10, p. 152] with permission.)*

Parkinson's disease is defined by (1) degeneration of dopaminergic neurons in the BG in the pars compactus of the substantia nigra that produce *dopamine* and (2) as the disease progresses and neurons degenerate, the presence of cytoplasmic inclusion bodies, called *Lewy bodies*. Substantial neurodegeneration occurs in PD before the onset of motor symptoms with clinical signs emerging at 30% to 60% degeneration of neurons. Loss of the melanin-containing neurons produces characteristic changes in depigmentation in the substantia nigra with a characteristic pallor.[11]

STAGES OF PARKINSON'S DISEASE

Postmortem studies by Braak and colleagues have yielded evidence supporting the view that PD is a widely dispersed neurodegenerative disease that demonstrates a progression through different stages. Early on (*stage 1*) lesions are found in the medulla oblongata (dorsal IX/X nucleus or intermediate reticular zone). In *stage 2,* pathology is expanded to involve lesions of the caudal raphe nuclei, the gigantocellular reticular nucleus, and coeruleus-subcoeruleus complex. In *stage 3,* involvement of the nigrostriatal system is apparent (pars compacta of the substantia nigra). In *stage 4,* lesions are also found in the cortex (temporal mesocortex and allocortex). In *stage 5,* pathology is extended to involve the sensory association areas of the neocortex and prefrontal neocortex. In *stage 6,* pathology is extended to involve the sensory association areas of the neocortex and premotor areas.[12-14]

CLINICAL PRESENTATION

Primary Motor Symptoms

Rigidity

Rigidity is one of the clinical hallmarks of PD and is defined as increased resistance to passive motion. Patients frequently complain of "heaviness" and "stiffness" of

their limbs. It is felt uniformly in both agonist and antagonist muscles and in movements in both directions. Spinal stretch reflexes are normal. Rigidity is fairly constant regardless of the task, amplitude, or speed of movement. Two types are identified: cogwheel or lead pipe. **Cogwheel rigidity** is a jerky, ratchet-like resistance to passive movement as muscles alternately tense and relax. It occurs when tremor coexists with rigidity. **Lead pipe rigidity** is a sustained resistance to passive movement, with no fluctuations. Rigidity is often asymmetrical, especially in the early stages of PD. It typically affects proximal muscles first, especially the shoulders and neck, and it progresses to involve muscles of the face and extremities. Rigidity may initially affect the left or right side, eventually spreading to involve the whole body. As the disease progresses, rigidity becomes more severe. Rigidity decreases the ability to move easily. For example, loss of bed mobility or lack of reciprocal arm swing during gait is often related to the degree of truncal rigidity. Active movement, mental concentration, or emotional stress may all increase rigidity. Prolonged rigidity results in decreased range of motion (ROM) and serious secondary complications of contracture and postural deformity. Rigidity also has a direct impact on increasing resting energy expenditure and fatigue levels.[9,10]

Bradykinesia

Bradykinesia refers to slowness of movement and is one of the cardinal features of PD. Weakness, tremor, and rigidity may contribute to bradykinesia but do not fully explain it. The principle deficit is the result of insufficient recruitment of muscle force during initiation of movement. Patients underscale movement commands in internally generated movements. The introduction of external cues (e.g., vision, sound) can partially ameliorate this and is used in treatment to guide movement. It is one of the most disabling symptoms of PD, with prolonged movement and reaction times resulting in increased time on task and dependence in daily activities. Slowness of thought, **bradyphrenia**, can contribute to bradykinesia.[15]

Akinesia refers to a poverty of spontaneous movement. For example, the patient with PD demonstrates **hypomimia** or masked facial expression, with significant social consequences. The absence of associated movements (e.g., arm swing during walking) or **freezing** (e.g., sudden stops in movement as in *freezing of gait [FOG]*) are other examples. Freezing episodes can be triggered by confrontation of competing stimuli. For example, the patient slows and stops walking (FOG) when exposed to a narrowed space or an obstacle. Freezing episodes are typically short-lived and usually can be overcome by attentional strategies or "behavioral tricks" using external cues (e.g., dropping a tissue initiates a stepping response). Stress can exacerbate freezing episodes. In advanced PD, freezing episodes can severely limit function and increase risk of falling. Akinesia can be influenced by the degree of rigidity, as well as stage of disease, fluctuations in drug action, and disturbances in attention and depression. [9]

Hypokinesia refers to slowed and reduced movements and can also be seen in PD. For example, patients with moderate or severe PD typically present with handwriting that may start out strong but becomes smaller and smaller as writing proceeds (**micrographia**). During walking, rotational movements of the trunk with arm swing may also start out strong and decrease over time.

Tremor

Tremor, a third cardinal feature of PD, involves involuntary shaking or oscillating movement of a part or parts of the body resulting from contractions of opposing muscles. In the early stages of the disease, about 70% of patients experience a slight tremor of the hand or foot on one side of the body, or less commonly in the jaw or tongue. It tends to be mild and occurs for only short periods. The tremor is known as a *resting tremor* because it is present at rest, suppressed briefly by voluntary movement, and disappears with sleep. Tremor in the lower limbs is most apparent while the patient is supine. Tremor of the head and trunk, **postural tremor**, can be seen when muscles are used to maintain an upright posture against gravity. *Action tremor*, tremor that continues with movement, can occur in patients with advanced disease. Tremor tends to be less severe when the patient is relaxed and unoccupied. It is aggravated by emotional stress or excitement. In later stages tremor can become severe, spread to the other side, and interfere with activities of daily living (ADL). Fluctuations in frequency and intensity are common.[9]

Postural Instability

Individuals with PD demonstrate abnormalities of posture and balance, resulting in postural instability. These changes are rare in the early years (i.e., the first 5 years after diagnosis). As the disease progresses, a number of problems become evident across a broad spectrum of movement control. Patients demonstrate abnormal and inflexible postural responses controlling their center of mass (COM) within their base of support (BOS). Narrowing of the BOS (tandem stance or single-limb stance) or competing attentional demands (divided attention situations) increases postural instability. Patients also experience increased difficulty during dynamic destabilizing activities such as self-initiated movements (e.g., functional reach, walking, turning) and perform poorly under conditions of perturbed balance.[16] The response to instability is an abnormal pattern of coactivation, resulting in a rigid body and an inability to utilize normal postural synergies to recover balance.[17,18] Patients also demonstrate difficulty in regulating feed-forward, anticipatory adjustments of postural muscles during voluntary movements. Sensorimotor integration is impaired as evidenced by difficulty in adapting movement strategies to changing sensory

conditions.[17] Visuospatial impairment has been identified in patients with advanced PD and correlates with lower scores in mobility.[19] Some patients are unable to perceive the upright or vertical position, which may indicate an abnormality in processing of vestibular, visual, and proprioceptive information contributing to balance. Contributing factors to postural instability include rigidity, decreased muscle torque production and weakness, loss of available ROM particularly of trunk motions, and axial rigidity. Medication side effects (e.g., postural hypotension and dyskinesias) also contribute.

Progressive development of postural deformity occurs. Weakness of antigravity muscles contributes to the adoption of a flexed, stooped posture with increased flexion of the neck, trunk, hips, and knees.[20] This results in a significant change in the center-of-alignment position, positioning the individual at the forward limits of stability. In the lower extremities (LEs), *contractures* develop in hip and knee flexors, hip rotators and adductors, and plantarflexors. In the spine, dorsal spine and neck flexors are involved, and in the upper extremities (UEs), shoulder adductors and internal rotators and elbow flexors are involved. Function becomes progressively more limited by these musculoskeletal constraints. Older individuals with reduced activity levels and poor diet are likely to develop *osteoporosis.*

Frequent falls and fall injury are the result of progressive disease. Falls are initially absent early in the disease, then become increasingly prevalent during the middle portion of disease progression, and as the patient becomes progressively immobile, disappear during late disease. About 70% of patients with PD report experiencing falls within the past year and 50% report recurrent falls. The rate of fall injury is about 40%. Although most injuries are not severe, some lead to hospitalization. Within 10 years of diagnosis, approximately 25% of patients will have developed a hip fracture. Disease severity, postural instability, and gait impairment including freezing are clearly linked to increased risk for falls.[21] Other risk factors include dementia, depression, postural hypotension, and involuntary movements associated with long-term use of anti-parkinsonian medication (dyskinesias).[22] Falls can lead to "fear of falling" with increasing levels of immobility and dependency with a deteriorating quality of life.[23]

Secondary Motor Symptoms

Muscle Performance

A reduction in strength is evident in patients with PD. Torque production is decreased at all speeds resulting in activity limitations and muscle weakness.[24-26] Changes in strength may be dopamine related as patients on dopamine replacement ("on" state) demonstrate increases in strength when compared to testing the same muscles during an "off" state.[27] Electromyography (EMG) studies reveal that motor unit recruitment is delayed with under-recruitment of muscles. Once initiated, contraction is characterized by multiple bursts and *asynchronization*, that is, pauses and an inability to smoothly increase firing rate as contraction continues.[28,29] These difficulties are compounded during the production of complex movements. As the disease progresses, disuse weakness evolves from inactivity and increases movement difficulties.

In patients with PD, *fatigue* is among the most common symptoms reported. The patient has difficulty in sustaining activity and experiences increasing weakness and lethargy as the day progresses. Repetitive motor acts may start out strong but decrease in strength and amplitude as the activity progresses. Performance decreases dramatically with great physical effort or stress. Rest or sleep may restore mobility. When L-dopa therapy is initiated, the patient may notice a dramatic improvement initially and feel significantly less fatigued. In long-standing disease and drug therapy, fatigue typically reappears. A common perception among patients is an increased sense of effort associated with movement that is manifested by difficulty activating and sustaining responses.

Motor Function

The striatum of the BG (caudate nucleus, putamen, and nucleus accumbens) receive input from all cortical areas and project throughout the thalamus to frontal lobe areas (prefrontal, premotor, and supplementary motor areas) concerned with motor planning. In PD, motor planning deficits are evident, involving a loss regulatory control of both automatic and voluntary movement responses directed through the pyramidal system.[30] Paucity of movement occurs with less accurate movements overall. This deficit in accuracy becomes more pronounced as the patient attempts to increase the speed of movement (**speed-accuracy trade-off**). This is a commonly observed problem in the elderly in general. Patients experience difficulty performing complex, sequential, or simultaneous movements (*dual-task control*). The difficulties combining tasks or shifting attentional sets from one to another can also be seen with cognitive tasks or when combining cognitive and motor tasks. Movement preparation (i.e., the when, where, and how to initiate movement) is significantly prolonged (a finding also seen with advancing age). This *start hesitation* is especially evident as the disease progresses.[31] For example, the patient is slow and hesitant in initiating movement during a transfer sequence.

Motor learning deficits are seen in patients with PD but are not universal. Learning of a new motor skills and fine-tuning of skills are intact at the early stage of PD for non-demented, medicated individuals. Retention tests may yield poorer performance but this is most likely due to problems in motor initiation than in actual retention. Deficits in motor skill learning have been demonstrated in advanced disease and for complex and sequential tasks. Thus, the processing requirements of the procedural task are critical in determining the degree of expected learning.

Learning is impaired with random presentations of stimulus conditions (random practice order) whereas blocked practice order reduces learning difficulty. Thus context interference degrades learning in patients with PD. Learning deficits can be expected to be severe if multiple motor programs are required either simultaneously or sequentially (i.e., switching among tasks). For example, the patient freezes up when asked to carry out another motor task while walking (*dual tasking*). Compounding variables that degrade learning include the severity of disease, dementia, and visual–perceptual deficits. Differences in learning can also be expected based on medication levels as motor learning is degraded when patients are in the "off" state of medication.[31-35]

Gait

Approximately 13% to 33% of patients present with postural instability and gait disturbances as their initial motor symptom and comprise a PIGD group. Gait disturbances are also a common feature of late-onset or advanced PD.[36] The patient with PD demonstrates a number of significant gait changes resulting from impoverished movement. There is a reduction in arm swing with asymmetry. An abnormal stooped posture contributes to development of a **festinating gait** pattern, characterized by a progressive increase in speed with a shortening of stride. Thus, the patient takes multiple short steps to catch up with his or her COM to avoid falling, and may eventually break into a run or trot. Gait can be *anteropulsive* (a forward festinating gait) or less commonly *retropulsive* (a backward festinating gait). Some patients are able to stop only when they come in contact with an object or a wall. Patients who are toe-walkers owing to plantarflexion contractures exhibit an additional postural instability from narrowing of their BOS. Turning or changing direction is particularly difficult and typically accomplished by taking multiple small steps. Problems with controlling posture and balance limit independence, community ambulation, and safety.[37-41] In early disease FOG is generally short in duration and rarely leads to falls. With disease progression FOG becomes more common and disabling, often leading to falls. Patients who are in the "off" state experience increased FOG and deterioration in gait performance whereas gait patterns improve when peak medication prevails.[42] Most patients with mild gait deficits can compensate at least partially using external cues and attentional strategies.

Nonmotor Symptoms

Sensory Symptoms

Patients with PD do not suffer from primary sensory loss. However, as many as 50% experience paresthesias and pain, including sensations of numbness, tingling, cold, aching pain, and burning. Pain may be due to the disease's effect on central nociception. Symptoms are typically intermittent, and vary in intensity and location. Some patients report their pain is linked to the motor fluctuations experienced during L-dopa therapy (e.g., pain is more intense in an "off" state). Pain may also be increased in patients experiencing depression.[43] It is also important to remember that some of the discomfort and pain can result from **postural stress syndrome** secondary to faulty posture, ligamentous strain, lack of movement, and muscle rigidity. For example, back pain may accompany a prolonged, stooped, kyphotic posture.

Proprioceptive regulation of voluntary movement may also be impaired. Patients with PD perform significantly worse than control subjects on tests of kinesthesia and proprioceptive position sense. Without visual guidance, patients demonstrate increased difficulty in accurately perceiving the extent of movement, consistently underscaling their movements. Deficits in visuospatial skills may also occur. Patients demonstrate significantly more errors than normal on visual perception tasks involving spatial organization.[44,45]

Olfactory dysfunction is common, with some studies showing up to 100% of patients affected. Most patients with PD report a decline or loss of sense of smell (**anosmia**), often years before motor symptoms develop. Loss of smell therefore has important implications for diagnosis of early disease. It also increases the difficulty individuals have in maintaining a healthy diet and adequate nutrition.[46]

Conventional drugs (e.g., anticholinergic drugs) used in PD can cause visual disturbances (e.g., blurred vision and sensitivity to light [photophobia]). These drugs can also worsen the normal visual changes associated with aging (presbyopia). Conjugate gaze and saccadic eye movements may also be impaired. Eye pursuit movements may have a jerky, cogwheeling quality. Decreased blinking can produce bloodshot, irritated eyes that burn and itch.

Dysphagia

Dysphagia, impaired swallowing, is present in as many as 95% of patients and is the result of rigidity, reduced mobility, and restricted range of movement.[47] It is often an early symptom of the disease though it is present in all stages. Individuals with PD experience problems in all four phases of swallowing: oral preparatory, oral, pharyngeal, and esophageal. Thus, the patient demonstrates abnormal tongue control and problems with chewing, bolus formation, delayed swallow response, and peristalsis. Dysphagia can lead to choking or aspiration pneumonia and impaired nutrition with significant weight loss. Nutritional inadequacy can contribute to the fatigue and exhaustion typically experienced by patients with PD.[48] Patients also typically experience excessive drooling (**sialorrhea**) as a result of increased saliva production and decreased spontaneous swallowing. Drooling is particularly problematic while sleeping or initiating speech and in advanced cases increases the risk

of aspiration. Excessive drooling has important negative social implications.

Speech Disorders

Speech is impaired in 75% to 89% of patients and is the result of primary symptoms of PD (rigidity, bradykinesia, hypokinesia, and tremor).[47] Patients with PD experience **hypokinetic dysarthria**, which is characterized by decreased voice volume, monotone/monopitch speech, imprecise or distorted articulation, and uncontrolled speech rate. Vocal quality is degraded with speech described as hoarse, breathy, and harsh. In addition, patients experience timing difficulty of vocal onsets and offsets. Reduced mobility, restricted range, and uncontrolled rate of movement of muscles controlling respiration, phonation, resonation, and articulation are present. Reduced vital capacity results in reduced air expended during phonation. In advanced cases, the patient may speak in whispers or not at all, demonstrating **mutism**. Sensory problems may also contribute to speech difficulties. Patients who are instructed to upscale their speech sounds to produce increased volume consistently describe their speech as "too loud." Speech difficulties contribute to social isolation and impaired activity participation.[47,48]

Cognitive Dysfunction

Impairments in cognitive function can be mild (e.g., mildly impaired memory) or severe (e.g., psychosis). PD dementia occurs in approximately 20% to 40% of the patients. Older patients appear to be at greatest risk for dementia, with reported rates 4.4 times higher for individuals 80 years of age or older.[49] Dementia is associated with increased mortality rates. Coexisting Alzheimer's disease and multi-infarct dementia secondary to atherosclerotic disease are also common in the elderly and may be contributory factors in some patients. Dementia associated with PD is characterized by loss of executive functions (planning, reasoning, abstract thinking, judgment, and so forth) and changes in visuospatial skills, memory, and verbal fluency. **Bradyphrenia**, slowed thinking, is seen in patients with PD and may be one of the early nonspecific features of the disease. Cognitive performance is degraded in the "off" state. Hallucinations, delusions, and psychosis are common complications owing to L-dopa toxicity.

Depression and Anxiety

Depression is common in patients with PD. Major depression is reported to occur in approximately 40% of patients.[50] A significant number of patients develop depression before or just after onset of motor symptoms, suggesting an endogenous cause that may be related to underlying deficiencies of dopamine, serotonin, and norepinephrine. Patients demonstrate a variety of symptoms, including feelings of guilt, hopelessness, and worthlessness; loss of energy; poor concentration; deficits in short-term memory; loss of ambition or enthusiasm; and disturbances in appetite and sleep. Suicidal thoughts may also be present. **Hypomimia**, a reduction in facial expressiveness, can give the appearance of depression. Patients can also demonstrate **dysthymic disorder** characterized by chronic depression and dysphoric mood, resulting in poor appetite or overeating, insomnia or hypersomnia, low energy, low self-esteem, and poor concentration.

Anxiety is a common symptom in PD, occurring in up to 38% of patients. Clinically patients may present with symptoms of a panic attack (e.g., palpitations, sweating, trembling, shortness of breath, and so forth) as well as social phobia (social withdrawal), agoraphobia, obsessive-compulsive disorder, or panic disorder. Anxiety symptoms may not be simply related to the psychological or social difficulties patients experience, but due to specific neurobiological processes associated with the disease. Patients who are in the "off" medication state experience significant worsening of depression and anxiety.[51]

Autonomic Dysfunction

Autonomic dysfunction occurs with PD and is a direct manifestation of the disease, as evidenced by the presence of Lewy bodies found in the autonomic nervous system.[52] Thermoregulatory dysfunction includes excessive sweating and abnormal or uncomfortable sensations of warmth and coldness. Patients in the "off" state experience impaired peripheral vasodilation with difficulty dissipating body heat. *Seborrhea* (increased oil secretion of the sebaceous glands of the skin) and *seborrheic dermatitis* (oily, chafing, and reddened skin) are also common. Patients with PD exhibit abnormally slow pupillary responses to light and pain and reduced overall response to changes in light.[53]

Gastrointestinal disorders include poor motility, changes in appetite, inadequate hydration, sialorrhea, and weight loss. *Constipation* is a common problem for most patients and typically occurs early in PD. *Urinary incontinence* occurs with associated symptoms of urinary frequency, urgency, and nocturia. Many of these problems occur in the aging population in general and in men with benign prostatic hypertrophy. *Erectile dysfunction* is often present in males, including impotence and reduced rates of sexual activity.[53]

Early and progressive sympathetic denervation of the heart occurs in the majority of patients with PD. This results in diminished heart function, which may be a contributory factor to the fatigue that most patients experience.[53] Patients with advanced PD exhibit altered heart rate (HR) and blood pressure (BP) during exercise with decreased exercise efficiency.[54] Patients with mild to moderate PD do not appear to demonstrate significantly different exercise capacity (maximal HR, maximal oxygen consumption) when compared to age-matched controls. However, these patients did demonstrate decreased peak power and higher submaximal HRs and oxygen consumption rates than controls.[55-57]

Orthostatic hypotension (**OH**) is common in middle and late PD and is caused by a sharp drop in BP that occurs with position changes (e.g., supine-to-sit or sit-to-stand). Typical symptoms include lightheadedness or dizziness. Patients can also experience pallor, diaphoresis, weakness, trembling, nausea, difficulty thinking, or syncope. The condition puts individuals at risk for loss of balance, falls, and fall injury. Medications (e.g., levodopa/carbidopa, bromocriptine) can contribute to orthostatic hypotension.[53]

Patients with PD demonstrate respiratory impairments, reported in as many as 84% of patients. *Airway obstruction* (e.g., air trapping, lung insufflation) is the most frequently reported pulmonary problem and has been linked to episodes of pulmonary failure. The etiology remains unknown but may be linked to bradykinetic disorganization of respiratory movements. *Restrictive lung dysfunction* is common and is linked to the decreased chest expansion that occurs as a result of rigidity of the trunk muscles, loss of musculoskeletal flexibility, and kyphotic posture. Patients with PD demonstrate lower forced vital capacity (FVC), lower forced expiratory volume in 1 second (FEV_1), and higher residual volume (RV) and residual airway resistance (RAW) values when compared to age-matched controls. Daily function and activity participation are reduced in patients with pulmonary dysfunction.[58,59] A sedentary lifestyle with decreased activity levels contributes to cardiopulmonary deconditioning.

In long-standing disease, the LEs may exhibit circulatory changes owing to venous pooling as a result of decreased mobility and prolonged sitting. Thus, patients can present with mild to moderate edema of the feet and ankles, which usually subsides during sleep.

Sleep Disorders

Individuals with PD can experience *excessive daytime somnolence* (sleepiness). At night, *insomnia* (disturbed sleep pattern) may occur. This includes problems in falling asleep, staying asleep, and good quality of sleep. REM sleep behavior disorder (RBD) occurs early in PD and affects as many as 50% to 60% of patients. In a person with RBD, the paralysis that normally occurs during REM sleep is incomplete or absent, allowing the person to "act out" his or her dreams that are vivid, intense, and violent. Dream-enacting behaviors include agitation and physical activity during sleep (e.g., talking, yelling, punching, kicking, arm flailing, and grabbing).[60,61] Box 18.2 provides a summary of the cardinal features and clinical manifestations of PD.

MEDICAL DIAGNOSIS

Diagnosis at onset of PD is difficult with accurate diagnosis possible only with continued observation of evolving clinical signs and symptoms. There is no single definitive test or group of tests used to diagnose the disease. The diagnosis is made on the basis of history and clinical examination. Handwriting samples, speech analysis, interview questions that focus on developing symptoms, and physical examination are used. In the preclinical stage, nonmotor symptoms predominate. There is an increasing focus on use of questionnaires and tests (e.g., olfactory testing, imaging of cardiac sympathetic innervation) that focus on emerging nonmotor symptoms.[62-64] Often symptoms of loss of smell, sleep disturbances, vivid dreams with REM alterations, foot dystonia and foot cramping similar to restless legs syndrome, orthostatic hypotension, and constipation are symptoms that are present many years before an official diagnoses of PD is made. A diagnosis of PD is typically made if at least two of the four cardinal motor features are present. Exclusion of Parkinson-plus syndromes is necessary. The presence of extrapyramidal signs that are bilaterally symmetrical and do not respond to L-dopa and dopamine agonists (apomorphine test) is suggestive of these syndromes, not PD. Imaging can be used to rule out other pathologies. In vivo functional imaging (magnetic resonance imaging [MRI]) using chemical markers to identify dopaminergic deficits in PD and related disorders identifies dopamine deficiency but does not discriminate between PD and other causes of parkinsonism.[65]

CLINICAL COURSE

The disease is progressive, with a long subclinical period (without apparent clinical manifestations) estimated to be at least 5 years. Mean PD duration is approximately 13 years. There is variability of the rate of progression. Patients with a young age at onset or who are tremor predominant typically demonstrate a more benign progression. Patients with PD who present with postural instability and gait disturbances (the PIGD group) tend to have more pronounced deterioration with a more rapid disease progression. Neurobehavioral disturbances and dementia are also more common in this group. With L-dopa therapy, progression is generally slower with an overall improvement in mortality rates. The most common causes of death are cardiovascular disease and pneumonia.[65]

Hoehn-Yahr Classification of Disability Scale

An estimate of the stage and severity of the disease can be made using a staging scale. The most widely used in clinical practice and research trials is the *Hoehn-Yahr Classification of Disability Scale* (Table 18.1).[66] It provides a broad measure for charting the progression of the disease using motor signs and elements of functional status. Stage I is used to indicate minimal disease involvement, whereas stage V is indicative of severe deterioration in which the patient is confined to bed or a wheelchair.[67]

Unified Parkinson's Disease Rating Scale (UPDRS)

The *Unified Parkinson's Disease Rating Scale (UPDRS)* has been the "gold standard" for measuring the progression

Box 18.2 Cardinal Features and Clinical Manifestations of Parkinson's Disease

Cardinal Features

Rigidity
Bradykinesia
Tremor
Postural instability

Clinical Manifestations

Motor Performance
Decreased torque production
Fatigue
Contractures and deformity common
Masked face
Micrographia

Motor Planning
Start hesitation
Freezing episodes
Poverty of movement

Motor Learning
Slower learning rates, reduced efficiency
Increased context-specificity of learning.
Procedural learning deficits for complex and sequential tasks

Gait
Reduced stride length; increased step-to-step variability
Reduced speed of walking
Cadence (steps per minute) typically intact; may be reduced in advanced PD
Increased time: double-limb support
Insufficient hip, knee, and ankle flexion: shuffling steps
Insufficient heel strike with increased forefoot loading
Reduced trunk rotation: decreased or absent arm swing
Festinating gait: anteropulsion common
Freezing of gait (FOG)
Difficulty turning: increased steps per turn
Difficulty with dual tasking: simultaneous motor and/or cognitive tasks
Difficulty with attentional demands of complex environments

Posture
Kyphosis with forward head
Leaning to one side with tonal asymmetries
Increased fall risk

Sensation
Paresthesias
Pain
Akathisia

Speech, Voice, and Swallowing Disorders
Hypokinetic dysarthria
Dysphagia

Cognition Function and Behavior
Dementia
Bradyphrenia
Visuospatial deficits
Depression
Dysphoric mood

Autonomic Nervous System
Excessive sweating
Abnormal sensations of heat and cold
Seborrhea
Sialorrhea
Constipation
Urinary bladder dysfunction

Cardiopulmonary Function
Low resting blood pressure (BP)
Compromised cardiovascular response to exercise
Impaired respiratory function

of PD since 1987.[68] The original UPDRS was composed of four parts: Part I, Mentation, Behavior, and Mood; Part II, Activities of Daily Living; Part III, Motor Examination; and Part IV, Complications of Therapy. Goetz and colleagues reported on a modification of this scale renamed the Movement Disorder Society–sponsored revision of the Unified Parkinson's Disease Rating Scale (MDS-UPDRS).[69-71] The goals of the revision were to improve ability to detect slower and smaller changes in mildly disabled patients and increase focus on nonmotor symptoms. It retains the 4-part structure with substantial reworking of questions and an additional 6 items (most on nonmotor aspects of PD), bringing the total to 48. A four-point scale is used for all items (as opposed to some items graded as 0, no, or 1, yes, in the original scale). A score of 0 means normal or no problems; 1, minimal problems; 2, mild problems; 3, moderate problems; and 4, severe problems. Descriptors are added for each question. Parts I and II have been renamed: Part I is now *Non-motor Aspects of Experiences of Daily Living* and Part II is now *Motor Experiences of Daily Living*. Part III is *Motor Examination* (same title) and Part IV is renamed *Motor Complications*.[70] The total time to administer the test is an estimated 30 minutes, with Parts I and II designed to be self-administered by the patient. See Appendix 18.A.

Table 18.1 Hoehn-Yahr Classification of Disability

Stage	Character of Disability
I	Minimal or absent; unilateral if present.
II	Minimal bilateral or midline involvement. Balance not impaired.
III	Impaired righting reflexes. Unsteadiness when turning or rising from chair. Some activities are restricted, but patient can live independently and continue some forms of employment.
IV	All symptoms present and severe. Standing and walking possible only with assistance.
V	Confined to bed or wheelchair.

From Hoehn and Yahr,[66, p. 433] with permission.

MEDICAL MANAGEMENT

Medical management is directed at slowing disease progression using neuroprotective strategies, and symptomatic treatment of motor and nonmotor symptoms. Management becomes increasingly more challenging over time for patients with moderate and advanced disease (i.e., Stage III or higher on the Hoehn-Yahr Classification of Disability Scale).[72-76]

Pharmacological Management

A number of agents are available as first-line neuroprotective and symptomatic therapy. Selection is individualized according to the patient's characteristics with the benefits and risks of adverse side effects carefully weighed. Starting medication early has been shown to be beneficial in slowing the progression of the disease. Drug delivery should be as close to constant as possible to avoid large peaks and valleys. The importance of taking the medication on a fixed schedule should be stressed to patients, family members, and caregivers. When patients with PD are hospitalized it is important that they continue to receive their medication on schedule.[77] Currently three out of four patients with PD do not receive their medications on time when they are in a hospital setting. Sixty-one percent of patients who did not receive their medications on time had serious complications.[78] The *Aware in Care kit* from the National Parkinson Foundation can be helpful in avoiding these complications (www.awareincare.org).

Levodopa/Carbidopa

Levodopa/carbidopa (Sinemet) is the gold standard drug therapy for PD. Levodopa (L-dopa) was first introduced in 1961 as an experimental drug and came into widespread clinical use in the late 1960s. It is a dopamine precursor that is metabolized to dopamine in the brain. Thus, administration of the drug represents an attempt to correct the essential neurochemical imbalance. Most of L-dopa (almost 99%) is metabolized before reaching the brain, requiring administration of high doses that can produce numerous side effects. Today, L-dopa is commonly administered with carbidopa, a decarboxylase inhibitor that allows a higher percentage of L-dopa to enter the brain. Thus, lower doses of L-dopa can be used with fewer adverse side effects. Sinemet is available in immediate-release (IR) and controlled-release (CR) formulations. The IR form has a short half-life requiring multiple oral dosing throughout the day. The CR form is a long-acting, sustained-release preparation. Both are equally effective.[79,80]

The primary benefits of dopamine replacement include controlling the PD motor symptoms of bradykinesia and rigidity. Increased movement velocity, initial burst of motor activity, and increased strength are all positive outcomes.[80] The effects on reduction of tremor are more varied. Some individuals demonstrate little or no response whereas others demonstrate a positive reduction in tremor amplitude. It does not appear to have a direct impact on postural instability. The decision about when to start levodopa/carbidopa is determined by the neurologist and is different for every person. Initial dosing improves low levels of levodopa often with dramatic improvements in functional status. This is sometimes referred to as the *honeymoon period,* in which there is clear-cut drug effectiveness.

There are numerous *adverse effects* of dopamine replacement therapy. For many patients the typical therapeutic window is 4 to 6 years before optimal benefit wears off (termed *wearing-off state*). At this point, a significant number of patients experience disabling dyskinesias, dystonia, and motor fluctuations. **Dyskinesias** are dynamic uncontrolled or involuntary movements that occur typically at peak L-dopa dose or when the patient is transitioning between "on" and "off" states. The movements are choreo-athetotic in quality and may initially appear as facial grimacing with twitching of the lips and tongue protrusion. With time the involuntary movements become more prevalent, vigorous, and more extensive, involving the limbs, trunk, and neck. Dyskinesias are estimated to develop and increase at a rate of 10% per year following start of dopamine therapy. **Dystonia**, a prolonged involuntary contraction that causes twisting or torsion of body segments, can also occur. The patient typically complains of clawing of the toes or fingers, or cramping of the calf, neck, face, or paraspinal muscles. Dystonia is associated with pain and occurs typically during "off" periods. Motor fluctuations include both the "on–off" phenomenon and wearing-off. The term **"on–off" phenomenon** refers to abrupt, random fluctuations in motor performance and responses. Production of movement errors is common. *Wearing-off* refers to

end-of-dose deterioration, a worsening of symptoms toward the end of the expected timeframe of medication effectiveness.[79] Patients may experience **akathisia**, a motor restlessness. In general, they experience an intolerance of inactivity (sitting still) and experience significant disruptions in sleep and relaxation. This affects as many as 25% of patients and is relieved with movement (e.g., walking). Akathisia is associated with advanced PD and is more commonly seen in the "off" state.

Deprenyl can be administered with levodopa/carbidopa to control mild wearing-off phenomena. Unsupervised reduction or sudden discontinuation of levodopa/carbidopa is contraindicated and may produce dangerous, life-threatening adverse effects. Adverse interactions can occur with several medications, including antacids, antiseizure drugs, antihypertensives, and antidepressants.[80]

Patients may also experience other changes that are dose related and may indicate the need for drug modification. These include (1) disabling psychiatric toxicity (visual hallucinations, delusions, and paranoia); (2) depression; (3) gastrointestinal changes (nausea, dry mouth); (4) cardiovascular changes (hypotension, dizziness, arrhythmias); (5) genitourinary changes (dysuria); and (6) sleep disturbances (insomnia, sleep fragmentation).[79,80]

Dopamine Agonists

Dopamine agonists (DAs) are a class of drugs designed to directly stimulate postsynaptic dopamine receptors. They are administered alone as a first-line monotherapy or along with levodopa/carbidopa, allowing lower doses to be administered with prolonged effectiveness (i.e., L-dopa–sparing therapy). Patients with moderate to advanced PD who demonstrate declining responses to levodopa/carbidopa therapy may benefit. The most commonly prescribed DA drugs include ropinirole (Requip) and pramipexole (Mirapex); bromocriptine (Parlodel) is less commonly used. The greatest benefit of these drugs is reducing rigidity, bradykinesia, and motor fluctuations. Adverse effects are similar to those of L-dopa with nausea, sedation, dizziness, constipation, and hallucinations being the most common. These medications have also been linked to an increased risk of impulse control disorders (e.g., pathological gambling, compulsive shopping, hypersexuality, overeating).[80]

Anticholinergics

Anticholinergic agents may be used in early PD or as an adjunct for patients on carbidopa/levodopa. They block cholinergic function and have the most benefit moderating tremor and the dystonia that may accompany the wearing-off; they have little or no effect on other PD symptoms. The drugs commonly prescribed in this group include trihexyphenidyl (Artane) and benztropine mesylate (Cogentin). Anticholinergic adverse effects include blurred vision, dry mouth, dizziness, and urinary retention. Central toxicity is indicated by impaired memory, confusion, hallucinations, and delusions.[80]

Monoamine Oxidase B Inhibitors

Monoamine oxidase B (MAO-B) is the major enzyme that acts to degrade dopamine in the brain. MAO-B inhibitors include selegiline, also called deprenyl (Eldepryl) and rasagiline (Azilect). Patients in the early stages of PD may be given MAO-B inhibitors to enhance levels of dopamine. Clinically, early monotherapy treatment with selegiline has been shown to have a modest effect in slowing, but not halting, disease progression. Once L-dopa therapy is started, selegiline in combination improves symptom control and permits a lower dose to be used. MAO-B inhibitors have a low risk of dyskinesias. There are few adverse effects, including mild nausea, dry mouth, dizziness, orthostatic hypotension, confusion, hallucinations, and insomnia.[80]

Implications for the Physical Therapist

The therapist needs to be fully aware of each of the medications the patient is taking and potential adverse effects. It is important to remember that patients on dopamine replacement will develop motor complications at some point. Optimal performance can be expected at peak dosage whereas worsening performance is associated with end-of-dose cycle and medication depletion.[81] Timing of physical therapy examination and intervention should be consistent and occur whenever possible during optimal dosing cycle. Therapists are involved in monitoring drug effectiveness on motor performance, function, and activity participation. As the disease progresses, patients may develop an intolerance for a particular medication, necessitating a change in prescription. Often, it is the therapist who first notices a change in functional status as the patient's system adapts to either the amount or type of drug prescribed. Accurate observation, examination, and reporting of these changes greatly assists the physician in modifying a drug prescription. Therapists may also be involved with clinical drug trials as new medications or combinations are developed. Table 18.2 presents an overview of the pharmacology of PD.

Nutritional Management

A high-protein diet can block the effectiveness of L-dopa. The dietary amino acids in protein compete with L-dopa absorption. This is particularly problematic in patients with chronic disease who exhibit fluctuations in motor performance. Thus, patients are generally advised to follow a high-calorie, low-protein diet. Generally no more than 15% of calories should come from protein. Dietary recommendations may also include shifting the intake of daily protein to the evening meal when patients are less active. These modifications

Table 18.2 Pharmacology of Parkinson's Disease[80]

Drug Class	Example	Average Dosage	Possible Adverse Effects
Anticholinergics	Trihexyphenidyl	2 mg tid	Dry mouth, dizziness, blurred vision
	Bentropin	1 mg bid	Tachycardia, dry mouth, nausea, vomiting, confusion
Dopamine replacement	Levodopa/carbidopa	10 mg /100 mg tid/qid	Dystonia
	(generic)	25 mg/100 mg tid/qid	Abnormal, involuntary movements
	Sinemet	25 mg/250 mg tid	Nausea, vomiting
	Sinemet CR (controlled release)	25 mg/100 mg tid	Confusion
		25 mg/200 mg bid	Dreams, hallucinations
Dopamine agonists	Pergolide	1 mg tid	Nervousness, dyskinesias, insomnia, hallucinations, nausea, confusion, erythromelalgia
	Bromocriptine	5 mg bid	Nausea, headache, dizziness, fatigue, cramps/constipation, confusion, pulmonary/peritoneal fibrosis
Amantadine	Symadine	100 mg bid	Lightheadedness, livedo reticularis, edema

bid = twice a day; mg = milligram; tid = three times a day; qid = four times a day.

minimize motor fluctuations and maximize responsiveness to L-dopa therapy. The patient is encouraged to eat a variety of foods and may be advised to take dietary supplements to ensure adequate intake of vitamins and minerals. Patients are also advised to increase their daily intake of water and dietary fiber to help control problems of constipation.[76]

Rigidity and bradykinesia can limit upright posture and UE feeding movements. Learned motor plans, for example, using a cup or eating utensils, may also be difficult. Occupational therapy intervention to improve feeding and recommend adaptive eating devices is of considerable importance in helping to maintain nutrition and general health status. The speech-language pathologist also has an important role in the evaluation of dysphagia and the recommendation of strategies to assist with swallowing dysfunction. Patient, family, and caregiver education should focus on the importance of maintaining good nutritional intake. Percutaneous endoscopic gastrostomy (PEG) is reserved for advanced disease when all other strategies for dysphagia fail.

Deep Brain Stimulation

Deep brain stimulation (DBS) involves the implantation of electrodes into the brain where they block nerve signals that cause symptoms. Brain electrodes are placed in the subthalamic nucleus (STN) or less frequently the globus pallidus (GPi). An impulse generator (IPG), similar to a pacemaker, is implanted in the subclavicular area and a thin wire goes under the skin to connect to the brain electrodes. High-frequency stimulation is provided. The patient can control the pacemaker's "on–off" switch using a controller while the physician determines the amount of stimulation it delivers, tailoring it to the individual's needs.[82]

DBS is effective for the treatment of advanced PD. Improvement of tremor that is refractory to pharmacological therapy is seen in approximately 90% of patients with one-third to one-half of patients experiencing total suppression with DBS of the STN. DBS has been shown to successfully control PD symptoms of motor overactivity (dyskinesias), substantially increase "on" time, and improve ADL scores. DBS has also been shown to reduce the medication requirements and is a treatment of choice in patients with medication-resistant motor fluctuations and dyskinesia. Other motor symptoms of akinesia, rigidity, weakness, and reduced walking speed may improve with DBS though the responses are more variable. Possible adverse effects include confusion, headache, speech problems, gait disturbances, and falling. Most of the complications are temporary and resolve within 6 months. Surgical risks (intracerebral hemorrhage, infection) and mechanical problems with the device (lead breakage, generator malfunction) are also possible. Deep brain stimulation has largely replaced stereotaxic surgical procedures of the brain (thalamotomy and pallidotomy).[82-86]

FRAMEWORK FOR REHABILITATION

Rehabilitation has an important role in reducing activity limitations while promoting activity participation and independence. In addition, known complications of PD can be reduced or prevented while quality of life is promoted. Optimal management involves a coordinated interdisciplinary team to oversee a comprehensive plan of care to address the patient's individual clinical problems,

concerns, and needs. The team typically includes the physician, nurse, physical therapist, occupational therapist, speech-language pathologist, and social worker. Referral to other specialists may also be necessary, for example, psychologist, nutritionist, gastroenterologist, urologist, pulmonologist, and so forth. As with any team, the patient is the central figure with family and caregivers being key members.

The ideal rehabilitation program considers the patient's disease history, course, and symptoms, together with impairments, activity limitations, and participation restrictions. Of equal importance are the patient's abilities (assets), priorities, and resources, including family, home, and community resources. Deterioration of condition and medication-induced fluctuations in performance should be expected. Depression and anxiety are common and should be carefully monitored. The overall focus is on long-range planning, with anticipated episodes of care including hospital-based, outpatient, and home/community-based care.

Therapeutic Care Continuum

A therapeutic care continuum based on disease stage (early, middle, late) is an effective way to organize care. Interventions are restorative (aimed at improving impairments, activity limitations, and participation restrictions), preventative (aimed at minimizing potential complications and indirect impairments), and compensatory (aimed at modifying the task, activity, or environment to improve function) (see discussion in Chapter 1). It is critical for the whole team to provide a supportive environment to assist patients and their family members in the difficult adjustment to living with a chronic and progressive disease.

In the *early* stage of the disease, patients are functional and independent with minimal impairments. A referral for physical therapy is often delayed at this stage, although benefits could clearly be obtained in improving fitness levels and delaying or preventing indirect impairments. Patients are typically seen on an outpatient basis.

During the *middle* stage of the disease, symptoms are more readily apparent and activity limitations emerge. The patient may still be independent in gait and ADL, although performance is slowed and less efficient. Some assistance may be required. The patient may be seen as an outpatient, during home care, or during a brief inpatient admission. There are numerous benefits to rehabilitation services. Exercise training programs have been shown to be effective for patients with mild to moderate PD in improving motor performance.[87-93] Perceived quality of life and subjective well-being are also improved.[94] Family and caregiver instruction is intensified to assist the patient in remaining as functionally independent as possible.

In the *late* stage, disease progression leads to increased and more severe impairments and complications. Patients are dependent in many or most of their daily functional mobility skills and ADL and are typically wheelchair bound or bedridden. Family and community resources are vital in maintaining the patient in the home. Some patients may require placement in a chronic care facility. These changes can be a source of great anxiety and frustration to the patient and family. Goals need to be restructured. The therapist needs to focus on preventative care to avoid secondary complications that may be life threatening (e.g., pneumonia, pressure ulcers, and so forth). Compensatory training focuses on maintaining function, including being upright and out of bed as much as possible. Safety for both the caregiver and the patient becomes a primary concern as maximal assist dependent transfers become the norm. Often, environmental adaptations may mean the difference between total dependence and modified dependence. The rehabilitation team should be supportive of the patient's efforts no matter how small they may be. Patients in late-stage PD demonstrate extremely limited skills to interact with their environment, with increasing social isolation and withdrawal. Families also suffer from the increasing demands of care, burnout, and social isolation. Therapists need to maximize psychosocial support and be readily available for consultation. Table 18.3 presents an overview of Parkinson's disease stages and intervention strategies.

The preferred practice pattern for patients with PD from the *Guide to Physical Therapist Practice* is 5E, *Impaired Motor Function and Sensory Integrity Associated with Progressive Disorders of the Central Nervous System—Acquired in Adolescence or Adulthood.*[97, p. 375] In this document the reader will find relevant information on patient/client diagnostic classification; ICD-9-CM codes; examination components; considerations for evaluation, diagnosis, and prognosis; and suggested interventions. Thus, the *Guide to Physical Therapist Practice* serves as a primary resource in designing an appropriate plan of care (POC) and documenting the services provided and outcomes achieved.

PHYSICAL THERAPY EXAMINATION AND EVALUATION

A comprehensive examination is required to determine the level of impairments and degree of function. Subsequent reexamination at specified intervals is used to distinguish change in status as well as effects of treatment. Data are obtained from the history, systems review, and relevant tests and measures (Box 18.3).[97] The selection of examination procedures and instruments is determined by the patient's unique status. The severity of problems, stage of disease, age, phase and setting of rehabilitation, and other factors must all be taken into account in structuring the examination and evaluating data. During the early and middle stages of PD, measures of impairment and physical performance are relatively stable. During late stages of the disease and under conditions of fluctuating symptoms with pharmacological instability, measures can be expected to be less stable.[98]

Table 18.3 Parkinson's Disease Stages, Common Impairments and Activity Limitations, and Intervention Strategies

Stage	Common Impairments and Activity Limitations	Intervention Strategies
Early/Mild PD	• Few/minimal impairments and activity limitations with independence maintained • Movement symptoms present but do not interfere with daily activities • Movement symptoms, often tremor, occur on one side of the body • Changes noted in posture, walking ability, or facial expression • Parkinson's medications effectively suppress movement symptoms	***Preventative and Restorative*** • Regular exercise to improve/maintain motor performance, strength, mobility, flexibility, range of motion (ROM), balance, locomotion, endurance, and perceived quality of life • Community classes to improve/maintain socialization, camaraderie, positive outlook and life purpose ***Compensatory*** • Patient/family/caregiver education about disease process, rehabilitation, energy conservation • Determine need for adaptive or assistive devices • Determine need for environmental modification of home/workplace • Provide psychological support with early referral to support groups for patient and family/caregiver • Referral to other health care professionals as needed
Middle/ Moderate PD	• Increasing number and severity of impairments • Minimal to moderate activity limitations, participation restrictions • Movement symptoms occur on both sides of the body • The body moves more slowly against increasing stiffness • ADL with modified dependence (assistance) • Difficulty with balance, postural instability; stooped posture; increasing number of falls • Gait impairments evident; freezing episodes may occur • Locomotion with modified dependence (assistance) • Parkinson's medications may "wear off" between doses • Parkinson's medications may cause side effects, including dyskinesias	***Preventative and Restorative*** • Regular exercise to maintain/improve motor performance, strength, mobility, flexibility, ROM, balance, locomotion, endurance, and perceived quality of life • Community classes to improve/maintain socialization, camaraderie, positive outlook and life purpose ***Compensatory*** • Assistive devices to maintain function • Wheelchair for community mobility • Environmental modifications to home • Patient/family/caregiver education and training • Psychological support for patient and family/caregiver • Referral to other healthcare professionals as needed; occupational therapy may provide strategies for maintaining independence

Late/ Advanced PD	• Numerous impairments with increasing severity
	• Severe activity limitations with dependence in most activities:
	• Great difficulty walking; typically in wheelchair or bed most of the day
	• Assistance needed with all ADL
	• Severe participation restrictions:
	  • Not able to live alone
	  • Typically requires full time assistance or placement in chronic care facility
	• Social interactions restricted
	• Cognitive problems may be prominent, including dementia, hallucinations and delusions
	• Increasing medication intolerance with dyskinesias
	• Balancing the benefits of medications with their side effects becomes more challenging
		Preventive
		• Maximize upright posture, out-of-bed time
		• Maximize participation in activities of daily living
		• Prevention of contractures, pressure wounds, pneumonia, and so forth
		Compensatory
		• Family/caregiver education and training: safety education, transfers, positioning, turning, skin care
		• Pressure relieving devices
		• Hospital bed, wheelchair, mechanical lift
		• Psychological support for patient and family/caregiver
		• Referral to other healthcare professionals as needed

Adapted from Dal Bello-Haas[95] and Cutson et al.[96]

Box 18.3 Elements of the Examination for a Patient with Parkinson's Disease[97]

Patient/Client History

- Age, sex, race/ethnicity, primary language, education
- Social history: cultural beliefs and behaviors, family and caregiver resources, social support systems
- Occupation/employment/work
- Living environment: home/work barriers
- Hand dominance
- General health status: physical, psychological, social, and role function, health habits
- Family history
- Medical/surgical history
- Current conditions/chief complaints
- Medications
- Medical/laboratory test results
- Functional status and activity level: premorbid and current

Systems Review

- Neuromuscular
- Musculoskeletal
- Cardiovascular/pulmonary
- Integumentary

Tests and Measures/Impairments

- Cognition: mental status, memory: hesitation, slowness of thought processes
- Oromotor function: communication (fluctuations, reduced volume), swallowing
- Psychosocial function: motivation, anxiety, depression
- Anthropometric characteristics: body mass index, girth, length; edema
- Circulation: response to position change, orthostatic hypotension
- Aerobic capacity and endurance: during functional activities and standardized exercise protocols including cardiovascular and pulmonary signs and symptoms
- Ventilation and gas exchange
- Integumentary integrity: skin condition, pressure-sensitive areas; activities, positioning, and postures to relieve pressure
- Autonomic nervous system integrity: thermal responses, sweating
- Sensory integrity and integration
- Pain: intensity and location
- Perceptual function: visuospatial skills
- Joint integrity, alignment, and mobility: range of motion (active and passive); muscle length, and soft tissue extensibility
- Posture: alignment and position, symmetry (static and dynamic); ergonomics, and body mechanics
- Muscle performance: strength, power, and endurance
- Motor function: motor control and motor learning: tone, voluntary movement patterns; involuntary movements; hesitation, slowness, arrests of movements; poverty of movements
- Procedural learning for complex and sequential tasks
- Postural control and balance: degree of postural instability, balance strategies; safety
- Gait and locomotion: gait pattern and speed, safety
- Functional status and activity level: performance-based examination of functional skills (FIM level), basic and instrumental ADL; functional mobility skills; home management skills
- Assistive or adaptive devices: fit, alignment, function, use; safety
- Environment, home, and work barriers
- Work, community, and leisure activities: ability to participate in activities, safety

This section presents strategies for examination as well as relevant tests and measures. Complete descriptions of many of the tests and measures identified are provided in earlier chapters focusing on examination.

Cognitive Function

Memory, orientation, conceptual reasoning, problem solving, and judgment should be examined. Speed of information processing, attention, and concentration are particularly important to determine if bradyphrenia is suspected. A brief screen of cognitive function can be obtained using the *Mini-Mental Status Examination (MMSE).*[99]

Psychosocial Function

The therapist should determine overall levels of depression, stress and anxiety, and available coping strategies. It is important to ask the patient about the presence of depressive symptoms such as sadness, apathy, passivity, insomnia, anorexia, weight loss, inactivity and dependency, inability to concentrate and impaired memory, or suicidal ideation. Useful instruments include the *Geriatric Depression Scale*[100] and the *Beck Depression Inventory.*[101] Anxiety is prevalent and disabling in this patient population. The *Hospital Anxiety and Depression Scale* is reliable in detecting and grading the severity of depression and anxiety in the hospital setting.[102,103]

Sensory Function

A screening examination of sensation is indicated (superficial and deep sensations, combined cortical sensations). Sensory changes can be expected with aging (blunting of touch sensations and proprioception with greater losses in LEs than UEs, and distal more than proximal). Specific areas of sensory loss may be indicative of co-morbid pathology, for example, stroke, diabetic neuropathy, and so forth. The patient with PD should be asked about the presence of paresthesias (sensations of numbness or tingling) and pain. Mild aching and

cramplike sensations are common and are often poorly localized. It is important to examine for musculoskeletal aches and pains linked to lack of movement, faulty movements or posture, and ligamentous strain.

An examination of vision should include a determination of acuity, peripheral vision, tracking, accommodation, light and dark adaptation, and depth perception. Visual changes can be expected with aging such as loss of visual acuity, inability to focus on printed word (presbyopia), decreased adaptation to light, sensitivity to light and glare, and loss of color discrimination. Patients with PD may experience blurring of vision and difficulty reading not improved by corrective lenses, as well as problems with eye pursuit (cogwheeling). Specific deficits may be indicative of co-morbid pathologies that are common in the elderly, such as cataracts (clouding of central vision first, then peripheral), glaucoma (early loss of peripheral vision), senile macular degeneration or diabetic retinopathy (early loss of central vision), and cerebrovascular accident (homonymous hemianopsia). Medications may also produce impaired or fuzzy vision, for example, antidepressants and anticholinergics.

Musculoskeletal Function

Joint Flexibility and Posture

An examination of musculoskeletal ROM and flexibility is important. The therapist can document specific active range of motion (AROM) and passive range of motion (PROM) impairments using goniometric measurement. Patients with PD are likely to present with losses in hip and knee extension, dorsiflexion, shoulder flexion, elbow extension, dorsal spine and neck extension, and axial rotation. To a lesser extent, these impairments are also generalizable to the geriatric population.

It is particularly important to examine spinal ROM (ability to rotate, flex, and extend the spine) because patients with PD have been shown to exhibit impairments in this area.[104] All segments of the spine should be examined, including cervical, thoracic, and lumbar segments. Spinal inclinometers such as the Back Range of Motion II™ (BROM II) and Cervical Range of Motion™ (CROM) instruments have been shown to be valid and reliable in measuring spinal ROM and forward head posture (www.spineproducts.com).[105] The use of a head-mounted laser and wall measurements is a novel way to assess transverse plane spine ROM. Standing with feet stationary, the patient rotates as far as possible to one side. An objective measurement of full body (trunk) rotation is obtained by measuring the distance that the laser moves along the wall. This multisegmental measurement may be a better predictor of functional trunk mobility than isolated measurements of cervical and lumbar ROM. The mobility of the spine can also be examined using a series of functional movements, such as axial rotation (looking behind) in sitting and standing and walking. Hamstring length can be determined using a straight leg test.

An examination of resting posture and changes in posture that occur with movement is indicated. The therapist can use posture grids, plumb lines, still photography, or videotape to document changes. A flexible ruler contoured to the patient's spine in standing and then traced onto graph paper can be used to record static sagittal plane posture. This technique is affordable, with good intratester and intertester reliability, and was shown to have a high correlation to radiographic measurements of the lumbar and thoracic spine.[106-108] In standing, patients with PD typically assume a flexed, stooped posture (kyphosis with forward head) with the COM placed forward within the limits of stability (LOS) (Fig. 18.4). In supine, the flexed posture with forward head is still evident (shadow pillow posture) (Fig. 18.5).

Muscle Performance

An examination of strength and endurance is indicated. The therapist can measure strength using manual muscle testing (MMT). Handheld and isokinetic dynamometry can be used to quantify peak force (torque output). Patients with PD have been shown to exhibit impairments in the rate of force development and in maximum torque production capability. Isokinetic dynamometry can also be used to document muscle endurance and has been suggested for documenting tremor, using slow speeds of movement (25 mm/sec) and low torques.[26]

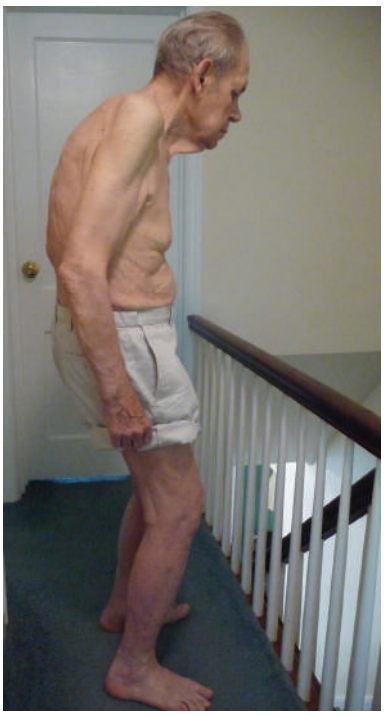

Figure 18.4 In standing, patient with PD demonstrates the typical flexed, stooped posture with kyphosis, forward head, and hip and knee flexion.

Figure 18.5 In supine, the patient with PD demonstrates the typical flexed posture (shadow pillow posture).

Motor Function

Rigidity

Rigidity is usually equal in both agonist and antagonist muscle groups. As mentioned earlier, it can be sustained (lead pipe) or intermittent (cogwheel). Distribution of rigidity is often asymmetrical especially in the early stages of the disease and can vary during the course of the day, point in the medication cycle, and with stress. It is therefore important to determine which body segments are affected and the severity of involvement. The patient should be seated or supine in a relaxed position. The therapist moves each extremity through full PROM. For head and neck and spinal PROM the patient can be seated on a mat or at the edge of a chair, perch sitting, to allow for excursion of spinal motions (flexion, extension, rotation). A determination of severity of rigidity can be made based on the level of resistance to passive movement and availability of ROM. For example, a determination of severe rigidity is made if full PROM can only be achieved with difficulty. Tone changes in the neck and shoulders are suggestive of early disease, whereas tone changes in the trunk and extremities are typically present with moderate and extensive disease. Deficits in functional mobility and postural reactions should be suspected in the presence of significant trunk rigidity. The patient should also be examined for facial mobility (e.g., hypomimia or masked face) including ability to produce spontaneous expressions and part the lips; the ability to smile or use the muscles of facial expression should also be examined. An inspection of voluntary repetitive movements should be performed to determine active limitations imposed by rigidity.

Bradykinesia

Initially movements are slowed, then movements decrease in amplitude (hypokinesia); in later stages, movements become arrhythmic with frequent start hesitations and arrests (akinesia). A stopwatch can be used to quantify detectable slowing of movement (*movement time*) and start hesitancy or *reaction time* (elapsed time between the patient's desire to move and the actual movement response). The therapist should examine overall amplitude of movement and fluctuations in amplitude. For example, impaired coordination and asymmetry of arm swing during walking is a common finding in early PD. As the disease progresses, movements are characterized by marked slowness, poverty, and reduced amplitude. Timed tests for rapid alternating movements (RAM) can be used to determine the effects of bradykinesia. Examples of RAM include repeated opposition of the forefinger and thumb, alternating between pronation and supination, opening and closing of hands, and tapping (finger or foot tapping). Dexterity in complex motor tasks (e.g., writing, dressing, skilled object manipulation) can be expected to be impaired and should be examined. This is also true for motor tasks involving simultaneous use of both sides (e.g., bilateral RAM between pronation and supination). See Chapter 6, Examination of Coordination and Balance, for additional test examples.

More sophisticated methods have been used to study movement in patients with PD, largely in the research setting. EMG has been used to quantify the effects of rigidity and bradykinesia on motor performance. Long-latency EMG responses (50 to 120 msec) have been observed when muscles are subjected to sudden stretch. Abnormal patterns of motor unit recruitment have also been observed.[109]

Tremor

The location, persistence, and severity (amplitude) of tremor should be recorded. The therapist should determine if tremor is present at rest (initial typical pattern) or present with action and interferes with function. This latter pattern may occur in severe, long-standing disease. UE functional skills such as drinking from a cup, feeding, dressing, and writing can be used to test for the effects of tremor during movement. With severe tremor, the patient will be unable to complete the functional task. Stress can increase tremor. The use of simultaneous cognitive tasks such as serial seven subtractions (i.e., counting backward from 100 by 7) can be used to test the impact of dual-task performance.[110]

Postural Control and Balance

A thorough examination of postural control and balance is indicated. The therapist should first observe the patient's resting posture in sitting and standing. The patient's perception of vertical may be impaired, as some patients with advanced disease will perceive themselves as fully upright when they are actually leaning forward.

Clinical measures of balance performance have been shown to be reliable and sensitive in the examination of functional performance and balance in patients with Parkinson's disease.[111-120] These include the *Berg Balance Scale* (BBS),[121] the *Functional Reach Test* (FRT),[122]

the *Timed Up and Go test* (TUG),[123] the *Cognitive Timed Up and Go* (CTUG),[124] and the *Dynamic Gait Index* (DGI).[125] These tests are discussed in Chapter 6, Examination of Coordination and Balance. The BBS correlates well with the UPDRS and has been found to be a good overall measure of function in this population.[111,112] Dibble and Lange[113] demonstrated that each of these tests has the ability to discriminate among people with PD who had a history of falls from those without a history of falls and suggested cutoff scores to maximize sensitivity and minimize false negatives. False negatives can also be reduced when interpretation is based on the collective interpretation of multiple balance tests. A clinical decision making algorithm that involves the serial use of clinical balance tests has been proposed.[114] Leddy et al[115] examined the BBS, the Functional Gait Assessment (FGA),[126] and the *Balance Evaluation Systems Test (BESTest)*[127] and found that all three demonstrated high reliability scores and that the BESTest was most sensitive for identifying fallers. Steffen and Seney[118] also found high reliability scores for the BBS, the 6-Minute Walk Test (6-MWT), and gait speed. Minimal detectable change (MDC) values were identified with MDC for the BBS = 5/56, the 6-MWT = 82 m, comfortable gait speed = 0.18 m/sec, and fast gait speed = 0.24 m/sec. In contrast, the *Tinetti Gait Assessment (TGA)* was not sensitive for detecting change in gait impairments in people with moderately disabling PD.[128] Strong stability of measurements on balance tests occurs during the "on" phase of the medication cycle while stability of measurements is not maintained during the "off" period.[129]

Reduced postural control is evident during quiet standing (static control), with increased oscillations in both medial-lateral and anterior-posterior planes.[130] During dynamic posturographic tests, postural restabilization strategies are often inadequate to maintain balance. Available postural strategies and reactions should be carefully documented (e.g., use of ankle, hip, and stepping strategies). Healthy individuals typically respond initially using an ankle strategy with small shifts in their COM, followed by hip and stepping strategies with larger shifts in the COM. Persons with PD and the elderly population in general typically respond to destabilizing forces with postural strategies involving more the hip joints than ankle joints. Start hesitation, abnormal coactivation patterns (rigid body) with an inability to recover a stable posture, is common. An absence of postural strategies (i.e., patient would fall if not for overhead body support harness) is also seen in advanced disease. During complex postural situations involving sensory conflict (e.g., the Sensory Organization Test), persons with advanced PD typically demonstrate reduced postural performance, suggesting inadequate sensory organization.[131] Balance control can also be expected to degrade under conditions of reduced cognitive monitoring. Patients with PD especially in the early stages of the disease may not demonstrate balance impairments in response to steady standing with normal BOS or self-initiated movements as along as their attention is fully directed to the task at hand. However, if competing attentional demands are instituted (i.e., *dual-task interference* such as talking while balancing), instability can be seen.[132] Balance confidence is also related to functional mobility and falls in people with PD.[133]

Gait

Parameters and characteristics of gait that should be examined during unobstructed walking on level surfaces include start time or gait initiation, speed of walking, stride length, cadence, stability, variability, and safety. The *10-Meter Walk Test* can be used to determine speed, average stride, and cadence or more sophisticated kinetic analysis can be obtained from embedded force plates, body markers, and computerized equipment (motion analysis systems typically seen in the laboratory setting). Persons with PD frequently demonstrate decreased step length and trunk rotation, difficulty initiating gait, and difficulty attaining increased walking speed. When instructed to walk as fast as possible, the movements produced are smaller and more variable when compared to healthy elders.[134,135]

Gait should be examined for kinematic or qualitative changes, including reductions in hip, knee, and ankle motions that result in a short-stepped, shuffling (festinating) gait pattern with reduced trunk rotation and arm swing. Postural abnormalities that contribute to the development of a festinating gait pattern should be documented (i.e., flexed, stooped posture). Gait should be examined in all movement directions: forward, backward, and sideward. A complex gait pattern such as cross-stepping or braiding can be used to examine deficits in motor planning. Patients with advanced PD typically experience difficulty with adaptability and cannot easily vary walking or walk in complex confined areas such as narrow doorways or open environments. Walking should be examined in varied environments (e.g., community environment) or negotiating an obstacle course. Increased difficulty in walking is also experienced in response to varying attentional demands and dual-task interference. Changes in gait speed, stride length, and cadence can be observed while simultaneously performing a secondary cognitive task (e.g., *Walkie-Talkie Test)* or walking while simultaneously performing a secondary motor task (e.g., carrying objects on a tray). The degree of change was not significantly different with regard to type of dual task interference.[132] Clinical measures of locomotor performance shown to be reliable and sensitive for people with PD include the DGI, the FGA, and the TUG (all previously discussed). Huang et al[136] identified the minimal detectable change values for both the TUG and the DGI.

Freezing of Gait

Freezing of gait, an episodic inability to generate effective stepping in the absence of any known cause, has a

dramatic effect on quality of life and risk of falls for patients with PD.[137,138] Assessment is often difficult due to the unpredictable nature of the episodes. The therapist needs to document triggers or provoking factors. Common triggers for FOG include initiating gait, walking through narrow passages (e.g., doorway) or turning in tight spaces, a change in the environment or attentional demands, and walking under time pressure, anxiety, or stress. In the early stages of the disease, episodes are levodopa sensitive and more common in the "off" time. In advanced stages, FOG can occur during the "on" time.[139] The *New Freezing of Gait Questionnaire (NFOG-Q)* is a reliable three-part questionnaire and short video to detect and rate FOG severity and impact.[140]

Fall Risk

A determination of fall history and fall injuries is an important component of the examination of balance and gait function. There is a strong association between duration and severity of PD with increased risk of falls. Of particular significance is balance and walking impairments including FOG, anterior displacement of COM, decreased postural righting reactions, and the presence of dyskinesias. Other linked factors include postural hypotension, dementia, depression, and prior history of falls.[112-115] A *fall risk diary* can be used to assist the patient and family/caregivers in accurately recording a fall event and the context of daily life in which the fall occurred. For example, activity at the time of the fall, relation to timing of medication and food intake, type of footwear, degree of fatigue and injury, and other risk factors all should be documented. The need for assisted gait and frequency of contact guarding from family members or caregivers during walking should also be documented.

Fatigue

Fatigue is a common impairment associated with PD. As the disease process progresses so does the prevalence of fatigue and its impact on quality of life.[141,142] The Movement Disorders Society (www.movementdisorders.org) created a task force to evaluate and make recommendations on available fatigue rating scales.[143] Following the systematic review, the task force recommended the *Multidimensional Fatigue Inventory (MFI)* and the *Fatigue Severity Scale (FSS)* for assessment of fatigue in patients with PD. The MFI is a 20-item self-report scale that measures general fatigue, physical fatigue, mental fatigue, reduced motivation, and reduced activity.[144] The FSS is a self-administered 9-item rating scale that emphasizes the functional impact of fatigue.[145]

Dyskinesias

Drug-induced dyskinesias have a profound effect on physical and social functioning. Risk factors include high total dosage of dopaminergic drugs, young age at onset of PD, and extended duration of the disease process.[146,147] The *Rush Dyskinesia Scale* assesses functional disability by grading the subject walking, drinking from a cup, and putting on and buttoning a coat. The scale is recommended by the Movement Disorders Society (MDS) Task Force on scales to assess dyskinesia in PD and has been used extensively in clinical trials and patient care, and has undergone extensive clinimetric testing.[148]

The therapist can explore the impact of motor fluctuations using questions that address changes in performance during the day. Sample questions might include the following:

- Do you experience increasing difficulties with your functional activities during certain times of the day?
- What time of day do you experience the greatest difficulty?
- How long after you take your medications do you start to move better?
- Do you experience increasing difficulties as your medications wear off?

Swallowing and Speech

An examination of swallowing function, feeding, and speech is important. Referral to a speech-language pathologist may be indicated if the patient demonstrates significant limitations in any of these areas.

Autonomic Function

The therapist should examine for problems with autonomic dysfunction. Excessive drooling (salivation) or sweating, greasy skin, and abnormalities in thermoregulation should be noted. Excessive sweating and flushing during the "on" state is linked to the presence of dyskinesias.

Cardiorespiratory Function

Endurance may be reduced as a result of impaired cardiorespiratory function and long-standing inactivity, both common problems in PD. An examination of respiratory function should include inspection of rib cage compliance, chest wall mobility, and thoracic expansion. Visual inspection of breathing patterns and an examination of the influence of posture and activity on breathing should be performed. Objective measurements include respiratory rate (RR) and circumferential measurements of the chest. Specific ventilation parameters may be determined in patients with significant respiratory compromise. These can include FVC, FEV_1, maximal expiratory flow (MEF), maximal inspiratory flow (MIF), total lung capacity (TLC), residual volume (RV), and RAW.

Individuals with mild PD (Hoehn-Yahr Classification Stages I and II) can demonstrate aerobic exercise capacities similar to healthy adults. Individuals with more advanced disease (Hoehn-Yahr Classification Stages III and IV) demonstrate greater variability and lower aerobic capacities compared to healthy adults. It is important to remember that many older adults are at high risk for latent cardiovascular disease. Exercise testing can be used to determine the patient's level of fitness before commencing

an exercise program. Patients who have balance deficits or freezing episodes should not be tested on a treadmill without the use of a safety harness. Cycle ergometry (arm or leg) may be an acceptable alternative. A *6- or 12-Minute Walk Test* can be used to determine endurance capacity and walking velocity. The therapist should document vital signs (HR, RR, BP), exertional symptoms (dyspnea, dizziness or confusion, excessive fatigue, pallor, and so forth), time, distance, and number of rest stops.[54] For patients with advanced PD (Hoehn-Yahr Classification Stages III and IV), Light et al[149] used a *2-Minute Walk Test* to evaluate walking endurance and found it to be a sensitive and feasible test. Perceived exertion can be documented using Borg's Rating of Perceived Exertion Scale (RPE Scale).[150]

Orthostatic Hypotension

Orthostatic hypotension (OH) with positional change should be examined. Subjective signs and symptoms of OH on sitting up and standing up are documented (e.g., dizziness, light-headedness, pallor, diaphoresis, or syncope). A drop in systolic blood pressure (SBP) of 20 mm Hg, or a drop of 10 mm Hg in diastolic blood pressure (DBP), *and* a 10% to 20% increase in pulse rate is diagnostic of the condition. The examination begins with the patient resting in supine for 2 to 3 minutes. Resting BP and HR are taken. The patient is then asked to move from supine-to-sitting. After at least 1 minute, BP and HR are taken. If the patient is stable after at least 3 minutes (no symptoms), testing can be performed in the standing position. The patient is asked to move from sitting-to-standing with BP and HR again taken after at least 1 minute and repeated between 3 and 5 minutes. BP that continues to drop after at least 1 minute of standing is problematic and is evident in advanced PD.[151]

Integumentary Integrity

Sympathetic skin responses may be abnormal. For example, the skin may become oily (e.g., on face). Seborrhea or seborrheic dermatitis occurs frequently in patients with PD. The therapist should examine the patient closely for areas of bruising and skin breakdown. Patients who are severely disabled (Hoehn-Yahr Classification Stage V) are restricted to bed, wheelchair, or both. Incontinence may occur during late-stage disease. The effect of these problems on skin integrity should be carefully documented. Use and effectiveness of pressure-relieving strategies and devices should also be documented.

Functional Status

An examination of functional status is indicated, including performance of functional mobility skills, basic activities of daily living (BADL), and instrumental activities of daily living (IADL). For patients undergoing inpatient rehabilitation, the *Functional Independence Measure (FIM)* is commonly administered[152] (see Chapter 8, Examination of Function). Need for and appropriate use of protective and supportive devices is an important component of the functional status examination. Close collaboration with the occupational therapist is essential.

During functional performance tests, each skill should be analyzed to determine the impact of direct and indirect impairments on performance. For example, sit-to-stand transfers typically present a significant challenge for patients with moderate to severe PD as evidenced by increased time and increased falls. These changes have been attributed to hypokinesia, decreased rates of force production, and changes in distal muscle timing.[153,154] The *Five Times Sit-to-Stand Test (FTSTS)* is a timed test that has been used to determine performance in patients with PD at different disease stages and to discriminate between fallers and nonfallers with PD. In one study the average time for FTSTS performance for community-dwelling individuals with PD was 20 seconds with a cut-off time of 16 seconds discriminating between fallers and nonfallers.[155] Timed performance can also be used for other functional tasks such as rolling over in bed or moving from supine-to-sitting that are likely to prove difficult. These activities have a large rotational component of the trunk, typically lacking in many patients with PD.

Functional testing should be balanced with adequate rest to ensure that fatigue does not degrade performance with resultant fluctuations. Repeat testing should be undertaken at the same time of day and importantly at the same time in the medication cycle. Filming task activities can provide an objective record of functional performance. This is particularly useful to document motor fluctuations and dyskinesias. An examination of functional performance in the home (or work) environment is also indicated. The patient's physical environment is examined for barriers, access, and safety.

Profile of Function and Impairment Level Experience with Parkinson's Disease

The *Profile of Function and Impairment Level Experience with Parkinson's Disease* (*Profile PD*) was developed to assist the physical therapist's examination and evaluation of individuals with PD in the early and middle stages of disease. It uses a 0 to 4 scale with 0 = no problem and 4 = severe or marked difficulty with descriptive anchors for each score. Approximately 50% of the test relates to deficits in body systems and cognitive/emotional factors. These include questions on tremor (with activity and at rest), rigidity, posture, postural stability, dyskinesia, dystonia, clinical fluctuations, falling, FOG, bradykinesia, speech, depression, memory, and involvement (routine daily/leisure/social activities). The remaining 50% of items focus on functional activities that are typically difficult for individuals with PD (e.g., dressing, hygiene, mealtime activities, transfers, bed mobility, chair rise, gait, fine and gross motor performance). Initial testing revealed it to be a reliable and valid scale with an inter-rater reliability of 0.97 and construct validity with the UPDRS of 0.86. It has an estimated administration time of 15 minutes.[156]

Global Health Measures

Global health measures can be used to determine individual outcomes across a broad spectrum of populations. Instruments typically include items that examine ability to perform routine daily activities and quality of life (e.g., physical and social function, general health and vitality, emotional well-being, bodily pain, and so forth). General health measures have been used to study large populations and are most useful in determining long-term health outcomes. They lack the sensitivity needed to document short-term outcomes of treatment. Commonly used measures of general health status include the *Rand 36-Item Health Survey SF-36*[157] and the *Sickness Impact Profile.*[158]

Disease-Specific Measures

Disease-specific measures are designed to determine attributes unique to a specific disease entity. Items are included that provide information about the disease process and outcomes, and ideally document clinically meaningful change over time. Thus, these instruments have greater responsiveness or sensitivity to change than general health measures. The *Parkinson's Disease Questionnaire (PDQ-39)* is a 39-item questionnaire developed from in-depth interviews with patients with PD.[159] It focuses on the subjective report of the impact of PD on daily life and addresses eight health-related quality-of-life dimensions (mobility, ADL, emotional well-being, stigma, social support, cognition, communication, and bodily discomfort). The PDQ-39 produces a profile of scores on the eight individual dimensions. A summary score using the *Parkinson's Disease Summary Index* (PDSI) can also be determined, with scores that range from 0 (perfect health) to 100 (worst health). It provides a useful indication of the global impact of PD on health status. Internal and test–retest reliability were found to be moderate to high with reported ranges from 0.68 to 0.96. Construct validity was examined by comparing the PDSI with other measures of health. Significant and high correlations were found between the PDQ-39 and the SF-36 and the Hoehn and Yahr staging score.[160]

A determination of goals and outcomes is based on careful examination and evaluation of the patient's individual abilities, impairments, activity limitations, and disability. Box 18.4 provides examples of general goals

Box 18.4 Examples of General Goals and Outcomes for Patients with Progressive Disorders of the Central Nervous System,* adapted from the *Guide to Physical Therapist Practice*[97]

Impact of pathology/pathophysiology is reduced.

- Patient/client, family, and caregiver knowledge and awareness of the disease, prognosis, and plan of care is enhanced.
- Symptom management is enhanced.
- Risk of secondary impairment is reduced.
- Intensity of care is decreased.

Impact of impairments is reduced.

- Cognitive function is improved.
- Joint integrity and mobility are improved.
- Sensory awareness and skin integrity are improved.
- Pain is decreased.
- Motor function is improved.
- Muscle performance (strength, power, and endurance) is improved.
- Postural control and balance are improved.
- Gait and locomotion are improved.
- Management of fatigue is enhanced.
- Aerobic capacity is increased.

Ability to perform physical actions, tasks, or activities is improved.

- Independence in activities of daily living is increased.
- Tolerance of positions and activities is increased.
- Activity pacing and energy conservation skills are enhanced.
- Problem solving and decision making skills are enhanced.
- Safety of patient/client, family, and caregivers is improved.

Disability associated with chronic illness is reduced.

- Ability to assume/resume self-care and home management is improved.
- Ability to assume work (job/school/play), community, and leisure roles is improved.
- Patient/client and family knowledge and awareness of personal and environmental factors associated with worsening of the condition are enhanced.
- Awareness and use of community resources are improved.

Health status and quality of life are improved.

- Sense of well-being is enhanced.
- Stressors are reduced.
- Insight, self-confidence, and self-management skills are improved.
- Health, wellness, and fitness are improved.

Patient/client satisfaction is enhanced.

- Access to and availability of services are acceptable to patient/client and family.
- Quality of rehabilitation services is acceptable to patient/client and family.
- Care is coordinated with patient/client, family, caregivers, and other professionals.

*Anticipated goals and expected outcomes are specific to the individual patient.

and outcomes for patients with progressive disorders of the CNS and is adapted from the *Guide to Physical Therapist Practice*.[97]

PHYSICAL THERAPY INTERVENTION

A combined approach of physical therapy and pharmacological intervention plays a key role in the management of the patient with PD. Despite best efforts, progressive disability develops and affects the patient's quality of life. A variety of interventions to maximize functional ability and minimize secondary complications are used to achieve goals and outcomes, including direct interventions, supervision of assistive personnel, patient/family/caregiver instruction, environmental modification, and supportive counseling. Early intervention is critical in preventing the devastating musculoskeletal impairments these patients are so prone to develop. Interventions also focus on improvement of motor function, exercise capacity, functional performance, and activity participation. Education and support of patients, family members, and caregivers at each stage of the disease is critical to attaining optimal outcomes. The research team for the Cochrane Database of Systematic Reviews found that there was insufficient evidence to support or refute the efficacy of any given form of physical therapy over another in PD. The researchers stressed the need for improved research in this area, including large well-designed placebo-controlled randomized controlled trials (RCTs) to demonstrate the efficacy and effectiveness of "best practice" physical therapy in PD.[161,162]

Motor Learning Strategies

Patients with PD typically demonstrate motor learning deficits, including slower learning rates reduced efficiency, and increased context-specificity of learning. Learning complex movement sequences and movements dependent on internally generated cues are more difficult than those dependent on external cues. In the early and middle stages of the disease, patients can improve their performance through practice and by using additional sensory information. The amount and persistence of learning are variable and can be expected to be lower than in healthy age-matched people. In more advanced stages and in the presence of pronounced cognitive deficits, training will likely be less successful.[163-165] The therapist needs to structure treatment sessions to optimize motor learning.

Critical elements of practice include a large number of repetitions to develop procedural skills. The therapist should instruct the patient to deliberately focus his or her full attention on the desired movement. The environment should also be modified to reduce clutter and competing attentional demands that may trigger freezing episodes. The task should be modified to minimize competing cognitive demands (e.g., dual tasking). Long and complex movement sequences should be avoided or broken down into component parts. Initially, *random practice order* (i.e., practice in which the patient switches back and forth between tasks) should be avoided in favor of a *blocked practice order*, thereby reducing the effects of contextual interference. Use of *structured instructional sets* has been shown to improve movement speed and consistency.[166] For example, walking patterns can be improved with focused instructions of "swing your arms," "walk fast," or "take large steps." For the patient with advanced disease and cognitive deficits, repetitive drill-like practice should be used together with an increased focus on caregiver training to ensure safety.

External cues have been shown to be effective in triggering sequential movements and improving movement characteristics in individuals with mild to moderate PD.[167] Box 18.5 Evidence Summary presents a review of selected research in this area. *Visual cues* include stationary floor markings (e.g., brightly colored lines on the floor placed perpendicular to the gait path and spaced about one step length apart) and dynamic transportable cues (e.g., laser light signals). A laser light that projects a line onto the floor in front of the patient can be mounted on an assistive device (cane or walker) or on a subject's chest harness. [168] Visual cues have been shown to improve stride length and velocity while cadence was relatively unchanged. Freezing episodes are also reduced.[169] *Rhythmic auditory stimulation (RAS)* includes use of a metronome beat or a steady beat from a musical listening device. RAS has been shown to improve gait speed, cadence, and stride length.[170-172] The beat is typically set 25% faster than the patient's preferred pace. Auditory cues such as "Big step" have also been shown to improve gait. Examples include "1, 2, 3 stand, ready set go, big first step." Cues should be consistent, not rushed and have a rhythmical quality to them. Auditory cues appear to have a greater influence on the temporal components of movement (e.g., gait cadence, stride synchronization) rather than on spatial components. *Multisensory cueing* (use of both visual and auditory cueing) has been used for patients with PD. When sensory enhanced therapy using multisensory cueing was compared with conventional therapy, significant improvements were found in the sensory training group.[173-182]

External cues appear to facilitate movement by utilizing different brain areas. For example, the premotor cortex is active in the generation of movement in response to visual or auditory stimuli. Normally the supplementary motor area (SMA) with inputs from the BG is involved in the initiation of self-generated movements and the performance of well-learned, repetitive movement sequences. External cues heighten patient attention through a common mode of action, that is, to bypass the diminished internal cueing of the BG. Thus, focus is shifted to less automatic movement using alternative, more conscious motor control pathways. This is supported by the finding that when patients were requested to carry out a secondary task while walking (dual-tasking), the beneficial effects of visual and attentional cues was reduced.[183]

Box 18.5 Evidence Summary Effect of Visual and Auditory Cues on Gait in Individuals with Parkinson's Disease

Reference	Subjects	Design Intervention	Results	Comments
Frazzitta et al[182] (2009)	40 subjects with PD, randomly assigned to 2 groups	Cohort study that examined difference between conventional and treadmill (TM) locomotor training using cues. Group 1: TM training with RAS and visual cues. Group 2: rehabilitation protocol with RAS and visual cues and no TM. *Outcome measures:* UPDRS III, FOGQ, 6-MWT, gait speed, and stride cycle.	Both groups had significant improvement in all variables; TM group had more improvement in most functional indicators (FOGQ, 6-MWT, gait speed, stride cycle); most striking change was in 6-MWT.	TM training using auditory and visual cues might give better results than more conventional treatments; the TM may act as a supplemental external cue.
Nieuwboer et al[181] (2009)	133 subjects with PD (part of RESCUE trial), able to walk independently; freezing episodes were identified using FOGQ	Cohort study that examined the effect of 3 different cue modalities on a turning task. *Procedure:* Subjects walked at preferred speed, completing a functional task and synchronizing each step to external cueing (auditory, visual, somatosensory); order of cueing was varied. *Duration:* Test repeated 8 times: 1 baseline, 6 cueing trials, and 1 post trial. *Outcome measures*: Functional test consisting of walking 6 m, picking up a tray, turning 180º, carrying tray back to start position, and stop; using an activity; FOGQ.	Cueing, all types, increased the speed of turn in all subjects; no difference in turn performance between freezers and nonfreezers in cued and no cued conditions; auditory cueing made turning significantly faster than visual cues. Short carryover was evident in noncued trial.	Researchers used 3 types of cueing. Rhythmic cueing resulted in faster performance of a functional turn in both freezers and nonfreezers. May be explained by enhanced attention mechanisms.
Arias and Cudeiro[178] (2008)	25 subjects with PD grouped into mild (n = 16) and severe (n = 9) disease and 10 age-matched controls	Cohort, repeated measures study; examined kinematic parameters of gait (cadence, step length, velocity, coefficient of variability [CV]) at rest and in response to RAS and visual stimulation.	Patients with mild PD demonstrated altered step length, velocity and CV. Those with severe PD (III-IV Hoehn and Yahr) showed greater changes; RAS at preferred walking speed led to a dec. in CV and an inc. in step length. Visual stimulation did not modify any of the kinematic parameters for either group.	RAS is effective in facilitating gait in patients with PD. A decrease in CV may reduce risk of falling.

Box 18.5 Evidence Summary Effect of Visual and Auditory Cues on Gait in Individuals with Parkinson's Disease—cont'd

Reference	Subjects	Design Intervention	Results	Comments
Jiang et al[175] (2006)	14 subjects with PD	Cohort, repeated measures study. Analysis of first 2 steps of gait initiation with RAS and visual cues (transverse lines). *Duration*: 1 time visit. *Outcome measures:* Computerized gait way/ force platform (velocity, step length, push-off force).	Visual cue condition resulted in inc. push-off force and velocity compared to baseline; no significant effect of RAS on these measures.	RAS does not appear to influence the first 2 steps of gait initiation whereas visual cues do.
Lim et al[167] (2005)	24 studies identified (total number of patients = 626) out of 159 screened studies	Systematic review of literature.	Best evidence synthesis showed strong evidence for improving walking speed with the help of RAS. Insufficient evidence was found for the effectiveness of visual and somatosensory cues.	More high-quality research is needed. Unclear whether positive effects found in the laboratory can be generalized to improved ADL and reduced frequency of falls. The sustainability of a cueing training program remains uncertain.
Rochester et al[179] (2005)	20 subjects with PD and 10 age-matched controls	Cohort, repeated measures study, examined effect of cues on walking in home. *Procedure:* Walking while performing simple task (dual-motor task); performed with and without RAS and visual cues. *Outcome measures:* Walking speed, step length, and step frequency.	Use of auditory cues was useful in reducing interference and maintaining gait performance during dual-tasking, with significant inc. in step length.	RAS may be useful in counteracting the effects of interference during more complicated functional activities.
Del Olmo and Cudeiro[172] (2005)	15 subjects with PD and 15 age-matched controls	Cohort, repeated measures study. *Procedure:* Program of RAS and walking with and without secondary UE tasks. *Duration*: 1 hr/day 5(/wk for 4 wk. *Outcome measures:* Computerized walkway (gait velocity, step length, cadence, CV).	PD group improved temporal stability of walking; no significant difference from controls.	RAS is a valuable method of improving gait in patients with PD.
Lehman et al[173] (2005)	Part 1: 5 subjects, no controls Part 2: 11 subjects with early stage,	Cohort, repeated measures study. *Procedure:* PD group: walked 30 feet using verbal cueing ("take long steps") 10 times/	Significant inc. in gait velocity and step length; reduced cadence.	Significant effects noted in both groups but more pronounced in PD group.

Box 18.5 Evidence Summary Effect of Visual and Auditory Cues on Gait in Individuals with Parkinson's Disease—cont'd

Reference	Subjects	Design Intervention	Results	Comments
	stable PD (Hoehn and Yahr Stage 2–2.5); within 1–2 hours on PD meds Training group = 6 Control group = 5	session; control group: walking with no verbal cueing. *Duration*: 3 training sets/day for 10 days. *Outcome measures*: Step length, velocity, and cadence, preferred walking speed (GaitRite® electronic walkway).		
Mak and Hue-Chan[177] (2004)	30 subjects: 15 subjects with PD (Hoehn and Yahr Stage 2.5) Patients stable, within 1 hour on PD medication: 15 healthy controls matched for age, gender, weight, height (no PD)	Cohort, repeated measures study. *Procedure*: 2 conditions STS: (1) self-initiated; (2) with auditory cues (verbal) and visual cues (circular light at eye level). *Duration*: 2 test trials: self-initiated and cue-initiated STS. *Outcome measures*: Force through feet (force plate); kinematic analysis of movements (reflective markers, high-speed video camera).	PD group: STS self-initiated; significant dec. in hip flex and ankle DF torques; dec. velocities; prolonged MT to complete STS STS cued: Significant inc. all torque values; time to peak torque reduced by 23%–27%; no improvement in peak velocity; significant dec. in MT. Control group—STS cued: Small but significant inc. knee ext torque.	Verbal and visual cueing significantly improved performance in STS.
Suteerawattananon et al[176] (2004)	24 subjects with PD	Cohort study that examined effect of cues on gait. *Procedure:* 2 trials for each of 4 conditions (random order) that included walking: without cues; with a visual cue; with an auditory cue (25% faster speed); and with both cues. *Outcome measures*: Gait speed, cadence, stride length.	Significantly improved velocity, cadence, and stride length when cues were used; auditory cues improved cadence and speed more; visual cues improved stride length more.	The combined condition did not improve gait significantly over using each cue alone; cueing may be used to reduce gait difficulties.
Freedland et al[174] (2002)	16 subjects with PD, able to walk independently without assistive device	Cohort study, examined \effect of pulsed auditory stimulation on gait. *Procedure:* Pre-test/post-test; walking using ASM set 10% above baseline cadence. *Outcome measures*: Functional Ambulation Profile (FAP); electronic walkway (GaitRite system): footfall data, velocity; heart rate.	With ASM: FAP scores inc.; dec. in cycle time and double support; inc. in step length and step-extremity ratio.	Results confirm prior findings that ASM positively influences gait of persons with PD.

COM = center of mass; COP = center of pressure; dec. = decrease; DF = dorsiflexion; f = female; flex = flexion; FOGQ = Freezing of Gait Questionnaire; inc. = increase; indep = independent; m = male; meds = medications; MMSE = Mini-Mental State Examination; MT = movement time; PD = Parkinson's disease; RAS = rhythmic auditory stimulation; 6-MWT = 6-Minute Walk Test; STS = sit-to-stand; UPDRS = Unified Parkinson Disease Rating Scale.

Selection of the type of cue and successful use will depend on the individual patient with predicted long-term benefit of a particular type of cue linked to its initial success. External cues are clearly not effective for all patients with PD. For patients with advanced disease and severe reductions in stride length, cueing is not effective. When cueing is withheld, performance can be expected to deteriorate. Focused attention with cueing requires constant vigilance and is cognitively demanding. Thus, cueing is not suitable for patients with dementia.

Cueing may also not be effective when medication instability and disease fluctuations are present. However, for many patients, use of external cues is a valid treatment strategy and one in which improved performance can be anticipated.

Exercise Training

Amplitude-based behavioral intervention is a concept that can be applied in different contexts in the treatment of PD.[184] The "Training Big" program, also known as the Lee Silverman Voice Treatment (LSVT) Big program, is based on the concept that repetitive high-amplitude movements yield greater improvements in motor performance and possibly have a neuroprotective effect.[185] Patients are guided by a physical therapist to exercise at a high intensity (8/10 Borg's RPE Scale) for 1 hour 4 times a week for 4 weeks with large amplitude, multiple repetitions, and whole body movements that increase in complexity (Fig. 18.6). Examples of the exercises and patient directions include the following:

- "Reach left arm across the body to opposite side, keep hand open, palm up, right leg fully extended, toe pushing into the floor. Repeat on other leg and alternate."
- "Step out and land 'Big,' pushing the left foot into the floor while reaching with bilateral 'Big arms,' open hands, palms up (Fig. 18.7). Return the foot back to the start, end 'Big.' Repeat on other leg and alternate."[186]

Figure 18.6 The patient with young-onset PD steps "Big" to the side with bilateral "Big arms" and hands open, palms up.

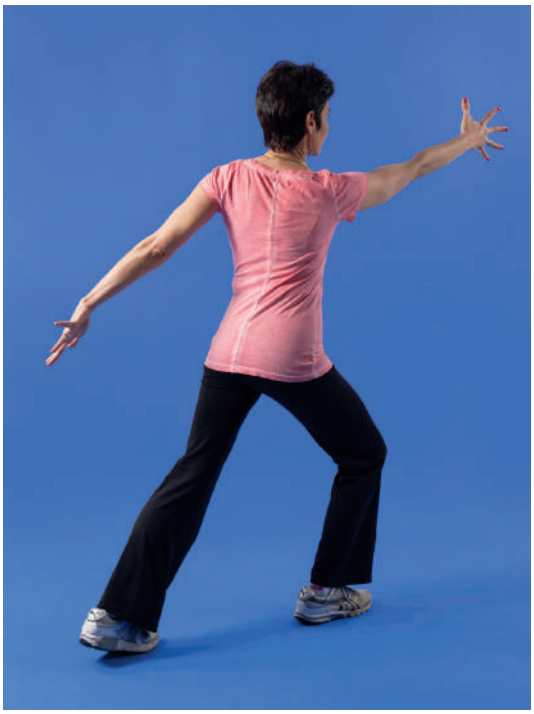

Figure 18.7 The patient with young-onset PD steps out and lands "Big," pushing the left foot into the floor while reaching with bilateral "Big arms," hands open.

These vigorous large movements of the trunk and extremities are counter to the paucity of movement normally associated with PD. After a 4-week program of LSVT "Big" training the subjects had significant improvements in UPDRS motor scores, TUG, and timed 10-m walking.[187]

Relaxation Exercises

Gentle rocking can be used to produce generalized relaxation of excessive muscle tension owing to rigidity. Professor Charcot, who noted dramatic improvement in patients with PD following rides in bumpy, horse-drawn carriages, first described this effect almost 100 years ago in Paris. Following this observation he constructed a vibrating chair to use with his patients.[188] Although the exact mechanism underlying rigidity has not been identified, the beneficial effects of slow rocking on excess tone have been demonstrated.[189] Following Charcot's lead, a rocking chair can be used to temporarily relax the patient and enhance sit-to-stand transfers. During therapy, slow, rhythmic, rotational movements of the extremities and trunk can precede interventions such as ROM and stretching, and functional training. For example, hook-lying, lower trunk rotation, or side-lying rolling can be used to promote relaxation. The proprioceptive neuromuscular facilitation (PNF) technique of *rhythmic initiation (RI),* in which movement progresses from passive to active-assistive to lightly resisted or active

movement, was specifically designed to help overcome the effects of rigidity in PD.[190,191]

Another strategy to promote relaxation is emphasis on diaphragmatic breathing during exercise. For example, bilateral symmetrical PNF D2 flexion patterns are important patterns that can be used to expand the restricted chest and promote shoulder ROM (Fig. 18.8). The patient's attention can be focused on deep inspiration during D2F ("breathe in deeply") while during D2E patterns attention is focused on expiration ("breathe out deeply").[191] Patients may also benefit from cognitive imaging or meditation techniques (e.g., the relaxation response of Benson[192]). Relaxation audiotapes can be used at home as part of the home exercise program (HEP). Stress management techniques are an important adjunct to relaxation training. A daily schedule needs to be planned to accommodate the restrictions of the disease and the functional needs of the patient. Lifestyle modifications and time management strategies reduce anxiety associated with movement difficulties and prolonged times required to complete basic functional tasks.

Flexibility Exercise

The purpose of flexibility exercise (stretching) is to improve ROM and physical function. A combination of static (PROM), dynamic (AROM), and facilitated PNF exercises is used to achieve maximum ROM. Flexibility exercises should be performed a minimum 2 to 3 days per week and ideally 5 to 7 days per week. A minimum of 4 repetitions per stretch held for 15 to 60 seconds is recommended.[54] Special consideration should be given to stretching common areas of limitation (Table 18.4). Stretching can be combined with joint mobilization techniques to reduce tightness of the joint capsule or of ligaments around a joint (Fig. 18.9). By using selected grades of accessory movement, both improved ROM and decreased pain can be achieved. The stretching will be more effective if the muscles have been warmed with active exercise or with an external heating modality. Stretching exercises are an important component of the HEP. The patient and caregiver should be instructed in the appropriate stretching exercises.

Figure 18.8 The patient with PD performs bilateral symmetrical PNF D2 flexion patterns while sitting (note the difficulty in achieving full shoulder flexion with the LUE).

A yoga sequence can be used effectively to focus attention on developmental postures, core stability, and stretching of structures that are traditionally restricted with PD, as well as to promote relaxation (Appendix 18.B).

Patients with PD have a minimum of energy to expend and multiple clinical problems. They may benefit from ROM exercises in physiological patterns of motion. For example, PNF patterns combine several motions at once while emphasizing rotation, a movement component typically lost early in PD. In the UEs, bilateral symmetrical D2 flexion patterns are ideal in promoting upper trunk extension and in counteracting kyphosis. Unilateral bridging with trunk rotation, bilateral bridging, and high-kneeling with anterior pelvis translation can all be used to stretch tight hip flexors and strengthen spinal and hip extensors. In the LEs, hip and knee extension should be emphasized, ideally in a D1 extension pattern (hip extension, abduction, internal rotation) to counteract the typical flexed, adducted position of the LEs. Muscle contractures typically respond well to PNF facilitated stretching techniques such as the *hold–relax (HR)* or *contract–relax (CR) techniques*.[191,192] Of the two, CR is the preferred technique because it combines autogenic inhibition from isometric contraction of the tight agonist muscle and active rotations of the limb. A 6-second contraction followed by a 10- to 30-second assisted stretch is recommended for these PNF techniques.[54]

Patients with PD benefit from additional attention and cueing strategies during active stretching exercises. Patients are instructed to "Think BIG, and move through the whole range" and maintain full focus and attention during each repetition. Additional tactile or visual cueing can assist in maximizing range during active motions. For example, during active trunk rotation and reaching movements in sitting, the patient can be cued to touch an object or target. Ballistic stretches (high-intensity bouncing stretches) should be avoided because they are linked to increased injury. Muscle tears or ruptures of weakened tissues are especially prevalent in elderly, sedentary individuals. Vigorous stretching can stimulate pain receptors and cause rebound muscle contraction. Patients with PD who are elderly and have long-standing disease must be considered at risk for osteoporosis and therefore

Table 18.4 Common Areas of Limitation and Suggested Stretching Exercises

Areas of Limitation	Suggested Stretching Exercises
Cervical retraction	• Sitting, back against wall (or supine), head retractions (chin tuck position)
Cervical rotation	• Sit (or supine), with head retracted, head turns side-to-side
Shoulder flexion with trunk extension	• Sitting, hands clasped together, overhead arm lifts with thoracic extension • Supine, pillow under thoracic spine, hands clasp together, overhead arm lifts with thoracic extension
Elbow extension	• Sitting (or standing, modified plantigrade) weight-bearing with both upper extremities (UEs), elbows extended
Trunk extension	• Sitting, thoracic extension over the back of a chair with elbows bent and shoulders retracted • Prone lying, prone push-ups (press-ups) • Standing trunk extension, hands positioned on hips
Trunk rotation	• Supine, upper trunk rotation, hands clasped together (or holding a small ball), arms move with trunk rotation side-to-side • Hook-lying, lower trunk rotation, knees move with trunk rotation side-to-side • Sitting or standing, both arms out to one side (clasped together or holding a small ball), arms move with trunk rotation side-to-side
Hip extension	• Supine with one lower extremity (LE) over edge of mat (hip extended, knee flexed), other knee held to chest • Supine, hips and knees extended • Hook-lying bridging • Standing, active hip extension or forward lunge • High-kneeling with hips extended
Hip abduction	• Supine, one LE extended and abducted, other LE in hook-lying
Knee extension	• Standing, forward lean with wall push-ups
Ankle dorsiflexion	• Standing, both forefeet on edge of step or block, heels off step, lower heels down with light touch-down support of both hands • Standing, forward lean with wall push-ups

Figure 18.9 Shoulder ROM with scapular mobilization performed in the side-lying position.

must be stretched accordingly. The therapist should also use caution when stretching edematous tissue, a common LE problem associated with prolonged immobility, because risk of injury is also increased in this situation.

Positioning can also be used to stretch tight muscles and soft tissues. Patients in late-stage PD are likely to demonstrate severe flexion contractures of the trunk and limbs. Early on, the patient may benefit from daily positioning in prone-lying. As the disease progresses and significant postural deformity and cardiorespiratory impairments develop, the patient may not tolerate this position. The patient with a developing lateral curvature can be positioned in side-lying with a small pillow under the lateral trunk. Positional stretching is prolonged, with times typically ranging from 20 to 30 minutes. Additional mechanical stretching can be achieved through the use of a tilt table, for example, the patient is positioned with fixed leg straps to reduce hip and knee flexion contractures and toe wedges to reduce plantarflexion contractures.

Resistance Training

Resistance training is indicated for patients with PD who demonstrate primary muscle weakness with impaired motor unit recruitment and rate of force development and disuse weakness associated with prolonged inactivity. Specific areas of weakness are targeted, such as the

antigravity extensor muscles. Weakness of these muscles is associated with poor posture (e.g., a flexed, stooped posture) and functional deficits (e.g., inability to get out of a chair, limitations in gait function).[193-195] Weakness also contributes to postural instability, falls, and fall injury, as well as increased sense of effort.[196] The benefits of strength training in the frail elderly have been well documented by the *Frailty and Injuries: Cooperative Studies of Intervention Techniques (FICSIT) trials*.[197] Collectively these studies have shown that the frail elderly improve on measures of strength, functional mobility, balance, gait, fall risk, and quality of life following interventions that include strength training.[198,199] Strength training has also been shown to improve muscle force, bradykinesia, and quality of life in patients with PD.[200] Hirsch et al[201] compared two different exercise training programs for patients with PD. They found significantly greater improvements in balance and strength using a combined program of balance training and high-intensity resistance training for knee extensors and flexors and ankle plantarflexors as compared to balance training alone.

Resistance training is based on the *progressive overload principle*. The amount of resistance is increased during training. Load can be applied using resistance machines, free weights, elastic resistance bands, or manually. With older adults the recommendation is to begin at a lower intensity (e.g., using an RPE Scale of somewhat hard, 5 to 6 on a 10-point scale), ensuring that a set of 10 to 12 repetitions per set can be completed.[202] Progression is as tolerated. Each repetition should be held for 10 seconds. Strength training can be performed 2 days per week on nonconsecutive days. Exercise machines may be safer than free weights for patients with more advanced disease because the movements are more controlled, especially for the patient who demonstrates dyskinesias at peak dose or cognitive changes.[54] Because patients with PD already demonstrate too much stiffness and coactivation, isometric training is generally contraindicated. Functional training activities (see next section) can also be effective interventions to improve strength.

Corcos et al[24] found a significant interaction between medication and strength. Withdrawal of L-dopa during an "off" state period caused a decrease in strength and rate of force development. Exercise training should therefore optimally be timed for "on" periods when the patient is at his or her best (i.e., 45 minutes to 1 hour after medication has been taken). Exercising during an "off" period may not be possible or pose great difficulty for the patient. The patient should consistently exercise at the same time during a medication cycle.

Functional Training

An exercise program should be based on focused practice of functional skills. The overall emphasis is on improving functional mobility with specific emphasis on improving mobility of axial structures, the head, trunk, hips, and shoulders. Progression to more difficult motor activities should be gradual. The more severely involved patient may benefit initially from assisted movements progressing to active movements (e.g., the PNF technique of RI) to improve initial motor performance.[203]

Bed mobility skills (i.e., rolling, bridging, supine-to-sit transitions) are essential skills that are often very difficult owing to truncal rigidity and bradykinesia. Side-lying rolling activities that emphasize segmental rotation patterns (i.e., isolated upper and lower trunk rotations) should be practiced rather than a log-rolling pattern. Patients with very stiff trunks may benefit from compensatory rolling strategies using the UE or LE to reach over and initiate the movement (e.g., D1F patterns of the UE or LE). Rolling should be practiced on different surfaces progressing from firm to soft and finally simulating the patient's bed surface at home. Bridging is an important activity that improves scooting in bed as well as sit-to-stand transfers (Fig. 18.10).

Sitting can be enhanced through exercises designed to improve pelvic mobility as the patient with PD typically sits with a stiff and posteriorly tilted pelvis (i.e., sacral sitting position) along with a flexed upper trunk. Anterior and posterior tilts, side-to-side tilts, and pelvic clock exercises can be practiced while sitting on a therapy ball, which enhances ease of movement (Fig. 18.11). These activities can then be progressed to sitting on a stationary surface such as a mat table using an inflatable disc to finally no apparatus. Sitting activities should include weight shifting emphasizing upper trunk rotations and reaching. PNF extremity patterns in sitting can be used to enhance trunk mobility. For example, bilateral symmetrical UE D2F and D2E patterns are ideal to promote upper trunk extension. Or a lift/reverse lift pattern can be used to promote upper trunk extension with rotation.

Sit-to-stand (STS) is a difficult activity for many patients with PD, especially with moderate or advanced disease or when in the "off" state. Issues in poor dynamic stability and inadequate limb support contribute to falls. Patients demonstrate poor timing in controlling their COM forward velocity, which tends to be slower. Insufficient upward momentum (LE extension torques) in

Figure 18.10 The patient with PD practices bridging (note the difficulty in achieving full hip extension).

Figure 18.11 The patient with PD practices sitting on ball with UEs abducted to the sides, hands open.

standing up is also problematic.[194] Other factors include level of agonist-antagonist coactivation and rigidity. STS training begins with the patient scooting to the edge of the mat and placing both feet under the knees and apart. Forward trunk flexion can be enhanced through initial rocking, which encourages relaxation. Cueing strategies (e.g., counting, placing one hand between the patient's shoulder blades) can be used to assist the forward lean. Sitting on an inflated disc can also assist in the forward weight shift and seat-off. Standing-up is enhanced by improved LE muscle strength. Strengthening of the hip and knee extensors can be achieved using modified wall squats. Practice standing up from a firm *raised* seat decreases the total excursion and work of extensor muscles and promotes ease of rise. Once control is achieved, progression is then to lower, standard height seats. Standing directly in front of the patient should be avoided, because this may block initial standing attempts. Instead, the therapist or caregiver should stand to the patient's side. If safety issues are apparent, a safety gait belt should be used. The more involved patient can practice STS from a chair with both hands on armrests.[193]

Standing activities can model the progression used in sitting. The patient needs to first gain the fully upright position with symmetrical weight-bearing over the BOS. Tactile cueing or light resistance can be used on the anterior pelvis to encourage movement of the hips forward into full extension. Once standing, weight shifts and rotational movements of the trunk should be practiced (e.g., reciprocal arm swings or reaching movements). Step-ups using a low platform step (forward, lateral) should be practiced. Backward stepping can be used to strengthen hip and spinal extensors and promote upright posturing. To increase the challenge during stepping, elastic resistive bands can be used (Fig. 18.12). The patient can also practice standing with UEs extended and hands weight-bearing on a wall to promote upper trunk extension.

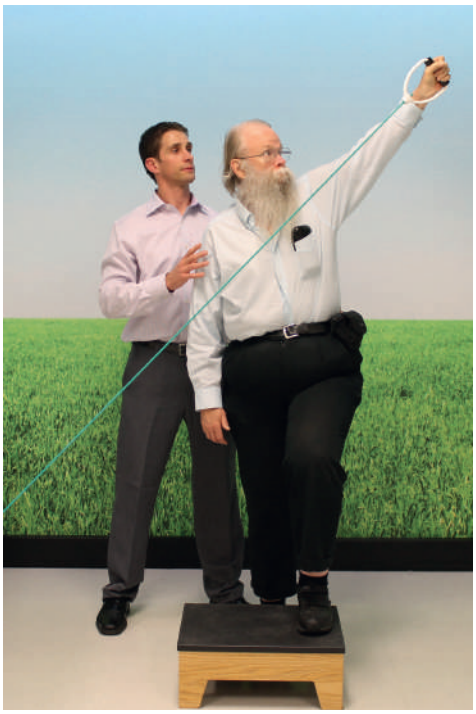

Figure 18.12 The patient with PD practices maintaining a step-up position while performing resisted UE shoulder abduction and flexion using elastic band resistance. The patient is encouraged to turn and look at the hand.

Patients with PD typically experience a high number of falls and should be taught how to get up after a fall. To that end, skills in quadruped creeping should be practiced so the patient is able to move to a nearby stable chair or couch at home. The patient should also practice transitions moving from quadruped to kneeling to half-kneeling and finally to standing using UE support.

Mobilizing facial muscles is another important component of the exercise program because the patient will have limited social interaction and poor feeding skills in the presence of marked facial rigidity and bradykinesia. These factors can greatly influence the patient's overall psychological state, motivation, and social participation. Massage, stretch, manual contacts, and verbal cueing can be used to enhance facial movements. The patient can be instructed to practice lip pursing, movements of the tongue, swallowing, and facial movements such as smiling, frowning, and so forth. A mirror can be used to provide visual feedback. In cases where eating is impaired by immobility, the movements of opening and closing the mouth and chewing should be combined with neck stabilization in a neutral position. Verbal skills should be practiced in association with breath control.

Balance Training

It is important to recall that learning is task and context specific. Thus, a balance training program should include a variety of activities that alter task demands and expose the patient to varying environmental conditions. Whenever possible the therapist should try to duplicate

the conditions the patient will encounter in everyday life. The level of challenge is important. A therapist should know the limitations of the patient and the specific demands of the task and environment in order to select and progress tasks accordingly and ensure patient safety. See Chapter 10, Strategies to Improve Motor Function, for a more complete discussion of balance training.

An important focus of balance training for the patient with PD is COM and LOS control training. Patients should be instructed in how COM influences balance and how to improve posture in sitting, in standing, and during dynamic movement tasks. Patients should also explore their LOS and practice working toward expanding them in both sitting and standing. In standing, patients with PD typically demonstrate restricted LOS with forward displacement of center of foot pressure. Patients should be instructed in how to improve postural alignment and in ways to avoid postural disturbances and falls. The therapist can assist with postural and safety awareness by using appropriate verbal, tactile, or proprioceptive cues to facilitate the desired responses. For example, the patient is instructed to "sit tall" or "stand tall" and a mirror is used to provide feedback concerning upright posture. A standing platform training device (i.e., posturography system) can be valuable in providing COM position and LOS biofeedback. The patient is instructed in weight shifting that expands the LOS. The Nintendo Wii Balance Board is a widely available and economical force platform and biofeedback system. When compared to a laboratory-grade force platform the Nintendo Wii Balance Board was valid in quantifying center of pressure, an important component of standing balance.[204] Subjects with poor positional awareness who trained on the Wii Balance Board with real-time visual biofeedback demonstrated significant improvements in weight-bearing symmetry.[205] Elderly subjects who trained with this device over a 4-week period improved on average 9.14 points on the BBS.[206]

Balance training should emphasize practice of dynamic stability tasks (e.g., weight shifts, alternating unilateral weight-bearing, reaching, axial rotation of the head and trunk, axial rotation combined with reaching, and so forth). Seated activities can include sitting on a compliant surface (inflatable disc) or a therapy ball. Challenges to balance can also be introduced in quadruped (Fig. 18.13), kneeling (Fig. 18.14), half-kneeling (Fig. 18.15), and standing on a disc (Figs. 18.16 and 18.17). Altering arm positions (e.g., arms out to side, arms folded across chest, reaching); altering foot/leg positions (e.g., feet apart, feet together); or adding voluntary movements (e.g., overhead arm clapping, head and trunk rotations, single leg raises, stepping or marching in place) can all be used to increase difficulty of the activity. Training should focus on achieving faster initiation and execution movement times supported by the use of appropriate cueing strategies.[166] Externally induced perturbations in the form of gentle manual displacements of the patient's COM are generally contraindicated for many patients with PD because they can produce an increase in postural stiffness and fixation. Strategies for varying environmental demands include altering the support surface (e.g., standing on foam), visual inputs (e.g., reduced lighting, eyes closed), or challenging the patient with a variable open environment (e.g., busy clinic setting).

Figure 18.13 The patient with PD practices contralateral UE/LE lifts in quadruped over a ball.

Figure 18.14 The patient with PD practices kneeling on a BOSU™ disc. The therapist provides resistance using an elastic band to promote full hip extension.

Adequate strength and ROM are important components needed to withstand the challenges of balance. The patient can be instructed in standing exercises to enhance balance, including heel-rises and toe-offs, partial wall squats and chair rises, single-limb stance with side-kicks or back-kicks, and marching in place. Collectively these exercises are sometimes referred to as the *"kitchen sink exercises"* and are important components of the HEP

Figure 18.15 The patient with PD practices half-kneeling on a BOSU™ disc while performing resisted UE shoulder abduction and flexion using elastic band resistance.

Figure 18.16 The patient with PD practices standing on an inflated disc while reaching across, promoting upper trunk rotation.

for patients with balance deficiencies. The patient may require light touch-down support of the hands to start in order to stabilize; progression should be to no support as soon as possible.

Whole body vibration (WBV) is gaining popularity as a treatment for patients with neurological diseases. It is theorized that the seesaw-like displacement of the platform mimics human gait[207] and that postural responses are induced by vibration of the foot soles.[208,209] It is also believed that WBV increases efficiency of agonist/antagonist pairs.[210,211] Systematic literature reviews reveal insufficient high-quality studies and only minor

Figure 18.17 The patient with young-onset PD practices standing with one foot on an inflated disc with bilateral "Big arms" and hands open, palms up.

evidence from the current literature that WBV improves strength, proprioception, gait, and balance.[212,213] For people with PD, WBV seated in a physioacoustic chair resulted in improved gait, UPDRS scores, and upper limb control and significant reductions in tremor and rigidity.[214] Another study examined the effect of treatment standing on a random multidirectional vibrating platform. After WBV, subjects presented with significantly improved scores on the UPDRS with reductions in tremor and rigidity.[215] Additional quality research examining the efficacy of WBV in the treatment of people with PD is needed.

Locomotor Training

Locomotor training goals focus on reducing primary gait impairments, which typically include slowed speed, decreased stride length, lack of a heel-toe sequence with forward progression characterized by a shuffling (festinating) gait pattern, diminished contralateral trunk movement and arm swing, and an overall attitude of flexion while walking. Goals also focus on increasing the patient's ability to safely perform functional mobility activities and prevent falls.[216] Effective strategies for improving upright alignment and safety include having the patient walk with vertical poles (pole walking) (Fig. 18.18). Strategies to enhance posture, step length, velocity, and arm swing include the use of *verbal instructional sets* (e.g., "Walk tall," "Walk fast," "Take large steps," "Swing both arms"). Behrman et al[217] found that commands for large step and arm swing were more effective instructional strategies than the command to walk

Figure 18.18 The patient with PD practices walking using two vertical poles.

Figure 18.19 The patient with young-onset PD practices cross-step walking.

fast. As previously discussed, visual and auditory cues are also effective in improving gait speed and step length. Transverse visual–spatial cues (across the gait path) were more beneficial than parallel visual cues (alongside the gait path) in improving gait velocity, stride length, and percentage of leg stance time.[218] Strategies to improve foot placement can include use of floor markers or footprints on the floor. Strategies to improve step height include practice marching in place progressing to walking using an exaggerated high stepping pattern. Brisk marching music can be used to enhance pace. Sidestepping and crossed-step walking can be practiced (Fig. 18.19). The PNF activity of braiding, which combines side-stepping with alternate crossed-stepping, is an ideal training activity for the patient with early PD because it emphasizes lower trunk rotation with stepping and side-stepping movements. It can be practiced with the patient holding on lightly to a dowel held jointly with therapist or as a free walking pattern. Advanced stepping and balancing can be achieved by having the patient practice juggling scarves (Fig. 18.20). Reciprocal arm swing during gait can be enhanced by having the patient and therapist hold onto a set of two dowels (one in each hand). The therapist walks behind the patient and uses his or her arm swing to assist the patient's.

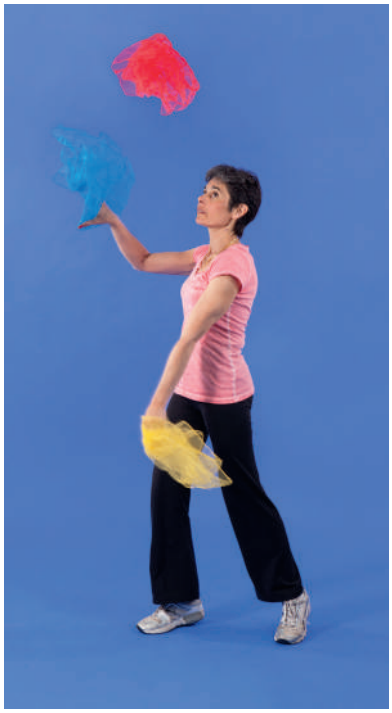

Figure 18.20 The patient with young-onset PD practices stepping and juggling a set of scarves.

Patients with PD who practiced locomotor training on a motorized treadmill with an overhead harness demonstrated improvements in postural stability, gait (e.g., walking speed, step and stride length), motor function, and quality of life.[219-227] Both body weight support (e.g., up to 20%)[220] and no body support have been used.[219] In a long-term study, Miyai et al[221] found that gains in walking speed and number of steps following this type of training were maintained at 4 months. The researchers stated that attentional strategies were not used and speculate that the enhancement of gait might

be due to activation of central pattern generators as is thought the case in stroke and spinal cord injury (SCI) studies. The treadmill may be acting as an external cue to enhance gait rhythmicity and reduce gait variability.[224] The benefits of treadmill training, as with exercise training in general, are dose dependent. More pronounced improvements are noted with high-intensity practice and incremental increases in treadmill speed.[225,226] High-intensity treadmill training has been shown to normalize corticomotor excitability in early PD.[226] The motorized treadmill has also been used for step training in people with PD. While supported in a safety harness, patients practiced stepping in all four directions in response to suddenly turning the treadmill on and off.[228]

Locomotor training should also include task-specific training designed to promote full participation in social roles pertaining to family life, leisure, and community participation. This includes varying the walking task (e.g., walking on a tile floor, on carpet, outdoors on sidewalks and grassy terrain). Additional challenges include walking in the community (e.g., variable open environments), stair climbing, up and down curbs, and ramp walking. Patients with PD often demonstrate difficulties in obstacle stepping due to minimized foot clearance. Foot clearance can be improved with repeated practice of stepping over horizontal floor markers or laser light signals.

Patients in the advanced stage of the disease will be limited in terms of walking and variations that can be utilized. The overall goal at this stage is to promote regular walking while maintaining safety and preventing falls. Compensatory training strategies are indicated. Caregiver instruction regarding assisted walking and safety is imperative. Freezing episodes are common and are often resistant to drug therapy. The therapist and patient should identify and practice strategies for unfreezing gait.[229] For example, cueing or "trick" movements such as dropping a tissue that the patient must step over can be successful in reducing freezing. Some patients, especially those in the postural instability gait disturbed group, can benefit from walking with a therapy dog. The dog provides an assist in balance and momentum, and a source of external cueing of stepping movements (Fig. 18.21).

Figure 18.21 The patient with young-onset PD and primary impairments in postural stability and gait walks with the assist of canine partner.

Spinal Orthotics

Spinal bracing may be an appropriate adjunct to therapy for patients with postural deformities common to PD (e.g., increased thoracic kyphosis, decreased costal expansion, and forward head posture). The Spinomed thoracolumbar orthosis is unique in that it not only corrects faulty posture but also has been shown to increase trunk stability, increase respiratory vital capacity, and improve a patient's self-report of well-being.[230,231] When the brace was worn for 6 months the subjects had a 73% increase in back extensor strength and a 58% increase in abdominal flexor strength. These strength gains are attributed to increased muscular activity in response to the proprioceptive biofeedback of the brace.[232] A study investigating gait stability and physical functioning in women with postmenopausal osteoporosis demonstrated decreased double limb stance time associated with a beneficial impact on gait stability.[233] Further research is warranted to determine if this type of orthotic intervention holds potential for patients with PD.

Pulmonary Rehabilitation

The four main classifications of respiratory disorders in patients with PD are medication complications, upper airway obstructions, restrictive disorders, and aspiration pneumonia.[234] Since respiratory dysfunction in the neurological movement disorders population is linked to a high rate of disability and mortality, it is critical that the prevention and treatment of these dysfunctions take priority. Components include diaphragmatic breathing exercises, air-shifting techniques, and exercises that recruit neck, shoulder, and trunk muscles. Manual techniques such as vibration and shaking can be used to ensure complete exhalation, distal alveoli opening, and to assist with secretion clearance. The patient should be instructed in deep-breathing exercises to improve chest wall mobility and vital capacity. Air shifts are promoted to lesser-ventilated areas of the lung. For example, basal expansion can be promoted using side-lying recumbent positioning, manual stretch, and resistance to those segments. Upper body resistance training exercises are

indicated. These can include raising and lowering a dowel with light weights added to increase resistance (e.g., 1 lb [453.5 g]). Weights are increased as function improves. As previously mentioned, chest wall mobility can be improved by using PNF UE bilateral symmetrical D2 flexion and extension patterns. Light weights (wrist cuffs) can also be added to these exercises. Patients are encouraged to coordinate breathing with UE movement. Exercises are performed in unsupported sitting to promote trunk stabilization. A focus on improving trunk extension is especially important in improving breathing patterns in patients with postural kyphosis. Pulmonary rehabilitation programs have been shown to be safe and effective for patients with PD in improving pulmonary function (i.e., oxygen consumption [VO_2], minute ventilation [VE], respiratory rate, inspiratory muscle strength)[235,236] and perception of dyspnea.[237]

Speech Therapy

The quality of speech in patients with PD is often a breathy monotone, soft voice that is perceived by the patient to be of normal loudness. Hypophonia is caused by a bradykinetic bellows mechanism (chest wall and diaphragm) and patients' inaccurate perception of their own speech effort. Speech deficits are seen in 80% of patients with PD and have a dramatic effect on function with 30% reporting it as the most disabling part of the disease.[239] As mentioned earlier, the Lee Silverman Voice Treatment (LSVT) was designed specifically for patients with PD.[239] It focuses on intensive high-effort exercise with a single functionally relevant target (loudness) and a recalibration of self-perception of vocal loudness. This technique effectively increases vocal loudness and improves facial expressions in patients with PD.[240-242]

Aerobic Exercise

An individualized exercise prescription is developed based on the ACSM guidelines for frequency, intensity, duration, and progression.[54] Intensities will be less than normal training intensities or submaximal (i.e., 60% to 80% of maximum HR), based on the patient's level of disease, fitness, and lifestyle. When lower intensities are used, longer-duration or more frequent exercise sessions are necessary to improve fitness. Careful monitoring is indicated, because autonomic dysfunction is common. Long-term L-dopa use can produce arrhythmias and OH along with dyskinesias. The therapist should monitor vital signs (HR, RR, BP), RPE, fatigue levels, and symptoms of exertional intolerance (e.g., significant dyspnea, hypotensive response, and so forth).

Training modes can include leg and arm ergometry and walking. Selection will depend on the specific abilities of the patient; for example, postural instability and increased risk of falls may rule out use of a treadmill without an overhead harness. Recumbent or seated LE ergometry is a suitable alternative. For most patients a program of regular walking is recommended. The duration, speed, and terrain covered can be modified, based on individual ability. Accessibility to a supervised walking program using an indoor walking track is important for some to ensure safety. A shopping mall can provide an acceptable environment for community walkers in case of inclement or extremes of weather. A supervised aerobic pool program can also provide an acceptable mode of exercise for some patients. The warmth of the water may be relaxing and the buoyancy may enhance stepping movements. The minimum recommended aerobic exercise frequency is 3 sessions per week. Daily walking with short multiple bouts (20 to 30 minutes) spaced throughout the day is recommended for individuals with lower functional capacity. Intermittent exercise with adequate rest intervals is indicated for those patients who are elderly and deconditioned, and who present with restrictive pulmonary dysfunction. Aerobic training programs have been shown to be safe and effective for patients with PD in improving aerobic capacity.[243,244]

Group and Home Exercises

Community-based group exercise classes can be valuable for patients with PD. Patients benefit from the positive support, camaraderie, and communication the group situation offers.[245,246] Careful evaluation of each patient before admission into a group is essential. Patients should be able to perform the therapeutic core of the class. Selecting patients with similar levels of disability is often advisable because the sense of competition can frequently be a key factor in motivating groups. The ratio of staff to patients should be kept small (ideally 1:8 or 1:10), and extra staff should be added if patients are unable to work on their own. A variety of activities can be used to stimulate and motivate patients. The patients can begin in the seated position and progress to standing, using light, touch-down support of the back of the chair. Stretching exercises or calisthenics involving large muscle groups and multijoint compound movements can be used as an initial warm-up activity. Progression is to combination movements (UEs and LEs with axial trunk rotation). Well-structured, low-impact aerobics are an appropriate focus for a group class. For example, patients can march in place, first in sitting, then in standing. The group can then practice walking with an emphasis on taking large, high steps. Music is used to provide necessary stimulation to movement and movement pacing. Exercise stations (e.g., stationary bicycle, mats, pulleys, and so forth) can also be used. Exercises done by the whole group together should focus on important exercise goals (e.g., improving ROM, mobility, and so forth). Recreational activities can follow the aerobic portion, such as line dancing, ball activities, beanbag toss, and so forth. The activities selected should be interesting and varied. A relaxation segment should be incorporated into each class. Yoga and Tai Chi group classes effectively address multiple components of PD by improving posture, flexibility, core stability, functional

mobility, balance, relaxation, and socialization.[247-251] King and Horak[252] recommend incorporating Tai Chi with other agility exercises (e.g., kayaking, boxing, lunges, agility training, and Pilates exercises) to delay loss of mobility in people with PD.[252]

The home-based exercises include exercises designed to improve relaxation, flexibility, strength, and cardiopulmonary function (all previously discussed). A key element is stressing the importance of regular daily exercise and avoidance of prolonged periods of inactivity. The HEP should be realistic and of moderate duration and intensity. The patient should be cautioned against overdoing activity, which could result in excessive fatigue. Early morning warm-up calisthenics are often helpful in reducing the increased stiffness patients may experience on arising. Stretching and strengthening exercises are performed in supine, sitting, and standing positions. Home ROM exercises can often be assisted by use of adaptive equipment. For example, to reduce the effects of forward head and kyphotic posture, the patient can be instructed to hang by the hands using an overhead bar. Standing, corner wall stretches can also be used to provide a maintained stretch on the upper trunk flexors. Use of a wand or cane can be effective in promoting overhead motions. In standing, a countertop or back of a sturdy chair can be used to assist in stabilization during standing calisthenics and balance activities. Home-based exercise programs have been found to be effective in improving postural control and mobility in people with PD.[253,254]

ADAPTIVE AND SUPPORTIVE DEVICES

Attention should be directed toward needs for adaptive and supportive devices that can improve function. To promote bed mobility, the patient can be helped to assume a sitting position by elevating the head of an electronic hospital bed or with commercially available blocks approximately 4 in (10 cm) high (furniture legs fit into a recess in the block). A simpler solution might include attaching a knotted rope or canvas "ladder" to the end of the bed to pull on. The bed should be stable and the mattress firm to facilitate mobility. Satin sheets and pajamas have sometimes been helpful to enhance bed mobility. Patients should be instructed to select firm chairs with armrests and avoid soft, low seats such as a low sofa. The chair can be raised (i.e., 4 in [10 cm] and secured with blocks, or tilted forward by elevating only the back legs about 2 in [5 cm]). Some patients benefit from the use of a rocking chair to facilitate independent sit-to-stand transfers. Chairs that have spring-loaded seats that push the patient into standing are heavily marketed to the geriatric population but should be used with caution. The patient is propelled into standing but may have difficulty stopping the movement and/or getting his or her balance within an appropriate time frame when first reaching the standing position. A raised toilet seat and toilet rails are also essential devices to facilitate ease of sit-to-stand transitions in the bathroom.

Loose-fitting clothing and sneakers with hook and loop closures can be used to facilitate dressing. If the patient demonstrates a shuffling gait, shoes should have leather or hard composition soles, because shoes with crepe or rubber soles will not slide easily and can result in falls. A festinating gait can sometimes be alleviated by the addition of modified heel or shoe wedges. A flat heel or toe wedge may slow down a propulsive gait. The use of assistive devices can be problematic owing to movement difficulties. A cane can be helpful for patients with mild to moderate disease to assist in balance or cue stepping (inverted walking stick). It is important that the height of the device not promote increased flexion of the trunk. Vertical poles (previously mentioned) can also be helpful to improve upright posture, trunk rotation, and arm swing during walking. Patients with more pronounced movement difficulties and poor balance are not likely to benefit from assistive devices. Walkers with wheels are particularly hazardous and are likely to increase a festinating gait; hand brakes are an essential requirement.

Most patients use adaptive devices to assist in ADL. Reachers can be used to provide assistance in dressing as well as for other activities. Eating can be facilitated in a number of ways. The patient should be seated properly, close to the table, with good posture. Specially adapted utensils, plate guards, and enlarged handles can aid the patient's efforts. Because eating time will be prolonged, heated plates or pads may help keep food warm and palatable. Drooling and/or spills should be anticipated and clothing protected. Extra time should be planned, and the patient should not feel rushed.

PSYCHOSOCIAL ISSUES

The progressive nature of PD necessitates frequent personal and social adjustments, and affects all aspects of life for both the patient and family. Disruptions in daily functions, roles, and activities are experienced. Some of the changes associated with PD are socially isolating (masked face, progressive immobility, and unintelligible speech) whereas other changes (increased salivation, perspiration, decreased sexual function) are distressing and can be socially embarrassing. The patient may feel increasingly isolated and family relationships may suffer. The principal goal for team members is to assist the patient and family in their understanding of the disease and in developing insights and adjustments that lead to more effective self-management. Some individuals are able to successfully deal with the changes associated with the disease; others are not. Coping skills can be facilitated. First and foremost, education is the key to assisting patients and family members assume responsibility. Feelings of hopelessness and dependency are reduced as the patient develops a sense of control over his or her own life. Self-management skills that should be

promoted include advanced planning of activities, effective time management strategies, and stress management techniques. It is equally important to ensure that patients do not become isolated and that appropriate services are available. Team members must be vigilant regarding their assumptions and expectations. A condescending or pessimistic and limiting attitude can become a self-fulfilling prophecy. Patients and family members need reassurances and encouragement. An overall emphasis on what patients *can do* rather than what they cannot do helps to empower patients. Therapists need to provide a message of *hope tempered with realism*.

PATIENT, FAMILY, AND CAREGIVER EDUCATION

The interdisciplinary team provides information about a variety of topics related to living with PD. These are presented in Box 18.6. Interventions can take the form of direct one-on-one instruction, group sessions, printed materials, and video or computer presentations. The therapist's overall approach needs to be positive and supportive.

Community support groups are available for patients and their families. They disseminate information and offer a chance to discuss common issues, problems, and management tips. They also can provide a stabilizing influence, assisting patients and families to focus on healthy behaviors, coping skills, and effective self-management. For some patients in the early stages of the disease, participation in a support group may increase levels of anxiety as they observe more disabled patients. Groups particularly targeted to patients with early-stage disease and similar ages may be more helpful.

Educational pamphlets, newsletters, and location of support groups can be obtained through national PD associations.

Web-based resources for clinicians and patients/families living with PD are presented in Appendix 18.C. A listing of sample educational and video materials can be found in Supplemental Readings and Materials.

Box 18.6 Elements of a Patient, Family, and Caregiver Education Program

- Parkinson's disease: clinical presentation, strategies to manage symptoms
- Medications: purpose, dosage, possible adverse side effects, signs of either overmedication or undermedication
- Preventative measures to minimize the secondary complications and impairments
- Impact of PD on movement and effective strategies to manage movement problems
- Barriers to exercise and effective solutions to regular exercise participation
- Impact of PD on function and effective strategies to maintain independent function in home, community, or work environments
- Strategies for energy conservation and activity pacing
- Strategies for ensuring activity participation in valued leisure and family activities
- Community resources for patients: support groups, in-home interventions, community training programs, day programs
- Community resources for caregivers: counseling, support groups, exercise programs, respite care

SUMMARY

PD is a chronic, progressive disorder of the BG characterized by the cardinal features of rigidity, bradykinesia, tremor, and postural instability. Additional impairments include the development of abnormal fixed postures, poverty of movement, fatigue, masked face, contractures, a festinating gait pattern, swallowing and communication difficulties, visual and sensorimotor disturbances, cognitive and behavioral dysfunction, autonomic dysfunction, and cardiopulmonary changes. Pharmacological interventions have become the mainstay of treatment and provide protective and symptomatic treatment. Effective rehabilitation focuses on the patient's stage of disease and symptoms, activity limitations, and residual abilities and assets. Interventions are restorative; that is, rehabilitation is focused on the improvement of strength, ROM, functional skills, endurance, and so forth. Individuals with PD also benefit from functional maintenance programs designed to manage the effects of progressive disease. Strategies are developed to prevent or reduce indirect impairments and promote regular exercise, good health, and self-management skills. A comprehensive team approach including active involvement of patient and family provides optimal benefits. Team members need to be active during all stages of the disease, assisting the patient and family in maintenance of function and providing psychosocial support as needed.

Questions for Review

1. What are the major CNS structures involved in Parkinson's disease and what are the pathophysiological changes associated with the disease?
2. Differentiate between cogwheel rigidity and lead pipe rigidity.
3. What impairments in postural stability are typically seen in patients with PD?
4. What are the nonmotor impairments in cognition associated with PD?
5. What are the major adverse effects associated with long-term use of levodopa/carbidopa?
6. How might the goals/outcomes and interventions vary by stage of disease?
7. Orthostatic hypotension is a common problem in patients with PD. How should it be examined?
8. Identify appropriate motor learning strategies for the patient with PD in terms of practice and feedback.
9. Describe the gait impairments common in patients with PD. What interventions can be used to improve locomotor function?
10. What guidelines for aerobic training are appropriate for the patient with early- to middle-stage PD?

CASE STUDY

The patient is a 60-year-old woman with a 7-year history of PD. Lately she has experienced increasing severity of symptoms and is referred for outpatient physical therapy and a home exercise program (HEP).

HISTORY

The patient first presented with tremor of her left hand that progressed to include stiffness and awkwardness of her left UE and LE. Her family physician referred her to a neurologist who found moderate tremor and rigidity on the left side. He prescribed Artane, which was helpful for a while. Eventually the tremor became worse, especially under conditions of stress when she was unable to use her left UE at all. She was then started on Sinemet and referred for an initial episode of physical therapy as an outpatient. Once Sinemet began to work and her symptoms dramatically lessened, she stopped physical therapy and her HEP. Over the next few years as her symptoms increased, her dose of Sinemet was increased.

CURRENT STATUS

The patient is currently taking Sinemet and bromocriptine. She reports bouts of dyskinesia about 45 minutes into taking her Sinemet that involve involuntary writhing movements of her LUE. Her chief complaints are:

- Difficulty walking, especially when she has to go through a narrow doorway, or walk in a crowded place.
- Episodes of gait blocks (freezing of gait); if she tries to do something while walking, such as take a tissue out of her pocket, she stops abruptly in her tracks. The harder she tries to move, the worse it gets. Episodes of freezing have lasted up to 20 minutes.
- Postural instability: over the past few years she has experienced increasing bouts of uncontrolled or unsteady balance. This is particularly disturbing to her because if it occurs while she is walking, it causes her to fall. She has fallen seven times in the past month, with no residual fall injury. Because of her increased fear of falling, she has stopped going out by herself.
- Experiences increased difficulty rolling over in bed, getting out of bed, and standing up from a chair independently. Her husband now has to provide assistance 90% of the time to accomplish these activities.
- Reports having trouble sleeping at night. She has stopped drinking coffee but this has not helped. She wakes four to five times a night, and requires assistance from her husband to go to the bathroom at night. She also has hallucinated at night, claiming to see bugs on the wall. During these periods she becomes extremely frightened.
- Complains her medication seems to be helping less and less. If she plans to go out, she takes an extra Sinemet. She revisited her neurologist in hopes that he would increase her dosage. Instead he told her the symptoms were most likely the result of excess medication. He instructed her not to take the extra Sinemet and adjusted her dosage.

EXAMINATION FINDINGS

Cognition
Alert, oriented × 3; she is displaying mild impairments in short-term memory.

Psychosocial
She is showing signs of depression; she is less interested in going out and socializing; she reports "it is just too much effort."

Speech
Mild dysarthria, hypophonia.

Sensation
Slightly decreased proprioception bilaterally in both ankles; otherwise intact.

Tone
Rigidity (cogwheel type) moderate in all extremities L > R.
- Marked rigidity throughout neck and trunk.
- Masklike face.

Range of Motion
Decreased due to moderate rigidity; with limitations in:
- Bilateral elbow extension (10° to 140°)
- Bilateral hip extension (0° to 10°)
- Bilateral knee extension (10° to 120°)
- Bilateral ankle dorsiflexion (0° to 15° RLE; 0° to 10° LLE).

Strength
Generally fair (3/5) to good minus (4–/5).
- Poor (2/5) dorsiflexor muscle grades in both ankles.

Motor Function
Moderate to severe resting tremors, L hand > R hand.
- Bradykinesia: marked slowness, poverty of movement.
- Hesitation on initiation of movement; frequent arrests of ongoing movement.
- Dyskinesias: LUE

Posture
Forward head position; flexed; kyphotic spine.
- Stands with flexion of elbows, hips, and knees.

Balance
Decreased limits of stability.
- Patient's forward alignment position increases her tendency to fall forward.
- Sitting static control: good (able to maintain balance without handhold).
- Sitting dynamic control: fair (accepts minimal challenge; able to lift both arms).
- Standing static control: good (able to maintain balance without handhold).
- Standing dynamic control: poor (unable to accept minimal challenge without handhold).
- She has slowed reactions to loss of balance with decreased rotational movements of head/trunk and ineffective use of stepping strategies.
- *Timed Up and Go* score is 36 seconds.
- Patient is fearful of falling.

Functional Mobility
Generally decreased.
- Requires moderate assist: rolling in bed, supine-to-sit and sit-to-stand transfers.
- Unable to bridge secondary to hip flexion contractures.
- Patient has good safety awareness.

Locomotion
Ambulates independently with a shuffling gait pattern with decreased step length and arm, trunk, hip, and knee motions; tendency for propulsive gait.
- Afraid to walk outside alone for fear of falling.
- Frequent freezing of gait.

Self-Care
Requires minimal assistance to supervision for feeding.
- Requires minimal to moderate assist for dressing/bathing.

Cardiopulmonary Function/Endurance
Shallow (upper respiratory) breathing pattern.

Generally decreased functional capacity (estimated functional work capacity [FWC] is 6 metabolic equivalents [METs]).

Patient fatigues easily and requires frequent rest periods.

Mild edema both ankles.

Skin

Intact, no areas of breakdown.

Experiences bouts of increased perspiration.

GUIDING QUESTIONS

1. Identify/categorize this patient's problems in terms of:
   a. Direct impairments
   b. Indirect impairments
   c. Activity limitations
   d. Participation restrictions/disability
2. Identify two outcomes (the remediation of activity limitations and disability) and two goals (remediation of impairments) for this patient.
3. Determine four interventions that could be used at the start of therapy to achieve the outcomes and goals provided for question 2. Provide a brief rationale for each.
4. What motor learning strategies will assist in improving her motor function?

For additional resources, including answers to the questions for review and case study guiding questions, please visit **http://davisplus.fadavis.com**

The reader is referred to video **Case Study 6: Patient with Parkinson's Disease** for additional review and study. The full written case study, including tables, figures, charts, and three video segments (examination, intervention, and outcome), appears online at DavisPlus. The case study poses questions for the reader's consideration with suggested answers to the case study questions, also posted online at DavisPlus.

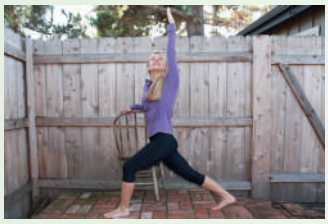
appendix
18.B



Yoga Sequence for Early/Mild Parkinson's Disease

	Marjaryasana (Cat Pose)	1. Start on your hands and knees. Tabletop position. 2. As you exhale round your spine toward the ceiling. Hold for 5 seconds.
	Bitilasana (Cow Pose)	1. As you inhale lift your sitting bones and chest toward the ceiling. Hold for 5 seconds.
	Bhujanga (Cobra Pose)	1. Lie on your stomach with your hands under your shoulders. 2. As you inhale press the shoulders and torso off the mat and look up. Hold for 5 seconds.
	Adho Mukha Svanasana (Downward-Facing Dog)	1. Start in the tabletop position. 2. As you exhale lift your knees and torso from the ground forming an inverted "V." 3. Push your shoulder blades against your back and heels to the ground. 4. Hold for 5 seconds.
	Anjaneyasana (Low Lunge)	1. Step your right foot forward and maintain your left knee on the ground. 2. As you inhale raise your arms to the sky and stretch your torso forward.
	Virabhadrasana II (Warrior II Pose)	1. Rise up from low lunge maintaining the right knee bent and the left knee straight. 2. Right foot should be straight ahead and the left foot should be turned out 90 degrees. 3. Ensure that outside border of the left foot stays on the ground. 4. With the right arm straight forward and the left arm straight back sink into the pose looking over the fingers of your right hand.

Yoga Sequence for Late Parkinson's Disease

	Marjaryasana (Chair Cat Pose)	1. Start perch sitting (body at front of chair), sitting tall and hands on the side of your head. 2. As you exhale round your spine toward the back of the chair, bring your shoulders and head forward while bringing your elbows together. Hold for 5 seconds.
	Bitilasana (Chair Cow Pose)	1. As you inhale arch your back and look up to the sky. Open your chest and spread your elbows wide. Hold for 5 seconds.
	Parighasana (Chair Gate Pose)	1. Start sitting tall with your right hand on the chair and left arm raised to the sky palm facing in. 2. Inhale deeply. 3. As you exhale side bend your torso to the right and look up to your left hand. Hold for 5 seconds. 4. Repeat on the opposite side.
	Ardha Matsyendrasana (Chair Spinal Twist)	1. Start sitting tall with your hands on the side of your head. 2. Inhale deeply. 3. As you exhale rotate to one side. Hold for 5 seconds. 4. Repeat on the opposite side.
	Eka Pada Rajakapotasana (Chair Pigeon Pose)	1. Start sitting tall with your legs crossed, right ankle on top of left knee. 2. As you exhale lean forward from the hips keeping your spine long. Hold for 5 seconds. 3. Repeat on the opposite side.
	Anjaneyasana (Modified Low Lunge) Variation A (Advanced) Variation B (Beginner)	Variation A: 1. Stand holding onto a stable surface for stability. 2. Left foot supported on chair behind you. 3. With a tall upright spine exhale, and bend the right knee while moving the pelvis forward. Hold for 5 seconds. 4. Repeat on the opposite side.

Continued

		Variation B: 1. Stand holding onto a stable surface for stability. Left foot forward and right foot back. 2. With a tall upright spine exhale while bending the left knee and maintaining the right leg straight. Hold for 5 seconds. 3. Repeat on the opposite side.
	Utthita Parsvakonasana (Modified Extended Side Angle Pose)	1. Hold on to a stable surface with your right hand, left foot forward and right foot back. 2. While maintaining a long spine bend the left knee moving the pelvis forward and keeping the right knee straight. 3. As you exhale raise the left arm to the sky and turn your head to the left looking up to your left hand. Hold for 5 seconds. 4. Repeat on the opposite side.

Traumatic Brain Injury

George D. Fulk, PT, PhD
Coby D. Nirider, PT, DPT

Chapter 19

LEARNING OBJECTIVES

1. Describe the pathophysiology of traumatic brain injury.
2. Analyze the impact of cognitive, neurobehavioral, and neuromuscular impairments on outcomes of people with traumatic brain injury.
3. Identify the different team members and settings in the management of the patient with traumatic brain injury.
4. Compare and contrast persistent vegetative state and minimally conscious state.
5. Identify key components of the physical therapy examination during the acute stage of recovery in patients with severe to moderate traumatic brain injury.
6. Create a plan of care for a patient with a severe to moderate traumatic brain injury in the acute stage of recovery.
7. Select evidence-based outcome measures to use during the physical therapy examination of a patient with moderate to severe traumatic brain injury during the active rehabilitation stage of recovery.
8. Explain the impact of cognitive and neurobehavioral impairments on the physical therapy plan of care in the active rehabilitation stage of recovery.
9. Create a plan of care for a patient with a severe to moderate traumatic brain injury in the active rehabilitation stage of recovery.
10. Select evidence-based outcome measures to use during the physical therapy examination of a patient with a mild traumatic brain injury.
11. Outline a return to play timeline for a patient with a mild traumatic brain injury.
12. Create a plan of care for a patient with a mild traumatic brain injury.

- Examination *880*
- Intervention *881*

SUMMARY *882*

A traumatic brain injury (TBI) is defined as "an alteration in brain function, or other evidence of brain pathology, caused by an external force."[1] The TBI population is one of the most challenging that a physical therapist is likely to encounter. Because of the multiple body systems affected by a brain injury and the strong likelihood of secondary impairments, a physical therapist must be proficient in a wide variety of examination procedures and intervention techniques. Owing to behavioral difficulties

encountered during recovery, a physical therapist working with this population must also possess strong communication and interpersonal skills, be able to react quickly and effectively to suddenly changing situations, and have keen observation skills. These factors and others can make working with this population challenging and exhausting, both emotionally and physically. However, the rewards of assisting a patient with a severe brain injury to return home or to school vastly outweigh the challenges of rehabilitation.

The patient with a brain injury is treated across a wide continuum of care, which includes the intensive care unit, acute hospitalization, rehabilitation centers, community reentry programs, outpatient therapy, schools, vocational rehabilitation, and assisted living centers. Because of the wide variety of presenting impairments and complications, rehabilitation for the patient with TBI requires a strong interdisciplinary team. A physical therapist is an important member of this team. It is crucial that there be open communication between and among all team members to ensure safe, timely, and consistent treatment. Regardless of the setting, it is important to remember that the patient is the central member of the team.

PREVALENCE AND IMPACT

Traumatic brain injury is the leading cause of injury-related death and disability in the United States. Approximately 1.7 million people in the United States are admitted to emergency departments with TBI each year.[2-4] Of these, 50,000 people die as a result of the injury and 300,000 require hospitalization.[3] In all likelihood these numbers underrepresent the true incidence of TBI. They do not take into account military personnel, people who seek medical attention in settings other than emergency departments, and many sports-related brain injuries that often go unrecognized.[2]

Falls are the leading cause of TBI (32%) followed by motor vehicle/traffic accidents (19%), struck by/against events (18%), and assaults (10%).[3,4] Children, older adolescents/young adults (less than 25 years old), and older adults are most at risk for experiencing TBI. Traumatic brain injuries are most common in young children (0 to 4 years old). However, hospitalization and death as a result of TBI is most common in older adults (65 years old and over).[3,4]

The long-term consequences of TBI on the health care system, society, and the individual are high. There are approximately 5.3 million people living in the United States who are disabled as a result of TBI.[5] Four out of ten are not working 1 year after injury and one-third have difficulty with social integration.[6] One quarter of people with severe to moderate TBI require assistance with activities of daily living (ADL), and approximately 40% report poor mental and physical health.[6]

MECHANISM OF INJURY AND PATHOPHYSIOLOGY

Traumatic brain injury is a heterogenous injury, with a wide variety of pathophysiological mechanisms.[7] The brain damage results from external forces that cause brain tissue to make direct contact with an object (bony skull or penetrating object), rapid acceleration or deceleration forces, or blast waves from an explosion.[8] Generally speaking, brain tissue damage can be categorized as either *primary injury* that is due to direct trauma to the parenchyma or *secondary injury* that results from a cascade of biochemical, cellular, and molecular events that evolve over time due to the initial injury and injury-related hypoxia, edema, and elevated intracranial pressure (ICP).[7,9]

Primary Injury

Primary TBI results from either brain tissue coming into contact with an object (e.g., bony skull or external object such as a bullet or sharp instrument creating a penetrating injury) or rapid acceleration/deceleration of the brain. Contact injuries often result in contusions, lacerations, and intracerebral hematomas. This damage is generally focal in nature as the brain comes into contact with bony protuberances on the inside surface of the skull or damage from the penetrating object. Common areas of focal injury are the anterior temporal poles, frontal poles, lateral and inferior temporal cortices, and orbital frontal cortices.

Acceleration and deceleration cause shear, tensile, and compression forces within the brain, which causes **diffuse axonal injury (DAI)**, tissue tearing, and intracerebral hemorrhages.[9] Diffuse axonal injury is the predominant mechanism of injury in most individuals with severe to moderate TBI.[10] It is common in high-speed motor vehicle accidents (MVAs) and can be seen in some sports-related TBIs.[11,12] The term *diffuse* is somewhat misleading because DAI most often occurs in discrete areas: the parasagittal white matter of the cerebral cortex, the corpus callosum, and the pontine-mesencephalic junction adjacent to the superior cerebellar peduncles.[13] The mechanism of DAI is microscopic, so often there are minimal initial findings on computed tomography (CT) and magnetic resonance imaging (MRI). The acceleration/deceleration forces cause disruption of neurofilaments within the axon leading to Wallerian-type axonal degeneration.[13]

Blast Injury

Blast injury is considered a signature injury of the U.S. military conflicts in the Middle East.[14,15] When an explosive device detonates a transient shock wave is produced, which can cause brain damage.[15,16] Primary blast injury results from the direct effect of blast overpressure on organs (in this case the brain), secondary injury results from shrapnel and other objects being hurled at the individual, and tertiary injury occurs when the victim is flung backward and strikes an object. Although

the exact mechanisms are not fully understood, there appear to be three mechanisms by which primary blast brain injury may occur: (1) direct transcranial blast wave propagation; (2) the transfer of kinetic energy from the blast wave through the vasculature, which triggers pressure oscillations in the blood vessels leading to the brain; and (3) elevations in cerebrospinal fluid (CSF) or venous pressure caused by compression of the thorax and abdomen and by propagation of a shock wave through the blood vessels or CSF.[15,16] Blast-related brain injury can result in edema, contusion, DAI, hematomas, and hemorrhage.[17,18] A wide spectrum of injury severities ranging from mild (blast concussion) to severe and fatal can result from blast TBI.

Secondary Injury

Secondary cell death occurs as a result of a chain of cellular events that follow tissue damage in addition to the secondary effects of hypoxemia, hypotension, ischemia, edema, and elevated ICP. Secondary processes develop over hours and days, and include glutamate neurotoxicity, influx of calcium and other ions, free radical release, cytokines, and inflammatory responses that can lead to cell death.[8,9] The release of glutamate and other excitatory neurotransmitters exacerbates ion-channel leakage and contributes to brain swelling and raised ICP.[8] Hypoxic-ischemic injury results from a lack of oxygenated blood flow to the brain tissue. It can be caused by systemic hypotension, anoxia, or damage to specific vascular territories of the brain. Because the rigid skull surrounds the brain, swelling, abnormal brain fluid dynamics, or hematoma can result in elevated ICP. Hematomas are usually classified according to their site (epidural, subdural, or intracerebral). Normal ICP is 5 to 20 cm H_2O.[19] Severely increased ICP typically results in herniation of the brain, requiring prompt emergency treatment. Common types of herniations are uncal, central, and tonsillar.

It is important to keep in mind that both primary and secondary mechanisms of injury are not mutually exclusive and often do not occur in isolation. This is one reason that the impact of TBI is so widespread across the International Classification of Functioning, Disability, and Health (ICF) spectrum.

SEQUELAE OF TRAUMATIC BRAIN INJURY

Traumatic brain injury is associated with a wide spectrum of neuromuscular, cognitive, and behavioral impairments that can lead to limitations in activity, restrictions in social participation, and diminished quality of life.[20] Box 19.1 identifies some of the prevalent body structure/function impairments associated with TBI. Although physical therapy interventions primarily address physical limitations related to mobility, the cognitive and behavioral changes associated with TBI are often more disabling.

Box 19.1 Impairments Commonly Associated With Traumatic Brain Injury

Neuromuscular

- Paresis
- Abnormal tone
- Motor function
- Postural control

Cognitive

- Arousal level

- Disinhibition
- Apathy
- Emotional lability
- Mental inflexibility
- Impulsivity
- Irritability

Communication

Swallowing

Neuromuscular Impairments

Individuals with TBI commonly exhibit impaired motor function.[21] Upper extremity (UE) and lower extremity (LE) paresis,[21,22] impaired coordination,[21-23] impaired postural control,[21,22,24-28] abnormal tone,[22] and abnormal gait[21,27] may be present as life-long impairments.[21] Abnormal, involuntary movements such as tremor and chorea form and dystonic movements are less common.[21] Patients may also present with impaired somatosensory function, depending on the location of the lesion.

Cognitive Impairments

Cognition is the mental process of knowing and applying information. Owing to the complex nature of many cognitive processes it is difficult to localize the exact neuroanatomical structures responsible for many different cognitive functions. However, many cognitive functions are controlled in the frontal lobes. This makes people with TBI particularly susceptible to cognitive impairments. Cognition includes many complex neural processes, including arousal, attention, concentration, memory, learning, and executive functions.[29-31] Executive functions can be categorized into the following main areas: planning, cognitive flexibility, initiation and self-generation, response inhibition, and serial ordering and sequencing.[31] Chapter 27, Cognitive and Perceptual Dysfunction, provides an in-depth discussion.

Altered levels of consciousness are commonly seen. Between 10% and 15% of patients with severe TBI are discharged from the acute hospital in a *vegetative state,*[32] and the prevalence of *minimally conscious state* is greater than that of vegetative state.[33] **Coma, vegetative state,** and **minimally conscious state** are disordered arousal states seen after severe brain injury. It can be difficult to distinguish among the disordered arousal states. Many severe injuries begin with coma. In a coma the arousal system is not functioning. The patient's eyes are closed, there are no sleep/wake cycles, and the patient is ventilator dependent. There is no auditory or visual function and no cognitive or communicative function.[33,34] Abnormal motor and postural reflexes may be present. A coma is usually not permanent. Patients may become brain dead, enter a vegetative or minimally conscious state, or go onto full recovery.

In a vegetative state there is disassociation between wakefulness and awareness.[34] The higher central nervous system (CNS) centers are not integrated with the brainstem. The brainstem is able to manage basic cardiac, respiratory, and other vegetative functions and the patient can be weaned off the ventilator. Sleep/wake cycles are present. The eyes may be open though awareness of surroundings is absent, and sleep/wake cycle is present. Patients may startle to visual or auditory stimuli and briefly orient to sound or visual stimuli. Meaningful cognitive and communication function is absent. Reflexive smiling/crying may be present.[33,34] A withdraw response to noxious stimuli is present. Although patients in a vegetative state may appear to have purposeful movement, these movements are nonpurposeful and reflexive in response to external stimuli. Movement will also not be reproducible. Patients in a permanent vegetative state may have no meaningful motor or cognitive function and a complete absence of awareness of self or the environment for a period greater than 1 year after TBI and greater than 3 months after anoxic brain injury.[35,36]

In a minimally conscious state there is minimal evidence of self or environmental awareness. Cognitively mediated behaviors occur inconsistently and are reproducible or sustained such that they can be differentiated from reflexive behaviors.[33] Similar to a vegetative state, sleep/wake cycles are present. However, instead of withdrawing or posturing to noxious stimuli, patients in a minimally conscious state will localize to noxious stimuli and may inconsistently reach for objects.[33,34] Patients may localize to sound location and demonstrate sustained visual fixation and visual pursuit.[33]

Commonly used terms to describe other altered levels of consciousness are *stupor* and *obtunded.* Stupor is an unresponsive state from which the patient can be aroused only briefly with vigorous, repeated sensory stimulation. The patient in an obtunded state sleeps often and when aroused exhibits decreased alertness and interest in the environment and delayed reactions.

Neurobehavioral Impairments

Patients can exhibit profound behavioral changes as they progress through recovery. These impairments can be closely linked to cognitive impairments and are often more debilitating in the long run than physical disability. Common behavioral sequelae include low frustration tolerance, agitation, disinhibition, apathy, emotional lability, mental inflexibility, aggression, impulsivity, and irritability.[31]

Communication

Language and communication deficits after brain injury are generally nonaphasic in nature[37] and are related to cognitive impairment. Common language and communication deficits include disorganized and tangential oral or written communication, imprecise language, word retrieval difficulties, and disinhibited and socially inappropriate language. Patients may also exhibit difficulties communicating in distracting environments, reading social cues, and adjusting communication to meet the demands of the situation.[38] These communication deficits can affect employability, social integration, and quality of life.[39,40] Chapter 28, Neurogenic Disorders of Speech and Language, provides more detail on communication deficits and intervention strategies.

Dysautonomia

Elevated sympathetic nervous system activity occurs as a normal response to trauma; following TBI this response may become overactive. Increased sympathetic activity results in increased heart rate, respiratory rate, and blood pressure; diaphoresis; and hyperthermia.[41,42] Other symptoms of dysautonomia include decerebrate and decorticate posturing, hypertonia, and teeth grinding.[42] The term *paroxysmal sympathetic hyperactivity* accurately describes this phenomenon.[41] The incidence of paroxysmal sympathetic hyperactivity ranges from 8% to 33% in patients with TBI in the intensive care unit.[42]

Post-traumatic Seizures

Between 12% and 50% of people with severe TBI develop post-traumatic seizures.[43-45] For adults with severe injury, phenytoin (an anticonvulsant) is effective in decreasing the risk of early post-traumatic seizures.[46]

Secondary Impairments and Medical Complications

Due to the high potential of prolonged immobility and concomitant injury, patients with TBI are at risk of developing a number of secondary impairments and other medical issues. Up to 50% of patients with severe brain injury develop gastrointestinal difficulties, 45% develop genitourinary problems, 34% develop respiratory problems, 32% develop cardiovascular problems, and 21% develop dermatological complications.[47] Box 19.2 lists some of the more common secondary impairments

Box 19.2 Secondary Impairments and Concomitant Injuries

- Deep vein thrombosis
- Heterotopic ossification
- Pressure ulcer
- Pneumonia
- Chronic pain
- Contractures
- Decreased endurance
- Muscle atrophy
- Fracture
- Peripheral nerve damage

and concomitant injuries associated with TBI,[45,48-50] including urinary and bowel incontinence, deep vein thrombosis (DVT), heterotopic ossification, pressure ulcer, pneumonia, and chronic pain.

DIAGNOSIS AND PROGNOSIS

Traumatic brain injury is generally categorized as severe, moderate, or mild using the *Glasgow Coma Scale* (GCS) (Fig. 19.1).[51] The GCS, developed by Teasdale and Jennett,[51] is the most widely used clinical scale that measures level of consciousness and helps define and classify the severity of injury. The GCS is comprised of three response scores: motor response, verbal response, and eye opening. The scores from the separate responses are summed to provide a score between 3 and 15. Scores of 8 or less are classified as severe, scores between 9 and 12 are defined as moderate, and scores of 13 to 15 are classified as mild brain injury. Table 19.1 provides an overview of some of the characteristics that distinguish mild, moderate, and severe brain injury. However, these categorizations can be somewhat misleading in that a mild TBI can have a profound impact across the ICF spectrum.

Glasgow Coma Scale

Activity	Score
Eye Opening	
Spontaneous	4
To speech	3
To pain	2
No response	1
Best Motor Response	
Follows motor commands	6
Localizes	5
Withdraws	4
Abnormal flexion	3
Extensor response	2
No response	1
Verbal Response	
Oriented	5
Confused conversation	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1

Figure 19.1 Glasgow Coma Scale. *(From Teasdale and Jennett,[51] with permission.)*

Owing to the wide range of cognitive, motor, and neurobehavioral impairments that accompany brain injury, it can be difficult to establish and predict long-term outcomes and set goals for these patients, even for an experienced clinician. However, researchers have identified some factors that can be useful in estimating future outcomes. Low initial scores on the GCS, particularly motor score and pupillary reactivity, have been identified by a number of studies as a predictor of poor recovery in patients with moderate to severe TBI.[52-56] Other factors associated with poor outcomes are age, race, and lower education level.[52,53,55,57] Petechial hemorrhages, subarachnoid bleed, obliteration of 3rd ventricle or basal cisterns, midline shift, and subdural hematoma findings on initial CT scan are also predictive of poor outcomes.[52,55,56]

The *Medical Research Council* (MRC) CRASH (corticosteroid randomization after significant head injury) study provides a Web-based calculator (www.crash2.lshtm.ac.uk/Risk%20calculator/index.html) that allows clinicians to enter demographic and prognostic information (country, age, GCS score, pupil reactivity to light, presence of major extra cranial injury, and CT findings if available); it calculates the 14-day mortality risk and unfavorable outcome at 6 months, along with the 95% confidence interval.[52] Unfavorable outcome is defined as dead, vegetative state, or severe disability as measured by the *Glasgow Outcome Scale* (GOS).

Duration of **post-traumatic amnesia** (PTA), the length of time between the injury and the time at which the patient is able to consistently remember ongoing events, is also an important factor in predicting recovery. Brown et al[58] found that duration of PTA as measured

Table 19.1 Characteristics of Mild, Moderate, and Severe Traumatic Brain Injury

Mild TBI	Moderate TBI	Severe TBI
LOC: 0–30 min	>30 min and <24 hr	>24 hr
AOC: brief >24 hr	>24 hr	>24 hr
PTA: 0–1 day	>1 and <7 days	>7 days
GCS: 13–15	9–12	<9
Neuroimaging: normal	Normal or abnormal	Normal or abnormal

TBI = traumatic brain injury, LOC = loss of consciousness, AOC = alteration of consciousness, PTA = post-traumatic amnesia, GCS = Glasgow Coma Scale.

by the *Galveston Orientation and Amnesia Test* (GOAT), the revised GOAT, or the *Orientation Log* (O-Log) during inpatient rehabilitation is able to predict functional independence, employment, good overall recovery, and independent living 1 year after injury. Patients with PTA less than 48.5 days are likely to have higher *Functional Independence Measure* (FIM) scores at discharge from inpatient rehabilitation; patients with PTA less than 27 days are likely to be employed; patients with PTA less than 34 days are likely to have a good overall recovery (as measured by the GOS); and those with PTA less than 53 days are likely to be living without assistance.[58]

CONTINUUM OF CARE AND INTERDISCIPLINARY TEAM

The rehabilitation of patients with TBI occurs across a continuum of care in a variety of settings (Fig. 19.2). Patients who are in a persistent vegetative state may receive ongoing therapy in a nursing home or other long-term care facility once they are medically stable. Patients who are beginning to recover from coma with moderate to severe cognitive, behavioral, and physical impairments often continue rehabilitation in either an acute or subacute inpatient rehabilitation facility. As patients progress in recovery, they will be discharged to other community-based settings depending on the needs of the individual patient.

The foundation for successful rehabilitation following TBI is an *interdisciplinary team*. An interdisciplinary team approach is essential to providing the most comprehensive care that will lead to maximizing functional recovery. An interdisciplinary approach to rehabilitation for this population has been shown to be effective for improving activity levels and participation in society.[59-61]

Within the context of the team, individual members collaborate, contributing their expertise in a specific area, thereby enhancing the team's overall effectiveness. Communication and open mindedness are key to any team. The different members must share their skills and findings with the whole team and be willing to learn from other team members to promote optimal recovery. The physical therapist must be willing to share a unique knowledge of movement and motor control, but be open to learning from other team members such as the speech-language pathologist (SLP) about cognitive deficits. Each team member should develop an approach to treatment that considers information obtained from all other participating disciplines. This will lead to a consistent and comprehensive approach to care.

Some members may play more prominent roles depending on the setting and stage of recovery. For example, a recreational therapist will not likely be involved with a patient in the acute hospital, but would play a vital role in a community reentry setting. The following subsections identify some of the team members involved in the care of individuals with brain injury and their roles in an acute rehabilitation hospital.

Patient and Family

The patient and family are at the center of the team. The lives of both the patient and family members are likely to be dramatically changed as a result of the injury. Familial roles often change. The patient who previously took care of the children may now be on the receiving end of care. The team must garner information regarding the patient's work, school, financial status, and social history. Family members should be interviewed to obtain information about the patient's lifestyle (work/school/leisure), favorite social and recreational activities, and so forth. Information about the family dynamics should be ascertained. What is the patient's role in the family (e.g., head of the household, primary wage earner)? Is the patient responsible for taking care of children? Is the patient in school? What level? Is the patient working? All of these and many other similar questions should be answered to develop a comprehensive plan of care (POC).

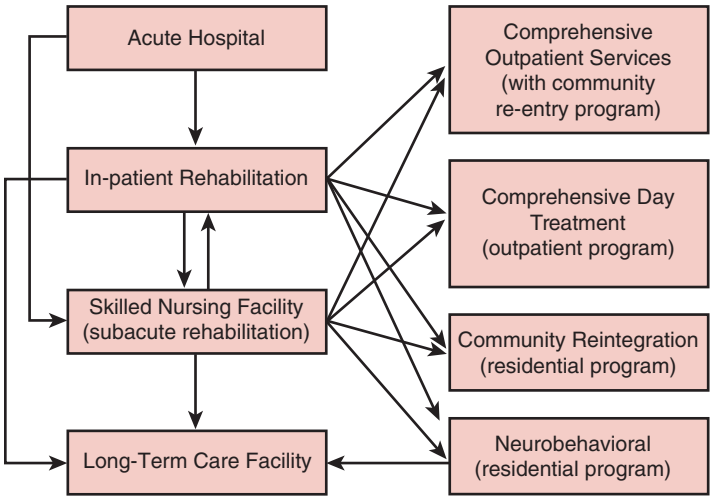

Figure 19.2 Rehabilitation settings for individuals with TBI across the continuum of care.

Physician

In the acute rehabilitation hospital, the physician overseeing the care of the patient with a brain injury is usually a physiatrist or neurologist. The physiatrist has expertise and training in physical medicine and rehabilitation. A neurologist's skills lie in the realm of the brain and nervous system. A neurologist will have particular knowledge related to how the brain may recover, and what impairments and activity limitations are likely to be seen given the location and the extent of the injury. Both a physiatrist and neurologist have vast knowledge in neuropharmacology, an extremely important part of management with this patient population. Certain medications may have harmful side effects that may not be readily apparent. For example, the physician may be able to prescribe a less sedating drug than would normally be used to treat a certain clinical problem in other patient populations.

Speech-Language Pathologist

Owing to the nature of a brain injury, the SLP plays an important and diverse role in rehabilitation. The SLP examines, evaluates, and treats communication, swallowing, and cognitive impairments. As can be seen from the cognitive and communication impairments described above, this can be a challenging task. It is important for the physical therapist to be in close communication with the SLP to provide consistency of care in relation to cognitive, swallowing, and communication impairments. With the guidance of the SLP, the team will be able to devise the most effective and consistent way to communicate with the patient. He or she will also be able to instruct the team in how the patient's cognitive impairments may impede new learning, which in turn will affect everyone's interactions with the patient and their approach to treatment.

Occupational Therapist

The occupational therapist (OT) examines, evaluates, and treats the patient's diminished ability to perform ADL, visual/perceptual impairments, UE functional loss, and sensory integration problems, and will often work with the SLP in treating cognitive impairments. **Basic ADL** (BADL) includes dressing, self-feeding, bathing, and grooming. **Instrumental ADL** (IADL) includes home management, housekeeping, grocery shopping, driving, and telephone use. In the rehabilitation hospital, the occupational and physical therapists often work very closely together. A useful treatment approach is co-treatments with the OT. Having two trained professionals working at the same time with the patient can be very productive. This is especially true with patients who have severe motor control and cognitive deficits. The OT will also work closely with the nursing staff to educate them on the best ways to assist the patient with ADL.

Rehabilitation Nurse

In a rehabilitation hospital, the nurse is responsible for dispensing medications and closely monitoring their effects. The nurse will initiate a bowel and bladder retraining program to assist the patient in learning to become continent again. Bowel and bladder control is extremely important for self-esteem and is related to discharge placement. The nurse performs daily monitoring of vital signs to make sure the patient remains medically stable. The nurse will inspect the patient's skin daily to ensure there are no signs of skin breakdown. The nurse also has the difficult task of consistently following through with the team's treatment plan throughout the day. For example, each shift of nursing staff must follow splinting schedules established by the physical and occupational therapists. The nurse often has the most interaction on a regular basis with the patient's family.

Case Manager/Team Coordinator

The case manager acts as the coordinator for the team. The case manager is often a nurse, social worker, or other health professional. The case manager will direct team meetings, schedule family conferences, and act as a liaison with third-party payers. He or she must promote good communication among all team members to ensure that the rehabilitation care being provided is truly team oriented. The case manager will also be in constant communication with the patient and family to ensure that their needs are being met and that questions and concerns are adequately addressed. The case manager will coordinate payment and insurance benefit issues with the case manager from the patient's insurance company. In addition, the case manager is responsible for setting up follow-up and discharge services for the patient and family.

Social Worker

The social worker provides much needed support to both the patient and family. During the first few days after the initial injury, the family is often in a state of crisis. They are thrown into a world that they, most likely, never knew existed. The social worker can support the family with education and counseling. As the patient progresses with recovery, the social worker will also provide counseling for the patient. This is particularly important as the patient begins to develop greater awareness and insight into his or her deficits. If the patient has behavioral impairments, the social worker can be pivotal in assisting both the patient and family. By providing counseling to both the patient and family, the social worker assists in the development of coping strategies for what may be a life-long disability.

Neuropsychologist

The neuropsychologist plays an important role on the team. He or she will often perform neuropsychological

testing when appropriate to determine the patient's baseline cognitive functioning. He or she will also assist the team in developing a behavioral management program. When the patient with a brain injury has severe behavioral impairments, the neuropsychologist may assume the role of the team leader.

Other Team Members

Many patients with severe brain injury may require ventilatory support. The respiratory care practitioner is a vital participant in the evaluation and treatment of respiratory impairments. In the rehabilitation hospital, the respiratory therapist contributes to monitoring the patient's pulmonary status and providing appropriate treatment.

A recreational therapist assists the patient's return to activities enjoyed before the accident, or in helping identify new activities that the patient will find rewarding. Therapeutic recreation is an extremely important part of rehabilitation. Being able to participate in some type of leisure or recreational activities is a significant step in returning to a fulfilling lifestyle.

EARLY MEDICAL MANAGEMENT

Medical treatment following brain injury starts at the scene of the accident. Early resuscitation with the goal of stabilizing the cardiovascular and respiratory systems is important to maintain sufficient blood flow and oxygen to the brain.[62,63] Once the patient arrives at the medical center the primary goals are to minimize secondary brain injury by optimizing cerebral blood flow and oxygenation, stabilize vital signs, perform a complete examination, identify and treat any nonneurological injuries, and continuously monitor the patient.[62,63] Systolic blood pressure should be kept above 90 mm Hg and oxygen saturation above 90%.[62] Patients with severe injury and some with moderate injury will need to be intubated. The patient's neck should be stabilized with a collar and the head elevated 30 degrees.[62] This is done to protect the spine in case of instability, as well as avoid an increase in ICP. The GCS is used to determine the severity of the brain injury. A complete neurological examination is also done. Additional information about the extent of the injury is obtained through x-ray films and neuroimaging studies such as CT and MRI. This is done to determine if neurosurgery is warranted. Large intracranial hematomas or other mass lesions may need to be surgically evacuated.

The patient is monitored continuously. For patients with a GCS of 8 or less, any acute abnormality on CT, a systolic pressure of less than 90 mm Hg, or age greater than 40 years, ICP monitoring is recommended.[62] An external ventricular drain provides the most accurate and reliable data and also provides a means to control ICP by cerebrospinal fluid removal. Other monitoring options that are less invasive include the subdural bolt and a fiberoptic catheter. Elevated ICP can be treated with the use of sedating medications, moderate head-up positioning (head elevated to 30°), osmotherapy, hypothermia, surgical decompression, and barbiturates.[62,63] Intracranial pressure should be less than 20 mm Hg and the cerebral perfusion pressure (CPP) greater than 60 mm Hg.[62] If ICP cannot be treated successfully, inducing a pharmacologic coma or surgical decompression may be necessary.

PHYSICAL THERAPY MANAGEMENT OF MODERATE TO SEVERE TRAUMATIC BRAIN INJURY IN THE ACUTE STAGE

The remainder of this chapter is divided into three main sections: (1) physical therapy management of patients with severe to moderate TBI during the early stages of recovery, (2) physical therapy management of patients with severe to moderate TBI during active rehabilitation, and (3) physical therapy management of patients with mild TBI. Patients in the early stage of recovery after severe to moderate TBI often demonstrate low levels of arousal. The primary goal of physical therapy is to prevent secondary complications due to the TBI and prolonged bedrest/immobilization, begin early mobilization when medical clearance is received, and initiate patient and family education. Depending on the patient's presentation, some of the examination and intervention procedures described in the section on physical therapy management during active rehabilitation can be used in the early stage of recovery as well.

Examination

The first step in beginning an examination at this early stage of recovery is to conduct a complete medical record review. Because the patient may not be medically stable and will likely have various precautions and complications, it is important to obtain all critical information from the medical record before actually seeing the patient. The patient may be on a ventilator with ongoing monitoring of ICP. He or she may have weight-bearing precautions and range of motion (ROM) restrictions owing to musculoskeletal injuries and/or interventions, and open wounds. A thorough medical record review provides a comprehensive perspective about the patient's condition, as well as a complete understanding of the precautions and contraindications that must be observed during the examination and subsequent treatment. Because the patient's medical status may be dynamic at these stages, it is important to check with the patient's primary nurse before beginning any session. Team members should always observe universal precautions and may need to wear gowns, gloves, and/or masks or other personal protective equipment when treating the patient.

After reviewing the medical record and receiving an update on the patient's status from the nursing staff, the

physical therapist is ready to begin the examination. Key areas to examine include the following:

- Arousal, attention, and cognition
- Integument integrity
- Sensory integrity
- Motor function
- Range of motion
- Reflex integrity
- Ventilation and respiration/gas exchange

Patients with severe TBI who are in low arousal state (coma, vegetative, or minimally conscious) may present with abnormal tone and posturing. Primitive postures may include those associated with **decorticate or decerebrate rigidity.** In decorticate rigidity, the upper extremities are in a flexed posture and the lower extremities are extended. With decerebrate rigidity, both the upper and lower extremities are positioned in extension. Abnormal tone may take the form of spastic hypertonia. This may range from spasticity that severely affects the entire body and greatly inhibits normal, functional movement, to lesser levels of tone that affect individual muscle groups.

If not medically contraindicated, the examination should include sitting on the side of the bed with assistance. The therapist should monitor vital signs and document any changes in tone or head and trunk control. When appropriate, the patient should be transferred into a wheelchair. The patient may require the assistance of two to three people to transfer at this stage. In most cases, a reclining or tilt-in-space wheelchair is the best option for positioning, with a specialized pressure-reducing cushion. Often it may require several treatment sessions to complete the entire examination. Because early patient status is often dynamic, any signs of progress or regression should be carefully monitored and documented.

Outcome Measures

Arousal, Attention, and Cognition

The *Coma Recovery Scale–Revised* (CRS-R) is recommended to assess patients with disordered consciousness.[64] The CRS-R is a valid and reliable 23-item measure with six subscales: auditory, visual, motor, oromotor, communication, and arousal.[65,66] Scores range from 0 to 23. Data are useful in distinguishing between different states of consciousness (vegetative state, minimally conscious state, and emerging), determining the prognosis, and informing treatment planning.[65]

The *Disorders of Consciousness Scale* (DOCS) is a valid and reliable scale also designed to measure arousal and neurobehavioral recovery in patients with disorders of consciousness.[67,68] It consists of 23 items, which assess social knowledge, taste/swallowing, olfactory function, proprioception, tactile sensation, auditory function, and visual function. Scoring is based on patient response and includes no response, generalized response, or localized response. The DOCS can be used to differentiate states of consciousness (i.e., vegetative state and minimally conscious state) and assist in determining prognosis for recovery.[64,67-70] A manual and video training are available for the DOCS at www.queri.research.va.gov/ptbri/docs_training/default.cfm.

The *Rancho Los Amigos Levels of Cognitive Functioning* (LOCF) scale is a descriptive scale used to examine cognitive and behavioral recovery in individuals with TBI (Box 19.3) as they emerge from coma.[71] This scale does not address specific cognitive deficits, but is useful for communicating general cognitive and/or behavioral status and for treatment planning. The eight categories describe typical cognitive and behavioral progress after a brain injury. Patients may plateau at any level. The LOCF has been shown to be a reliable and valid measure of cognitive and behavioral function for individuals with brain injury.[72]

Plan of Care

Outcomes/Goals

A list of general goals and outcomes anticipated for patients in Levels I, II, and III (LOCF) adapted from the American Physical Therapy Association's *Guide to Physical Therapist Practice*[73] are presented in Box 19.4. They can be used to guide the development of specific anticipated goals and expected outcomes for an individual patient.

Interventions

Preventing Secondary Impairments

Because of the patient's inability to move at these levels, he or she is susceptible to indirect impairments such as contractures, decubiti, pneumonia, and DVT.[47] If prevention is not addressed early in rehabilitation, these impairments are likely to impede future progress, and can be life threatening. Proper positioning both in bed and in a wheelchair is essential. Appropriate positioning will assist in preventing skin breakdown and contractures, improve pulmonary hygiene and circulation, and may modify muscle tone. When the patient is in bed, the head should be kept in neutral. The hips and knees should be slightly flexed, but ROM should be monitored to ensure that contractures do not develop. Splints may be used to assist in positioning. Special boots can be used to position the foot to prevent foot drop and skin breakdown on the heel (Fig. 19.3). Turning will help prevent skin breakdown and pneumonia. Patients should be repositioned every 2 hours when in bed. Specialized air mattresses are another effective way to assist with the prevention of pressure sores.

Serial casting may be used to maintain or improve ROM.[74-77] Serial casting is often used for plantarflexor or biceps contractures resulting from either increased tone or prolonged shortening of the muscle. With a

Box 19.3 Rancho Los Amigos Levels of Cognitive Functioning (LOCF)[a]

I. No Response

Patient appears to be in a deep sleep and is completely unresponsive to any stimuli.

II. Generalized Response

Patient reacts inconsistently and nonpurposefully to stimuli in a nonspecific manner. Responses are limited and often the same regardless of stimulus presented. Responses may be physiological changes, gross body movements, and/or vocalization.

III. Localized Response

Patient reacts specifically but inconsistently to stimuli. Responses are directly related to the type of stimulus presented. May follow simple commands such as closing eyes or squeezing hand in an inconsistent, delayed manner.

IV. Confused-Agitated

Patient is in a heightened state of activity. Behavior is bizarre and nonpurposeful relative to immediate environment. Does not discriminate among persons or objects; is unable to cooperate directly with treatment efforts. Verbalizations frequently are incoherent and/or inappropriate to the environment; confabulation may be present. Gross attention to environment is very brief; selective attention is often nonexistent. Patient lacks short- and long-term recall.

V. Confused-Inappropriate

Patient is able to respond to simple commands fairly consistently. However, with increased complexity of commands or lack of any external structure, responses are nonpurposeful, random, or fragmented. Demonstrates gross attention to the environment but is highly distractible and lacks ability to focus attention on a specific task. With structure, may be able to converse on a social automatic level for short periods of time. Verbalization is often inappropriate and confabulatory. Memory is severely impaired; often shows inappropriate use of objects; may perform previously learned tasks with structure but is unable to learn new information.

VI. Confused-Appropriate

Patient shows goal-directed behavior but is dependent on external input or direction. Follows simple directions consistently and shows carryover for relearned tasks such as self-care. Responses may be incorrect due to memory problems, but they are appropriate to the situation. Past memories show more depth and detail than recent memory.

VII. Automatic-Appropriate

Patient appears appropriate and oriented within the hospital and home settings; goes through daily routine automatically, but frequently robot-like. Patient shows minimal to no confusion and has shallow recall of activities. Shows carryover for new learning but at a decreased rate. With structure is able to initiate social or recreational activities; judgment remains impaired.

VIII. Purposeful-Appropriate

Patient is able to recall and integrate past and recent events and is aware of and responsive to environment. Shows carryover for new learning and needs no supervision once activities are learned. May continue to show a decreased ability relative to premorbid abilities, abstract reasoning, tolerance for stress, and judgment in emergencies or unusual circumstances.

[a]Condensed form. From Professional Staff Association, Ranchos Los Amigos Hospital, with permission.[71]

Box 19.4 General Goals and Outcomes Anticipated for Patients With Severe to Moderate Traumatic Brain Injury in the Acute Stage

- Physical function and level of alertness are increased.
- The risk of secondary impairments is reduced.
- Motor control is improved.
- The effects of tone are managed.
- Postural control is improved.
- Tolerance of activities and positions is increased.
- Joint integrity and mobility are improved or remain functional.
- Family and caregivers are educated on patient's diagnosis, physical therapy interventions, goals, and outcomes.
- Care is coordinated among all team members.

plantarflexion contracture, the ankle is stretched into as much dorsiflexion as possible and then a short leg cast is applied. In approximately 2 to 5 days the cast is removed. The muscle is stretched again and another cast is applied (Figs. 19.4, 19.5, and 19.6). This procedure is repeated until satisfactory gains in ROM have been achieved, or no further progress is made. Because the individual with brain injury is likely to have impaired sensation and communication, as well as behavioral deficits, there is a risk of skin breakdown or the patient hurting himself or herself or others with the cast. The decision to use casts should be made carefully. The benefits and possible side effects should be thoroughly discussed with input from appropriate team members. It is also important to monitor the patient after the cast is applied. Hands-on experience under the supervision

Figure 19.3 Multi-podus boot used for ankle and foot positioning and to prevent skin breakdown on the heel. This type of positioning device may not be beneficial for the patient with moderate to severe tone at the ankle; it is not strong enough to prevent the ankle from plantarflexing.

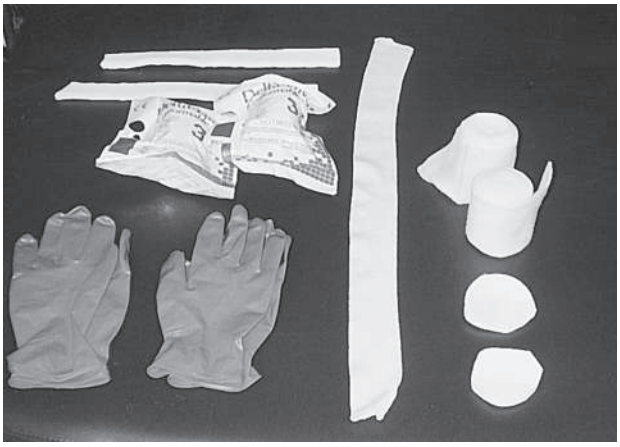

Figure 19.4 Materials used for serial casting: fiberglass casting material, rubber gloves, stockinette, a layer of padding to wrap around the lower leg and foot, and padding for the malleoli and proximal and distal ends of the cast.

of a skilled clinician is recommended before attempting cast applications.

Proper wheelchair positioning is important.[78] Because of reduced postural control at these levels, a reclining wheelchair or a tilt-in-space wheelchair is typically required. Proper pelvic positioning and head positioning are key elements in promoting good posture in a wheelchair. Refer to Chapter 32, The Prescriptive Wheelchair, for further discussion of this topic.

Respiratory care practitioners, physical therapists, and nurses often use postural drainage, percussion, vibration, and positioning to prevent pulmonary complications and improve pulmonary function.[79] Irwin and Tecklin[80] provide in-depth coverage of different interventions to improve ventilation and respiration.

Figure 19.5 Serial casting: first a layer of padding is wrapped around the lower leg and foot.

Figure 19.6 Serial casting: then the fiberglass casting material is wrapped around the lower leg and foot. One clinician does the wrapping, while another holds the leg and foot in the proper position.

Early Mobility

Upright sitting is extremely important because it addresses elements of treatment goals for the early levels of recovery. As soon as medically stable, the patient should be transferred to a sitting position and out of bed to a wheelchair. All precautions should be observed. The head

should be properly supported, because the patient is not likely to have adequate neck and head control to maintain an upright posture without support. Co-treatment with an occupational therapist provides two skilled professionals to assist the patient, because maximal assistance is often required. Use of a tilt table is also advantageous because it allows early weight-bearing through the LEs. The upright position, both on a tilt table and in a wheelchair, may improve overall level of alertness.

Sensory Stimulation

Sensory stimulation is an intervention used to increase the level of arousal and elicit movement in individuals in a coma or persistent vegetative state. The theory is that by providing stimulation in a controlled, multisensory manner, with a balance of stimulation and rest, the reticular activating system may be stimulated causing a general increase in arousal. Theoretical support for such programs comes from research in four areas: (1) effects of sensory deprivation on neurological recovery; (2) effects of "enriched" environments on behavior and nervous system structure and function; (3) nervous system plasticity; and (4) effects of environmental input during sensitive periods of neurodevelopment.[81] In general, multisensory stimulation involves the presentation of sensory stimulation in a highly structured and consistent manner. The following sensory systems are systematically stimulated: auditory, olfactory, gustatory, visual, tactile, kinesthetic, and vestibular.[82,83] During this type of intervention, the patient should be closely monitored for any changes in behavior.

The value of sensory stimulation for patients who are slow to recover remains unproven. A systematic review published by the Cochrane library suggests that there is no reliable evidence to support or rule out the effectiveness of sensory stimulation programs for this patient population.[84]

Not all patients with severe TBI recover fully. Some may remain in a state of low arousal. In these cases, the interventions described above may need to be continued by caregivers.

PHYSICAL THERAPY MANAGEMENT OF MODERATE TO SEVERE TRAUMATIC BRAIN INJURY DURING ACTIVE REHABILITATION

As patients with severe to moderate TBI recover, they require extensive and protracted rehabilitation across a variety of settings throughout the continuum of care. This may include acute and subacute inpatient rehabilitation, postacute rehabilitation, day treatment program, and outpatient or home care. The many cognitive, physical, and/or behavioral impairments that affect activity levels and social participation often necessitate multiple episodes of physical therapy care over the patient's lifetime. Goals and interventions should be focused on the patient's abilities and personal goals regardless of the setting.

Examination

Irrespective of injury chronicity, some patients with TBI will have cognitive and behavioral impairments that pose barriers to the examination process. These barriers may include disorientation, confusion, physical aggression, memory deficits, and limited attention span. It may be difficult to gather data using standardized tests and measures, such as goniometry or manual muscle testing, because the patient may be unable to cooperate. In these cases, the therapist must utilize observation skills as the patient moves to gain insight to the extent of the body structure/function impairments and activity restrictions. The physical therapist should determine the patient's cognitive abilities, because these will affect the ability to relearn motor skills. This will include orientation, attention span, memory, insight, safety awareness, and alertness. Key initial questions that warrant consideration include the following:

- Is the patient able to follow commands: one-step, two-step, or multistep commands?
- Is the patient oriented to person, place, and/or time?
- Does the patient recognize family members?
- Does the patient demonstrate any insight into what has happened?

It is beneficial to consult with other team members, especially the SLP, to obtain additional information about the patient's cognitive status.

As the patient's cognitive and behavioral impairments become less obtrusive to the process, the physical therapy examination should include the elements and outcome measures found in Box 19.5.[73]

Depending on the status of the individual patient, some of these areas may be screened whereas others require more in-depth examination. Determination of the patient's functional abilities should be done in a variety of environments, because some patients may perform well in the closed environment of a private room, but performance may deteriorate in an open environment with multiple distractions. Section One of this book (Chapters 1 through 9 on clinical decision making and examination) provides a detailed description of procedures, tests and measures, and specific outcome measures for examining the above-mentioned areas. A brief description of some of the more clinically useful outcome measures for individuals with TBI follows.

Outcome Measures: Body/Structure Function

Balance

The Berg Balance Scale (see Chapter 5) is a valid and clinically useful measure of balance in individuals with TBI.[85,86] The Berg Balance Scale, together with functional status measured using the Functional Independence Measure (FIM), may assist predicting inpatient

Box 19.5 Elements of the Examination and Outcome Measures

- Aerobic capacity/endurance
- Arousal, attention, and cognition
  - *Coma Recovery Scale–Revised, Disorders of Consciousness Scale, Rancho Los Amigos Levels of Cognitive Functioning, Moss Attention Rating Scale, Test of Everyday Attention, Trail Making Test Part B, Galveston Orientation and Amnesia Test, Orientation Log*
- Behavioral status
  - *Supervision Rating Scale, Neurobehavioral Rating Scale–Revised, Agitated Behavior Scale*
- Cranial nerve integrity
- Gait, locomotion, and balance
  - *Berg Balance Scale, Community Balance and Mobility Scale, High-Level Mobility Assessment Tool, Rancho Los Amigos (RLA) OGA System, 10-Meter Walk Test, 6-Minute Walk Test, Modified Walking and Remembering Test*
- Integumentary integrity
- Joint integrity and mobility
- Motor function (motor control and motor learning)
- Muscle performance, including strength, power, and endurance
- Neuromotor development and sensory integration
- Pain
- Posture
- Range of motion
- Reflex integrity
- Self-care and ADL skills
  - *Functional Independence Measure, Functional Assessment Measure*
- Sensory integrity
- Ventilation and respiration/gas exchange
- Work/leisure/community reintegration
  - *Mayo-Portland Adaptability Inventory, Community Integration Questionnaire*

rehabilitation length of stay, falls during rehabilitation stay, and functional gains during rehabilitation.[85,86] However, as patients improve the Berg Balance Scale may exhibit a ceiling effect.[87]

The *Community Balance and Mobility Scale* (CB&M) by Howe et al[88] is an instrument developed specifically for patients with persistent balance deficits following TBI. The CB&M is a reliable and valid tool that assesses higher-level balance abilities typically associated with community mobility. This tool shares similarities to the *High-Level Mobility Assessment Tool* (HiMAT) developed by Williams et al.[89,90] This is a unidimensional measure of higher-level motor performance for individuals with TBI. The test items are more difficult than general measures of balance and functional mobility and are intended to quantify abilities required of physically demanding vocational and social roles, as well as sporting activities. A revised version of the HiMAT has a minimal detectable change score of 2 points.[91]

Attention and Cognition

The Moss Attention Rating Scale (MARS) is an observational rating scale that provides a reliable and valid measure of attention-related behavior after TBI. The scale allows the therapist to rate a patient's behavior on a 5-point scale across 22 items that capture the effects of impaired attention on cognitive and motor performance.[92] Other measures of attention most often employed by neuropsychologists include the *Test of Everyday Attention*[93] and the *Trail Making Test Part B*.[94] Though all three of these measures capture attentional deficits and may serve as useful global outcome measures, they will be less helpful in measuring changes in attention behavior attributable to physical therapy interventions.

The *Galveston Orientation and Amnesia Test* is a measure of PTA.[95] The GOAT is administered by asking a series of standardized questions related to orientation and the ability to recall events before and after the injury. Scores between 100 and 76 are considered normal and patients with scores below are considered to have PTA. The GOAT has high interrater reliability and is a valid measure of PTA.[95,96] The *Orientation Log* (O-Log) measures orientation to time, place, and circumstance.[97] The O-Log can be used for serial assessment of orientation to document improvements during rehabilitation.[98] It is reliable, is valid, and can be used to predict outcome.[96,97,99] Measures of dual-task performance (see later discussion) are more specific to physical therapy practice.

Behavior and Safety

Rehabilitation teams often use an outcome measure that captures the impact of behavior and safety on overall independence. The *Supervision Rating Scale*[100] provides a one-step method for rating a patient's current level of supervision ranging from independent to full-time direct supervision. The *Neurobehavioral Rating Scale–Revised* (NRS-R) is a 29-item multidimensional, clinician-based assessment instrument designed to measure neurobehavioral disturbances.[101] The items cover numerous cognitive and behavioral constructs such as memory, attention, communication, mood, and agitation. The *Agitated Behavior Scale* (ABS) measures the type and degree of agitation after TBI.[102]

Outcome Measures: Activity and Participation

Global Functioning

The *Functional Independence Measure*[103,104] is a commonly used measure of functional mobility, ADL function, cognition, and communication. The FIM was designed to measure level of disability and burden of care in individuals undergoing inpatient rehabilitation,

and is useful for monitoring patient progress and evaluating outcomes. The *Functional Assessment Measure (FAM)*[105,106] was developed as an adjunct to the FIM. It includes functional areas not addressed in the FIM that are important for individuals with TBI and stroke. The other items include community access, reading, writing, safety, employability, and adjustment to limitations. The FIM, in combination with the FAM, is a valid and reliable measure of disability after TBI.[107] In addition to measuring the amount of physical assistance required to perform a functional task, the therapist should also analyze how the patient performs the task. A thorough movement analysis of how the FIM items and other functional tasks are performed will aid the therapist in identifying the motor function and other impairments that underlie specific activity limitations.

Community Reintegration

Rehabilitation teams commonly employ the use of a participation-level measure that quantifies the extent of reintegrate into social, familial, and vocational roles. One such measure is the *Mayo-Portland Adaptability Inventory* (MPAI-4),[108,109] which is frequently used in postacute TBI rehabilitation. Another, similar measure is the *Community Integration Questionnaire* (CIQ).[110] The CIQ consists of 15 items relevant to home integration, social integration, and productive activities.

Locomotion

Spatiotemporal gait deficits are common following TBI, yet, to date, no classification system of gait disorders exists for this population.[111] There are many different methods of examining gait and walking ability. Physical therapists use *observational gait analysis* (OGA) as a preferred method in the clinic.[112] One instrument used clinically is the *Rancho Los Amigos (RLA) OGA System*. Refer to Chapter 7, Examination of Gait, for further discussion of this instrument. The RLA OGA instrument gathers data on the cyclical movements of walking that occur from one stride cycle to the next. The gait cycle is divided into stance and swing phases. The physical therapist visually analyzes a patient's walking pattern, looking for asymmetries and deviations from normal. Based on these observations, the physical therapist gains insight into which impairments may be the cause of the deviations. Specific interventions are then designed to address the possible causes of the gait deviations. However, caution should be used when interpreting OGA findings. Some gait abnormalities identified by quantitative gait analysis may not be detected by OGA.[113] Chapter 7 reviews instrumented walkways and other methods of more precisely and accurately measuring specific kinematics and kinetics associated with gait.

Gait speed is also an important measure of walking ability. The *10-Meter Walk Test* (10MWT) is a reliable measure of both fast-paced and self-paced gait speed in patients with TBI.[114,115] Caution should be used when interpreting gait speed measured with the 10MWT, because there is evidence suggesting that the 10MWT may not fully reflect the many different demands of walking in the community (e.g., crossing a busy street, walking in a crowded mall, walking on uneven surfaces, and so forth).[114]

Fatigue and deconditioning are common following TBI.[116,117] As such, measuring walking endurance is clinically useful. The *6-Minute Walk Test* (6MWT) is a common, reliable, and valid way to measure this aspect of walking ability.[118,119] Normative values from healthy adults are available for this test.[120] Other methods of assessing cardiorespiratory fitness have also been validated for patients with TBI, including the *graded exercise test*[121] and a *modified shuttle test*.[122]

Several tests of dynamic balance (see above) and walking ability are appropriate for this population; however, they do not offer insight into how walking and balance are affected by the addition of a cognitive load. Measures of *dual-task performance* allow the therapist to examine the extent to which deficits in attention and memory affect gait speed and safety. These two cognitive abilities (attention and memory) are strongly associated with dual-task performance and also commonly impaired in persons with TBI.[123,124] There are a variety of clinical tests of dual-task performance that can be used for clients with acquired brain injury. A review of several dual-task performance measures is available.[125] One such measure is the *Modified Walking and Remembering Test* (WART) developed by McCulloch et al.[123] The WART involves a single-task condition (simple walking task) and a dual-task condition (walking task and cognitive task).

Further information on these and other outcome measures specifically used in TBI rehabilitation can be found at the *Center for Outcome Measurement in Brain Injury (COMBI)* website (www.tbims.org/combi/index.html).

Plan of Care

Goals/Outcomes

Persons with moderate to severe TBI present with a wide variety and degree of physical, cognitive, and behavioral limitations. As the patient progresses in these areas, anticipated goals and expected outcomes will move from basic mobility and self-care, toward skills that facilitate community inclusion and social participation. The American Physical Therapy Association's *Guide to Physical Therapist Practice*[73] offers examples of general anticipated goals and expected outcomes pertinent to patients with TBI. Examples include the following:

- The risk of secondary impairments is reduced.
- Performance of functional mobility and ADL skills is increased.
- Ability to assume or resume self-care and home management roles is improved.

These can be used to guide the development of specific anticipated goals and expected outcomes tailored to each individual patient. Refer to Chapter 15, Box 15.6, for more examples of goals and outcomes for patients with impaired motor function and sensory integrity associated with nonprogressive disorders of the CNS—stroke and TBI (Practice Pattern 5 D).[73]

Interventions

Motor (Re)Learning Strategies

Treatment sessions should be thoughtfully planned to maximize the patient's motor learning capabilities. Practice should be *distributed*, with frequent rest periods. Owing to cognitive impairments, patients may experience mental as well as physical fatigue during treatment sessions. Signs of mental fatigue may include increased irritability, decreased attention and concentration, deterioration in performance of physical skills, and delayed initiation. Treatment sessions should include sufficient rest periods to minimize both physical and mental fatigue and maximize motor relearning.

The impact of manipulating motor learning variables on motor skill acquisition and generalizability has not been thoroughly studied in patients with TBI. Refer to Chapter 10, Strategies to Improve Motor Function, for an in-depth discussion of motor learning principles. There are a few studies with a limited number of subjects, however, that suggest the use of *video self-modeling*,[126] and the *concept of self-generation*[127] may be beneficial to the relearning of functional tasks. With video self-modeling the patient watches himself or herself engaging in skillful behavior on edited videotapes. The self-generation concept is a phenomenon whereby items that are self-generated are better learned and remembered compared to information that is provided. As the cognitive and behavioral barriers to treatment become less intrusive, sessions can be progressively more challenging both mentally and physically. A *random practice schedule* may be more beneficial to learning,[128] although this schedule can be employed only after the patient has demonstrated some initial learning of the task's dynamics.[129] Feedback is also very important. Owing to cognitive, sensory, and perceptual impairments, *explicit or augmented feedback* may be more beneficial in the early stages of motor learning as opposed to intrinsic feedback. However, care should be taken not to overwhelm the patient with feedback.

Restorative Versus Compensatory-Based Interventions

As discussed earlier, an early, interdisciplinary approach to rehabilitation after TBI has been shown to be beneficial. There are many intervention approaches available to the physical therapist that can promote functional recovery following brain injury. Two basic treatment strategies are a *compensatory* and a *restorative* (recovery) approach. The compensatory approach seeks to improve functional skills by compensating for the lost ability. A simple example of this would be teaching one-handed dressing techniques to a patient with UE hemiparesis resulting from a TBI. A restorative approach seeks to restore the "normal" use of the affected UE. Both approaches seek to reinstitute functional independence, and the exact definition of each approach is a subject of ongoing debate.

Compensation is commonly defined as the resumption of the ability to complete a task using alternative motor patterns and strategies. The definition of recovery varies. Some feel that it refers to the resumption of the ability to complete a task using the same motor patterns and strategies as before. Another, more liberal, definition is completing a task using similar strategies despite inferior efficiency, speed, and/or accuracy. Levin et al[130] addressed this topic and proposed explicit definitions for recovery and compensation. The authors argue that the definitions of recovery and compensation will change based on whether performance or function is measured. To make this point clearer, the authors used the framework of the *World Health Organization's ICF Model*. Refer to Table 19.2 for more details.

In most cases involving moderate to severe TBI, clinical management will likely require a balance between both restorative and compensatory approaches. As an example, a therapist may determine that a restorative approach to gait training is indicated but may also choose to ensure that the client and caregiver have adequate training in the use of an assistive device for safety during the earlier stages of recovery should it be needed. Current literature offers little guidance for the practitioner attempting to choose between approaches. Table 19.3 offers questions that can guide this aspect of clinical decision making. After a thorough examination and consideration of the patient's unique personal and environment barriers and facilitators, these questions can help lead the clinician and patient to a shared agreement about which approach will be used.

The last decade of translational and applied research in the areas of neural plasticity, motor learning, and neurological rehabilitation has heightened awareness that (re)learning is directly related to the rehabilitative experiences patients are exposed to. Using the example above, interventions that seek compensation will result not only in learning how to use the less affected UE but also learning "not" to use the more affected UE. (See the discussion of "learned nonuse" in Chapter 15.) Alternatively, a restorative rehabilitative experience that allows the patient to practice using the affected arm for everyday tasks will result in greater functional independence and affected UE use. This knowledge is useful in clinical decision making when developing the POC.

Restorative Interventions and Neural Plasticity

No studies to date have identified what types of restorative interventions are the most beneficial to persons with

Table 19.2 Motor Recovery and Compensation Across Three Levels of the ICF

Level	Recovery	Compensation
ICF: Health Condition (neuronal)	*Restoring function in neural tissue that was initially lost after injury.* May be seen as reactivation in brain areas previously inactivated by the circulatory event. Although this is not expected to occur in the area of the primary brain lesion, it may occur in areas surrounding the lesion (penumbra) and in the diaschisis.	*Neural tissue acquires a function that it did not have prior to injury.* May be seen as activation in alternative brain areas not normally observed in nondisabled individuals.
ICF: Body Functions/ Structure (performance)	*Restoring the ability to perform a movement in the same manner as it was performed before injury.* This may occur through the reappearance of premorbid movement patterns during task accomplishment (voluntary joint range of motion, temporal and spatial interjoint coordination, etc).	*Performing an old movement in a new manner.* May be seen as the appearance of alternative movement patterns (i.e., recruitment of additional or different degrees of freedom, changes in muscle activation patterns such as increased agonist/antagonist coactivation, delays in timing between movements of adjacent joints, etc.) during the accomplishment of a task.
ICF: Activity (functional)	*Successful task accomplishment using limbs or end effectors typically used by nondisabled individuals.*[a]	*Successful task accomplishment using alternate limbs or end effectors.* For example, opening a package of chips using one hand and the mouth instead of two hands.

ICF = World Health Organization International Classification of Functioning.
[a]Note that task performance may be successful using compensatory motor strategies and movement patterns.
Levin, MF, Kleim, JA, and Wolf, SL: What do motor "recovery" and "compensation" mean in patients following stroke? Neurorehabilitation and Neural Repair 23(4):313–319, 2009.[130] Reprinted by permission of SAGE Publications.

Table 19.3 Compensation Versus Restoration: Guiding Questions to Consider

Injury Severity	• Are sensorimotor deficits so severe that restorative approaches are not possible or appropriate?
Motor Learning	• Do secondary complications or comorbidities exist that pose barriers to recovery (e.g., contractures, fractures)?
	• Is an appropriate motor recovery program (specificity, intensity, frequency, duration, difficulty) feasible?
	• How chronic is the injury?
	• What strengths and weaknesses does the patient have relative to his or her ability to learning motor tasks?
Resources	• Are there significant cognitive, behavioral, or medical barriers?
	• Does the patient have any financial or support barriers?
	• Will funding lapse before functional recovery occurs?
	• Do financial resources suggest that a more rapid approach be used?
	• What impact will discharge destination have on the prescribed treatment approach?

TBI. Current research has demonstrated that task-specific interventions with large amounts of practice can induce beneficial neuroplastic changes in the CNS and restore function.[131-133] Studies involving monkey and rat models of brain injury have demonstrated the importance of intensive, task-oriented training on neuroplastic changes in the motor cortex and functional recovery.[134,135] This line of research was extended to include human models with neurological deficits and later the sum of these findings was translated into tangible principles of experience-dependent neural plasticity.[131,136,137] Table 19.4 provides examples of several of these principles. Current evidence suggests that treatment interventions that are most beneficial will be specific to the function/task being retrained, meaningful to the client, and challenging to the cortical systems involved in the activity.

Task-Oriented Approach

Also in line with these principles, current theories of motor control and motor learning advocate for a task-oriented approach to interventions for individuals with neurological deficits.[129] The majority of research on the principles that underpin effective, task-oriented interventions for clients with neurological disorders has been done with persons with stroke. Despite this, these same principles will serve the physical therapist well in selecting and applying appropriate interventions for persons

Table 19.4 Principles of Experience-Dependent Neuroplasticity

Principle	Description
Use It or Lose It	Failure to drive specific brain functions can lead to functional degradation.
Use It and Improve It	Training that drives a specific brain function can lead to an enhancement of that function.
Specificity	The nature of the training experience dictates the nature of the plasticity.
Repetition Matters	Induction of plasticity requires sufficient repetition.
Intensity Matters	Induction of plasticity requires sufficient training intensity.
Time Matters	Different forms of plasticity occur at different times during training.
Salience Matters	The training experience must be sufficiently salient to induce plasticity.
Age Matters	Training-induced plasticity occurs more readily in younger brains.
Transference	Plasticity in response to one training experience can enhance the acquisition of similar behaviors.
Interference	Plasticity in response to one experience can interfere with the acquisition of other behaviors.

From Kleim, JA, and Jones, TA: Principles of experience-dependent neural plasticity: Implications for rehabilitation after brain damage. J Speech Lang Hear Res 51(1):S225–239, 2008, with permission.[136]

with TBI.[138] Locomotor training, utilizing body weight support (BWS) and a treadmill,[139-141] and constraint-induced movement therapy (CIMT) for improving UE function[142,143] are two interventions that have shown potential. See additional discussion in Chapter 15, Stroke, and Chapter 20, Traumatic Spinal Cord Injury.

Another task-oriented approach for improving mobility skills such as walking and running was developed by Williams and Schache.[144] They used a conceptual framework based on the hierarchical ordering of high-level mobility tasks based on the HiMAT (see above) and biomechanical parameters associated with normal walking and running as the basis for the specific interventions. Easier items on the HiMAT are set as goals and mastered before moving on to more difficult tasks. For example, once a patient can walk backwards, the next, more difficult tasks (walking on toes and walking over obstacles) are set as goals. Important biomechanical aspects of walking and running, such as the generation of ankle and hip flexion power at push-off, are targeted through the specific interventions.

An important consideration for these and other task-oriented strategies is treatment dosing. Although not well researched for persons with TBI, literature on UE rehabilitation and locomotor training after stroke suggest that these interventions are commonly underdosed[145-147] and that there is a dose-response relationship.[148]

Locomotor Training with Body Weight Support

Locomotor training with BWS and a treadmill involves suspending the client in a parachute-like overhead harness that allows for a percentage of body weight to be relieved. Therapists assist the patient by providing trunk/pelvic stabilization, assistance with weight shifting, and advancing the LEs. Locomotor training with BWS is commonly combined with treadmill ambulation (Fig. 19.7), but can be done overground as well. Locomotor training with BWS and a treadmill allows for repetitive training throughout a complete gait cycle. Progressively decreasing the amount of BWS and increasing the treadmill speed allows the physical therapist to gradually increase the difficulty of the task as walking ability improves. Locomotor training with BWS and a treadmill has a solid theoretical basis. However, it is not clear what the optimal parameters for treatment should be for

Figure 19.7 Locomotor training utilizing a body weight support system and treadmill. One trainer is assisting with the trunk and pelvic stability and weight shifting, while another trainer is facilitating stepping at the left LE.

patients with TBI, and it has not been demonstrated that it is more effective than conventional gait training (see Chapter 20, Traumatic Spinal Cord Injury).

Constraint-Induced Therapy

Constraint-induced movement therapy involves promoting the use of the more affected UE for up to 90% of waking hours and reducing the use of the least affected UE. Intensive, task-oriented training is provided for the affected UE for up to 6 hours per day over a 2- to 3-week period.[149] Most of the research published on CIMT has been done in people with stroke (see Evidence Summary Box 10.1 in Chapter 10). However, this same intervention may also be useful for people with TBI.[142,143] Given the frequency of behavioral and cognitive impairments after TBI, patients undergoing CIMT may require greater structure and caregiver support outside of therapy to maximize their adherence to the protocol.

Aerobic and Endurance Conditioning

Fatigue and cardiopulmonary pathology are common after TBI.[116] The severity of deconditioning found in persons with TBI is significantly greater than that found in sedentary persons without disabilities.[117] Aerobic training is effective for persons with TBI.[138,150] Appropriately dosed aerobic exercise has the potential to not only reduce long-term cardiovascular risks, but also may improve sleep hygiene and reduce both depression and reports of fatigue.[150]

There are many options when developing an endurance-training program. The mode of training can vary from traditional exercises (e.g., walking, jogging, treadmill, elliptical machines, and ergometers)[150] to circuit training.[151] Intensity should be at 60% to 90% of age predicted maximal heart rate, for 20 to 40 minutes per session, three to four times a week.[150] Hassett et al[152] studied a program that combined both aerobic and strengthening exercises for 62 participants with severe TBI. They found that the program, whether performed in a fitness center or at home, had a positive impact on cardiorespiratory fitness. The physical therapist will need to carefully consider both cognitive and physical abilities when developing an aerobic conditioning program for an individual patient.

Resistance Training

Interventions aimed at improving force-production capacity may be beneficial supplements to the physical therapist's POC.[153,154] There is currently a dearth of literature investigating the role of strength training in TBI rehabilitation. There is, however, evidence of a positive effect in other progressive and nonprogressive neurological disorders. A recent review by Pak and Patten[155] suggest that for persons with stroke, resistance training is associated with improved force production, functional abilities, and quality of life. Similar findings have been demonstrated for persons with Parkinson's disease,[156] and it is plausible that patients with TBI might also achieve similar benefits. Strength training should be done 2 to 3 days a week at an intensity of 3 sets of 8 to 12 repetitions at 10 repetition max.[157] Postural and balance impairments require modification of positions used.

Electrical Stimulation

The application of *functional electrical stimulation* (FES) to motor rehabilitation has increased significantly in the last decade. Several manufactures have developed various types of FES foot-drop stimulators. All rely on peroneal nerve stimulation to increase active dorsiflexion during the swing phase of gait. The devices range from traditional electrical stimulation devices with manual stimulation triggers to cuff-type units that employ inclinometers or pressure sensors. Similar units can be used to augment active wrist extension during UE reaching tasks. Little research exists on use of this modality with patients with TBI,[158] and there is limited evidence as to their long-term efficacy in other populations.[158] These devices, however, can be used to increase both the quality and number of repetitions of a desired task (e.g., steps or reaching) and can be an effective addition to early, task-oriented training sessions.

Dual-Task Performance

As mentioned above, many patients make significant improvements in physical function at this stage of rehabilitation. Many will demonstrate independence with basic ambulation as examined with measures of gait speed and dynamic balance. Most will also have persisting cognitive deficits. Beyond basic locomotor recovery, another important consideration is how these ongoing cognitive deficits affect mobility and community reentry. As discussed in the examination section, a dual-task paradigm can give valuable insight into how safely and efficiently patients will ambulate when also performing secondary, cognitive tasks. Research suggests that dual-task decrements, such as reduced walking speed and postural stability, are common after brain injury.[125]

Like many other interventions, improvements in dual-task performance are training specific. This should be taken into consideration when designing and progressing a dual-task training regimen. The tasks and environments used in training should match those that the patient is anticipated to return to. Progressing this type of training can involve manipulation of the training environment, motor task (type and difficulty), and also the cognitive demands of the secondary task. A training program to improve dual-task performance can coincide with the achievement of independence in walking across different terrains. For example, once independent with walking down a corridor, progressively more challenging cognitive tasks such as serial subtraction or visual

scanning tasks can be added. Furthering this example, the client might be asked to ambulate in a parking lot and scan for vehicles with certain characters in their license plate or walk the aisle of a busy grocery store and find specific items. Training speed can also be varied to add challenge. Walking on a treadmill while reading is one example of a dual-task intervention.

Patient/Family/Caregiver Education

Patient/family/caregiver education and training are important goals across each level of rehabilitation. The goals of this education and training will vary based on the cognitive and behavioral abilities of the patient.

Clients in the early phase of recovery may go through a period where they are significantly confused and agitated. It is difficult to provide education for the patient at this level; the patient has very little, if any, ability for new learning. However, it is extremely important to provide education for the patient's family. Above all, the family should understand that the patient does not have control of his or her behavior. The patient is not striking out or cursing because of intent to hurt others, but because of agitation and confusion. Many times families do not understand why a patient is performing these behaviors. They should be educated that these behaviors are a symptom of the brain injury just as the patient's inability to walk or eat is. It is important to educate the family that entering this level of recovery is a good sign because it indicates the patient is moving toward the next level of recovery. Aggressive behaviors are usually short lived, typically lasting only a few weeks at most. Family members should also be taught to use specific behavioral strategies (see below) when interacting with their loved one. Consistency is important for everyone, including family members. If a behavioral plan is being implemented, the family should be a part of devising it and carrying it out.

It is important to emphasize safety awareness education with the patient and caregivers. The individual is beginning to exhibit improved mobility skills at these levels, but may lack the insight to recognize that he or she may not yet be safe to ambulate or transfer alone. Family members and caregivers should learn how to safely assist the patient with functional mobility. This typically includes training in bed mobility, transfers, ambulation, and wheelchair mobility skills. They should be instructed in proper body mechanics when assisting with functional mobility, so as to avoid risking injury to the patient or themselves. Family members/caregivers should be educated about how to assist the patient with strengthening exercises, passive ROM, and other elements of the exercise program. They should also be made aware of methods to enhance the patient's decision making skills and safety awareness. Family members typically become the primary caregiver for the patient upon discharge to home.

Behavioral Factors

Therapists may encounter a variety of behavioral barriers to examining and treating patients with moderate to severe TBI. As the patient begins to emerge from coma, he or she often experiences a period of acute post-traumatic agitation.[31,159,160] The confusion, amnesia, and disorientation during this phase of recovery often result in agitation, aggression, noncompliance, and combative behavior.[31,160] The therapist should incorporate creativity and flexibility when designing and providing interventions. This is particularly true with individuals who are in the confused and agitated stage of recovery. At this stage, the therapist should work near the patient's physical level of function using familiar activities, rather than progress to more challenging skills that require new learning, because the patient does not have the capacity for new learning at this level of recovery. The neuropsychologist can assist the team by providing insight into different ways to manage the patient's agitated behavior and may set up a behavioral modification program. Behavioral modification techniques such as positive reinforcement using a point or reward system, redirection, and compliance training are useful in managing these inappropriate behaviors and improving participation in therapy.[159] Different medications may be effective in helping the patient manage behavior as well.[160] Table 19.5 summarizes special considerations for the management of patients who display significant cognitive and/or neurobehavioral impairments.

Professionals who frequently encounter aggressive and disruptive behaviors from patients with TBI may benefit from further training in managing these events. *Nonviolent Crisis Intervention® Training* and *Brain Injury Specialist Training* through the Brain Injury Association of America are two such training programs.

Community Reentry Programs

Many clients will make significant progress in the early phase of rehabilitation. Before discharge, it is crucial to begin to wean the patient from the external structure provided by the hospital setting that was so important in the early stages of recovery. As the patient becomes better able to control himself or herself, external control provided by the environment should be lessened. Doing so will prepare the patient for the challenges of the next level of rehabilitation, postacute, community reentry programming.

This level of therapy is often delivered in a comprehensive day treatment setting, with an interdisciplinary emphasis on community reentry, return to work or school, and cognitive, behavioral, and psychosocial issues.[161,162] In this setting, the patient goes to therapy throughout the day for 4 to 5 days a week and returns home in the late afternoon. Individuals with more severe physical impairments may continue their rehabilitation in a residential-based community reentry program, whereas those with continued, severe behavioral issues may require a residential neurobehavioral program.

Table 19.5 Special Considerations for Confused and Agitated Patients

Strategy	Rationale and Clinical Application
Consistency	• Consistency is important. All team members, including family members, should interact and address inappropriate behaviors in a consistent manner. • Remember that the patient is confused. To help decrease confusion, the patient should be seen by the same person at the same time and in the same location every day. • Establishing a daily routine is very important. It is calming and reassuring to have a sense of familiarity. Additionally, orientation (i.e., person, place, and time) should be provided frequently and in a nonthreatening manner. At this level, it is often better to provide orientation information than to challenge the patient to provide it, particularly if the patient is not expected to succeed.
Expect No Carryover	• Teaching new skills at this level is unrealistic. The patient may begin to perform a functional task, such as brushing teeth or ambulating. However, this does not indicate a general learning ability, because brushing one's teeth and especially walking are automatic skills with an ingrained neural network. • The use of charts or graphs may be useful to help the patient progress each day. Without the use of such aids, the patient is likely to have no recall of the previous day's performance.
Model Calm Behavior	• The patient is likely to perceive, and may reflect, the demeanor of the caregiver. Therefore, it is important for the therapist to assume a calm and focused affect. • The patient may not be able to control his or her behavior and may not feel safe. To help the patient feel safe, it is important for the therapist to be perceived as in control of his or her emotions and behavior.
Expect Egocentricity	• At this level of recovery, the patient cannot be expected to see another's point of view. He or she will tend to think only of himself or herself and, at this point, it is unwise to stress the patient with attempts to do otherwise.
Flexibility/Options	• The patient will have a limited attention span and may not be able to concentrate on any given activity for a very long time. It is important to be prepared with numerous activities. If the patient cannot be redirected to the selected task, it is appropriate to attempt to engage him or her in another. For example, it may be difficult for a client to tolerate a full constraint-induced therapy protocol. You might, however, be able to engage the client in a variety of UE reaching tasks in various environments allowing the patient's level of attention and tolerance to dictate the duration of each. • Treat the patient at an appropriate age level. • Give control to the patient when it is safe and appropriate. Control can be given while maintaining focus on therapeutic goals by phrasing questions as, "Would you rather play ball or go for a walk?" This prevents situations where the patient chooses an undesirable or unrealistic activity if asked, "What would you like to do?" or the case where the patient simply answers "No" when asked, "Would you like to . . . ?" • Provide safe choices for the patient. This allows the patient to feel that he or she has some control over the situation. This is important, because the patient typically feels considerable loss of control during prolonged hospitalization.
Safety	• Owing to the patient's often unpredictable and inappropriate behaviors, it is important to keep the patient and those interacting with him or her safe. • In addition to utilizing some of the above-mentioned behavioral strategies, patients in this level of recovery may be kept on a locked unit of the hospital. Patients may require one-to-one staff supervision and assistance throughout the day.

The major goal of treatment at this level is to assist the patient in integrating the cognitive, physical, and emotional skills necessary to function in the community. Skills in judgment, problem solving, planning, self-awareness, health and wellness, and social interaction are emphasized. For the demands of treatment to approximate the demands of the real world, treatment focuses on advanced activities such as community skills, social skills, and daily living skills. Examples of these skills are presented in Table 19.6. The interdisciplinary team emphasizes patient assumption of self-responsibility. Because the patient now has some insight into his or her own strengths and weaknesses, it is important to involve the individual in decision making.

Table 19.6 Components of Community Skills, Social Skills, and Daily Living Skills Programs

Daily Living	Social Skills	Community Skills
Food preparation	Introductions	Shopping
Housekeeping	Nonverbal communication	Public transport
Money management	Assertiveness	Map reading
Meal planning	Listening skills	Leisure planning
Telephone use	Giving/receiving feedback	Community resources
Time management		

Independent as well as cooperative work with others is encouraged. Group treatment sessions are often the basis of interventions. Honest feedback from the therapist and support group is crucial for the patient to learn how to function in society with his or her present abilities and limitations. Trial periods of independent living and supported work are important. Adaptations are often required by the family, work, and school to accommodate to the needs of the individual.

MILD TRAUMATIC BRAIN INJURY

The military conflicts in the Middle East and increased media attention to sports-related concussion has highlighted the impact of *mild TBI* (mTBI) or postconcussion injury and the need for appropriate assessment and management. Between 1.6 and 3.8 million sports-related mTBIs occur annually in the United States,[2,163] and approximately 12% of military personnel report symptoms consistent with blast-related mTBI.[164] There are varying definitions of mTBI.[165] As mentioned above, the GCS defines mTBI as a score between 13 and 15. Generally speaking, mTBI is characterized by varying degrees of loss of consciousness (0 to 30 minutes; it is important to recognize that no loss of consciousness may occur) and PTA and altered mental state for up to 24 hours. Individuals with mTBI often experience a combination of neurocognitive deficits, postural control and balance impairments, and self-report symptoms such as blurred vision, nausea, light sensitivity, sleep disturbance, and ringing in the ears. It is also important to keep in mind that the appearance of symptoms may be delayed several hours.

Mild TBI often results in a functional injury of the CNS rather than a structural one, which is thought to be due to metabolic dysfunction.[166] Fortunately, most individuals with mTBI fully recover in approximately 3 months.[167] However, up to 10% to 20% of people with mTBI experience postconcussive syndrome and have deficits months to years after the initial injury.[168-170]

Physical Therapy Management of mTBI

The Proponency Office for Rehabilitation and Reintegration, Office of the Surgeon General, and the United States Army developed physical therapy guidelines for assessment and intervention of working service members with mTBI.[171] The main areas recommended to assess and provide intervention for are patient education, activity intolerance, vestibular dysfunction, high-level balance dysfunction, post-traumatic headache, temporomandibular disorder, attention and dual-task performance, and participation in exercise (Box 19.6).[171] A full guide to mTBI developed by the Department of Defense and Veterans Affairs is available online at www.healthquality.va.gov/mtbi/concussion_mtbi_full_1_0.pdf. Although there are differences between sports- and blast-related mTBI, these guidelines can also be applied to those with sports-related mTBI.

Return to Play/Activity

Cognitive and physical rest until symptoms resolve followed by a graded exercise program is recommended.[172] It is important to recognize that not only physical activity, but activities that require attention and concentration (e.g., school work), can exacerbate symptoms and prolong recovery. Return to play or activity after an mTBI should follow a graduated, stepwise progression of increasing activity levels (Table 19.7).[172] Each step should take 24 hours, so that it will take approximately 1 week to return to full active duty or full-contact sports activity. If any postconcussive symptoms return during the progressive increase in activity, the patient should step back to the previous stage and attempt to progress again after a 24-hour period of rest.[172] Results from baseline neurocognitive tests, balance tests, and self-report symptoms should all be used in the return to play/activity decision. No one test should be used by itself. If the medical professional has any doubts about whether or not the patient experienced an mTBI or is ready to return to play/activity, the patient should be removed from the game and return to activity delayed until a full recovery is achieved.

Box 19.6 Areas for Physical Therapist to Examine and Intervene in Patients With Mild Traumatic Brain Injury

- Patient education
- Activity intolerance
- Vestibular dysfunction
- High-level balance dysfunction
- Post-traumatic headache
- Temporomandibular disorder
- Attention and dual-task performance
- Participation in exercise

Table 19.7 Graduated Return-to-Play Protocol

Rehabilitation Stage	Functional Exercise at Each Stage of Rehabilitation	Objective of Each Stage
1. No activity	Complete physical and cognitive rest.	Recovery.
2. Light aerobic exercise	Walking, swimming, or stationary cycling keeping intensity at 70% of maximum predicted heart rate. No resistance training.	Increase heart rate.
3. Sport-specific exercise	Skating drills in ice hockey, running drills in soccer. No head-impact activities.	Add movement.
4. Noncontact training drills	Progression to more complex training drills (e.g., passing drills in football and ice hockey). May start progressive resistance.	Exercise, coordination, and cognitive load.
5. Full-contact practice	Following medical clearance, participate in normal training activities.	Restore confidence and assess functional skills by coaching staff.
6. Return to play	Normal game play.	

From McCrory, P, et al: Consensus Statement on Concussion in Sport: The 3rd International Conference on Concussion in Sport held in Zurich, November 2008. British Journal of Sports Medicine 43(Suppl 1):i76–90, 2009, with permission.[172]

Examination

Ideally, there should be a baseline assessment of cognition and balance, which can be used for comparison as the patient recovers to assist in the return to play/activity decision.

Arousal, Attention, and Cognition

Computerized tests have been developed to assess cognition after mTBI. One such test is the *Immediate Post-Concussion Assessment and Cognitive Testing* (ImPACT). The ImPACT assesses attention span, working memory, sustained and selective attention time, response variability, nonverbal problem solving, and reaction time. The ImPACT can be used to track recovery and assist in the return-to-play decision after mTBI.[173-175]

The *Standardized Assessment of Concussion* (SAC) is a short test that can be completed on the sideline of a sports event within minutes of injury to assess mental status.[176-178] The instrument is intended as a supplement to other methods of mTBI assessment (e.g., neuropsychological evaluation, postural stability testing). It should not be used as the only means of determining the severity of the injury and return to play.

Vestibular and Balance

The incidence of vestibular-related symptoms (e.g., dizziness, vertigo, imbalance) after blast mTBI range from 24% to 83%, and is seen in the acute (1 to 3 days), subacute (3 to 30 days), and chronic (30 to 360 days) stage.[179] Vestibular and postural control deficits are also seen in sports-related mTBI.[180] Vestibular dysfunction after blast-related mTBI includes benign paroxysmal positional vertigo (BPPV) of the posterior or lateral canals and unilateral vestibular hypofunction of central origin.[181] Positional tests such as the Dix-Hallpike test and supine roll test and dynamic visual acuity testing should be performed.[171] Chapter 21, Vestibular Disorders, provides detailed information on these and other tests of vestibular function.

The *NeuroCom Sensory Organization Test* (SOT) is a computerized dynamic posturography test that assesses the ability to use and integrate sensory information from the visual, somatosensory, and vestibular systems to maintain balance.[180,182] The *Balance Error Scoring System* (BESS) is a clinical analog to the SOT. Both of these measures (SOT and BESS) have been used to demonstrate impaired postural control in people with sports-related mTBI.[180,183] It also appears that balance deficits as measured with the SOT or BESS generally resolve within 3 to 7 days after injury.[180,182,184] Other measures of high-level balance activity such as the HiMAT[89,90] (see above), *Dynamic Gait Index*,[185,186] *Functional Gait Assessment*,[187, 188] and *Balance Evaluation Systems Test*[189] can also be used to assess balance.

Self-Report

There are many self-report symptom scales.[190] These scales ask patients to rate the severity of postconcussion symptoms such as headache, dizziness, blurred vision, difficulty concentrating, fatigue, and sensitivity to light. The *Post-Concussion Scale* (revised)[191] is a 21-item checklist that is commonly used. The *Sport Concussion Assessment Tool Post-Concussion Symptom Scale* (SCAT) is another.[192] The SCAT scale contains 18 items used to screen for an acute concussion and another 7 items to gather information at a follow-up visit. Self-report measures specific to the impact of impaired balance include the *Dizziness Handicap Inventory*[193] and the *Activities-specific Balance Confidence* scale.[194]

Other

Post-traumatic headache and temporomandibular disorder can be assessed using a standard musculoskeletal

examination of the neck, shoulders, and jaw along with standardized pain questionnaires.[171] Dual-task performance should be assessed as described above. Box 19.7 lists some of the more commonly used outcome measures and tests and measures.

Intervention

As mentioned above, physical and cognitive rest is critical for recovery. Patients should be carefully monitored during treatment sessions to determine if the intervention exacerbates any symptoms. If so the intensity, duration, and frequency should be reduced. The evidence supporting physical therapy for patients with mTBI consists mostly of case studies, case series, and retrospective reviews.[195-198] Box 19.8 Evidence Summary summarizes some of these studies.

Vestibular, Balance, and Dual Task

If the patient has BPPV, canalith repositioning treatment can be performed for the posterior semicircular canals, anterior semicircular canals, or horizontal semicircular canals. These treatment techniques involve moving the patient's head into different positions in a specific sequence to move the debris out of the involved semicircular canal back into the vestibule. Gaze stabilization exercises should be done in patients with unilateral vestibular hypofunction. See Chapter 21, Vestibular Disorders, for specifics on these interventions.

High-level, task-oriented balance and gait training as described above in the section on interventions for persons with moderate to severe TBI can be performed. Activities that are challenging to the vestibular system such as walking with head turns and on uneven, varied surfaces are recommended, as well as sport-specific skill training.[171] Balance training that incorporates the use of different sensory modalities such as standing on dense foam with eyes open and eyes closed can be performed. Balance training using computerized dynamic posturography can also be performed. Dual-task training as described above is another important intervention. See additional discussion in Chapter 10, Strategies to Improve Motor Function.

Box 19.7 Tests and Measures/Outcome Measures Commonly Used in Patients With Mild Traumatic Brain Injury

- Immediate post-concussion assessment and cognitive testing
- Standardized Assessment of Concussion
- Vestibular positional tests
- Sensory Organization Test
- Balance Error Scoring System
- Dynamic Gait Index
- Functional Gait Assessment
- High-Level Mobility Assessment Tool
- Post-Concussion Scale–Revised
- Sport Concussion Assessment Tool Post-Concussion Symptom scale
- Dizziness Handicap Inventory
- Activities-specific Balance Confidence scale

Other

Musculoskeletal-based interventions such as stretching, strengthening, and manual therapy and modalities can be used when appropriate for patients with post-traumatic headache or temporomandibular disorder.[171]

Patient Education

Patients should be provided with educational material about the symptoms of mTBI, informed that in most cases symptoms will resolve in days to a few months, and informed about the dangers of second impact syndrome. If appropriate, depending on the patient's symptoms and status, patients can be taught how to perform neck ROM and isometric strengthening exercises, appropriate sleep posture, vestibular positional techniques, gaze stabilization exercises, and balance exercises. Patients can also be instructed to begin an aerobic and strengthening exercise program.

Box 19.8 Evidence Summary Evidence-Based Summary of Selected Studies of Physical Therapy for Patients With Mild Traumatic Brain Injury

Reference	Subjects	Methods/Procedure	Results	Comments
Gurr and Moffat (2001)[196]	18 subjects with complaints of vertigo and balance deficits after mTBI	Vestibular rehabilitation × 1/week for 6 weeks. Intervention consisted of education, "vertigo exercises," graded exposure to movement and activity, anxiety management, and coping strategies.	Significant decrease in self-reported vertigo symptoms and anxiety, as well as less postural sway on unstable surface with eyes open.	Pre-test/post-test design with no comparison group. The authors do not provide sufficient detail on the characteristics and etiology of the mTBI of the subjects.

Continued

Box 19.8 Evidence Summary Evidence-Based Summary of Selected Studies of Physical Therapy for Patients With Mild Traumatic Brain Injury—cont'd

Reference	Subjects	Methods/Procedure	Results	Comments
Gagnon et al (2009)[197]	16 children/ adolescents ages 8–17 who sustained a concussion, with postconcussive symptoms >4 weeks after injury	Graded rehabilitation consisting of submaximal aerobic conditioning for up to 15 minutes; coordination exercises tailored to subject's sport for up to 10 minutes; sports-related visualization; and home program of the same activities. Subjects were closely monitored, and any increase in symptoms and the activities were stopped. Mean duration of intervention was 4.4 weeks.	Decrease in Post-Concussion Scale–Revised, all subjects were able to resume normal physical activity participation.	Retrospective review of the program, lack of standardized outcome measures presented.
Hoffer et al (2004)[198]	58 active duty or retired military personnel within 1–3 days post-mTBI; subjects subdivided into 3 groups: post-traumatic positional vertigo, PTMAD, and post-traumatic spatial disorientation	6–8 weeks of vestibular rehabilitation for the PTMAD and post-traumatic spatial disorientation groups consisting of VOR exercises, COR exercises, somatosensory exercises, and aerobic activity.	84% of PTMAD group and 27% of post-traumatic spatial disorientation group demonstrated improvement in VOR tests. Significantly shorter time to return to work and resolution of symptoms in the PTMAD group compared to post-traumatic spatial disorientation group.	Specific results of VOR tests and subject self-report measures (DHI and ABC) not presented.
Alsalaheen et al (2010)[195]	114 children (≤18 years old) and adults (>18 years old) referred for vestibular rehabilitation after concussion; 96 days median time from concussion to evaluation	30 subjects came for only one session, 84 returned for a median of 4 visits (range 2–13) over a median of 33 days (range 7–181). Vestibular rehabilitation consisted of gaze stabilization exercises (VOR × 1 in sitting and standing), standing balance on foam surface with EO and EC, walking with balance challenges, and canalith repositioning maneuvers when indicated.	Significant improvement in all self-report measures and performance measures: ABC, DHI, DGI, FGA, gait speed, TUG, FTST, and SOT. Only three measures demonstrated significantly greater improvement in children compared to adults: DHI, FGA, and FTST.	Retrospective review.

PTMAD = post-traumatic migraine-associated dizziness, VOR = vestibular-ocular reflex, COR = cervico-ocular reflex, DHI = Dizziness Handicap Inventory, ABC = Activities-specific Balance Confidence scale, EO = eyes open, EC = eyes closed, DGI = Dynamic Gait Index, FGA = Functional Gait Assessment, TUG = Timed Up and Go, FTST = Five Time Sit to Stand, and SOT = Sensory Organization Test.

SUMMARY

A TBI is a devastating and life-changing event for the individual and his or her family. The resulting impairments make working with the patient with brain injury extremely rewarding and challenging. There are a multitude of issues to consider. The physical therapist must adapt traditional physical therapy examination procedures and interventions to the unique motor function, cognitive, and behavioral challenges presented. The interdisciplinary

team offers a unique opportunity for the physical therapist to learn and collaborate with experienced professionals. By working together with a team, the physical therapist is able to provide appropriate care that will help the individual with a TBI to maximize performance of activities and enhance social participation.

Questions for Review

1. List primary and secondary mechanisms of TBI.
2. Identify common neuromuscular, cognitive, and neurobehavioral impairments that result from TBI.
3. Contrast persistent vegetative state and minimally conscious state.
4. Identify key prognostic factors for individuals with TBI.
5. Identify and describe the roles of the interdisciplinary team members working with a patient with TBI.
6. Discuss the primary goals of physical therapy during the early stage of recovery in patients with severe to moderate TBI.
7. Select key outcome measures to use during the active rehabilitation stage in patients with severe to moderate TBI.
8. Describe strategies that should be taken into account when designing a plan of care for a patient with a severe to moderate TBI with cognitive and neurobehavioral deficits.
9. Contrast recovery- versus compensation-based interventions.
10. Develop a physical therapy plan of care for a patient with a severe to moderate TBI, which incorporates key elements of neuroplasticity.
11. Outline a graduated return to play for a patient that has experienced a mild TBI.
12. Develop a physical therapy plan of care for a patient with a mild TBI.

CASE STUDY

The patient is a 22-year-old male who was involved in a motor vehicle accident (MVA). He was struck by another car as he exited his car. The patient suffered a severe closed brain injury, GCS score of 7 at the emergency department, and both pupils were reactive to light. He was taken to a local hospital. CT scan revealed a left parietal subarachnoid hemorrhage. He also experienced a fracture of his right scapula. Two weeks after his injury, the patient is now transferred to an acute rehabilitation hospital.

MEDICATIONS

Ritalin, tegretol, zanaflex, and ativan prn.

SOCIAL HISTORY

Patient is a graduate student in a computer science program at a local college. His parents live approximately 2 hours away. They are very supportive, and his mother has taken a leave of absence from her job in order to be with the patient and assist in his rehabilitation. He has private insurance through his parents, which covers inpatient and outpatient rehabilitation.

PHYSICAL THERAPY EXAMINATION

I. Screening: cardiopulmonary: HR 78, BP 110/76; integumentary: intact; musculoskeletal: see below; neuromuscular: see below.

II. Arousal, attention and cognition: Rancho Los Amigos Levels of Cognitive Functioning: Level V. Easily distracted.

A. Agitated behavior scale: 26/56

B. Galveston Orientation and Amnesia Test: 66

C. Moss Attention Rating Scale:

1. Total Raw Score: 84
2. Average MARS Item Score: 3.82
3. Factor 1 (Restlessness/Distractibility) Score: 4.60
4. Factor 2 (Initiation) Score: 4.00
5. Factor 3 (Consistent/Sustained Attention) Score: 3.67

III. Assistive and adaptive devices: currently uses a standard wheelchair in the hospital environment with gel cushion and solid back.

IV. Gait, locomotion, and balance:

A. Able to ambulate with small based quad cane (SBCQ) with minimal assistance for 150 feet using 3-point step to/through pattern

B. Gait speed: 0.44 m/s

C. Observational gait assessment: difficulty clearing right foot in swing, right knee in extension throughout swing phase, circumducts and hip hikes right hip to clear foot, initial contact with mid foot on right

D. Sitting balance: able to sit on edge of bed or mat with supervision

E. Standing balance: able to stand with close supervision, decreased WB on right LE, Berg Balance Scale score: 36/56

V. Joint mobility: decreased posterior and inferior glide R glenohumeral joint.

VI. Motor function: tone: increased extensor tone in right hip and knee and ankle, 2 on Modified Ashworth Scale, increased flexor tone in right UE, 2 on MAS. Able to isolate movement in left UE and LE, not able to isolate movement in right UE or LE. However, he does exhibit active right dorsiflexion, wrist, and finger extension.

VII. Orthotic, protective, and supportive devices:

A. Has a bivalve cast at ankle and elbow from the acute care hospital for positioning ankle into dorsiflexion and elbow into extension.

VIII. Range of motion: passive WNL except:

A. Right LE

1. Dorsiflexion: has 5 degree plantar flexion contracture
2. Knee extension: has 5 degree flexion contracture

B. Right UE

C. Shoulder flexion: 95, abduction: 90, external rotation: 65, internal rotation: 80, extension: 45

D. Elbow extension: has a 10 degree flexion contracture

E. Wrist extension: 0 degrees

IX. Self-care and home management:

A. FIM score:

Self-Care	Score	Self-Care	Score	Self-Care	Score
Eating	4	Bowel	4	Cognition	4
Grooming	4	Transfers	4	Comprehension	4
Bathing	3	Toilet	3	Expression	4
Dressing UE	3	Tub/shower	3	Problem solving	3
Dressing LE	2	Bed/wheelchair	4	Memory	2
Toileting	3	Locomotion	4	Social interaction	3
Sphincter control	4	Walk/wheelchair	4	Total	75
Bladder	4	Stairs	2		

X. Sensory integrity:

A. Proprioception, light touch, and sharp/dull discrimination intact right and left extremities

CASE STUDY GUIDING QUESTIONS

1. List factors that support a good prognosis for this patient, as well as factors that support a poor prognosis.
2. What factors make a restorative intervention approach appropriate for this patient? What factors make a compensatory approach appropriate for this patient?

3. List three long-term goals for this patient related to balance, walking ability, and transfer ability that are appropriate for discharge from the acute rehabilitation hospital.
4. Describe interventions to improve his walking ability.

DavisPlus | For additional resources, including answers to the questions for review and case study guiding questions, please visit **http://davisplus.fadavis.com**

For this chapter, see also:
Web-Based Resources for Clinicians, Families, and Patients with Traumatic Brain Injury (Appendix 19.A) online at Davis Plus.

The reader is referred to the following video case studies for additional review and study.
- **Case Study 7: Patient with Traumatic Brain Injury and Shoulder Amputation**
- **Case Study 8: Patient with Traumatic Brain Injury**

The full written case study including all tables, figures, charts and 3 video segments (examination, intervention, and outcome) appear online at DavisPlus. The case studies poses= questions for the reader's consideration with suggested answers to the case study questions, also posted online at DavisPlus.

Traumatic Spinal Cord Injury

George D. Fulk, PT, PhD
Andrea L. Behrman, PT, PhD, FAPTA
Thomas J. Schmitz, PT, PhD

Chapter 20

LEARNING OBJECTIVES

1. Identify the major etiological factors associated with traumatic spinal cord injury.
2. Describe the clinical presentation following damage to the spinal cord.
3. Given a patient with a spinal cord injury, identify the motor and sensory level of injury and the American Spinal Injury Association impairment scale classification.
4. Analyze the impact of complications associated with spinal cord injury on the physical therapy plan of care and outcomes.
5. Identify the expected functional outcomes for patients with spinal cord injury at various lesion levels.
6. Explain how common precautions will affect physical therapy interventions.
7. Evaluate different outcome measures commonly used in people with spinal cord injury.
8. Analyze and interpret patient data, formulate anticipated goals and expected outcomes, and develop a plan of care when presented with a clinical case study.
9. Justify the selection of different interventions for the acute and active rehabilitation stages of recovery.
10. Discuss the use of neurotechnologies for people with spinal cord injury.

SUMMARY *955*

Spinal cord injury (SCI) is a relatively low-incidence, high-cost injury that results in tremendous change in an individual's life. Paralysis of the muscles below the level of the injury can lead to limited and altered mobility, self-care, and ability to participate in valued social activities. In addition to the musculoskeletal system, many other body systems are impaired after a SCI, including the cardiopulmonary, integumentary, gastrointestinal, genitourinary, and sensory systems. The psychosocial impact of SCI can be just as great as the physical impact. Changes in body image and sexual function, incontinence, and having to rely on others to complete everyday tasks that were previously done without thought or effort can profoundly influence a person's identity. Rehabilitation is an important element toward achieving a fulfilling and active life after SCI. Physical therapists play a key role in the rehabilitation process.

DEMOGRAPHICS AND ETIOLOGY

It is estimated that approximately 11,000 new cases of SCI occur in the United States annually. Between 225,000 and 288,000 individuals with SCI are currently

living in the United States.[1] Spinal cord injury is generally thought to primarily affect young adults. However, the age at injury has steadily increased. During the 1970s the average age at the time of injury was 28.7 years old. Between 2005 and 2008 this increased to 37.1 years old.[1] This may be due to the aging of the U.S. population and an increase in falls as a cause of injury. The majority of persons with SCI are male (78.3% male vs. 21.7% female). Ethnic distributions indicate that whites represent 66.5% of those with SCI, followed by African Americans (26.8%), Hispanics (8.3%), and Asians (2.0%).[2]

Spinal cord injuries can be grossly divided into two broad etiological categories: *traumatic* injuries and *nontraumatic* damage. Trauma is the most frequent cause of injury in adult rehabilitation populations. Injury results from damage caused by traumatic events such as motor vehicle accidents (40.4%), falls (27.9%), violence (15.0%), and sports (8.0%).[2] Nontraumatic damage in adult populations generally results from disease or pathological influence. Conditions that may damage the spinal cord are vascular dysfunction (arteriovenous malformation [AVM], thrombosis, embolus, or hemorrhage); vertebral subluxations secondary to rheumatoid arthritis or degenerative joint disease; spinal neoplasms; syringomyelia; abscess of the spinal cord; infections, such as syphilis or transverse myelitis; and neurological diseases, such as multiple sclerosis and amyotrophic lateral sclerosis. Nontraumatic etiologies account for approximately 39% of all SCIs.[3]

Fifty-six percent of patients experience cervical lesions resulting in tetraplegia, whereas 43% of SCIs result in paraplegia from thoracic, lumbar, or sacral lesions. The number of people with neurologically incomplete lesions has increased since the 1970s from 43.9% to 52.7% in 2008. The most common type of injury is incomplete tetraplegia (39.5%), followed by complete paraplegia (22.1%), incomplete paraplegia (21.7%), and complete tetraplegia (16.3%). This trend may be partially attributed to improved emergency medical services delivered at the scene of the injury. The length of hospital stay, both in acute care and inpatient rehabilitation, has also changed considerably since the 1970s. The median length of stay in the acute care hospital has decreased from 24 days in the 1970s to 12 days in 2005. This trend is true for length of stay of inpatient rehabilitation as well, 98 days in the 1970s compared to 37 days in 2005.[2]

Life expectancy has increased over the years but is still less than that for individuals without a SCI. Factors that influence life expectancy are age at onset and level and extent of neurological injury. Individuals with an incomplete neurological SCI have a longer life expectancy than those with a complete injury, and individuals with more caudal injuries also have a greater life expectancy. A 20-year-old healthy individual without a SCI has a life expectancy of an additional 58.6 years (total life expectancy of 78.6 years). A person who experiences a SCI at age 20 with a neurologically incomplete injury has a life expectancy of an additional 52.6 years, a person with complete paraplegia an additional 45.2 years, low tetraplegia (C5–C8) an additional 40.0 years, and a person with high tetraplegia (C1–C4) an additional 35.7 years. Mortality rate is also significantly higher during the first year after injury.

The financial impact of SCI is extremely high. Spinal cord injury is characterized by lengthy hospitalization, medical complications, extensive follow-up care, and recurrent hospitalizations. The costs of medical care in 2009 during the first year after injury were approximately $986,000 for high tetraplegia (C1–C4), $712,000 for low tetraplegia (C5–C8), and $480,000 for paraplegia. Average lifetime costs for an individual injured at 25 years of age are $3.5 million for high tetraplegia (C1–C4), $2.5 million for low tetraplegia (C5–C8), and $1.6 million for paraplegia.[4] These numbers do not take into account lost wages, fringe benefits, and productivity.

This brief presentation of demographic information provides some important general perspectives on characteristics of SCI. It is a relatively low-incidence disability affecting predominantly younger males, although more older adults are experiencing SCI likely due to falls, and SCI is associated with lengthy and costly care.

CLASSIFICATION OF SPINAL CORD INJURIES

Spinal cord injuries typically are divided into two broad functional categories: tetraplegia and paraplegia. **Tetraplegia** refers to complete paralysis of all four extremities and trunk, including the respiratory muscles, and results from lesions of the cervical cord. **Paraplegia** refers to complete paralysis of all or part of the trunk and both lower extremities (LEs), resulting from lesions of the thoracic or lumbar spinal cord or cauda equina.

Neuroanatomical Organization and Structure

Before considering designation of spinal cord lesions, it is useful to review briefly the anatomy of the spinal cord and its relationship with nerve roots to the vertebral bodies. The spinal cord exits the foramen magnum and extends to approximately the L1 vertebral level. It contains white matter, which consists of ascending sensory tracts, descending motor tracts, and an H-shaped central area of grey matter. The primary ascending tracts are the dorsal column (conveys proprioception, vibratory sensation, deep touch, and discriminative touch); anterolateral system consisting of the spinothalamic, spinoreticular, and spinotectal tracts (conveys pain, temperature, and crude touch); and the dorsal and ventral spinocerebellar tracts (conveys unconscious proprioception) (Fig. 20.1). The primary descending tracts are the lateral corticospinal (voluntary movement); anterior corticospinal (voluntary movement of axial muscles, minimal clinical significance due to small size); medial vestibulospinal (positioning of head and neck); lateral and medial vestibulospinal (posture and balance); lateral and medial reticulospinal (posture, balance, automatic gait-related movements);

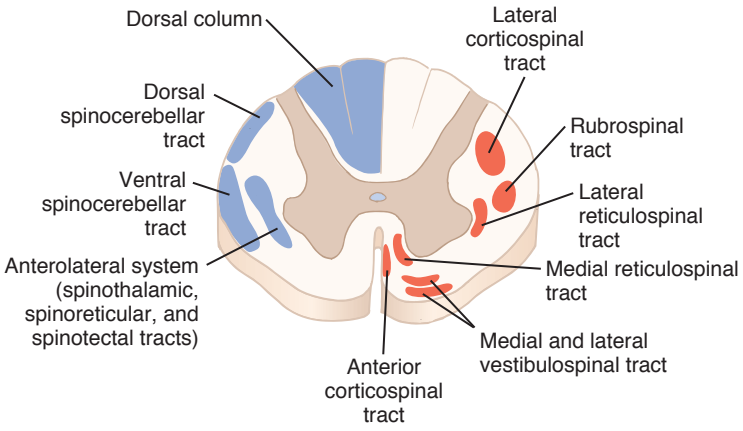

Figure 20.1 Main ascending sensor tracts: dorsal column, spinothalamic, spinoreticular, spinotectal, and dorsal and ventral spinocerebellar tracts. Main descending motor tracts: lateral corticospinal, anterior corticospinal, lateral and medial vestibulospinal, lateral and medial reticulospinal, and rubrospinal tracts.

and rubrospinal (movement of limbs) (see Fig. 20.1). In addition to these long tracts, the white matter contains axons of interneurons, which convey information between spinal cord segments. The H-shaped grey matter is arranged such that the dorsal section in each half contains neurons involved in sensory function, the middle portion contains interneurons, and the ventral section contains neurons involved in motor function (anterior horn cells) that project to the peripheral muscles.[5]

There are 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal (Fig. 20.2). The cervical nerves are relatively horizontal as they exit the intervertebral foramina. The nerve roots for C1–C7 exit above the corresponding vertebrae. C8 exits below the C7 vertebrae. The remaining nerves exit in a downward direction and do not emerge at the corresponding vertebral level. During fetal development the cord fills the entire length of the vertebral canal and the spinal nerves run in a horizontal direction. As the vertebral column elongates with growth, the spinal cord, which does not elongate at the same rate or as much, is drawn upward. In adults the spinal cord ends in the conus medullaris at the L1 vertebral level. The nerve roots assume an increasingly oblique and downward direction, running in an almost vertical direction in the lumbar area, giving the appearance of a "horse's tail" (cauda equina) (see Fig. 20.2). Because of this, in more caudal injuries the vertebral level of injury does not correspond directly to the spinal cord segment level of injury.

Designation of Lesion Level

It is extremely important for clinicians and researchers to be able to accurately determine the extent of neurological impairment in terms of motor and sensory loss when working with individuals with SCI. The extent of motor and sensory function after injury has a large impact on the medical and rehabilitation needs of the individual. The American Spinal Injury Association (ASIA) created the *International Standards for Neurological Classification of Spinal Cord Injury* (ISNCSCI)[6,7] (Fig. 20.3) in an effort to standardize the way in which severity of injury is determined and documented.

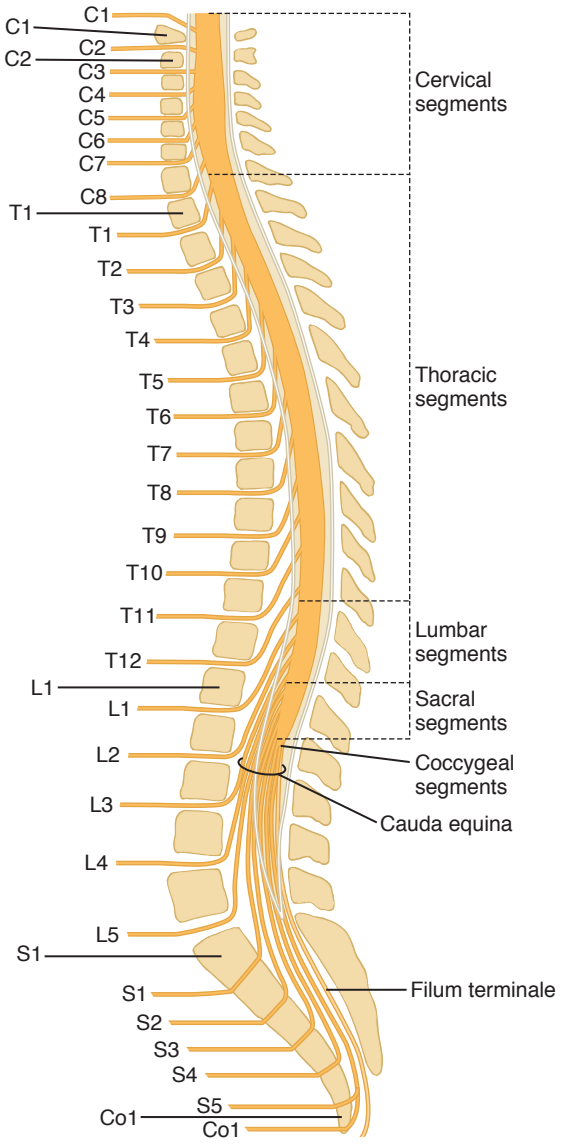

Figure 20.2 Relationship between spinal cord and nerve roots to vertebral bodies.

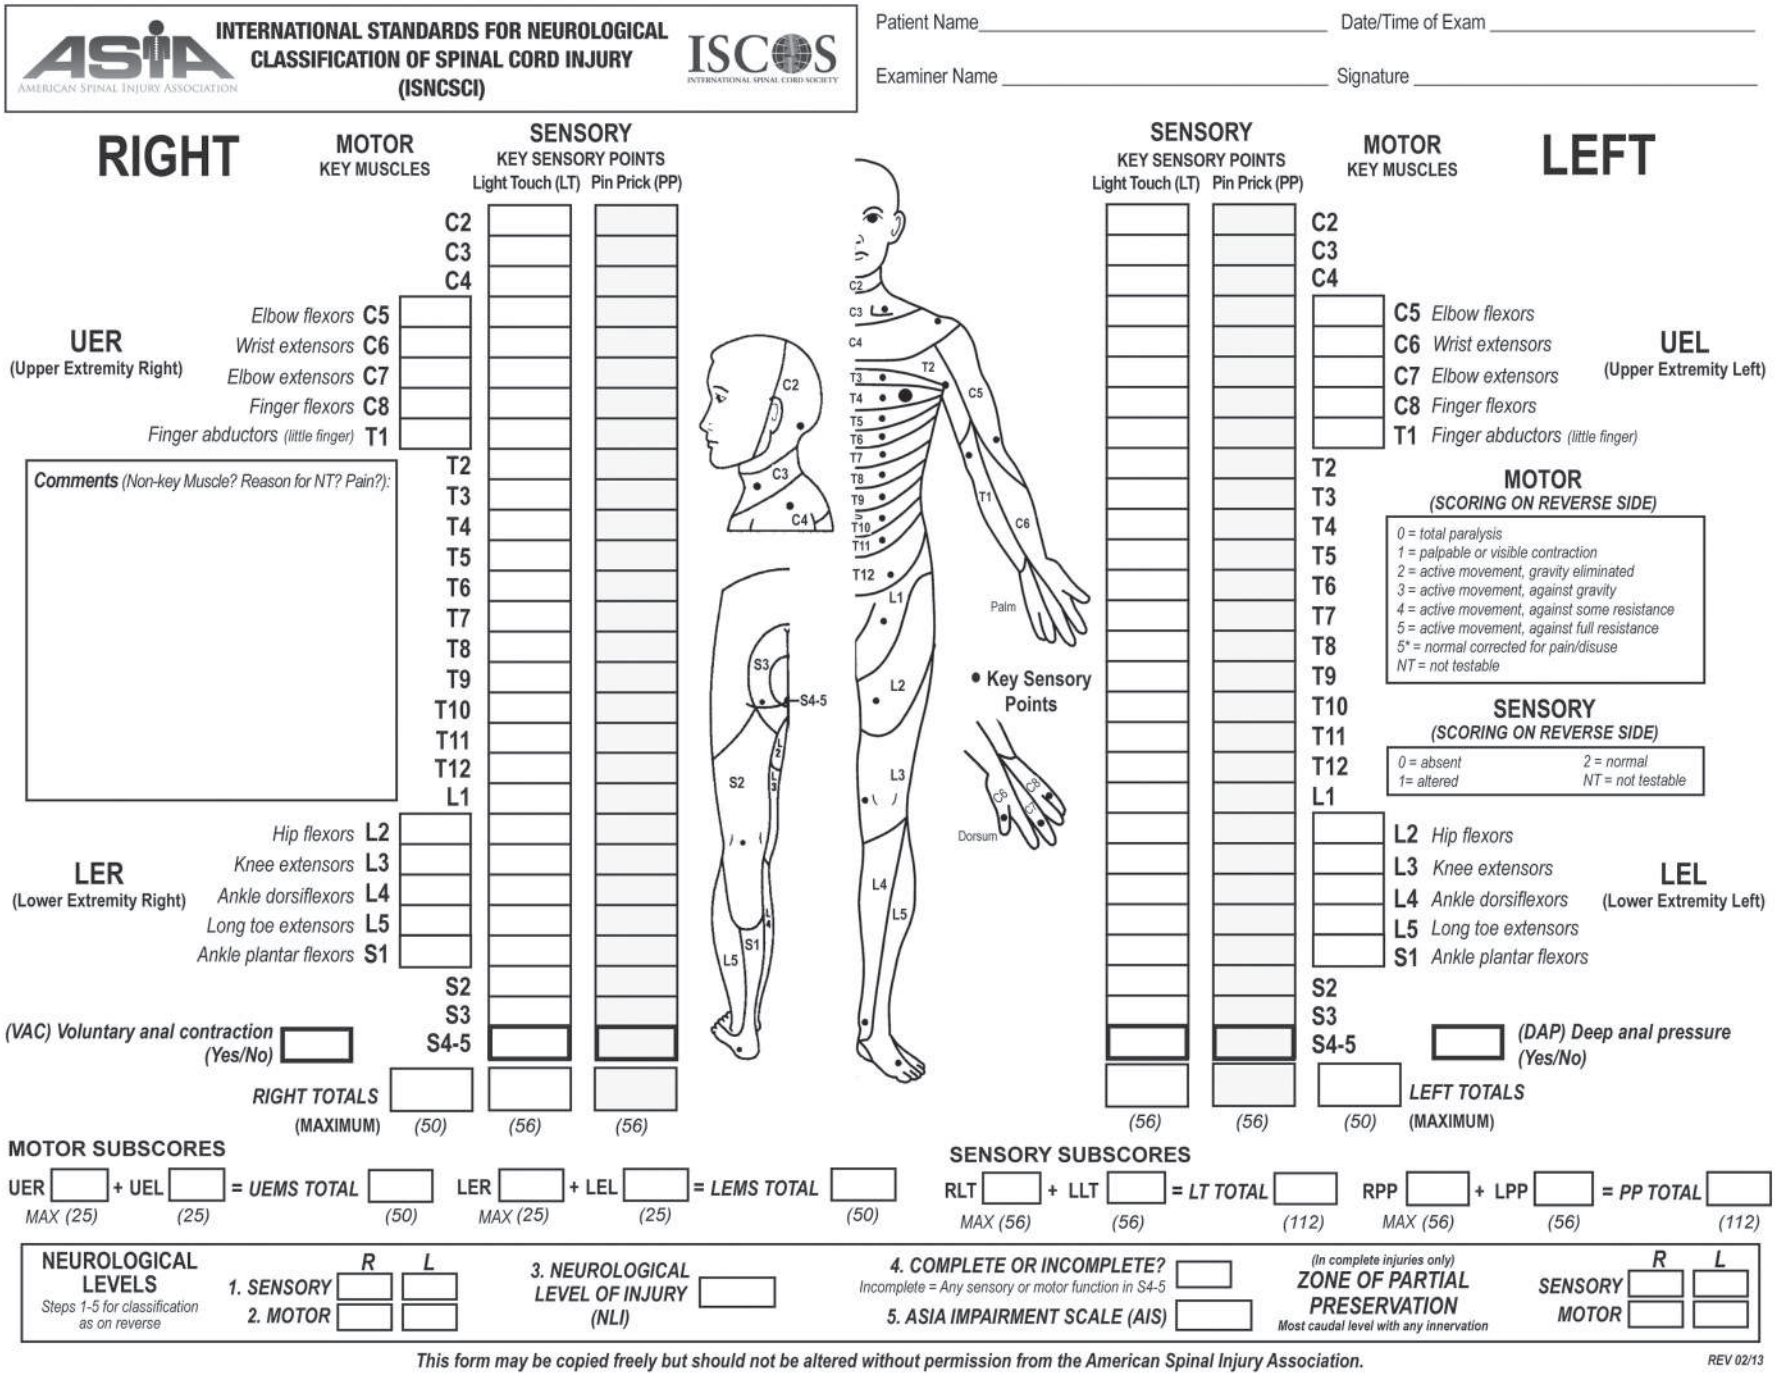

Figure 20.3 International Standards for Classification of Spinal Cord Injury. *(With permission from American Spinal Injury Association: International Standards for Neurological Classification of Spinal Cord Injury, revised 2013; Atlanta, GA. Reprinted 2013.)*

The ISNCSCI provides a standardized examination method to determine the extent of motor and sensory function loss after a SCI. It promotes better communication between and among professionals, provides guidance for establishing the prognosis, and is an important tool for clinical research trials.

The **neurological level** is defined as the most caudal level of the spinal cord with normal motor and sensory function on both the left and right sides of the body. **Motor level** is referred to as the most caudal segment of the spinal cord with normal motor function bilaterally. **Sensory level** is defined in the same way except in terms of sensory function. Sensory level is determined by testing the patient's sensitivity to light touch and pinprick on the left and right side of the body at key dermatomes (see Fig. 20.3). Scoring of sensation is based on a 3-point ordinal scale where 0 = absent, 1 = impaired, and 2 = normal. Motor level is determined by testing the strength of a key muscle on the right and left side of the body at myotomes adjacent to the suspected level of impairment (see Fig. 20.3 for key muscles). Key muscle strength is scored using the 6-point ordinal scale commonly used for manual muscle testing.

Assigning a single muscle to represent one myotome is a generalization. Most muscles are innervated by more than one segmental nerve root; usually two nerve roots innervate each muscle. For example, the extensor carpi radialis longus receives innervation from the C6 and C7 spinal nerve roots. For the purpose of determining motor and neurological level, the key muscle is defined as having intact innervation if it has a manual muscle test score of at least 3/5 (fair) and the next most rostral key muscle exhibits 5/5 (normal) strength on the manual muscle test. If the rostral key muscle does not demonstrate 5/5 strength, but the therapist feels that the muscle would test normally except for factors that would impede normal testing (e.g., pain with testing or difficulty with positioning), then this information should be carefully documented. For myotomes that are not clinically testable (i.e., C1–C4, T2–L1, and S2–S5) the motor level is defined as the same as the sensory level.[6,7]

In determining neurological level there may be differences in terms of level of sensory and motor function and between the left and right sides of the body. For example, a patient's sensory level may be at C5 on the left and C8 on the right, and the motor level may be C5 on the left and T1 on the right. In these cases, it is not appropriate to assign a single neurological level, because this can be misleading. Each of the sensory and motor levels on the right and left sides of the body should be documented separately.[6]

Complete Injuries, Incomplete Injuries, and Zone of Partial Preservation

A complete anatomical transection of the spinal cord is rare. However, even if the injury is not anatomically complete, it may present as clinically complete. The ISNCSCI defines a **complete injury** as having no sensory or motor function in the lowest sacral segments (S4 and S5). Sensory and motor function at S4 and S5 are determined by anal sensation and voluntary external anal sphincter contraction. An **incomplete injury** is classified as having motor and/or sensory function below the neurological level including sensory and/or motor function at S4 and S5. If an individual has motor and/or sensory function below the neurological level but does not have function at S4 and S5, then the areas of intact motor and/or sensory function below the neurological level are termed **zones of partial preservation**.[6]

ASIA Impairment Scale

Individuals with incomplete injuries may have variable clinical presentations in terms of motor and/or sensory function below the neurological level. For example, one patient may have close to normal sensory and motor function below the level of the lesion whereas another with the same lesion level may have impaired sensation and no motor function below the neurological level. The ASIA impairment scale (Table 20.1)[6] was created so that clinicians and researchers could better communicate the degree of motor and sensory impairment of individuals with SCIs.

Clinical Syndromes

Despite the disparity associated with incomplete lesions, several syndromes have emerged with consistent clinical features. Approximately one-fifth of all SCIs result in an

Table 20.1 ASIA Impairment Scale

☐ **A = Complete:** No motor or sensory function is preserved in the sacral segments S4 to S5.
☐ **B = Incomplete:** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4 to S5.
☐ **C = Incomplete:** Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3.
☐ **D = Incomplete:** Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade of 3 or more.
☐ **E = Normal:** Motor and sensory function is normal.

injury pattern similar to clinical SCI syndromes.[8] Information related to the anticipated sensory and motor functions of these syndromes is useful in establishing anticipated goals, expected outcomes, and plan of care (POC). The area of cord damage of each syndrome is presented in Figure 20.4. The corresponding clinical features of the different syndromes are explained by the anatomical organization of the motor and sensory pathways described earlier.

Brown-Sequard Syndrome

Brown-Sequard syndrome occurs from hemisection of the spinal cord (damage to one side) and is typically caused by penetration wounds, that is, gunshot or stab. Partial lesions (termed *Brown-Sequard plus syndrome*) occur more frequently; true hemisections are rare. The clinical features of this syndrome are asymmetrical. On the *ipsilateral* (same) side as the lesion, there is paralysis and sensory loss. The ipsilateral loss of proprioception, light touch, and vibratory sense is due to damage to the dorsal column; paralysis results from damage to the lateral corticospinal tract. On the side *contralateral* (opposite) to the lesion, damage to the spinothalamic tracts results in loss of sense of pain and temperature.[8] This loss begins several dermatome segments below the level of injury.[9] This discrepancy in levels occurs because the lateral spinothalamic tracts ascend two to four segments on the same side before crossing.[5,10,11] Individuals with Brown-Sequard syndrome typically achieve good functional gains during inpatient rehabilitation.[8]

Anterior Cord Syndrome

Anterior cord syndrome is frequently related to flexion injuries of the cervical region with resultant damage to the anterior portion of the cord and/or its vascular supply from the anterior spinal artery. There is typically compression of the anterior cord from fracture, dislocation, or cervical disk protrusion. This syndrome is characterized by loss of motor function (corticospinal tract damage) and loss of the sense of pain and temperature (spinothalamic tract damage) below the level of the lesion. Proprioception, light touch, and vibratory sense are generally preserved, because they are mediated by the dorsal columns with a separate vascular supply from the posterior spinal arteries.[5,8,10,11] Individuals with anterior cord syndrome often require a longer length of stay during inpatient rehabilitation compared to people with other types of SCI clinical syndromes.[8]

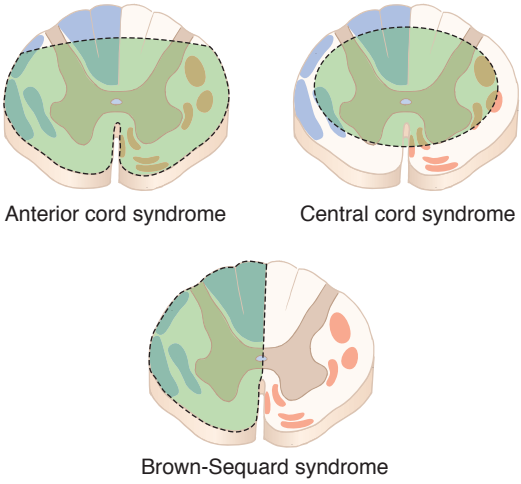

Figure 20.4 Areas of spinal cord damage in clinical syndromes.

Central Cord Syndrome

Central cord syndrome is the most common SCI syndrome.[8,12] It generally occurs from hyperextension injuries to the cervical region.[13] It also has been associated with congenital or degenerative narrowing of the spinal canal. The resultant compressive forces give rise to hemorrhage and edema, producing damage to the most central aspects of the cord. There is characteristically more severe neurological involvement of the upper extremities (UEs) (cervical tracts are more centrally located) than of the LEs (lumbar and sacral tracts are located more peripherally).[8] Varying degrees of sensory impairment occur but tend to be less severe than motor deficits. With complete preservation of sacral tracts, normal sexual, bowel, and bladder function may be retained. Patients with central cord syndrome typically recover the ability to ambulate. Some distal UE weakness and loss of fine motor control remain, which can result in moderate to severe limitations in the ability to perform functional tasks.[12]

Cauda Equina Injuries

The spinal cord tapers distally to form the conus medullaris at the lower border of the first lumbar vertebra. Although some anatomical variations exist, this is the typical termination point of the spinal cord. Below this level is the collection of long nerve roots known as the *cauda equina*. Complete transections in this area are rare. **Cauda equina lesions** are frequently anatomically incomplete owing to the great number of nerve roots involved and the comparatively large surface area they encompass (i.e., it would be unlikely that an injury to this region would involve the entire surface area and all the nerve roots).

Individuals with cauda equina injuries exhibit areflexic bowel and bladder and saddle anesthesia. Lower extremity paralysis and paresis is variable depending on the extent of the injury to the cauda equina.[8] Cauda equina lesions are peripheral nerve (**lower motor neuron** [LMN]) injuries. As such, they have the same potential to regenerate as peripheral nerves elsewhere in the body. However, full return of innervation is not common because (1) there is a large distance between the lesion and the point of innervation; (2) axonal regeneration may not occur along the original distribution of the nerve; (3) axonal regeneration may be blocked by glial-collagen

scarring; (4) the end organ may no longer be functioning once reinnervation occurs; and (5) the rate of regeneration slows and finally stops after about 1 year.

NEUROLOGICAL COMPLICATIONS AND ASSOCIATED CONDITIONS

Spinal cord injury results in a disruption of communication from higher centers in the central nervous system to the periphery. This disruption results in loss of motor and sensory function, as well as impaired autonomic function.

Spinal Shock

Immediately following SCI there is a period of areflexia that is part of **spinal shock**. This period of transient reflex depression is not clearly understood.[14] It is believed to result from the very abrupt withdrawal of connections between higher centers and the spinal cord.[5,10] It is characterized initially by an absence of all reflex activity, impairment of autonomic regulation resulting in hypotension and loss of control of sweating and piloerection.[10] In addition to the loss of deep tendon reflexes, there is a loss of the bulbocavernosus reflex, the cremasteric reflex, a Babinski response, and a delayed plantar response.

Spinal shock evolves over time. The initial period of total areflexia lasts approximately 24 hours. This is followed by a gradual return of reflexes 1 to 3 days after injury, a period of increasing hyperreflexia lasting 1 to 4 weeks, and final hyperreflexia 1 to 6 months after injury.[14]

Motor and Sensory Impairments

Following SCI there will be either complete (paralysis) or partial (paresis) loss of muscle function below the level of the lesion. Disruption of the ascending sensory fibers following SCI results in impaired or absent sensation below the level of the lesion.

The clinical presentation of motor and sensory impairments depends on the specific features of the lesion. These include the neurological level and the completeness of the lesion.

Autonomic Dysreflexia

Autonomic dysreflexia (AD, also referred to autonomic hyperreflexia) is a pathological autonomic reflex that can be life threatening. Typically AD occurs in lesions above T6 (above sympathetic splanchnic outflow).[15] However, it has been reported in patients with lower injuries. Incidence of this problem varies. One study found a 48% occurrence in a group of 213 patients.[16] Although AD is more common in the chronic stage of recovery (more than 3 to 6 months after injury), it may also occur in the early stages after SCI.[17] It is more common with complete injury, but it may also occur with an incomplete SCI.[18]

This clinical syndrome produces an acute onset of autonomic activity from noxious stimuli below the level of the lesion. Afferent input from these stimuli reach the lower spinal cord (lower thoracic and sacral areas) and initiate a mass reflex response resulting in elevation of blood pressure. Normally, the impulses stimulate the receptors in the carotid sinus and aorta, which signal the vasomotor center to readjust peripheral resistance. Following SCI, however, impulses from the vasomotor center cannot pass the site of the lesion to counteract the hypertension by vasodilation.[19] This is a critical, emergency situation. Owing to the lack of inhibition from higher centers, hypertension will persist if not treated promptly. Hypertension triggered by AD can result in seizures, cardiac arrest, subarachnoid hemorrhage, stroke, or even death.

Initiating Stimuli

The most common cause of this pathological reflex is bladder and bowel distention/irritation.[19] Common bladder issues that may trigger AD are distended bladder, blocked catheter, urinary tract infection, kidney stones, and irritation of bladder or urethra during catheterization or other procedures. Other precipitating stimuli include pressure sores, noxious cutaneous stimuli below the level of the lesion, kidney malfunction, electrical stimulation below the level of the lesion, sexual activity, labor, and skeletal fracture below the level of the lesion.[19] Table 20.2 summarizes stimuli that may trigger an onset of AD, as well as common associated signs and symptoms.

Symptoms

The symptoms of AD include hypertension, bradycardia, headache (often severe and pounding), profuse sweating, increased spasticity, restlessness, vasoconstriction below the level of lesion, vasodilation (flushing) above the level of the lesion, constricted pupils, nasal congestion, piloerection (goose bumps), and blurred vision.[19] Less commonly, AD may also present as asymptomatic. A rise in systolic blood pressure of 20 to 30 mm Hg is diagnostic of an episode of AD[15] (such a rise may appear to be within normal range for a person without SCI). People with SCI typically have lower than normal resting blood pressure; systolic may be in the range of 90 to 110 mm Hg for those with neurological level above T6. During an episode of AD, systolic blood pressure may rise to 250 to 300 mm Hg and diastolic to 200 to 220 mm Hg.

Intervention

The onset of symptoms should be treated as a medical emergency. If lying flat, the patient should be brought to an upright position, inasmuch as blood pressure will be lowered in this position, and loosen any tight clothing or restrictive devices. Blood pressure and pulse should be monitored. The individual should be questioned as to possible triggers, starting with urinary system. Because bladder

Table 20.2 Initiating Stimuli and Signs and Symptoms of Autonomic Dysreflexia

Initiating Stimuli	Signs and Symptoms
Bladder distention/irritation*	Hypertension (rise in systolic BP 20–30 mm Hg)
Bowel distention/irritation*	Bradycardia
Stimuli that would normally be painful below level of lesion	Severe headache
Gastrointestinal irritation	Feeling of anxiety
Sexual activity	Constricted pupils
Labor	Blurred vision
Skeletal fracture below level of injury	Flushing and piloerection above level of lesion
Electrical stimulation below level of lesion	Dry, pale skin below level of lesion (due to vasoconstriction)
	Nasal congestion
	Increased spasticity
	May be asymptomatic

*Most common triggers of AD.

distention is a primary cause of AD, the drainage system should be examined first. If the patient is using an indwelling catheter it should be checked to make sure it is not blocked. If any type of blockage is found it should be removed immediately. If the patient catheterizes intermittently, a catheter should be placed and the bladder drained. The patient should then be questioned about when the last bowel movement occurred and checked for an impaction. The patient's body should be examined for triggering stimuli such as tight clothing, restricting catheter straps, abdominal binders, or anything that may be a noxious stimulus.[20,21]

If hypertension and other symptoms do not subside with the identification and elimination of specific triggers, medical and/or nursing assistance should be sought emergently. Pharmacological intervention may be required to lower blood pressure. Nifedipine, nitrates, and captopril are commonly used antihypertensive medications.[22]

Education related to triggers, signs and symptoms, and management of AD is critical. A recent study found that 41% of people with SCI above T6 reported never having heard about AD, and 22% of those who did know about it did not know how to respond to an episode of AD.[23] Because, in most cases, AD is not manifested until the chronic stages of recovery, people with SCI may no longer be in a health care setting when they first experience an episode. People with SCI who are at risk of experiencing AD should be educated on initiating stimuli, symptoms, and management.

Spastic Hypertonia

Individuals with SCI and other central nervous system disorders such as traumatic brain injury, multiple sclerosis, and stroke often present with spastic hypertonia. Approximately 65% of people with SCI have spasticity, and it is more common in people with cervical-level injuries.[24] Spastic hypertonia is part of upper motor neuron (UMN) syndrome, which encompasses a range of conditions including spasticity, muscle spasms, abnormally high muscle tone, hyperactive stretch reflexes, and clonus.[25] These terms are sometimes used interchangeably in the literature. The classic definition of spasticity is a velocity-dependent increase in resistance to passive stretch.[26] Spastic hypertonia is thought to be a result of altered input at the spinal segmental level, which causes an imbalance between excitation and inhibition of the spinal motor neurons. Descending, suprasegmental signals are altered or eliminated following SCI, the anterior horn cell may become hyperexcitable, and there are changes in afferent input.[25]

Spastic hypertonia typically emerges below the level of lesion after spinal shock evolves. There is a gradual increase in spastic hypertonia during the first 6 months and a plateau is usually reached 1 year after injury. Various stimuli including positional changes, cutaneous stimuli, environmental temperatures, tight clothing, bladder or kidney stones, fecal impactions, catheter blockage, urinary tract infections, decubitus ulcers, and emotional stress may trigger or increase spasticity and muscle spasms.

Spasticity varies in the degree of severity. Approximately 50% of people with SCI report that their spasticity is problematic.[24,27] Patients with minimal to moderate involvement may learn to trigger the spasticity or muscle spasm at appropriate times to assist in functional activities. However, strong spasticity can be a deterrent to independent function. For example, severe spasms during transfers may cause loss of balance and a fall. The management of spasticity must balance the potential benefits against the negative effects.

Spasticity is generally managed through a variety of methods including stretch, modalities, and medications.[28-30] Although stretch is commonly used in the

clinic,[28] a recent systematic review found that stretch had no clinically important impact on spasticity in people with neurological conditions.[31] This may be due to the differences in how spasticity was measured and length of time and force used while providing the stretch between studies.

Medications typically used include muscle relaxants and spasmolytic agents such as baclofen,[30,32] tizanidine,[33] diazepam,[34] and dantrolene sodium.[34] Intrathecal baclofen (where an implanted pump delivers small amounts of baclofen directly at the spinal cord level to minimize side effects) can be used in cases of severe spasticity when individuals do not respond well to oral administration.[35] Intramuscular injection of botulinum neurotoxin can be used to manage focal spasticity.[36] Pharmacological management is usually not completely successful in alleviating spasticity, and its benefits must be weighed against potentially adverse side effects (e.g., weakness, dizziness, drowsiness). In addition, patients may develop a tolerance to prolonged use of individual drugs. Despite the widespread use of pharmacological agents to treat spasticity, few clinical trials directly support their use in people with SCI.[37]

Surgical approaches also have been used to combat spasticity in more severe cases and are only considered after all other alternative interventions have been tried.[30] Surgical procedures used include myotomy, a sectioning or release of a muscle; tenotomy, a sectioning of a tendon that allows subsequent lengthening (e.g., heel cords); and a dorsal rhizotomy (cutting of the posterior nerve roots to disrupt the stretch reflex arc).[30]

Cardiovascular Impairment

In healthy individuals with an intact spinal cord, cardiovascular function is regulated by the brainstem and hypothalamus via the sympathetic and parasympathetic nervous systems.[5,38] Parasympathetic signals to the heart arise from the vagus nerve, decreasing heart rate and contractility. Sympathetic input comes from spinal segments T1 to L2 through the sympathetic trunk, which runs parallel to the spinal cord. Sympathetic input increases heart rate and contractility and peripheral vasoconstriction.[5]

A rostral SCI will result in a loss of sympathetic communication between the brainstem and the heart, while parasympathetic input remains intact. This causes bradycardia and dilation of the peripheral vasculature below the level of the lesion. Because of the disrupted balance between sympathetic and parasympathetic input, as well as a lack of or decrease in active muscle contraction and prolonged time in bed, orthostatic hypotension is often experienced during early transitions to a more upright posture. Symptoms of orthostatic hypotension include blurred vision, ringing in the ears, light-headedness, and fainting. Orthostatic hypotension is usually only significant in people with SCI above T6. Although the exact mechanism is not clearly understood, the cardiovascular system, over time, gradually reestablishes sufficient vasomotor tone to allow assumption of the vertical position.[39]

To minimize these effects when mobilizing patients early after SCI, the cardiovascular system should be allowed to adapt gradually by a slow progression to the vertical position. This frequently begins with elevation of the head of the bed and progresses to a reclining wheelchair with elevating leg rests and use of a tilt table. Vital signs should be monitored carefully, and the patient should always be moved very slowly. Use of compressive stockings and an abdominal binder may further minimize these effects.[40] Pharmacological therapy may be indicated (e.g., ephedrine to increase blood pressure or low-dose diuretics to relieve persistent edema of legs, ankles, or feet). As vasomotor stability returns, tolerance to the vertical position will gradually improve.

Past the acute stage of injury, people with SCI below or within the thoracolumbar sympathetic output will exhibit a reduced exercise tolerance, lower stroke volume, and reduced cardiac output.[41,42] Deconditioning often occurs due to physical inactivity and an impaired cardiovascular system. A regular cardiovascular fitness exercise program is an important component of rehabilitation. Programs should be designed based on the level of injury and include careful patient monitoring.[42]

Impaired Temperature Control

After damage to the spinal cord the hypothalamus can no longer control cutaneous blood flow or level of sweating. This autonomic (sympathetic) dysfunction results in loss of internal thermoregulatory responses. The ability to shiver below the level of the injury is also lost. The degree of impaired thermoregulation will vary depending on the level of the injury and whether the injury is complete or incomplete. Individuals with cervical-level injuries and complete injuries demonstrate more impairment. Initially after injury hypothermia may occur due to peripheral vasodilation. Later, hyperthermia is more likely due to the lack of sympathetic control of sweat glands. Although some improvement in thermoregulatory responses occurs over time, patients with tetraplegia typically experience long-term impairment of body temperature regulation, especially in response to extreme environmental changes.

Pulmonary Impairment

Ventilatory and respiratory function varies considerably, depending on the level of lesion. In people with high cervical injuries, pulmonary problems are the leading cause of death both in the early and late stages of recovery.[43,44] Individuals with injuries below T10 are likely to have near-normal ventilatory and respiratory function. Paralysis or paresis of the muscles of respiration leads to poor ventilation, which may then cause impaired respiration leading to atelectasis and pneumonia. Ten percent of people with complete tetraplegia develop pneumonia or atelectasis 1 year after injury.[45]

With high spinal cord lesions at C1 and C2, phrenic nerve innervation and spontaneous respiration are lost. The only muscles of respiration that are intact are accessory muscles: sternocleidomastoid, upper trapezius, and cervical extensors. An artificial ventilator or phrenic nerve stimulator is required to sustain life. Expiration is passive; as a result, individuals with SCI at these levels require assistance for airway clearance. C3- and C4-level injuries have partial diaphragm innervation, as well as scalenes, levator scapulae, and trapezius. In the acute stage of recovery individuals with an injury at these levels will require mechanical ventilation. With recovery and training they will likely be able to breathe on their own.[46] However, they may need part-time ventilatory support, especially individuals with C3-level injury. Because they do not have abdominal or intercostal muscle innervation, these individuals will also need assistance for airway clearance. Patients with mid to lower cervical level injuries have better pulmonary function than those with higher cervical level injuries. Injuries at C5–C8 have a fully innervated diaphragm, as well as many accessory muscles. Some cough ability is preserved; however, it is usually weak. Although individuals with paraplegia have better respiratory function than people with tetraplegia, they still have impaired respiratory function compared to healthy individuals without a SCI.[47] Pulmonary impairment increases with the more rostral the injury. Individuals with weak or absent abdominal and intercostal musculature will have impaired airway clearance ability and be at a greater risk for developing pneumonia and atelectasis.

The primary muscles of expiration are the abdominals and internal intercostals. Normally, relaxed expiration is essentially a passive process that occurs through elastic recoil of the lungs and thorax. However, the abdominals and internal intercostals contribute several important functions related to movement of air out of the lungs. Loss of these muscles significantly decreases expiratory efficiency. Control of the abdominal muscles originates from T5–T12. When fully innervated, they play an important role in maintaining intrathoracic pressure for effective respiration. They support the abdominal viscera and assist in maintaining the position of the diaphragm. They also function to push the diaphragm upward during forced expiration. With paralysis of the abdominals this support is lost, causing the diaphragm to assume an unusually low position in the chest. This lowered position and lack of abdominal pressure to move the diaphragm upward during forced expiration results in a decreased expiratory reserve volume. This subsequently decreases cough effectiveness and the ability to expel secretions. Table 20.3 summarizes respiratory muscle function by level of SCI.[48]

Paralysis or paresis of the scalenes and intercostal muscles also results in the development of an altered breathing pattern, called *paradoxical breathing pattern*.[49] This pattern is characterized by flattening of the upper chest wall, decreased chest wall expansion, and a dominant epigastric rise during inspiration. This breathing pattern is inefficient, requiring more energy to breathe, and as a result patients can become fatigued quickly.

Table 20.3 Neurological Level of Spinal Cord Injury and Muscles of Respiration

Level of Injury	Respiratory Muscles*
C1–C2	Sternocleidomastoid, upper trapezius, cervical extensors
C3–C4	Partial diaphragm, scalenes, levator scapulae
C5–C8	Diaphragm, pectoralis major and minor, serratus anterior, rhomboids, latissimus dorsi
T1–T5	Some intercostals, erector spinae
T6–T10	Intercostals and abdominals
T11 and below	All of the muscles above

*Each successive level has the muscles of the more rostral levels.

Other factors may further impair respiratory status. Additional trauma sustained at the time of injury, premorbid respiratory problems, age, weight, and smoking history can all further compromise respiratory function.[47,50]

Bladder and Bowel Dysfunction

Bladder Dysfunction

The effects of bladder dysfunction following SCI pose a serious medical complication requiring consistent and long-term management. Urinary tract infections (UTIs) are a major cause of mortality and morbidity in people with SCI. Spinal cord injury alters the complex reflexive and voluntary control of **micturition**. As a result, people with SCI often require a catheter to drain the bladder.

Spinal control for micturition originates from the sacral segments of S2, S3, and S4.[5] The level of the SCI dictates the type of bladder dysfunction. Patients with lesions that occur above the conus medullaris and sacral segments develop a *spastic* or *hyperreflexic bladder*.[5] This is also termed a *UMN bladder*. Following a lesion of the sacral segments or conus medullaris, a *flaccid* or *areflexic bladder* develops.[5] This is also termed a *LMN bladder*.

A spastic or hyperreflexic bladder (UMN lesion) contracts and reflexively empties in response to a certain level of filling pressure. The reflex arc is intact with this type of injury. The detrusor muscle is generally hyperreflexive. There can be increased tone of the sphincter, contraction of the detrusor with small urine volumes, and lack of coordination between detrusor and sphincters (dyssynergia). A flaccid or areflexive bladder (LMN lesion) is essentially flaccid because there is no reflex action of the detrusor muscle.

There are generally two types of bladder dysfunction: failure to store urine and failure to empty urine.[51]

These can be due to detrusor muscle or sphincter impairment. Inability to store urine may be due to an areflexive sphincter or spastic detrusor muscle. Inability to empty the bladder sufficiently may be due to an areflexive bladder or a sphincter that is unable to relax. Dyssynergia between the detrusor and sphincter can also cause incomplete drainage of the bladder.[51]

Bladder Management

The primary goal of bladder management is to prevent or minimize urinary tract complications. These include UTIs, *hydronephrosis* (swelling of kidney due to backup of urine), renal calculi, bladder calculi, and *vesicoureteral reflux* (backward flow of urine up the ureter).[51] Because urinary incontinence has very strong psychosocial implications for the patient, a coordinated approach to this problem is particularly important. Knowledge of and participation in the bladder management program is an important consideration for the physical therapist.

In the early stage of recovery, while the patient is still in spinal shock, the bladder is flaccid and an indwelling catheter is inserted. After the patient is stable during rehabilitation, the most frequently used method of bladder management is *intermittent catheterization*.[51,52] Briefly stated, the program involves establishing a fluid intake pattern of approximately 2000 mL/day. Intake is stopped late in the day to reduce the need for catheterization during the night. Initially, the patient is catheterized every 4 hours. A record is maintained of voided and residual urine. While in the hospital, sterile intermittent catheterization should be done; after discharge, a clean technique can be used.

Although intermittent catheterization is the most common method of bladder management after discharge from the rehabilitation hospital, many males switch to the use of an external, condom catheter.[52] Other methods of bladder management include suprapubic tapping and the Valsalva maneuver. *Suprapubic tapping* involves tapping directly over the bladder with fingertips, causing a reflexive emptying of the bladder. This technique only works for individuals with an UMN bladder without dyssynergia between the detrusor and sphincter, because the sphincter must open for the bladder to reflexively drain.[51,52] Individuals with an areflexive bladder can use the *Valsalva maneuver*, which is done by straining.[51,52] In some individuals a suprapubic catheter may need to be surgically inserted.

The exact method or combination of methods used for bladder management will depend on a variety factors: type of bladder dysfunction, level of injury, functional ability, and personal preference. Whichever method(s) is used, the goal is for the patient to be catheter free, have low postvoid residual volume of urine in the bladder, and be without high bladder pressure during voiding.[53] Urodynamic testing is done after spinal shock resolves, approximately 3 months after injury, to help diagnose the specific type of bladder dysfunction and guide the selection of management strategies.

Because of impaired bladder function almost 50% people with SCI will develop UTIs.[54] Further urinary system complications linked to chronic UTIs are development of bladder and kidney stones and kidney dysfunction.

Bowel Dysfunction

As with bladder dysfunction, bowel dysfunction is a major concern after SCI. Over 98% of people with SCI report problems with bowel care and 34% require some level of assistance with bowel care.[55] People with SCI report that bowel function has a greater impact on daily life than many other impairments after SCI, including sexual function, bladder function, pain, spasticity, and skin integrity.[55-57] Bowel function also has a large impact on social activities and quality of life.[56] Neurogenic bowel conditions that develop after spinal shock subsides are of two main types. In spinal cord lesions above S2 there is a *spastic or reflex bowel* (UMN lesion). Because the parasympathetic and internal sphincter connections from S2–S4 are intact, reflex defecation can occur when the rectum fills with stool. In S2–S4 or cauda equina (peripheral nerves) lesions a *flaccid or areflexive bowel* (LMN lesion) develops. With an areflexive bowel the parasympathetic connections from S2–S4 are not intact so the bowel will not reflexively empty. This can cause feces to become impacted and, because the external sphincter is flaccid, incontinence can occur.[5,51]

Bowel Management

Safety and an appropriate, well-timed bowel care routine are common goals for bowel management. Safety includes continence in order to maintain intact and healthy skin, prevent damage to colorectal structures, and prevent AD due to bowel dysfunction.[53] In addition to type of neurogenic bowel (UMN or LMN), the bowel care program will also depend on presence of other health conditions that may affect gastrointestinal function, medications, dietary habits, fluid intake, and functional ability.[51] A typical bowel program involves establishing a daily (or every other day) pattern of eliciting a bowel movement. The exact time of day is chosen by the patient based on lifestyle needs and should be done consistently at the same time of day. This is usually in the morning or late evening. People with a reflex bowel require the use of suppositories and digital stimulation techniques to cause a reflex defecation. Digital stimulation involves manual stretch of the anal sphincter, either with a lubricated gloved finger or an orthotic digital stimulator. This stretch stimulates peristalsis of the colon and evacuation of the rectum (mediated by S2, S3, and S4).[51] Valsalva maneuver and abdominal massage may also be performed. Nonreflex bowel management relies on manual evacuation techniques and gentle Valsalva.[51] Other factors that can play a role in maintaining a consistent, safe bowel program include

eating a diet with appropriate amount of fiber, fluid intake, physical activity, stool softeners, laxatives, and bulking agents.

Sexual Dysfunction

Sexuality encompasses much more than just the physical ability to have sexual intercourse. It is an important part of an individual's makeup and sense of self-esteem. Spinal cord injury not only affects the physiological ability to have intercourse but the psychosocial aspect of sexuality as well. People with paraplegia report that improved sexual function is the primary factor that would improve their quality of life. For people with tetraplegia it is the second most important after regaining hand function.[57] Education so that the patient can fully understand the impact of SCI on sexual function and support so the patient can become confident in his or her new sexuality are an important part of rehabilitation.

Male Response

Sexual response is directly related to level and completeness of injury. As with bowel and bladder function, sexual capabilities are broadly divided between UMN (damage to the cord above S2–S4) and LMN lesions. Generally speaking, erectile capacity is greater in UMN lesions than in LMN lesions and greater in incomplete lesions than in complete lesions. There are two types of erections: reflexogenic and psychogenic. *Reflexogenic erections* occur in response to external physical stimulation of the genitals or perineum. An intact reflex arc is required (mediated through S2, S3, and S4). *Psychogenic erections* occur through cognitive activity such as erotic fantasy. They are mediated from the cerebral cortex either through the thoracolumbar or sacral cord centers.[5,51] Medications such as Viagra, Levitra, and Cialis; injectable medications that relax penile smooth muscle; topical agents; and mechanical devices can also be used to improve erectile function.[51,58,59]

There is a higher incidence of ability to ejaculate with LMN lesions than with UMN lesions and incomplete as compared with complete lesions.[51] Historically, relatively few patients with SCI were able to sire children. This low level of fertility was associated with impaired spermatogenesis and an inability to ejaculate. However, vibratory stimulation and electroejaculation may improve ejaculatory response and promote higher semen quality for fertility purposes.[51,59]

Orgasm and ejaculation are two separate events. *Orgasm* is a cognitive, psychogenic event, whereas *ejaculation* is a physical occurrence. Relatively little information is available related to the effects of SCI on orgasm. This likely relates to inherent difficulties in collecting such data. From self-report surveys, approximately 45% of men with SCI report achieving orgasm.[60,61]

Female Response

Female sexual responses also follow a pattern related to location of lesion. In patients with UMN lesions, the reflex arc remains intact. Therefore, components of sexual arousal (vaginal lubrication, engorgement of the labia, and clitoral erection) will likely occur through reflexogenic stimulation, but psychogenic response will be lost. Conversely, with LMN lesions, psychogenic responses will most likely be preserved and reflex responses lost.[51]

Fertility is not affected as severely in women as men with SCI. The menstrual cycle typically is interrupted for a period of 4 to 5 months following injury. After this time, normal menses return and the potential for conception remains unimpaired.[51] Women with SCI who want to bear children should be closely supervised during pregnancy. They are more likely to encounter complications during pregnancy and childbirth than woman without SCI. Problems include UTIs, anemia, and venous thrombosis.[62] Labor and delivery must be monitored. Depending on the neurological level of injury the woman may not feel labor. There is a risk of AD during labor. See reviews by Baker and Cardenas[62] and Smeltzer and Wetzel-Effinger[63] for in-depth reviews of pregnancy in women with SCI.

As with men with SCI, there is little information available on the impact of SCI on orgasm in women. Women with SCI appear to be less likely to achieve orgasm than women without SCI and those with LMN are less likely to achieve orgasm than those with UMN.[51]

A major consideration for the physical therapist regarding sexual dysfunction is that a patient will often direct questions to the individuals with whom he or she feels most comfortable. It is not uncommon for such a discussion to arise during a physical therapy session. These questions or issues should be addressed openly and honestly. In addition, the therapist must anticipate and be prepared for these situations by (1) obtaining accurate information about the patient's physiological state and anticipated sexual function, and (2) having knowledge of referral options and support services available to the patient for appropriate examination and counseling.

Secondary Medical Complications

Individuals with SCI are at great risk for secondary medical complications throughout their life because of prolonged immobilization and the wide-ranging effects of the SCI on multiple body systems. During rehabilitation 82% of patients develop secondary medical complications. One year after injury, the three most common secondary complications are **pressure ulcers** (15%), **pneumonia** (4%), and **deep vein thrombosis** (2.5%). Twenty-five years after injury, 25% of people with SCI develop pressure ulcers[64] (Box 20.1).

Box 20.1 Common Complications Following Spinal Cord Injury

- Pressure ulcer
- Deep vein thrombosis
- Pain
- Contractures
- Heterotopic ossification
- Fracture/osteoporosis
- Syringomyelia

Pressure Sores

Pressure sores (decubitus ulcers) are ulcerations of soft tissue (skin or subcutaneous tissue) caused by unrelieved pressure and shearing forces. They are subject to infection, which can migrate to bone. Pressure sores are a serious medical complication, are a major cause of delayed rehabilitation, and may even lead to death. Pressures sores are among the more frequent medical complications following SCI and are an important factor in increasing duration and subsequently cost of hospital stay. Up to 36% of people with SCI develop pressure sores during inpatient rehabilitation.[65]

Impaired sensory function and the inability to make appropriate and timely positional changes are influential factors in the development of pressure sores. Individuals with complete SCI are more likely to develop a pressure ulcer than patients with incomplete SCI (iSCI). Other important factors associated with the development of pressure ulcers are (1) tetraplegia; (2) spasticity; (3) bladder or bowel incontinence; (4) limited mobility and self-care; (5) nutritional deficiencies; (6) prolonged immobilization during recovery; (7) smoking; and (8) noncompliance with skin care.[65-67]

Pressure sores will develop over any bony prominence subjected to excessive pressure. The most common sites of involvement are the sacrum, heels, and ischium.[65] Other areas susceptible to skin breakdown are the greater trochanter, scapula, elbows, anterior iliac spines, and knees.

Deep Vein Thrombosis

Deep venous thrombosis (DVT) results from development of a thrombus within a vein. People with SCI are at risk of developing DVT due to lack of mobility and active muscle contraction of the LEs, which leads to stasis and hypercoagulability. The occurrence of such a clot is a dangerous medical complication. It has the potential to break free of its attachment and float freely within the venous bloodstream. Such mobile clots are known as *emboli.* They are particularly likely to block pulmonary vessels (pulmonary emboli), which can result in death. Reports of DVT vary widely and range from 0% to 100%.[68] Deep vein thrombosis is most likely to occur during the acute stage of recovery.[69]

The formation of a thrombus results in inflammation (thrombophlebitis) with characteristic clinical features of local swelling, erythema, and heat. These signs are similar to those of early ectopic bone formation and long bone fractures. Differential diagnosis is made on the basis of venous flow studies and venography.

Management of this secondary complication focuses on prevention. Nonpharmacological interventions include early mobilization, compression stockings and boots, and pneumatic compression sleeves. For people at high risk (motor complete, LE fracture, previous thrombosis, heart failure, and greater than 70 years of age), an inferior vena cava filter may be placed to prevent a pulmonary embolism.[69] Prophylactic anticoagulant drug therapy (heparin) is typically initiated following the acute onset of injury and routinely continued for 2 to 3 months.

Pain

Pain is a common occurrence following SCI both in the acute and chronic stages of recovery.[27,70-72] Between 26% and 96% of people with SCI report having chronic pain.[73] Pain can limit the performance of activities of daily living (ADL), affect sleep, and contribute to a lower quality of life.[74,75] Pain can be grossly divided into two broad categories: *nociceptive pain* and *neuropathic pain*. Nociceptive pain can be musculoskeletal or visceral in origin. Neuropathic pain can be below, at, or above the level of injury.[76]

Nociceptive Pain

Shoulder pain and pain in other UE joints and soft tissue is common in people with SCI.[77,78] Musculoskeletal injuries are often due to overuse or poor posture and commonly occur in the shoulder, wrist, or elbow joints involving capsule, tendon, ligament, and muscle tissue.[79] A variety of factors can cause musculoskeletal pain: mechanical injury to soft and bony tissue structures, inflammation, and muscle spasm. Muscular imbalances in the shoulder girdle, poor seated posture in a wheelchair, decreased flexibility, incorrect positioning in bed, older age, and higher body mass index (BMI) can all contribute to shoulder pain.[78] Overuse musculoskeletal injuries can be due to repetitive stress from propelling a wheelchair while in a biomechanically poor position, increased weight-bearing on the UEs while transferring, using assistive device(s) during ambulation, and pressure relief. Specific musculoskeletal injuries that may occur are biceps tendinitis, lateral epicondylitis, shoulder impingement, rotator cuff tears, carpal tunnel syndrome, and wrist tendonitis.[79]

Neuropathic pain

Neuropathic pain is pain due to injury to the central or peripheral nervous system. Neuropathic pain can occur below, at, or above the level of the spinal cord lesion.

Neuropathic pain below the level of the lesion is due to spinal cord damage and may take the form of **allodynia** or **hyperalgesia**. Damage to nerve roots or the spinal cord may be the cause of neuropathic pain at the level of the lesion. Neuropathic pain at the level of the lesion may also take the form of allodynia or hyperalgesia. Neuropathic pain above the level of the lesion is likely to be due to peripheral nerve damage associated with nerve impingement or compression. Neuropathic pain may be burning, shooting, or sharp. This type of pain below the level of the lesion is diffuse.[76]

Neuropathic pain is particularly challenging to treat and no single intervention option has established efficacy.[80,81] Nonpharmacological options include transcutaneous electrical nerve stimulation (TENS), massage, acupuncture, and mental imagery.[82] Pharmacological interventions commonly used are anticonvulsants such as gabapentin (Neurontin), pregabalin (Lyrica), and valproic acid (Depakote, Valparin); the antidepressant amitriptyline (Elavil, Vanatrip); and analgesics such as tramadol (Rybix, Ultram).[80,83] Chapter 25, Chronic Pain, provides an in-depth discussion of different types of pain, as well as interventions for pain management.

Contractures

Contractures develop secondary to prolonged shortening of structures across and around a joint, resulting in limitation in motion. Contractures initially produce alterations in muscle tissue but progress to involve capsular and pericapsular changes. Lack of active muscle function eliminates the normal reciprocal stretching of a muscle group and surrounding structures as the opposing muscle contracts. In addition, spasticity, positioning in wheelchair or bed for prolonged periods of time, and abnormal muscle tone are all factors that place people with SCI at a high risk for developing contractures. All joints are at risk for contractures. Contractures of the ankle, knee, hip, elbow, and shoulder joints may have significant negative impact on a person's ability to perform important activities and participate in valued social roles. Contractures may also be painful, make positioning and hygiene difficult, and lead to skin breakdown. The most important management consideration related to the potential development of contractures is prevention. Once contractures have developed it is extremely difficult to reverse the process.[31] A consistent and concurrent program of range of motion (ROM) exercises, positioning, and splinting is important to maintain joint motion and prevent contracture.

Heterotopic (Ectopic) Ossification

Heterotopic ossification (HO) is osteogenesis in soft tissues, usually near joints, below the level of the lesion. The etiology of this abnormal bone growth is unknown. The incidence of HO ranges from 10% to 53%.[84] Factors associated with HO include complete injury, trauma, severe spasticity, UTI, and pressure sores.[85,86] Care should be taken while performing passive range of motion (PROM). If it is too vigorous it may cause trauma, which may be a causative factor for HO. It most often occurs in the hip and knee joints. Early symptoms of HO including swelling, joint and muscle pain, decreased ROM, erythema, and local warmth near a joint.[87] Heterotopic ossification can lead to contractures, pressure sores, and impaired mobility skills and ability to perform ADL.

Management of ectopic bone formation utilizes several approaches, including pharmacological management, physical therapy, and, with severe activity limitations, surgery. Nonsteriodal anti-inflammatory medications are effective in preventing the formation of HO. Pulse low-intensity electromagnetic field may also be an effective method to prevent HO formation. Bisphosphonates are an effective pharmacological intervention, but are most effective when used early when radiographs may still be normal.[87] Finally, surgical excision is used when HO causes extreme limitations in activities and social participation.

Osteoporosis and Skeletal Fracture

Individuals with SCI may experience significant loss of bone both early after injury and long term. There is a rapid bone mineral loss in the first 4 to 6 months after injury. Bone mineral density (BMD) continues to decrease up to 3 years after injury; however, this may continue longer.[88,89] Although the exact etiology is not clear, the reduction in bone mineral density is thought to be due primarily to combination of no (or limited) muscle action and limited (or no) weight-bearing.[88,89] It is most common in the LEs, although osteoporosis may also occur in the UEs in people with cervical SCIs.

The reduction in BMD places people with SCI at a significant risk for fracture. Fracture incidence may be as high as 46%.[88] Risk factors for fracture include female, lower BMI, complete injury, paraplegia versus tetraplegia, and longer time since injury.[88,89] Falls or a forced maneuver during a transfer, ADL such as dressing, and stretching are common activities that precipitate a fracture. The onset of fracture can also be nontraumatic.[90] Intervention strategies focus on prevention in the early stage after injury or limiting/reversing BMD loss once osteoporosis has begun. Bisphosphonate is used in the early and later stages to prevent and reduce BMD loss.[88] Rehabilitation strategies used to prevent or reduce BMD loss are functional electrical stimulation and weight-bearing activities either with a standing frame or orthotics and assistive devices. The effectiveness of these rehabilitation interventions is not fully established.[88,89] This may be associated with study designs that did not have subjects standing for long enough and/or standing without sufficient loading on the LEs.

PROGNOSIS

One of the most common questions that patients and families have after a SCI is how much recovery of motor function will occur. The potential for recovery from SCI is directly related to the neurological level of lesion and completeness of the injury. An incomplete lesion (ASIA B, C, or D) is a good prognostic indicator of greater likelihood of recovery of motor function.[91,92] Even with complete lesions (ASIA A), 70% patients with cervical level injuries are likely to experience one level of motor recovery below the original neurological level.[93] Preservation of pinprick sensation at 4 months after injury in the LEs or sacral region is associated with a good prognosis for motor recovery at 1 year after injury.[94] Recovery of motor function generally plateaus around 12 to 18 months after injury.[92,95] Specific factors related to prognosis of walking ability are discussed below.

EARLY MEDICAL AND REHABILITATION MANAGEMENT IN THE ACUTE STAGE

Emergency Care

Management of SCI begins at the location of the accident. Techniques used in stabilizing, moving, and managing the patient immediately following the trauma can influence prognosis significantly. Rescue personnel must be adept at questioning and examining for signs of SCI before moving the individual. Signs of SCI after a traumatic event include paresthesias, lack of or impaired movement or sensation in the extremities, spinal pain, and altered cognitive status or level of alertness. When an SCI is suspected, efforts should be made to avoid both active and passive movements of the spine. If the injury caused a displaced fracture, further damage to the spinal cord can occur. Movement of the spine is minimized by strapping the patient to a spinal backboard or a full-body adjustable backboard, using a supporting cervical collar, immobilizing the head, and obtaining assistance from multiple personnel in moving the patient to safety.[96] These measures assist in maintaining the spine in a neutral, anatomical position and may prevent further neurological damage.

On arrival at the emergency department, initial attention is focused on stabilizing the patient medically with a primary emphasis on ventilation and circulation. Cardiac, hemodynamic, and respiratory status are closely monitored.[96,97] Diagnosis of SCI is based on the physical examination, neurological assessment, and imaging.[97] A complete neurological examination is performed once the patient is stabilized. Imaging studies assist in determining the extent of damage and plans for medical management.[96] Attention is directed toward preventing progression of neurological impairment by restoration of vertebral alignment and early immobilization of the fracture site.[97] A urinary catheter typically is inserted, and secondary injuries are addressed.[97]

High doses of methylprednisolone may be given early after the injury. The anti-inflammatory effect of this steroid may have an effect by lessening secondary damage due to the inflammatory process. A few large clinical trials have been done giving methylprednisolone within 3 to 8 hours after injury for 24 to 48 hours, with patients demonstrating improvement in motor and sensory function.[98-101] However, these results are somewhat controversial. It is not clear that the improvements in motor and sensory function directly result in improvement in mobility and ADL. Also, there may be serious complications associated with taking high doses of steroids over a prolonged time.[102,103]

Fracture Stabilization

The goal of fracture/spinal injury site management is to stabilize the spinal column to prevent further damage to the cord. Reduction and immobilization of spinal injuries can be achieved via conservative or operative methods. Indications for surgical stabilization are unstable fracture site, gross malalignment, cord compression, and deteriorating neurological status. Animal studies have demonstrated a beneficial effect of early surgical decompression.[104] In people with acute, traumatic SCI, early (within 24 hours) surgical decompression is recommended.[96] Approximately 60% of patients with SCI admitted to model SCI system centers underwent surgical stabilization.[105] Closed reduction is indicated for patients with cervical subluxation or fracture dislocation injuries.[106] It is achieved with the use of traction devices. Patients with thoracic or lumbar injuries that are managed conservatively without surgery require immobilization by positioning in a regular or rotating bed (Fig. 20.5).

Figure 20.5 Roto rest bed. *(Courtesy of Kinetic Concepts, Inc., San Antonio, TX 78265.)*

Immobilization

Following reduction of the fracture site, through either conservative or surgical means, the spine is immobilized for a period of time through the use of spinal orthoses and recumbent positioning.

Cervical Orthoses

Halos are used commonly to immobilize cervical fractures after both open and closed reduction. This spinal orthosis (Fig. 20.6) consist of a halo ring with four steel screws that attach directly to the outer skull. The halo is attached to a body jacket or vest by four vertical steel posts. A halo is extremely effective at limiting cervical motion in all planes. The most common complication of a halo orthosis is loosening of the pin site. This can create instability at the injury site in the vertebral column or be a sign of infection. Skin breakdown may also occur under the vest portion of the halo.

Although a halo is an effective means of immobilizing and protecting the injury site, it can make learning mobility skills even more challenging. The orthosis limits shoulder motion and changes the user's center of gravity. This may cause patients to feel unstable. It can also make bed and wheelchair positioning difficult.

The **Minerva** is another type of cervical orthosis (CO) that also effectively limits motion in all planes (Fig. 20.7). Like the halo, because it provides excellent cervical stability, the Minerva allows for early mobility and rehabilitation after SCI. The sterno–occipital–mandibular immobilizer (**SOMI**) is another type of CO. It is less effective in limiting cervical ROM than either the halo or Minerva. There are a variety of cervical collars that can be used. Generally these are constructed of semirigid foam and plastic and consist of two halves, which are held together with hook-and-loop closures. They do not effectively immobilize the spine. However, they may be used as transitional support following removal of a more rigid device (e.g., halo). Common types of collars include Philadelphia collar, Miami J collar, Aspen collar, and foam soft collar.

Figure 20.6 Halo orthosis. *(Courtesy of PMT Corp., Chanhassen, MN 55317.)*

Thoracolumbosacral Orthoses

A thoracolumbosacral orthosis (TLSO) is commonly used to immobilize the spine in patients with thoracic or lumbar injuries. A **TLSO** (Fig. 20.8) is made by an orthotist who takes a cast of the patient's trunk and makes the molded body jacket from the impression. Body jackets are typically bivalved and connected by hook-and-loop closures, which allows for removal during bathing and skin inspection. An extension is necessary with high thoracic injuries and low lumbar injuries in order to provide effective immobilization of the spine in these areas. A **Jewett** orthosis is a prefabricated device made of a metal frame and pads. The Jewett orthosis is not as effective for immobilizing the spine as a body jacket.

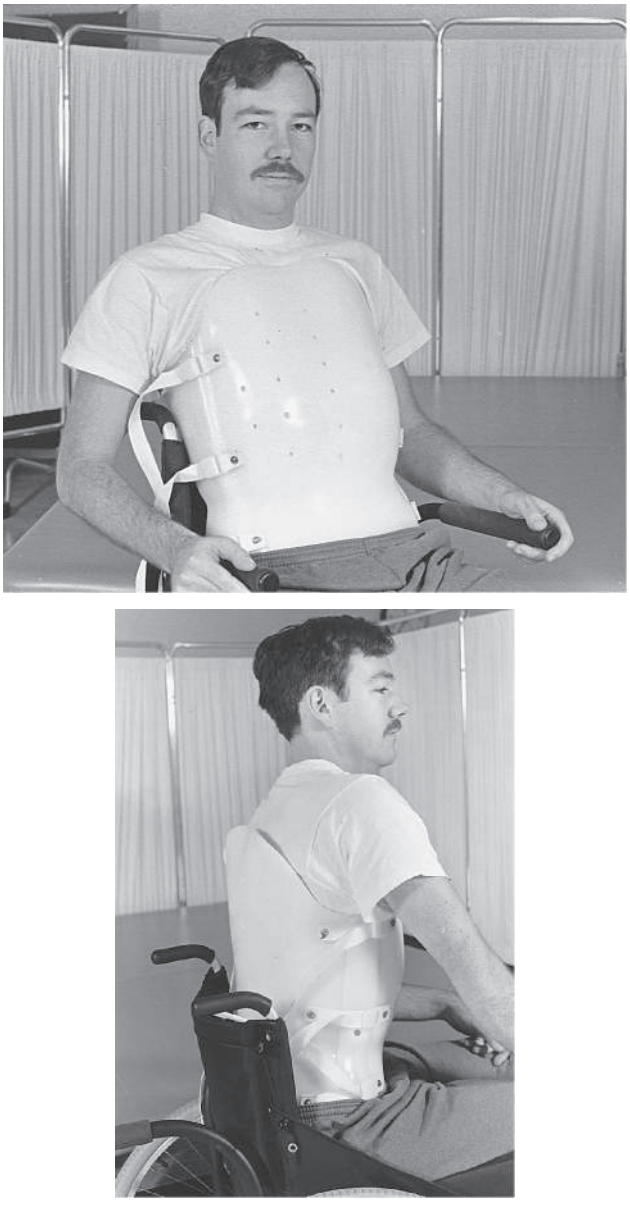

Figure 20.8 Anterior and lateral views of a thoracolumbosacral orthosis/plastic body jacket.

PHYSICAL THERAPY MANAGEMENT IN THE ACUTE STAGE OF RECOVERY

While hospitalized during the acute stage of recovery with immobilization in place, the patient may be on a period of bedrest. The primary goal of physical therapy is to prevent secondary complications, provide patient education, and begin early mobilization when medical clearance is received.

Physical Therapy Examination

Before beginning the initial examination, the patient must be sufficiently stable to undergo the examination and the therapist must be aware of any precautions. Spinal instability, orthotic devices, concomitant injuries, and need for medical support (e.g., ventilator) may preclude certain movements or positions. The primary areas of focus during this early stage of recovery are examination of sensory and motor function, respiratory function, skin integrity, PROM, and performance of early mobility skills.

Motor and Sensory Function

Motor and sensory function should be assessed using the ISNCSCI described earlier to determine the level of neurological injury (see Fig. 20.3). Care should be taken when performing manual muscle testing particularly if the spine is not yet stabilized or fully healed after surgery. Forceful contraction of muscles that originate from the spine may cause instability at the fracture site. Discretion should be used in applying resistance around the shoulders in tetraplegia and around the lower trunk and hips in paraplegia. In addition to testing the key muscles identified in the ISNCSCI, other muscle groups should be tested throughout the myotomes that have intact innervation. For example, if the C5 myotome is intact as indicated by normal strength in the biceps, then the strength of other muscles such as the deltoids and supraspinatus that are innervated by the C5 nerve root should also be determined. Standard techniques should be used for the manual muscle test (MMT)[107] and sensation (see Chapter 3, Examination of Sensory Function). Any alteration in testing position or procedure should be recorded.

Respiratory

The physical therapist should assess the strength of the diaphragm and intercostal muscles through observation while the patient is breathing.[49] Normally, the epigastric region should rise and the chest wall expands during inhalation while in supine. Contractions of the sternocleidomastoids and scalenes or paradoxical breathing patterns indicate weakness or lack of innervation of the diaphragm or intercostal muscles. Respiratory rate should be assessed while the patient is unaware that it is being done. Normal respiratory rate is between 12 and

20 breathes per minute.[49] To compensate for a weak diaphragm, the respiratory rate will typically increase.

Maximal chest excursion can be assessed using a tape measure with the patient supine. At both the level of the axilla and xiphoid process, the physical therapist should measure the chest's diameter at maximal exhalation and inhalation. Chest expansion measurements are the difference between chest measurements at maximal exhalation and at maximal inhalation. Normal chest expansion ranges from 2.5 to 3 in (6.35 to 7.62 cm), and negative values are an indication of paradoxical chest motions.[49]

Vital capacity (VC) should be measured often during the early stages of recovery. Vital capacity can be measured with a handheld spirometer and is strongly related to other measures of pulmonary function.[108] Forced vital capacity and volume of pulmonary secretion and gas exchange are predictive of airway management.[109] Typically, VC is approximately less than 25% of normal in individuals with high cervical lesions (above C3), 25% to 50% in mid cervical lesions, 50% to 75% in lower cervical and upper thoracic lesions, and 70% to 80% in mid to lower thoracic lesions.[49,50,110,111]

Owing to lack of full abdominal musculature innervation in many people with SCI, respiratory capability changes when the patient is sitting compared to supine. In sitting, the lack of abdominal muscle innervation causes abdominal contents to fall forward and pull down on the central tendon. This changes the motion of the diaphragm when it contracts during inspiration resulting in an inefficient breathing pattern.[112] The lack of full abdominal muscle function also impairs the ability to cough and clear the airway.

The ability to effectively cough is vital for the removal of secretions. The abdominal muscles are the major contributors to generating enough force to expel secretions or foreign objects. Cough function can be categorized into three types: functional cough, weak functional cough, and nonfunctional cough.[49,113] A *functional cough* is loud and forceful and the patient is able to generate two or more coughs with one exhalation. In this case the patient is able to clear all respiratory secretions. A *weak functional cough* is soft and the patient is only able to generate one per exhalation. The patient can clear small amounts of secretions and clear the throat. A *nonfunctional cough* is not a true cough; it is a clearing of the throat and has no expulsive force. In this case, assistance is needed to clear secretions from the airway.

Integument

During the acute phase, meticulous and regular skin inspection is a shared responsibility of the patient and the entire medical/rehabilitative team. As management progresses into the active rehabilitation phase, the patient will gradually assume greater responsibility for this activity. Patient education related to skin care is crucial and should be initiated early. The patient may view frequent position changes and skin inspection as bothersome or distracting from sleep if there is not adequate awareness of the importance and purpose of these activities.

Assessment for pressure ulcers should combine both direct skin inspection, which combines both visual observation and palpation, with assessment of risk factors. The patient's entire body should be observed regularly with particular attention to areas most susceptible to pressure (Table 20.4). Palpation is useful for identifying skin temperature changes that may be indicative of a hyperemic reaction. This is particularly important in examining individuals with dark skin, because early skin responses to pressure may not be readily apparent. Skin reactions to excess pressure include redness, local warmth, local edema, and small open or cracked skin areas. If the patient is wearing a halo, vest, or other orthotic device, contact points between the body and the appliance must also be inspected.

In addition to skin inspection, factors that increase the risk for skin breakdown should be considered. Spasticity, bladder or bowel incontinence, and nutritional deficiencies can increase the risk of developing skin ulcers. A number of specific scales can be used to assess the risk of developing a skin ulcer in people with SCI.[114] The Braden Scale is commonly used for a variety of patient groups who are at risk for developing pressure sores, including people with SCI.[114-116] The Braden Scale is more sensitive (75%) than specific (57%) and is easy to administer and has adequate validity.[114] The Spinal Cord Injury Pressure Ulcer Scale (SCIPUS) and SCIPUS-Acute were designed specifically for people

Table 20.4 Areas Most Susceptible to Pressure in Recumbent Positions

Supine	Prone	Side-lying
• Occiput	• Ears (head rotated)	• Ears
• Scapulae	• Shoulders (anterior aspect)	• Shoulders (lateral aspect)
• Vertebrae	• Illiac crest	• Greater trochanter
• Elbows	• Male genital region	• Head of fibula
• Sacrum	• Patella	• Knees (medial aspect from contact between knees)
• Coccyx	• Dorsum of feet	• Lateral malleolus
• Heels		• Medial malleolus (contact between malleoli)

with SCI in acute care and in active rehabilitation.[114,117,118] The SCIPUS is more specific (84%) than sensitive (37%), whereas the SCIPUS-Acute is more sensitive (88%) than specific (59%). Both of these scales have adequate validity and are easy to administer.[114]

If a patient develops a skin ulcer there are a variety of tools that can be used to examine the wound.[119-122] The location, shape, size, and stage of the wound should be documented. A photograph of the wound on a grid is also an effective method of documenting the wound. Chapter 14, Vascular, Lymphatic, and Integumentary Disorders, provides more detailed information on wound examination.

Passive Range of Motion

Goniometry can be used to assess joint ROM. Shoulder ROM is particularly important for patients with tetraplegia. Depending on the motor level of injury, people with tetraplegia may require more than normal ROM to perform certain mobility skills,[113] and decreased shoulder ROM is associated with shoulder pain.[123] Hamstring length, hip extension, and ankle dorsiflexion are important to measure as well, due to the potential for contractures in these joints.

Early Mobility Skills

During this early phase of recovery, patients may have restrictions on certain motions and positions, as well as limited ability to tolerate an upright posture for extended periods of time (sitting or standing). A detailed, accurate, and specific determination of functional skills is usually delayed until the active rehabilitation stage when the patient is medically stable and cleared for activity. An initial screening of functional ability may be done during the early acute stage, but the therapist must be aware of any contraindications or precautions to movement necessitated by healing and potentially unstable fracture sites. Basic mobility skills that should be examined when appropriate are rolling in bed, transitioning supine to and from sitting, management of LEs, long and short sitting balance, and transfers. The section on active rehabilitation below has specific outcome measures that may be used to assess these and other mobility skills.

Physical Therapy Interventions

The extent to which the following interventions are implemented is dependent on the medical stability of the patient, stability of healing fracture and surgical sites, and status of other injuries that may have occurred during the initial event that caused the SCI. Full activity should be restricted until the fracture sites are stable and the patient receives clearance from the surgeon. The physician should be consulted regarding any rehabilitation activities that may place stress on the spine while the spine is still unstable. Although the interventions described below are usually initiated in the early stages of recovery, they should be continued throughout the rehabilitation process and be incorporated into the patient's lifestyle to manage the long-term consequences of the SCI.

Respiratory Management

Respiratory care will vary according to the level of injury and individual respiratory status. Primary goals of management include improved ventilation, increased effectiveness of cough, and prevention of chest tightness and ineffective substitute breathing patterns.[49]

Individuals with cervical injuries at and above C5 often require ventilatory support using an intermittent positive pressure ventilator (IPPV). Approximately 40% of patients with cervical injuries require mechanical ventilation, with most of these occurring in the first 3 days after injury.[43] Invasive mechanical ventilation is often done through a tracheostomy and can be provided through a stationary or portable ventilator. Noninvasive positive pressure ventilation provides an alternative to invasive mechanical ventilation.[48,124] Intubation may impair the function of the airway cilia, leading to chronic bacterial colonization and chronic inflammatory changes of the airway. Patients may also prefer noninvasive ventilation.

Deep-Breathing Exercises

Diaphragmatic breathing should be encouraged. To facilitate diaphragmatic movement and increase VC, the therapist can apply light pressure during both inspiration and expiration. Manual contacts can be made just below the sternum. This will assist the patient to concentrate on deep-breathing patterns even in the absence of thoracic and abdominal sensation. To facilitate expiration, manual contacts are made over the thorax with the hands spread wide. This creates a compressive force on the thorax, resulting in a more forceful expiration followed by a more efficient inspiration. Patients immobilized in traction devices or limited to recumbent positions may benefit from use of a mirror to provide visual feedback during these activities.

Glossopharyngeal Breathing

Glossopharyngeal breathing may be appropriate for patients with high-level cervical lesions who are dependent on a mechanical ventilator for ventilation, as well as for patients with mid to high cervical level injuries who are not dependent on mechanical ventilation.[125] Glossopharyngeal breathing utilizes the lips, pharyngeal muscles, and the tongue to inhale air.[125,126] The patient is instructed to take in small amounts of air, using a "gulping" pattern, thus utilizing available facial and pharyngeal muscles.[125] The patient repeats this 6 to 10 times. By using this technique, enough air is gradually inspired. Exhalation occurs due to the elastic recoil of the lungs. Glossopharyngeal breathing provides a method for individuals with high cervical lesions who are dependent on mechanical ventilation to breathe independently for a period of time in

emergency situations[125] and as a way to increase vital capacity in people with cervical lesions who are not dependent on a mechanical ventilator.[127] Teaching a patient to perform glossopharyngeal breathing requires specialized skills and experience.[113]

Air Shift Maneuver

This technique provides the patient with an independent method of chest expansion. It involves closing the glottis after a maximum inhalation, relaxing the diaphragm, and allowing air to shift from the lower to upper thorax.[128] Air shifts can maintain and increase chest wall expansion. This technique may cause the patient to hyperventilate. The physical therapist should monitor the patient for dizziness and other signs of hyperventilation and allow for periods of rest as needed.[128]

Respiratory Muscle Strengthening

Similar to other muscles, strength training can improve respiratory muscle strength and endurance. Inspiratory muscles can be trained using relatively inexpensive handheld devices, which increase the resistive or threshold inspiratory load on muscles of inspiration (Fig. 20.9). There are generally two types of handheld inspiratory muscle training devices: resistive or threshold trainers. Breathing through these devices increases the resistive or threshold inspiratory load on the muscles. The load can be progressively increased as the patient progresses. Inspiratory muscle training can improve pulmonary function, reduce dyspnea, and improve cough function.[129-131]

Figure 20.9 Inspiratory muscle trainers. *(Courtesy of Respironics, Inc., Murrysville, PA 15668-8525.)*

Coughing

Patients who are not able to produce a functional cough should be taught to perform a self-assisted cough. Those who cannot perform a self-assisted cough may benefit from a manually assisted cough to help remove secretions (Fig. 20.10).[132] To assist with coughing and movement of secretions, manual contacts are placed over the epigastric area. The therapist pushes quickly in an inward and upward direction as the patient attempts to cough.

Abdominal Binder

An abdominal binder may improve respiratory function[40,133,134] and cough ability[135] in patients with high thoracic and cervical lesions. An abdominal binder may improve respiratory mechanics by compensating for nonfunctioning abdominal muscles. The binder compresses abdominal contents to increase intra-abdominal pressure, and elevate the diaphragm into a more optimal position for breathing. In addition, abdominal binders may provide the secondary benefits of maintaining intrathoracic pressure and decreasing postural hypotension.

Manual Stretching

Mobility and compliance of the thoracic wall can be facilitated by manual stretching chest wall muscles in supine.[49,128] This is done by placing one hand around the side of the chest wall with the fingertips on the transverse processes and the other hand on top of the chest with the heel on the edge of the sternum. The hands are moved in a wringing motion. Pressure should be distributed across the surface of the hands.[128]

Wetzel[126] and Tecklin[128] provide an in-depth discussion of interventions to enhance respiratory function.

Figure 20.10 Assisted cough using abdominal thrust maneuver to clear secretions.

Skin Care

Prevention is the most effective intervention for skin care; this entails positioning, consistent and effective pressure relief, skin inspection, and education. Areas that are susceptible to skin breakdown (see Table 20.4) should be adequately protected when the patient is in bed by using pillows, foam, and positioning devices (Fig. 20.11). Positioning should also be used to prevent development of joint contractures and secondary pulmonary complications. Specific positioning of the UEs and LEs to prevent contractures will depend on the level of the SCI. Certain joints may be more prone to contracture depending on which muscles surrounding the joint are innervated. For example, a patient with a C5-level injury may tend to position the shoulder in adduction and the elbow in flexion. When positioning this patient the shoulders should be abducted and elbows extended when possible.

When in bed, patients should be repositioned at least every 2 hours.[136] Increased and consistent pressure over bony prominences, shear forces, heat, and moisture should be minimized. A variety of special beds, mattresses, and overlays can assist in the prevention of skin breakdown and aid with healing: foam, air, low air loss, air fluidized, and rotating (Fig. 20.12).

The wheelchair and seating system should also assist in promoting optimal positioning for reducing pressure and shear forces on susceptible areas. The pelvis should be positioned in a neutral position or slightly tilted anteriorly and be symmetrical (i.e., left anterior-superior iliac spine [ASIS] even with the right ASIS). A variety of wheelchair cushion types are designed to assist with positioning and redistribution of pressure. The main types of cushions are foam, gel, air, and flexible matrix. Cushions are often contoured to further assist in the redistribution of pressure and to reduce shear. No one type of cushion is the most effective. The exact type of cushion selected should be based on the individual patient. Chapter 32, The Prescriptive Wheelchair, provides more detail about different types of cushions, as well as their advantages and indications for use.

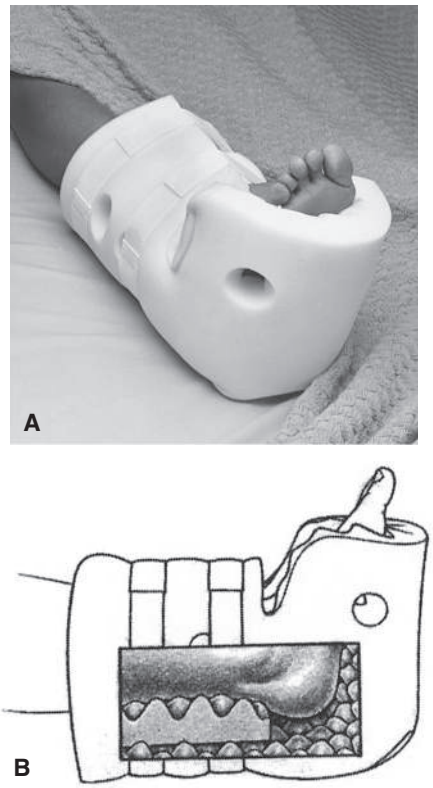

Figure 20.11 Ankle/foot positioning to prevent skin breakdown and contracture. *(Courtesy of DM Systems, Inc., Evanston, IL 60201.)*

Figure 20.12 Air fluidized bed. *(Courtesy of Hill-Rom, Inc., Batesville, IN 47006.)*

Patients should perform a pressure relief maneuver every 15 minutes when in the wheelchair, either with assistance or independently.[137] From the seated position, this can be done by using a push-up maneuver (Fig. 20.13), leaning to the side, or leaning forward (Fig. 20.14). If using a forward lean, the lean should be greater than 45 degrees.[138] Patients who are not able to perform these maneuvers initially can be assisted or their wheelchair can be tilted back. If tilting the entire wheelchair back, it should be tilted to at least 65 degrees.[138] All pressure relief maneuvers should be maintained for at least 2 minutes to be effective.[139] A tilt-in-space or reclining wheelchair can also be used to redistribute pressure.

The patient's skin should be routinely inspected to ensure there is no developing skin breakdown. Enhanced education on the prevention and management of pressure sores with consistent follow-up can reduce the development of skin breakdown and reduce the incidence recurrence.[140] As the rehabilitation program progresses,

Figure 20.13 Push-up in wheelchair for pressure relief.

Figure 20.14 Lateral lean in wheelchair for pressure relief.

the patient gradually assumes responsibility for skin care. Preparation for assumption of this responsibility will include patient education about the potential risks of pressure sores, the importance of hygiene, instruction in skin inspection techniques (Fig. 20.15), the use of pressure relief equipment and procedures, and what to do if a pressure ulcer develops.

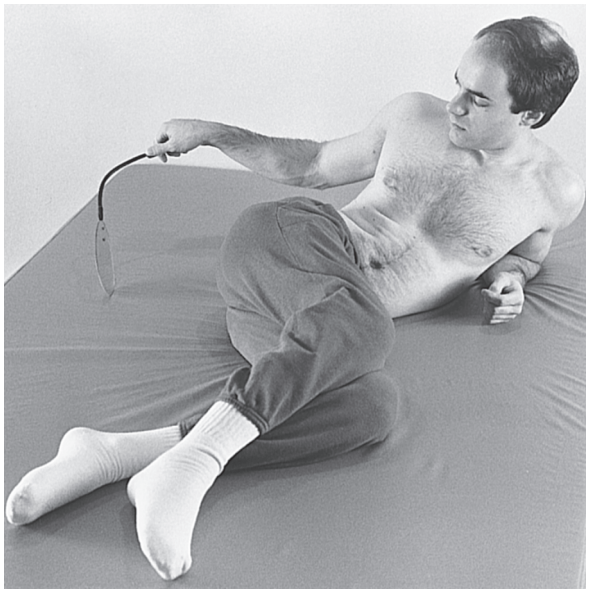

Figure 20.15 Skin inspection using a long-handled mirror.

If the patient develops a skin ulcer, the preventive measures described above should continue to be employed. Various therapies directed at wound healing should be initiated. Electrical stimulation,[141,142] hydrocolloid dressings,[143] and occlusive hydrogel dressings[144] can be used to facilitate the healing process. Chapter 14, Vascular, Lymphatic, and Integumentary Disorders, provides a comprehensive perspective on these and other specific wound healing interventions. The work of Sussman and Bates-Jensen[145] is also recommended for further information on wound care principles and management.

Early Strengthening and Range of Motion

Range of motion exercises should be completed daily except in those areas that are contraindicated or require selective stretching. In this early stage of recovery, ROM or strengthening exercises that are too intense may place increased pressure and stress on vertebral sites that may be unstable and are still healing. Motion of the trunk and some motions of the hip may be contraindicated depending on the location of the SCI. The pelvis should remain in a neutral position when ROM is performed on the LEs. When the injury is in the lumbar spine, straight leg raises more than approximately 60 degrees and hip flexion beyond 90 degrees (during combined hip and knee flexion) should be avoided. With tetraplegia, motion of the head and neck is contraindicated pending orthopedic clearance. Extreme caution should be used when stretching the shoulders. Generally, shoulder flexion and abduction beyond 90 degrees is contraindicated until orthopedic clearance is received indicating the spine is fully healed and stable.

Patients with SCIs do not require full ROM in all joints. Some joints benefit from allowing tightness to develop in certain muscles to enhance function.

For example, with tetraplegia, tightness of the lower trunk musculature may improve sitting posture by increasing trunk stability; tightness in the long finger flexors will provide an improved tenodesis grasp. Conversely, some muscles require a fully lengthened range. After the acute phase, the hamstrings will require stretching to achieve a straight leg raise of approximately 100 degrees. This ROM is required for many functional activities such as long sitting and LE dressing. Care should be taken not to overstretch the hamstring muscles because some tightness in this muscle group provides passive pelvic stabilization in sitting. This process of under-stretching some muscles and full stretching of others to improve function is referred to as *selective stretching*.

Positioning of the wrist, hands, and fingers is an important early consideration. Alignment of the fingers, thumb, and wrist must be maintained for functional activities or possible future splinting. Individuals with functional, active wrist extension can learn to use a tenodesis grasp to use the hand and fingers to perform ADL, manipulate objects, and hold objects without active finger control. The tenodesis grasp occurs through the biomechanics of the wrist and finger joints. When the wrist is actively extended, the tendons of the fingers are shortened causing the fingers to passively flex and grasp. When the wrist is flexed, the tension on the tendons is released and the hand opens providing release (Fig. 20.16) An *intrinsic-plus splint* can be used to position the wrist (20 degrees of extension), metacarpal phalangeal joints (80 to 90 degrees of flexion), interphalangeal joints (full extension or slight flexion), and the thumb (natural opposition) to maintain the joints in optimal intrinsic-plus position[146] (Fig. 20.17). This position helps reduce edema, preserve tenodesis function, and prevent contractures. As with any splint, the user's skin should be inspected for redness, irritation, or open areas and a progressive schedule should be used to slowly build up the wearing time to prevent skin irritation.

Figure 20.16 Patient extends the wrist, which causes the shortened long finger flexors to passively flex allowing a grasp.

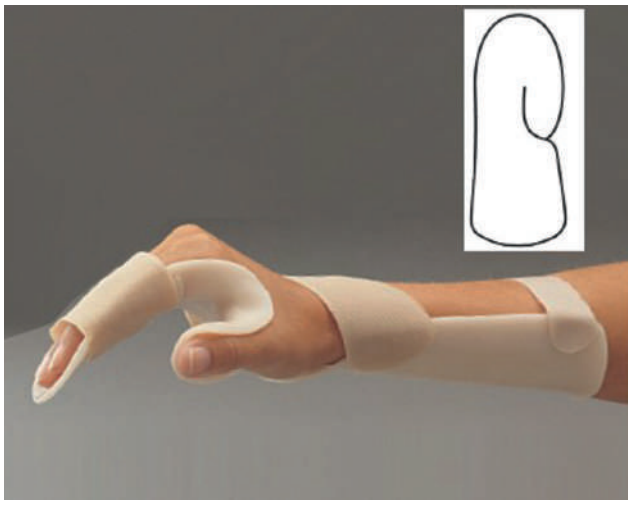

Figure 20.17 Intrinsic-plus splint. *(Courtesy 3Tailer, Charlotte, NC.)*

During the course of rehabilitation, all innervated musculature is strengthened maximally. However, during the acute phase certain muscles must be strengthened very cautiously to avoid stress at the fracture site. During the first few weeks following injury, application of resistance may be contraindicated to (1) musculature of the scapula and shoulders in people with tetraplegia and (2) musculature of the pelvis and trunk in those with paraplegia. Key muscles and strengthening techniques are discussed below.

Early Mobility Interventions

Once radiographic findings have established stability of the fracture site, or early fracture stabilization methods are complete, the patient is cleared for upright, functional activities. The patient typically will experience symptoms of postural hypotension (dizziness, nausea, ringing in ears, loss of vision, or loss of consciousness) when initially assuming sitting and standing (if able). A gradual acclimation to upright postures is necessary. The use of an abdominal binder and elastic stockings may reduce venous pooling and prevent orthostatic hypotension. During early upright positioning, elastic wraps may also be used in combination with (placed over) the elastic stockings.

Initially, upright activities can be initiated by slowly elevating the head of the bed and progressing to a reclining or tilt-in-space wheelchair with elevating leg rests. Use of the tilt-table provides another option for orienting the patient to a vertical position. Vital signs should be monitored carefully and documented during this acclimation period. If a patient experiences any of the signs or symptoms of orthostatic hypotension during sitting activities, the patient's legs can be elevated and the trunk reclined.

When the patient is cleared to participate more actively in therapy and is more acclimated to upright postures, specific training can begin on basic mobility

skills. Interventions designed to teach bed mobility skills such as rolling and transitioning supine to/from long and short sitting and transfer skills can be initiated. These and other functional mobility skills become the focus of rehabilitation once the patient is stable. Specific intervention techniques on these and other functional mobility skills are discussed below.

Education

Living with a SCI requires significant adaptations and changes on the part of the patient and his or her family. In order to meet the challenges presented by a SCI, patients must fully understand all the consequences of the injury. Patient and family/caregiver education should begin early after injury about the impact of SCI on the different body systems, secondary complications, and prognosis. Later in the recovery process it may be particularly helpful to have the patient meet individuals with long-standing SCI who have completed rehabilitation and are functioning in the community to gain an appreciation of the impact of the injury on day-to-day life.

ACTIVE REHABILITATION

The overarching goal of physical rehabilitation is for the patient to become as independent as possible and to achieve the functional mobility necessary for everyday living, work, and recreation. Independent mobility can be achieved in a way that (1) either uses new movement strategies to compensate for neuromuscular impairments; or (2) uses the neuromuscular system to accomplish the task with a movement pattern similar to that before the injury.[147,148] **Compensation** refers to use of an alternative or new movement strategy, or technology to compensate for neuromuscular deficits to accomplish a daily task.[149,150] **Recovery of function** refers to the restoration of the neuromuscular system so that the motor task is performed in the same manner as it was before the SCI.[147,149,150]

For instance, if a patient cannot actively flex the fingers to grasp a bottle due to weakness or paralysis of finger flexor muscles, use of wrist "tenodesis" is often taught as a compensatory strategy (Fig. 20.16). Active wrist extension simultaneously produces passive finger flexion and can be used to achieve a functional grasp. Knee-ankle-foot orthoses (KAFOs) may help a patient achieve the goal of standing, but do not have a therapeutic effect on retraining the neuromuscular system in the once familiar task of standing. Once the KAFOs are removed, the LEs cannot perform the task of standing. The braces compensate for the inability to activate antigravity LE muscles due to weakness or paralysis. The task of moving from sitting to standing with KAFOs entails the use of assistive devices and weight-bearing through the arms, further altering the preinjury movement pattern to accomplish the task. Transfers from a wheelchair to a bed that also incorporate weight-bearing through the arms and a *head-hips* movement strategy (the head moves in one direction to move the hips in the opposite direction; see below) is another example of a compensatory behavior using a biomechanical advantage to achieve a functional goal in a new way. Focusing on recovery of the once familiar task of sit-to-stand would require a movement pattern including weight shift from the buttocks forward over the feet, a powerful activation of antigravity muscles to lift the body off of the chair, the head moving up and forward, and then full extension of the limbs and trunk to achieve standing without the arms weight-bearing.

How a goal is achieved (or expected to be achieved) is thus important in treatment planning and goal-setting. Historically, rehabilitation for persons after SCI has employed compensation strategies using muscles spared above the level of the lesion, substitution, novel movement patterns, and assistive devices/braces as the primary means for achieving independent functional mobility skills. Recent advances in our understanding of the neurobiological control of walking and in activity-dependent plasticity have provided the basis for new, alternative therapies that generate activity below the level of the lesion with the goal of recovery.[147] Our assumption that the spinal cord was simply a conduit for neural signals from the brain was incorrect. In fact, the spinal cord is quite responsive to the ensemble of sensorimotor information provided during task execution to generate a motor output. Activity elicited through such therapies (e.g., locomotor training, task-specific practice) is used to retrain the neuromuscular control required for function, then used in everyday activities, and finally integrated into daily use.[151-153]

Although both compensation and recovery-based approaches (activity-based therapies) are used in rehabilitation for SCI, compensation dominates current clinical practice. However, a large and expanding body of literature is providing new insights about integration of activity-based therapies into the clinic,[154-156] the potential for improving outcomes with combinatorial approaches,[154,157,158] and the impact on functional outcomes advancing recovery and quality of life.

If independence cannot be achieved, whether using compensation or recovery-based strategies, then the patient may be interdependent on others for assistance in accomplishing certain tasks of daily life (e.g., the patient with a complete high cervical lesion). The patient, family, friends, and caregivers receive thorough instructions and training in the knowledge and skills required for care of the individual's daily needs.

Physical Therapy Examination

All the examination procedures completed during the acute phase are continued during the active rehabilitation phase. Inasmuch as greater patient mobility is now allowed, more complete testing of muscle strength, ROM, and functional skills can be performed. However, the physical therapist should confirm that the patient is no longer on any movement restrictions

(if so, the same precautions described earlier should be observed). A variety of standardized outcome measures and tests and measures are available to the physical therapist (Box 20.2). Some of the more frequently used tests and measures are discussed here.

Box 20.2 Commonly Used Outcome Measures and Tests and Measures Categories

Aerobic Capacity/Endurance
- A 6-minute arm test

Arousal, Attention, Cognition
- Mini Mental State Exam and the Montreal Cognitive Assessment

Environmental or Work Barriers

Gait, Locomotion, and Balance
- Wheelchair Skills Test, Wheelchair Circuit, Modified Functional Reach Test, Berg Balance Scale, Walking Index for Spinal Cord Injury, Spinal Cord Injury Functional Ambulation Inventory, 10-Meter Walk Test, 6-Minute Walk Test, Neuromuscular Recovery Scale

Integument
- Braden Scale
- Spinal Cord Injury Pressure Ulcer Scale
- Spinal Cord Injury Pressure Ulcer Scale–Acute

Motor Function
- Modified Ashworth Scale, Spinal Cord Injury Spasticity Evaluation Tool

Muscle Performance
- ASIA ISNCSCI, manual muscle test, handheld dynamometer

Pain
- Visual analog scale, International Spinal Cord Injury Basic Pain Data Set, Wheelchair User's Shoulder Pain Index

Range of Motion
- Goniometer

Self-Care and Home Management
- Functional Independence Measure, Spinal Cord Injury Independence Measure, Quadriplegia Index of Function, Capabilities of Upper Extremity Instrument

Ventilation
- Chest circumference with measuring tape
- Vital capacity with handheld dynamometer
- Respiratory rate

Work, Community, and Leisure Integration or Reintegration
- Craig Handicap Assessment and Reporting Technique, Assessment of Life Habits, and Reintegration to Normal Living Index

Aerobic Capacity/Endurance

A *6-minute arm test (6MAT)* can be used to assess aerobic capacity and cardiovascular endurance.[159] The 6MAT requires the patient to perform 6 minutes of submaximal cycling on an arm ergometer at a single, steady-state power output. It is a valid and reliable measure for people with either tetraplegia or paraplegia. Steady-state power output for clients with tetraplegia should be set between 10 and 30 watts depending on use of manual versus power wheelchair and activity level. For clients with paraplegia the power output should be set between 30 and 60 watts depending on gender and activity level.[159]

Arousal, Attention, Cognition

It is particularly important to screen patients for cognitive impairment because up to 60% of people who experience a traumatic SCI may also have a concomitant traumatic brain injury (TBI).[160] Although they have not been validated in people with SCI, the *Mini Mental State Exam* and the *Montreal Cognitive Assessment* are tools that could be used to screen for cognitive impairment.[161,162] If the physical therapist suspects that the patient has a TBI, the patient should be referred to a neuropsychologist or psychiatrist.

Environmental or Work Barriers

Because many people who experience a SCI will use a wheelchair as their primary means of mobility, it is essential that the physical therapist examine the patient's home and work environments to determine accessibility. Because structural modifications and/or additions to the home may be required to ensure patient safety and access, the rehabilitation team should perform a home evaluation early in the rehabilitation process (see Chapter 9, Examination of the Environment). Some general guidelines to allow wheelchair access are presented in Box 20.3.[113,163,164]

Gait, Locomotion, and Balance

Most individuals with SCI will rely on a wheelchair as their primary means of locomotion in the home and community. As such, it is important to examine the patient's ability to perform wheelchair skills. This includes setting and releasing the wheel locks, removing footrests and armrests, propelling the wheelchair on level surfaces, performing wheelies, ascending and descending curbs, and various other wheelchair skills necessary for independent mobility in the community. The *Wheelchair Skills Test* (Fig. 20.18) examines a wheelchair user's skills in performing 32 representative wheelchair skills.[165-167] The skills are categorized according to three levels that reflect difficulty and setting in which they will be performed: indoor, community, and advanced. The Wheelchair Skills Test can be used as a diagnostic measure to determine which wheelchair skills need to be addressed in therapy and to document improvement

Box 20.3 General Guidelines for Wheelchair Accessibility in the Home

- Ramp slope: 12:1 (12 ft [3.7 m] of horizontal distance for every 1 ft [0.31 m] of rise)
- Ramp width: 36 in (0.91 m)
- Ramp landings every 30 ft (9.1 m)
- No thresholds through doorways
- Lever-type door handles
- Door width at least 32 in (0.81 m)
- Open floor plan
- Tile or hardwood floors
- Wheelchair access to bathroom
- Toilet seat height same as wheelchair seat height
- Adequate clearance under sinks
- Insulated pipes
- Roll-in shower

during rehabilitation. The *Wheelchair Circuit* is another outcome measure that is designed to assess three aspects of manual wheelchair mobility: tempo, technical skill, and physical capacity.[168,169]

Sitting balance can be examined using the *Modified Functional Reach Test*.[170] For patients with iSCI who have some capability to stand and walk, balance can be assessed using the *Berg Balance Scale (BBS)*. See Chapter 6, Examination of Coordination and Balance, for a complete description of this instrument. Although originally developed for patients with acute stroke, it has been used extensively with older adults,[171] and the BBS has been validated in people with iSCI.[172,173]

Gait and walking ability should also be examined in patients with iSCI who maintain some ability to stand and walk. An observational gait analysis tool such as the *Rancho Los Amigos Observational Gait Analysis*[174] form can be used to identify gait deviations. See Chapter 7, Examination of Gait, for a complete description of this instrument. Identifying abnormal gait patterns will inform selection of additional tests and measures needed to determine the underlying impairments that may be causing the abnormal movements. This will also guide development of the POC.

The *Walking Index for Spinal Cord Injury (WISCI)* examines level of physical assistance, type of assistive device, and amount of bracing required to ambulate 10 meters.[175-178] Scores range from 0 (unable to stand or walk with assistance) to 20 (ambulates with no assistance, no braces, and no assistive device). The *Spinal Cord Injury Functional Ambulation Inventory (SCI-FAI)* (Fig. 20.19) is another outcome measure used to assess walking ability in people with iSCI.[179] It involves a 2-minute observational gait analysis performed using the patient's usual assistive device. Documentation includes the frequency and distances the patient typically walks in the home and community.

The *10-Meter Walk Test*[177,178,180] and *6-Minute Walk Test*[177,178,180] are reliable, valid, and responsive to change in people with iSCI. A change of 0.13 m/sec in gait speed is an indication that real change in walking speed has occurred. Gait speed is also able to distinguish between (predict) level of functional walking ability. People with iSCI who walk at 0.09 m/sec are likely to be supervised ambulators. Walking speed of 0.15 m/sec is an indication that the person can likely walk indoor but use a wheelchair outside the home. Walking speed of 0.44 m/sec is an indication that the person will likely use an assistive device or orthotic to walk in and outside the home. Finally, a walking speed of 0.70 m/sec indicates the person can walk in and outside the home without an assistive device or orthotic.[181] The minimal detectable change of the 6-Minute Walk Test is 46 meters.[180]

Motor Function

As described earlier, the ASIA ISNCSCI standards should be used to determine the level of lesion and intact motor function. The presence of spastic hypertonia should be assessed as part of the motor function examination. The *modified Ashworth Scale (MAS)* is commonly used to assess tone. The MAS is a 6-point ordinal scale that rates the amount of resistance to passive movement of the joint.[182] (See Chapter 5, Examination of Motor Function: Motor Control and Motor Learning, for a complete description of the MAS.) The *Spinal Cord Injury Spasticity Evaluation Tool (SCI-SET)* is a self-report measure of the impact of spasticity on everyday life activities. The individual rates how spasticity has affected 35 different areas on a 7-point ordinal scale that ranges from (3 (extremely problematic) to +3 (extremely helpful). Items include eating, sleeping, dressing, transferring, wheelchair use, social impact, ability to concentrate, and falls.[183]

Muscle Performance

Further MMT should be performed for all muscle groups that are innervated based on findings from the ASIA ISNCSCI. For example, if the biceps muscle is intact, then other muscles that are innervated by C5 such as the deltoids and rotator cuff muscles should be tested. Handheld dynamometry could also be used to examine muscle strength, including trunk strength.[184,185] There are several unique considerations when performing MMT for people with SCI. Patients often learn to functionally move joints by substituting intact muscle contraction for weak or paralyzed muscles. For example, supination of the forearm allows gravity to extend the wrist and lower abdominal muscles can substitute for hip flexion by causing the pelvis to tilt posteriorly. The physical therapist should carefully stabilize the proximal area to reduce substitution and palpate to ensure that the test muscle is contracting. Abnormal muscle tone

Wheelchair Skills Test 4.1
Manual Wheelchair - Wheelchair User

Name: _____

Date: _____ Tester: _____

Time start: _____ Time finish: _____

Scoring Guide (see over for details)
✓ = pass, safe
✖ = fail, unsafe
NP = no part (only for indicated skills)
TE = testing error

Type of Test
❑ Objective - Capacity
❑ Questionnaire - Capacity
❑ Questionnaire - Performance

	Individual Skills	Capacity/ Performance	Safety	Comments
1.	Rolls forward 10m			
2.	Rolls forward 10m in 30s			
3.	Rolls backward 5m			
4.	Turns 90° while moving forward L&R			
5.	Turns 90° while moving backward L&R			
6.	Turns 180°in place L&R			
7.	Maneuvers sideways L&R			
8.	Gets through hinged door in both directions			
9.	Reaches 1.5m high object			
10.	Picks object from floor			
11.	Relieves weight from buttocks			
12.	Transfers from WC to bench and back			
13.	Folds and unfolds wheelchair			
14.	Rolls 100m			
15.	Avoids moving obstacles L&R			
16.	Ascends 5° incline			
17.	Descends 5° incline			
18.	Ascends 10° incline			
19.	Descends 10° incline			
20.	Rolls 2m across 5° side-slope L&R			
21.	Rolls 2m on soft surface			
22.	Gets over 15cm pot-hole			
23.	Gets over 2cm threshold			
24.	Ascends 5cm level change			
25.	Descends 5cm level change			
26.	Ascends 15cm curb			
27.	Descends 15cm curb			
28.	Performs 30s stationary wheelie			
29.	Turns 180° in place in wheelie position L&R			
30.	Gets from ground into wheelchair			
31.	Ascends stairs			
32.	Descends stairs			
	Total Percentage Scores

SCI Functional Ambulation Inventory (SCI-FAI)

Name: Session: Date:

PARAMETER	CRITERION	L	R
A. Weight shift	Shifts weight to stance limb.	1	1
	Weight shift absent or only onto assistive device.	0	0
B. Step width	Swing foot clears stance foot on limb advancement.	1	1
	Stance foot obstructs swing foot on limb advancement.	0	0
	Final foot placement does not obstruct swing limb.	1	1
	Final foot placement obstructs swing limb.	0	0
C. Step rhythm (relative time needed to advance swing limb)	At heel strike of stance limb, the swing limb:		
	begins to advance in <1 second *or*	2	2
	requires 1–3 seconds to begin advancing *or*	1	1
	requires >3 seconds to begin advancing	0	0
D. Step height	Toe clears floor throughout swing phase *or*	2	2
	Toe drags at initiation of swing phase only *or*	1	1
	Toe drags throughout swing phase	0	0
E. Foot contact	Heel contacts floor before forefoot *or*	1	1
	Forefoot or foot flat first contact with floor.	0	0
F. Step length	Swing heel placed forward of stance toe *or*	2	2
	Swing toe placed forward of stance toe *or*	1	1
	Swing toe placed rearward of stance toe.	0	0
	Parameter total		Sum /20

ASSISTIVE DEVICES		L	R
Upper extremity balance/weightbearing devices	None	4	4
	Cane(s)	3	3
	Quad cane(s), Crutch(es) (forearm/axillary)	2	2
	Walker	2	
	Parallel bars	0	
Lower extremity assistive devices	None	3	3
	AFO	2	2
	KAFO	1	1
	RGO	0	0
	Assistive device total		Sum /14

TEMPORAL/DISTANCE MEASURES			
Walking mobility (typical walking practice as opposed to W/C use)	Walks…
