As new scientific information becomes available through basic and clinical research, recommended treatments and drug therapies undergo changes. The author(s) and publisher have done everything possible to make this book accurate, up to date, and in accord with accepted standards at the time of publication. The author(s), editors, and publisher are not responsible for errors or omissions or for consequences from application of the book, and make no warranty, expressed or implied, in regard to the contents of the book. Any practice described in this book should be applied by the reader in accordance with professional standards of care used in regard to the unique circumstances that may apply in each situation. The reader is advised always to check product information (package inserts) for changes and new information regarding dose and contraindications before administering any drug. Caution is especially urged when using new or infrequently ordered drugs.

PREFACE

With the sixth edition of *Physical Rehabilitation*, we continue a tradition of striving for excellence that began more than 25 years ago. We are gratified by the continuing wide acceptance of *Physical Rehabilitation* by both faculty and students.

The text is designed to provide a comprehensive approach to the rehabilitation management of adult patients. As such, it is intended to serve as a primary textbook for professional-level physical therapy students, and as an important resource for practicing therapists as well as for other rehabilitation professionals. The sixth edition recognizes the continuing growth of the profession and integrates basic and applied clinical research to guide and inform evidence-based clinical practice. It also integrates terminology, practice patterns, specific tests and measures, and interventions presented in the American Physical Therapy Association's *Guide to Physical Therapist Practice* and the World Health Organization's *International Classification of Functioning, Disability, and Health* (ICF).

Physical Rehabilitation is organized into three sections. Section One (Chapters 1–9) includes chapters on clinical decision making and examination of basic systems, as well as examination of functional status and the environment. Section Two (Chapters 10–29) addresses many of the diseases, disorders, and conditions commonly seen in the rehabilitation setting. Appropriate examination and intervention strategies are discussed for related body structure/function impairments, activity limitations, and restrictions in social participation. Health promotion and wellness strategies are also considered. Emphasis is placed on parameters of learning critical to ensuring the patient/client can achieve anticipated goals and expected outcomes. The final section, Section Three (Chapters 30–32), includes orthotics, prosthetics, and the prescriptive wheelchair.

A central element of the text is a strong pedagogical format designed to facilitate and reinforce the learning of key concepts. Each chapter of *Physical Rehabilitation* includes an initial content outline, learning objectives, an introduction and summary, review questions for self-assessment, and extensive references. Additional supplemental readings and recommended resources are also provided. Key terms are bolded throughout each chapter indicating their inclusion in a master glossary toward the end of the text. Application of important concepts is promoted through end-of-chapter case study examples and guiding questions designed to enhance clinical decision making skills. Disability-focused chapters contain *Evidence Summary Boxes* that summarize and critically appraise research focused on a particular topic or intervention relevant to the chapter content. Our hope is that the boxes may provide a model for readers to continue to critically examine clinical practice using validated clinical methodologies. We also hope it will inspire enthusiasm about the importance of continuous, lifelong, self-directed learning.

The visuals have been substantially enhanced with the addition of many new illustrations and photographs. Changes in design and the introduction of a full-color format provide a reader-friendly environment, as well as augment understanding of content. New to the sixth edition are 13 online case studies with accompanying video segments illustrating aspects of the initial examination, interventions, and outcomes for patients undergoing active rehabilitation. The cases were authored by practicing therapists from various parts of the country who were directly involved in the care of the case study patient participant. The case studies include patients with chronic obstructive pulmonary disease and respiratory distress syndrome, burns, amputation, spinal cord injury, Parkinson's disease, traumatic brain injury, stroke, and vestibular dysfunction. Questions are posed that address key elements in developing the plan of care for each patient. All case study materials (patient history, examination data, video segments, answers to guiding questions for student feedback) are available online at Davis*Plus*.

Also new to this edition are sample examination questions consistent with the format of the National Physical Therapy Examination. In separate files, answers to the questions are provided for student feedback that are also available at Davis*Plus*.

As we have noted in previous editions, our greatest asset and inspiration in preparing the sixth edition of *Physical Rehabilitation* has been an outstanding group of contributing authors. We are most fortunate to have this group of talented individuals whose breadth and scope of professional knowledge and experience seems unparalleled. These individuals are recognized experts from a variety of specialty areas who have graciously shared their knowledge and clinical practice expertise by providing relevant, up-to-date, and practical information within their respective content areas. To our group of contributors, we enthusiastically welcome the many talented, dedicated clinicians whose knowledge and clinical skills are well represented in the online case study materials that accompany the text. To the sixth edition, a welcome is also extended to George D. Fulk as a new contributing editor.

The sixth edition has also benefited from the input of numerous individuals engaged in both academic and clinical practice settings who have used and reviewed the content. We are grateful for their constructive feedback and have instituted many of their suggestions and

changes. As always, we welcome suggestions for improvements from our colleagues and students.

As physical therapists continue to take on more and greater professional responsibilities and challenges, the very nature of this text makes it a perpetual "work in progress." We are grateful for the opportunity to contribute to the academic literature in physical therapy, as well as to the professional development of those preparing to enter a career devoted to improving the quality of life of those we serve.

We acknowledge the very important contributions that physical therapists make in the lives of their patients. This book is dedicated to those therapists—past, present, and future—who guide and challenge their patients to lead a successful and independent life.

ACKNOWLEDGMENTS

The ongoing development of *Physical Rehabilitation* has been in all aspects a collaborative venture. Its fruition has been made possible only through the expertise and gracious contributions of many talented individuals. Our appreciation is considerable.

Heartfelt thanks are extended to our contributing authors. Each has brought a unique body of knowledge, as well as distinct clinical practice expertise, to their respective chapters. Their commitment to physical therapist education is collectively displayed in content presentations that carefully reflect the scope of knowledge and skills required of a dynamic, evolving physical therapy practice environment. We are extremely grateful to each of our contributors and heartened by the excellence they bring to the sixth edition.

Heartfelt thanks are also extended to the practicing clinicians who prepared the case studies and video segments. Their contributions expertly move text content to clinical practice and significantly add to the development of clinical reasoning skills of our readers. We would like to thank Edward W. Bezkor, who served tirelessly as Case Study and Multimedia Editor and effectively coordinated case study contributions, as well as many production elements. Thanks also to Yvonne Gillam, Freelance Editor and Media Consultant, and Liz Schaeffer, Developmental Editor/Electronic Products Coordinator, for their work in editing the patient videos.

A note of special thanks is extended to the following individuals for their assistance with filming the online video case studies: Jan BenDor, Producer and Videographer, Christine Flynn, New York College of Osteopathic Medicine of New York Institute of Technology, Don Packard, University of Michigan Hospital, Robert Price, University of Washington Medical Center, and Sarah Zaluski, New York University Langone Medical Center.

Many of the new patient photographs were possible owing to the efforts of Edward W. Bezkor and Robert J. Schreyer, and the photography expertise of Jason Torres, J. Torres Photography. We thank also those individuals and companies who contributed new photographs to the individual chapters and to those patients/clients who allowed their photographs to be used throughout the text.

We would like to thank Evangelos Pappas, Test Bank Editor, for his expertise and efforts in developing guidelines for questions consistent with the National Physical Therapy Examination format and soliciting expert item writers for the test bank of examination questions. Our hope is that the test bank will become a valuable resource for both faculty and students who use our book.

Our appreciation goes to the dedicated professionals at F.A. Davis Company, Philadelphia, PA: Margaret M. Biblis, Editor-in-Chief, Melissa Duffield, Senior Acquisitions Editor, Jennifer A. Pine, Senior Developmental Editor, Liz Schaeffer, Developmental Editor/Electronic Products Coordinator, Sharon Lee, Production Manager, and Paul Marone, Marketing Manager. These individuals are recognized for their continued support, encouragement, and unwavering commitment to excellence. Thanks also are extended to Cassie Carey, Senior Production Editor, and Rose Boul, Senior Art Coordinator, at Graphic World Publishing Services.

We wish to thank the numerous students, faculty, and clinicians who over the years have used *Physical Rehabilitation* and provided us with meaningful and constructive comments that have greatly enhanced this edition. It is our sincere hope that this feedback will continue.

Finally, we are grateful for our continuing strong and productive working relationship that has allowed us to complete a project of this scope through six editions.

—Susan B. O'Sullivan
Thomas J. Schmitz
George D. Fulk

Dr. Susan B. O'Sullivan is Professor Emerita, Department of Physical Therapy, University of Massachusetts Lowell. She holds an EdD in Human Development from the School of Education and Master of Science and Bachelor of Science degrees from Sargent College at Boston University. Dr. O'Sullivan's research, teaching, and clinical experience is in the area of adult neurological rehabilitation. She has also held academic appointments at Boston University. In 2012 the APTA Neurology Section honored Dr. O'Sullivan with the Award for Excellence in Neurologic Education. She is also the recipient of the University of Massachusetts Lowell Award for Teaching Excellence. She is the co-author of *Physical Rehabilitation,* now in its sixth edition, *Improving Functional Outcomes in Physical Rehabilitation,* and Therapy Ed's *National Physical Therapy Examination Review and Study Guide.*

Dr. Thomas J. Schmitz is Professor Emeritus, Department of Physical Therapy, Long Island University. He is coeditor and contributing author of *Physical Rehabilitation* and *Improving Functional Outcomes in Physical Rehabilitation.* He holds a PhD from New York University, a Master of Science degree from Boston University, and a Bachelor of Science degree from SUNY at Buffalo. His primary clinical experience is in the area of adult neurological rehabilitation. Dr. Schmitz is the recipient of Long Island University's David Newton Award for Excellence in Teaching and the Trustees Award for Scholarly Achievement. He has also held academic appointments at Boston University, Sargent College, and Columbia University, College of Physicians and Surgeons.

Dr. George D. Fulk is Associate Professor and Chair, Clarkson University. He received his entry-level physical therapy degree from the University of Massachusetts at Lowell and his PhD from Nova Southeastern University. Dr. Fulk's research, teaching, and clinical expertise are in the areas of enhancing motor recovery and quality of life in people with neurological involvement. He has also held a faculty appointment at Notre Dame College in Manchester, New Hampshire.

Dr. Fulk's research has focused on measuring and improving locomotor capability in people with stroke and he has authored numerous journal articles, conference papers, and textbook chapters in these areas. He is also the Digital Media Editor and an Associate Editor for the *Journal of Neurological Physical Therapy*, is on the Editorial Board for *PTNow*, and serves as a reviewer for many peer-reviewed journals.

Clinical Decision Making and Examination

Clinical Decision Making

Susan B. O'Sullivan, PT, EdD

Chapter 1

LEARNING OBJECTIVES

1. Define *clinical reasoning* and identify factors that affect clinical decision making.
2. Describe the key steps in the patient/client management process.
3. Define the major responsibilities of the physical therapist in planning effective treatments.
4. Identify potential problems that could adversely affect the physical therapist's clinical reasoning.
5. Discuss strategies to ensure patient participation in the plan of care (POC).
6. Identify key elements of physical therapy documentation.
7. Differentiate between the clinical decision making approaches used by the expert versus novice physical therapist.
8. Discuss the importance of evidence-based practice in developing the POC.
9. Analyze and interpret patient/client data, formulate realistic goals and outcomes, and develop a POC when presented with a clinical case study.

SUMMARY *20*

CLINICAL REASONING/ CLINICAL DECISION MAKING

Clinical reasoning is a multidimensional process that involves a wide range of cognitive skills physical therapists use to process information, reach decisions, and determine actions. Reasoning can be viewed as an internal dialogue that therapists continuously employ while meeting the challenges of clinical practice. *Clinical decisions* are the outcomes of the clinical reasoning process and form the basis of patient/client management. A number of factors influence decision making, including the clinician's goals, values and beliefs, psychosocial

skills, knowledge base and expertise, problem-solving strategies, and procedural skills. Many of these factors are the focus of discussion in later chapters in this text. Decision making is also influenced by patient/client characteristics (goals, values and beliefs, and physical, psychosocial, educational, and cultural factors) as well as environmental factors (clinical practice environment, overall resources, time, level of financial support, level of social support).

Decision making frameworks, such as algorithms, have been developed by experienced practitioners to guide clinicians in their reasoning processes. For example, Rothstein and Echternach developed the Hypothesis-Oriented Algorithm for Clinicians II (HOAC).[1] An algorithm is a graphically represented step-by-step guide designed to assist clinicians in problem solving by considering several possible solutions. It is based on specific clinical problems and identifies the decision steps and possible choices for remediation of a problem. A series of questions are posed, typically in yes/no format, addressing whether the measurements met testing criteria, the hypotheses generated were viable, goals were met, strategies were appropriate, and tactics were implemented correctly.

Hypotheses are defined as the underlying reasons for the patient's problems, representing the therapist's conjecture as to the cause. Problems are defined in terms of activity limitations. A "no" response to any of the questions posed in an algorithm is an indication for reevaluation of the viability of the hypotheses generated and reconsideration of the decisions made. In using HOAC II as a model for clinical decision making, the therapist also distinguishes between existing problems and anticipated problems, defined as deficits that are likely to occur if an intervention is not used for prevention. The value of an algorithm is that it guides the therapist's decisions and provides an outline of the decisions made. See Chapter 17, Figures 17.7 and 17.8, for examples of problem-centered algorithms.

Physical therapists today practice in complex environments and are called upon to reach increasingly complex decisions under significant practice constraints. For example, a therapist may be required to determine a POC for the complicated patient with multiple co-morbidities within 72 hours of admission to a rehabilitation facility. Reduced levels of treatment authorization with shorter and shorter stays in rehabilitation also complicate the decision making process. Novice practitioners can easily become overwhelmed. This chapter introduces a framework for clinical decision making and patient/client management that can assist in organizing and prioritizing data and in planning effective treatments compatible with the needs and goals of the patient/client and members of the health care team.

INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH (ICF)

The World Health Organization's (WHO's) *International Classification of Functioning, Disability, and Health (ICF) model* provides an important framework of terminology for understanding and categorizing health conditions and patient problems by clearly defining health condition, impairment, activity limitation, and participation restriction.[2] The American Physical Therapy Association (APTA) has joined the WHO, the World Confederation for Physical Therapy (WCPT), the American Therapeutic Recreation Association (ATRA), and other international professional organizations in endorsing the ICF classification. Figure 1.1 presents the ICF model of disability.

Impairments are the problems an individual may have in body function (physiological functions of body systems) or structure (anatomical parts of the body). The resulting significant deviation or loss is the direct result of the **health condition**, a disease, disorder, injury, or trauma, or other circumstance, such as aging, stress, congenital anomaly, or genetic predisposition. For example, a patient with stroke may present with sensory loss, paresis, dyspraxia, and hemianopsia *(direct impairments)*. Impairments may be mild, moderate, severe, or complete and may be permanent or resolving as recovery progresses. Impairments may also be *indirect* (secondary), the sequelae or complications that

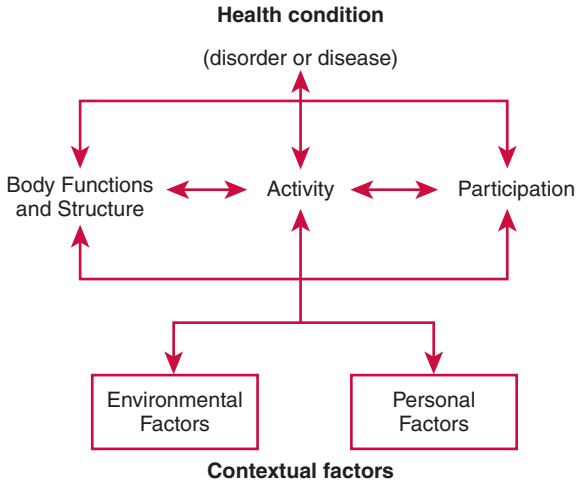

Figure 1.1 ICF Model of Disability. The WHO classification of functioning, disability and health (ICF). World Health Organization. originate from other systems. They can result from preexisting impairments or the expanding multisystem dysfunction that occurs with prolonged bedrest and inactivity, an ineffective POC, or lack of rehabilitation intervention. Examples of indirect impairments include decreased vital capacity and endurance, disuse atrophy and weakness, contractures, decubitus ulcers, deep venous thrombosis, renal calculi, urinary tract infections, pneumonia, and depression. The term *composite impairment* refers to impairments that are the result of multiple underlying origins, the combined effects of both direct and indirect impairments (e.g., balance deficits, gait deficits).

Activity limitations are difficulties an individual may have in executing tasks or actions. Activity limitations can include limitations in the performance of cognitive and learning skills, communication skills, ***functional mobility skills*** (**FMS**) (such as transfers, walking, lifting or carrying objects), and ***activities of daily living*** (**ADL**). ***Basic activities of daily living*** (**BADL**) include self-care activities of toileting, hygiene, bathing, dressing, eating, drinking, and social (interpersonal) interactions. The person with stroke may demonstrate difficulties in all of the above areas and be unable to perform the actions, tasks, and activities that constitute the "usual activities" for this individual.

Participation restrictions are problems an individual may experience in involvement in life situations and societal interactions. Categories of life roles include home management, work (job/school/play), and community/leisure. These include ***instrumental activities of daily living*** (**IADL**) such as housecleaning, preparing meals, shopping, telephoning, and managing finances, as well as work and leisure activities (e.g., sports, recreation, trips). Thus, the individual with stroke is unable to resume societal roles such as working, parenting, attending church, or traveling.

Performance qualifiers indicate the extent of participation restriction (difficulty) in performing tasks or actions in an individual's current real-life environment. All aspects of the physical, social, and attitudinal world constitute the environment. Difficulty can range from mild to moderate to severe or complete. ***Capacity qualifiers*** indicate the extent of activity limitation and are used to describe an individual's highest probable level of functioning (ability to do the task or action). Qualifiers can range from the assistance of a device (e.g., adaptive equipment) or another person (minimal to moderate to maximal assistance) or environmental modification (home, workplace). Thus, the patient with stroke may demonstrate moderate difficulty in locomotion in the home environment (performance qualifiers) and require the use of an ankle-foot orthosis, small-based quad cane, and moderate assistance of one (capacity qualifiers).

Environmental factors make up the physical, social, and attitudinal environment in which people live and function. Factors range from products and technology (for personal use in daily living, mobility and transportation, communication) and physical factors (home environment, terrain, climate) to social support and relationships (family, friends, personal care providers), attitudes (individual and societal), and institutions and laws (housing, communication, transportation, legal, financial services, and policies). Qualifiers include factors that serve as barriers (disablement risk factors) or facilitators (assets). Barriers can range from mild to moderate to severe to complete. Facilitators can also range from mild to moderate to substantial to complete.

Box 1.1 summarizes ICF disablement terminology. The ICF Checklist (Version 2.1a, Clinician Form for the International Classification of Functioning, Disability, and Health) is a practical tool to elicit and record information on functioning and disability of an individual.[3]

PATIENT/CLIENT MANAGEMENT

Steps in patient/client management include (1) examination of the patient; (2) evaluation of the data and identification of problems; (3) determination of the physical therapy diagnosis; (4) determination of the prognosis and POC; (5) implementation of the POC; and (6) reexamination of the patient and evaluation of treatment outcomes (Fig. 1.2).[4]

Examination

Examination involves identifying and defining the patient's problem(s) and the resources available to determine appropriate intervention. It consists of three components: the patient history, systems review, and tests and measures. Examination begins with patient referral or initial entry (direct access) and continues as an ongoing process throughout the episode of care. Ongoing reexamination allows the therapist to evaluate progress and modify interventions as appropriate.

History

Information about the patient's past history and current health status is obtained from review of the medical record and interviews (patient, family, caregivers). The medical record provides detailed reports from members of the health care team; processing these reports requires an understanding of disease and injury, medical terminology, differential diagnosis, laboratory and other diagnostic tests, and medical management. The use of resource material or professional consultation can assist the novice clinician. The types of data that may be generated from a patient history are presented in Figure 1.3.[4]

The interview is an important tool used to obtain information and gain understanding directly from the patient. The therapist asks the patient a series of questions regarding general health, past and present medical conditions/complications, and treatment. Specifically

Box 1.1 Terminology: Functioning, Disability, and Health

Health condition is an umbrella term for disease, disorder, injury, or trauma and may also include other circumstances, such as aging, stress, congenital anomaly, or genetic predisposition. It may also include information about pathogeneses and/or etiology.
Body functions are physiological functions of body systems (including psychological functions).
Body structures are anatomical parts of the body such as organs, limbs, and their components.
Impairments are problems in body function or structure such as a significant deviation or loss.
Activity is the execution of a task or action by an individual.
Activity limitations are difficulties an individual may have in executing activities.
Participation is involvement in a life situation.
Participation restrictions are problems an individual may experience in involvement in life situations.
Contextual factors represent the entire background of an individual's life and living situation.
- **Environmental factors** make up the physical, social, and attitudinal environment in which people live and conduct their lives, including social attitudes, architectural characteristics, and legal and social structures.
- **Personal factors** are the particular background of an individual's life, including gender, age, coping styles, social background, education, profession, past and current experience, overall behavior pattern, character, and other factors that influence how disability is experienced by an individual.

Performance qualifier describes what an individual does in his or her current environment. (The current environment includes assistive devices or personal assistance, whenever the individual uses them to perform actions or tasks.)
Capacity qualifier describes an individual's ability to execute a task or an action (highest probable level of functioning in a given domain at a given moment).

From World Health Organization (WHO): *International Classification of Functioning, Disability and Health* (ICF).[3]

the patient is asked to describe the current problems, primary complaint (reason for seeking physical therapy), and anticipated goals/expected outcomes for the episode of care. The patient will often describe his or her difficulties in terms of activity limitations or participation restrictions (what he or she can or cannot do). The patient is then asked a series of questions designed to explore the nature and history of the current problems/primary complaint. General questions about functional activities and participation should be directed toward delineating the difference between *capacity* and *performance*. For example, "Since your stroke, how much difficulty do you have walking long distances?" "How does this compare to before you had the stroke?" (capacity). Questions directed toward examining performance can include "How much of a problem do you have in walking long distances?" "Is this problem with walking made worse or better with the use of an assistive device?" Questions are also posed regarding the patient's social and physical environment, vocation, recreational interests, health habits (e.g., smoking history, alcohol use), exercise likes and dislikes, and frequency and intensity of regular activity. Sample interview questions are included in Box 1.2.[4, 5]

Pertinent information can also be obtained from the patient's family or caregiver. For example, patients with central nervous system (CNS) involvement and severe cognitive and/or communication impairments and younger pediatric patients will be unable to accurately communicate their existing problems. The family member/caregiver then assumes the primary role of assisting the therapist in identifying problems and providing relevant aspects of the history. The perceived needs of the family member or caregiver can also be determined during the interview.

The therapist should be sensitive to differences in culture and ethnicity that may influence how the patient or family member responds during the interview or examination process. Different beliefs and attitudes toward health care may influence how cooperative the patient will be. During the interview, the therapist should listen carefully to what the patient says. The patient should be observed for any physical manifestations that reveal emotional context, such as slumped body posture, grimacing, and poor eye contact. Finally, the interview is used to establish rapport, effective communication, and mutual trust. Ensuring effective communication with the patient and cooperation serves to make the therapist's observations more valid and becomes crucial to the success of the POC.

Systems Review

The use of a brief *screening examination* allows the therapist to quickly scan the patient's body systems and determine areas of intact function and dysfunction in each of the following systems: cardiovascular/pulmonary, integumentary, musculoskeletal, and neuromuscular. Information is also obtained about cognitive functions, communication, learning style, and emotional status. Areas of deficit together with an accurate knowledge of the main health condition (disorder or disease) (1) confirm the need for further or more detailed examination; (2) rule out or differentiate specific system involvement; (3) determine if referral to another health care professional is warranted (triage); and (4) focus

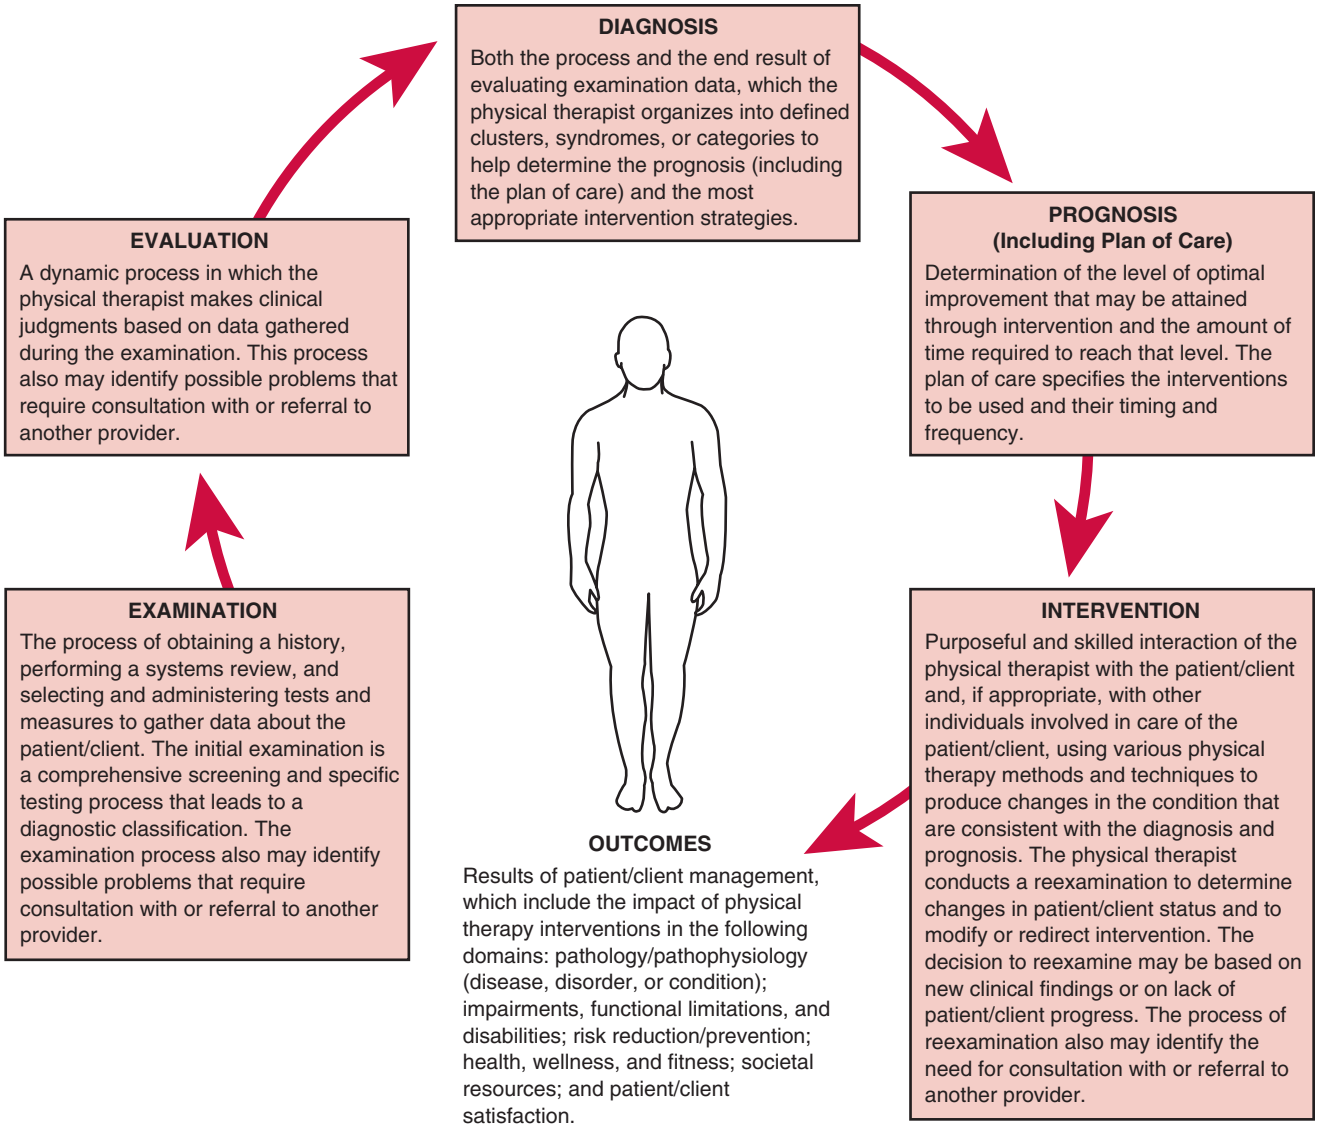

Figure 1.2 Elements of patient management leading to optimal outcomes. *(From APTA* Guide to Physical Therapist Practice [4, p. 35] *with permission.)*

the search of the origin of symptoms to a specific location or body part. An important starting point for identification of areas to be screened is consideration of all potential (possible) factors contributing to an observed activity limitation or participation restriction. Consultation is appropriate if the needs of the patient/client are outside the scope of the expertise of the therapist assigned to the case. For example, a patient recovering from stroke is referred to a dysphagia clinic for a detailed examination of swallowing function by a dysphagia specialist (speech-language pathologist).

Screening examinations are also used for healthy populations. For example, the physical therapist can screen individuals to identify risk factors for disease such as decreased activity levels, stress, and obesity. Screening is also conducted for specific populations such as pediatric clients (e.g., for scoliosis), geriatric clients (e.g., to identify fall risk factors), athletes (e.g., in pre-performance examinations), and working adults (e.g., to identify the risk of musculoskeletal injuries in the workplace). These screens may involve observation, chart review, oral history, and/or a brief examination. Additional screening examinations may be mandated by institutional settings. For example, in a long-term care facility, the therapist may be asked to review the chart for indications of changes in functional status or need for physical therapy. The therapist then makes a determination of the need for further physical therapy services based on completing a screening examination.

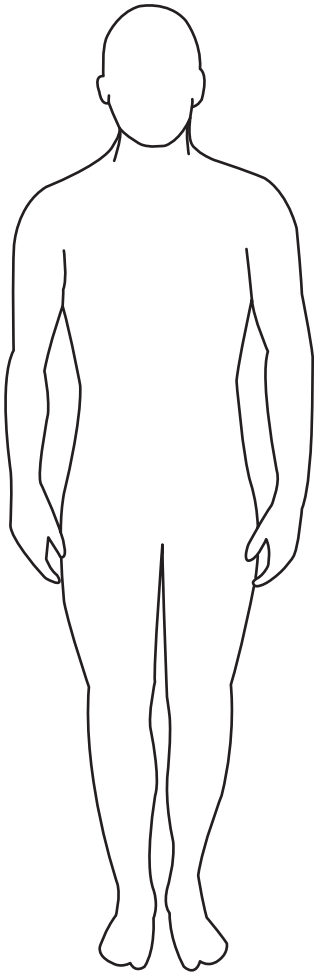
Tests and Measures

More definitive tests and measures are used to provide objective data to accurately determine the degree of specific function and dysfunction. Examination begins at the level of impairments, for example, diminished muscle strength (manual muscle test [MMT]) and impaired range of motion (ROM) (goniometric measurements), and progresses to functional activities (6-minute Walk Test, Timed Up and Go, Berg Balance Test). Alternatively,

General Demographics
- Age
- Sex
- Race/ethnicity
- Primary language
- Education

Social History
- Cultural beliefs and behaviors
- Family and caregiver resources
- Social interactions, social activities, and support system

Employment/Work (Job/School/Play)
- Current and prior work (job/school/play), community, and leisure actions, tasks, or activities



Growth and Development
- Developmental history
- Hand dominance

Living Environment
- Devices and equipment (eg., assistive, adaptive, orthotic, protective, supportive, prosthetic)
- Living environment and community characteristics
- Projected discharge destinations

General Health Status (Self-Report, Family Report, Caregiver Report)
- General health perception
- Physical function (eg., mobility, sleep patterns, restricted bed days)
- Psychological function (eg., memory, reasoning ability, depression, anxiety)
- Role function (eg., community, leisure, social, work)
- Social function (eg., social activity, social interaction, social support)

Social/Health Habits (Past and Current)
- General health perception
- Physical function (eg., mobility, sleep patterns, restricted bed days)
- Psychological function (eg., memory, reasoning ability, depression, anxiety)
- Role function (eg., community, leisure, social, work)
- Social function (eg., social activity, social interaction, social support)

Family History
- Familial health risks

Medical/Surgical History
- Cardiovascular
- Endocrine/metabolic
- Gastrointestinal
- Genitourinary
- Gynecological
- Integumentary
- Musculoskeletal
- Neuromuscular
- Obstetrical
- Prior hospitalizations, surgeries, and preexisting medical and other health related conditions
- Psychological
- Pulmonary

Current Condtion(s)/ Chief Complaint(s)
- Concerns that led the patient/client to seek the services of a physical therapist
- Concerns or needs of patient/client who requires the services of a physical therapist
- Current therapeutic interventions
- Mechanisms of injury or disease, including date of onset and course of events
- Onset and patterns of symptoms
- Patient/client, family, significant other, and caregiver expectations and goals for the therapeutic intervention
- Previous occurrence of chief complaint(s)
- Prior therapeutic interventions

Functional Status and Activity Level
- Current and prior functional status in self-care and home management, including activities of daily living (ADL) and instrumental activities of daily living (IADL)
- Current and prior functional status in work (job/school/play), community, and leisure actions, tasks, or activities

Medications
- Medications for current condition
- Medications previously taken for current condition
- Medications for other conditions

Other Clinical Tests
- Laboratory and diagnostic tests
- Review of available records (eg., medical, education, surgical)
- Review of other clinical findings (eg., nutrition and hydration)

Figure 1.3 Types of data that may be generated from patient history. *(From APTA* Guide to Physical Therapist Practice [4, p. 36] *with permission.)*

the therapist may begin with an examination of functional performance, during which the therapist analyzes the differences between the patient's performance and the "typical" or expected performance of a task. For example, the patient with stroke is asked to transfer from bed to wheelchair. The therapist observes the performance and determines that the patient lacks postural support (stability), adequate lower extremity (LE) extensor strength to reach the full upright position, and adequate ROM in ankle dorsiflexors. The therapist then progresses

Box 1.2 Sample Interview Questions

I. Interview questions designed to identify the nature and history of the current problem(s):
What problems bring you to therapy?
When did the problem(s) begin?
What happened to precipitate the problem(s)?
How long has the problem(s) existed?
How are you taking care of the problem(s)?
What makes the problem(s) better?
What makes the problem(s) worse?
What are your goals and expectations for physical therapy?
Are you seeing anyone else for the problem(s)?

II. Interview questions designed to identify desired outcomes in terms of essential functional activities include the following:
What activities do you normally do at home/work/school?
What activities are you unable to do?
What activities are done differently and how are they different (i.e., extra time, extra effort, different strategy)?
What activities do you need help to perform that you would rather do yourself?
What leisure activities are important to you?
How can I help you be more independent?

III. Interview questions designed to identify environmental conditions in which patient activities typically occur include the following:
Describe your home/school/work environment.
How do you move around/access areas in the home (i.e., bathroom, bedroom, entering and exiting the home)?
How safe do you feel?
How do you move around/access areas in the community (i.e., workplace, school, grocery store, shopping center, community center, stairs, curbs, ramps)? How safe do you feel?

IV. Interview questions designed to identify available social supports include the following:
Who lives with you?
Who assists in your care (i.e., basic activities of daily living [BADL], instrumental activities of daily living [IADL])?
Who helps you with the activities you want to do (i.e., walking, stairs, transfers)?
Are there activities you have difficulty with that would benefit from additional assistance?

V. Interview questions designed to identify the patient's knowledge of potential disablement risk factors include the following:
What problems might be anticipated in the future?
What can you do to eliminate or reduce the likelihood of that happening?

to a detailed examination of impairments. The decision as to which approach to use is based on the results of the screening examination and the therapist's knowledge of the health condition. Key information to obtain during an examination of function is the level of independence or dependence, as well as the need for physical assistance, external devices, or environmental modifications.

Adequate training and skill in performing specific tests and measures are crucial in ensuring both validity and reliability of the tests. Failure to correctly perform an examination procedure can lead to the gathering of inaccurate data and the formation of an inappropriate POC. Later chapters focus on specific tests and measures and discuss issues of validity and reliability. The use of disability-specific standardized instruments (e.g., for individuals with stroke, the Fugl-Meyer Assessment of Physical Performance) can facilitate the examination process but may not always be appropriate for each individual patient. The therapist needs to carefully review the unique problems of the patient to determine the appropriateness and sensitivity of an instrument. Box 1.3 presents the categories for tests and measures identified in the *Guide to Physical Therapist Practice*.[4]

Novice therapists should resist the tendency to gather excessive and extraneous data in the mistaken belief that more information is better. Unnecessary data will only confuse the picture, rendering clinical decision making more difficult and unnecessarily raising the cost of care. If problems arise that are not initially identified in the history or systems review, or if the data obtained are inconsistent, additional tests or measures may be indicated. Consultation with an experienced therapist can provide an important means of clarifying inconsistencies and determining the appropriateness of specific tests and measures.

Evaluation

Data gathered from the initial examination must then be organized and analyzed. The therapist identifies and prioritizes the patient's impairments, activity limitations, and participation restrictions and develops a *problem list*. It is important to accurately recognize those clinical problems associated with the primary disorder and those associated with co-morbid conditions. Table 1.1 presents a sample prioritized problem list.

Impairments, activity limitations, and participation restrictions must be analyzed to identify causal relationships. For example, shoulder pain in the patient with hemiplegia may be due to several factors, including hypotonicity and loss of voluntary movement, which are direct impairments, or soft tissue damage/trauma from improper transfers, which is an indirect impairment, resulting from an activity. Determining the causative

Box 1.3 Categories for Tests and Measures

Aerobic Capacity/Endurance

Adapted from APTA *Guide to Physical Therapist Practice*.[4]

factors is a difficult yet critical step in determining appropriate treatment interventions and resolving the patient's pain.

The skilled clinician is able to identify the role barriers and facilitators in the patient's environment in order to incorporate measures to minimize or maximize these factors into the POC. A POC that emphasizes and reinforces facilitators enhances function and the patient's ability to experience success. Improved motivation and engagement are the natural outcomes of reinforcement of facilitators. For example, the patient with stroke may have intact communication skills, cognitive skills, and good function of the uninvolved extremities. Facilitators can also include supportive and knowledgeable family members/caregivers and an appropriate living environment.

Diagnosis

A *medical diagnosis* refers to the identification of a disease, disorder, or condition (pathology/pathophysiology) by evaluating the presenting signs, symptoms, history, laboratory test results, and procedures. It is identified primarily at the cellular level. Physical therapists use the term **diagnosis** to "identify the impact of a condition on function at the level of the system (especially the movement system) and at the level of the whole person."[4] Thus, the term is used to clarify the professional body of knowledge as well as the role of physical therapists in health care. For example:

Medical diagnosis: Cerebrovascular accident (CVA)
Physical therapy diagnosis: Impaired motor function and sensory integrity associated with nonprogressive disorders of the central nervous system—acquired in adolescence or adulthood[4, p. 365]
Medical diagnosis: Spinal cord injury (SCI)
Physical therapy diagnosis: Impaired motor function, peripheral nerve integrity, and sensory integrity associated with nonprogressive disorders of the spinal cord[4, p. 437]

The diagnostic process includes integrating and evaluating the data obtained during the examination to describe the patient/client condition in terms that will guide the prognosis and selection of intervention strategies during the development of the POC. The *Guide to Physical Therapist Practice* organizes diagnostic categories specific to physical therapy by *preferred practice patterns.*[4] There are four main categories of conditions: Musculoskeletal, Neuromuscular, Cardiovascular/Pulmonary, and Integumentary, with preferred practice patterns identified in each (see Appendix 1.A). The patterns are described fully according to the five elements of patient/client management (i.e., examination, evaluation, diagnosis, prognosis, and intervention). Each pattern also includes reexamination to evaluate progress, global outcomes, and criteria for termination of physical therapy services. Inclusion and exclusion criteria for each practice pattern and criteria for multiple-pattern classification are also presented. The patterns represent the collaborative effort of experienced physical therapists who detailed the broad categories of problems commonly seen by physical therapists within the scope of their knowledge, experience, and expertise. Expert consensus was thus used to develop and define the diagnostic categories and preferred practice patterns. Given the central role of physical therapists as movement specialists, the therapist will need to focus the diagnosis on the results of activity analysis and movement problems identified during the examination when formulating the prognosis and POC.

The use of diagnostic categories specific to physical therapy, as Sarhman points out, (1) allows for successful communication with colleagues and patients/caregivers about the conditions that require the physical therapist's expertise, (2) provides an appropriate classification for establishing standards of examination and treatment, and (3) directs examination of treatment effectiveness, thereby enhancing evidence-based practice.[6] Physical therapy diagnostic categories also facilitate successful reimbursement when linked to functional outcomes and enhance direct access of physical therapy services.

Table 1.1 Sample Prioritized Problem List for a Patient With Stroke

Direct Impairments	Indirect Impairments	Composite Impairments	Activity Limitations	Participation Restrictions
R hemiparesis RUE > RLE	R shoulder subluxation	Balance deficits Standing > sitting	Dep bed mobility: minA	Dec community mobility
	Dec ROM R shoulder	Gait deficits	Dep BADL: min/mod A	IADL: unable
Hypotonicity RUE	Kyphosis, forward head	Dec endurance	Dep transfers: modA X 1	Dec ability to perform social roles: husband
Spasticity RLE: knee ext, plantiflexors			Dep locomotion: modA X 1	
Synergy patterns RLE > RUE			Stairs: unable	
Mild dysarthria			Inc fall risk	
Mild cognitive deficits: dec STM				
Dec motor planning ability				
CO-MORBIDITIES:	Diabetic Peripheral Neuropathy			
Dec sensation both feet		Dec balance	Inc fall risk	
Small ulcer L foot (5th toe)		Dec endurance		
		Gait deficits: requires special shoes		Dec community mobility

Contextual factors: physical, social, attitudinal
One-level ranch house; entry with 2 steps, no handrails
Highly motivated
Personal factors: individual's life and living situation
Spouse is primary caregiver; has osteoporosis and decreased vision (bilateral cataracts).
Has 2 involved sons living within 30 mile radius.
Key: BADL: basic activities of daily living; Dec: decreased; Dep: dependent; IADL: instrumental activities of daily living; Inc: increased; minA: minimal assistance; modA: moderate assistance; RLE: right lower extremity; RUE: right upper extremity; STM: short term memory.

Prognosis

The term **prognosis** refers to "the predicted optimal level of improvement in function and amount of time needed to reach that level."[4, p. 46] An accurate prognosis may be determined at the onset of treatment for some patients. For other patients with more complicated conditions such as severe traumatic brain injury (TBI) accompanied by extensive disability and multisystem involvement, a prognosis or prediction of level of improvement can be determined only at various increments during the course of rehabilitation. Knowledge of recovery patterns (stage of disorder) is sometimes useful to guide decision making. The amount of time needed to reach optimal recovery is an important determination, one that is required by Medicare and many other insurance providers. Predicting optimal levels of recovery and time frames can be a challenging process for the novice therapist. Use of experienced, expert staff as resources and mentors can facilitate this step in the decision making process. For each preferred practice pattern, the *Guide to Physical Therapist Practice* includes a broad range of expected number of visits per episode of care.[4]

Plan of Care

The **plan of care** (**POC**) outlines anticipated patient management. The therapist evaluates and integrates data obtained from the patient/client history, the systems review, and tests and measures within the context of other factors, including the patient's overall health, availability of social support systems, living environment, and potential discharge destination. Multisystem involvement, severe impairment and functional loss, extended time of involvement (chronicity), multiple co-morbid conditions, and medical stability of the patient are important parameters that increase the complexity of the decision making process.

A major focus of the POC is producing meaningful changes at the personal/social level by reducing activity limitations and participation restrictions. Achieving independence in locomotion or activities of daily living (ADL), return to work, or participation in recreational activities is important to the patient/client in terms of improving **quality of life** (**QOL**).[7] QOL is defined as the sense of total well-being that encompasses both physical and psychosocial aspects of the patient/client's life. Finally, not all impairments can be remediated by physical therapy. Some impairments are permanent or progressive, the direct result of unrelenting pathology such as amyotrophic lateral sclerosis (ALS). In this example, a primary emphasis on reducing the number and severity of indirect impairments and activity limitations is appropriate.

Essential components of the POC include (1) anticipated goals and expected outcomes; (2) the predicted level of optimal improvement; (3) the specific interventions to be used, including type, duration, and frequency; and (4) criteria for discharge.

Goals and Expected Outcomes

An important first step in the development of the POC is the determination of anticipated **goals** and **expected outcomes**, the intended results of patient/client management. Goal and outcome statements address patient-identified priorities and predicted changes in impairments, activity limitations, and participation restrictions. They also address predicted changes in overall health, risk reduction and prevention, wellness and fitness, and optimization of patient/client satisfaction. The difference is in terms of time frame. Outcomes define the patient's expected level at the conclusion of the episode of care or rehabilitation stay, whereas goals define the interim steps that are necessary to achieve expected outcomes.[4]

Goal and outcome statements should be realistic, objective, measurable, and time limited. There are four essential elements:

- ***Individual:*** Who will perform the specific behavior or activity required or aspect of care? Goals and outcomes are focused on the *patient/client.* This includes individuals who receive direct care physical therapy services and/or individuals who benefit from consultation and advice, or services focused on promoting, health, wellness, and fitness. Goals can also be focused on family members or caregivers, for example, the parent of a child with a developmental disability.
- ***Behavior/Activity:*** What is the specific behavior or activity the patient/client will demonstrate? Goals and outcomes include changes in impairments (e.g., ROM, strength, balance) and changes in activity limitations (e.g., transfers, ambulation, ADL) or participation restrictions (e.g., community mobility, return to school or work).
- ***Condition:*** What are the conditions under which the patient/client's behavior is measured? The goal or outcome statement specifies the specific conditions or measures required for successful achievement, for example, distance achieved, required time to perform the activity, the specific number of successful attempts out of a specific number of trials. Statements focused on functional changes should include a description of the conditions required for acceptable performance. For example, the functional levels of performance in the Functional Independence Measure (FIM) are used in the majority of rehabilitation centers in the United States. This instrument grades levels from No Helper/Independence (grade 7) to No Helper/Modified Independence (grade 6; device), to Helper/Modified Dependence (grades 5, 4, and 3; supervision, minimal, moderate, assistance), to Helper/Complete Dependence (grades 2 and 1; maximal, total assistance) (see Chapter 8 and Figure 8.5 for a complete description of this instrument).[8] The type of environment required for a successful outcome of the behavior should also be specified: clinic environment (e.g., quiet room, level floor surface, physical therapy gym), home (e.g., one flight of eight stairs, carpeted surfaces), and community (e.g., uneven grassy surfaces, curbs, ramps).
- ***Time:*** How long will it take to achieve the stated goal or outcome? Goals can be expressed as *short-term* (generally considered to be 2 to 3 weeks) and *long-term* (longer than 3 weeks). Outcomes describe the expected level of functional performance attained at the end of the episode of care or rehabilitation stay. In instances of severe disability and incomplete recovery, for example, the patient with traumatic brain injury, the therapist, and team members may have difficulty determining the expected outcomes at the beginning of rehabilitation. Long-term goals can be used that focus on the expectations for a specific stage of recovery (e.g., minimally conscious states, confusional states). Goals and outcomes can also be modified following a significant change in patient status.

Each POC has multiple goals and outcomes. Goals may be linked to the successful attainment of more than one outcome. For example, attaining ROM in dorsiflexion is critical to the functional outcomes of independence in transfers and locomotion. The successful attainment of an outcome is also dependent on achieving a number of different goals. For example, independent locomotion (the outcome) is dependent on increasing strength, ROM, and balance skills. In formulating a POC, the therapist accurately identifies the relationship between and among goals and sequences them appropriately. Box 1.4 presents examples of outcome and goal statements.

In rehabilitation settings, the POC also includes a statement regarding the patient's overall *rehabilitation*

Box 1.4 Examples of Outcome and Goal Statements

The following are examples of expected outcomes, all to be achieved within the anticipated rehab stay:

The patient will be independent and safe in ambulation using an ankle-foot orthosis and a quad cane on level surfaces for unlimited community distances and for all daily activities within 8 weeks.

The patient will demonstrate modified dependence with close supervision in wheelchair propulsion for limited household distances (up to 50 feet) within 8 weeks.

The patient will demonstrate modified dependence with minimum assistance of one person for all transfer activities in the home environment within 6 weeks.

The patient will demonstrate independence in basic activities of daily living (BADL) with minimal setup and equipment (use of a reacher) within 6 weeks.

The patient and family will demonstrate enhanced decision making skills regarding the health of the patient and use of health care resources within 6 weeks.

The following are examples of anticipated goals with variable time frames:

Short-Term Goals

The patient will increase strength in shoulder depressor muscles and elbow extensor muscles in both upper extremities from good to normal within 3 weeks.

The patient will increase ROM 10 degrees in knee extension bilaterally to within normal limits within 3 weeks.

The patient will be independent in the application of lower extremity orthoses within 1 week.

The patient and family will recognize personal and environmental factors associated with falls during ambulation within 2 weeks.

The patient will attend to task for 5 min out of a 30-min treatment session within 3 weeks.

Long-Term Goals

The patient will independently perform transfers from wheelchair to car within 4 weeks.

The patient will ambulate with bilateral knee-ankle-foot orthoses (KAFOs) and crutches using a swing-through gait and close supervision for 50 feet within 5 weeks.

The patient will maintain static balance in sitting with centered, symmetrical weight-bearing and no upper extremity support or loss of balance for up to 5 minutes within 4 weeks.

The patient will sequence a three- to five-step routine task with minimum assistance within 5 weeks.

potential. This is typically a one-word statement: *excellent, good, fair, or poor.* The therapist considers multiple factors when determining rehabilitation potential, such as the patient's condition and onset date, co-morbidity, mechanism of injury, and baseline data.

Interventions

The next step is to determine the **intervention**, defined as the purposeful interaction of the physical therapist with the patient/client and, when appropriate, other individuals involved in the care of the patient/client, using various physical therapy procedures and techniques to produce changes in the condition. Components of physical therapy intervention include coordination, communication, and documentation; patient/client-related instruction; and procedural interventions (Fig. 1.4).[4]

Coordination and Communication

Case management requires therapists to be able to communicate effectively with all members of the rehabilitation team, directly or indirectly. For example, the therapist communicates directly with other professionals at case conferences, team meetings, or rounds or indirectly through documentation in the medical record. Effective communication enhances collaboration and understanding.

Therapists are also responsible for coordinating care at many different levels. The therapist delegates appropriate aspects of treatment to physical therapy assistants and oversees the responsibilities of physical therapy aides. The therapist coordinates care with other professionals, family, or caregivers regarding a specific treatment approach or intervention. For example, for early transfer training to be effective, consistency in how everyone transfers the patient is important. The therapist also coordinates discharge planning with the patient and family and other interested persons. Therapists may be involved in providing POC recommendations to other facilities such as restorative nursing facilities.

Patient/Client-Related Instruction

In an era of managed care and shorter time allocations for an episode of care, effective patient/client-related instruction is critical to ensuring optimal care and successful rehabilitation. Communication strategies are developed within the context of the patient/client's age, cultural backgrounds, language skills, and educational level, and

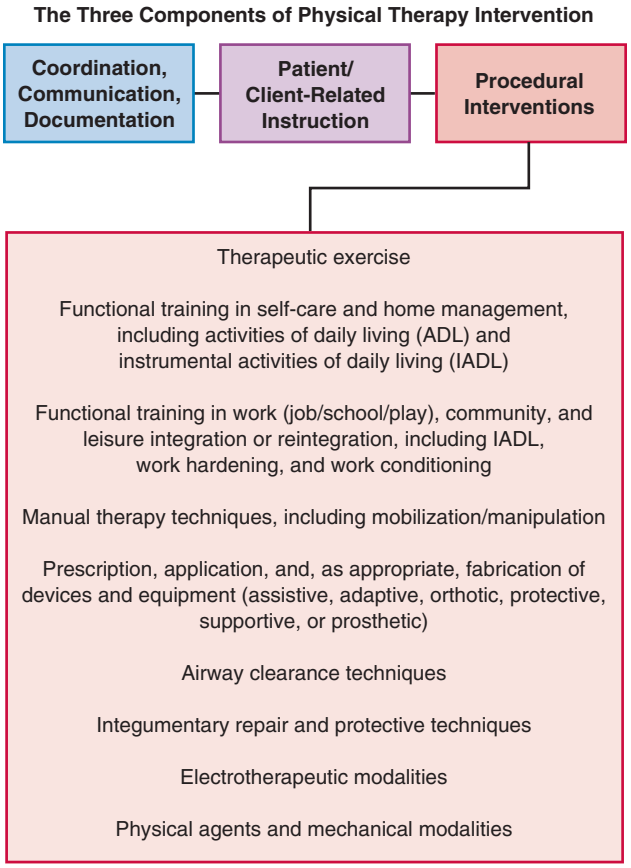

Figure 1.4 The three components of physical therapy intervention. *(From APTA* Guide to Physical Therapist Practice [4, p. 98] *with permission.)*

the presence of specific communication or cognition impairments. Therapists may provide direct one-on-one instruction to a variety of individuals, including patients, clients, families, caregivers, and other interested persons. Additional strategies can include group discussions or classes, or instruction through printed or audiovisual materials. Educational interventions are directed toward ensuring an understanding of the patient's condition, training in specific activities and exercises, determining the relevance of interventions to improve function, and achieving an expected course. In addition, educational interventions are directed toward ensuring a successful transition to the home environment (instruction in home exercise programs [HEP]), returning to work (ergonomic instruction), or resuming social activities in the community (environmental access). It is important to document what was taught, who participated, when the instruction occurred, and overall effectiveness. The need for repetition and reinforcement of educational content should also be documented in the medical record.

Procedural Interventions

Skilled physical therapy includes a wide variety of procedural interventions, which can be broadly classified into three main groups. **Restorative interventions** are directed toward remediating or improving the patient's status in terms of impairments, activity limitations, participation restrictions, and recovery of function. The involved segments are targeted for intervention. This approach assumes an existing potential for change (e.g., neuroplasticity of brain and spinal cord function; potential for muscle strengthening or improving aerobic endurance). For example, the patient with incomplete spinal cord injury (SCI) undergoes locomotor training using body weight support and a treadmill (BWSTT). Patients with chronic progressive pathology (e.g., the patient with Parkinson's disease) may not respond to restorative interventions aimed at resolving direct impairments; interventions aimed at restoring or optimizing function and modifying indirect impairments can, however, have a positive outcome.

Compensatory interventions are directed toward promoting optimal function using residual abilities. The activity (task) is adapted (changed) in order to achieve function. The uninvolved or less involved segments are targeted for intervention. For example, the patient with left hemiplegia learns to dress using the right upper extremity (UE); the patient with complete T1 paraplegia learns to roll using upper extremities (UEs) and momentum. Environmental adaptations are also used to facilitate relearning of functional skills and optimal performance. For example, the patient with TBI is able to dress by selecting clothing from color-coded drawers. Compensatory interventions can be used in conjunction with restorative interventions to maximize function or when restorative interventions are unrealistic or unsuccessful.

Preventative interventions are directed toward minimizing potential problems (e.g., anticipated indirect impairments, activity limitations, and participation restrictions) and maintaining health. For example, early resumption of upright standing using a tilt table minimizes the risk of pneumonia, bone loss, and renal calculi in the patient with SCI. A successful educational program for frequent skin inspection can prevent the development of pressure ulcers in that same patient with SCI.

Interventions are chosen based on the medical diagnosis, the evaluation of examination, the physical therapy diagnosis, the prognosis, and the anticipated goals and expected outcomes. The therapist relies on knowledge of foundational science and interventions (e.g., principles of motor learning, motor control, muscle performance, task-specific training, and cardiovascular conditioning) in order to determine those interventions that are likely to achieve successful outcomes. It is important to identify all possible interventions early in the process, to carefully weigh those alternatives, and then to decide on the interventions that have the best probability of success. Narrowly adhering to one treatment approach reduces the available options and may limit or preclude successful outcomes. Use of a protocol (e.g., predetermined

exercises for the patient with hip fracture) standardizes some aspects of care but may not meet the individual needs of the patient. Protocols can foster a separation of examination/evaluation findings from the selection of treatments.

Watts suggests that clinical judgment is clearly an elegant mixture of art and science.[9] Professional consultation with expert clinicians and mentors is an effective means of helping the novice sort through the complex issues involved in decision making, especially when complicating factors intervene. For example, a consultation would be beneficial for the inexperienced therapist who is treating a patient that is chronically ill, has multiple co-morbidities or complications, impaired cognition, inadequate social supports, and severe activity limitations.

A general outline of the POC is constructed. Schema can be used to present a framework for approaching a specific aspect of treatment and assist the therapist in organizing essential intervention elements of the plan. One such commonly used schema for exercise intervention is the *FITT equation (frequency-intensity-time-type),* presented in Box 1.5.

The therapist should ideally choose interventions that accomplish more than one goal and are linked to the expected outcomes. The interventions should be effectively sequenced to address key impairments first and to achieve optimum motivational effect, interspacing the more difficult or uncomfortable procedures with easier ones. The therapist should include tasks that ensure success during the treatment session and, whenever possible, should end each session on a positive note. This helps the patient retain a positive feeling of success and look forward to the next treatment.

Discharge Planning

Discharge planning is initiated early in the rehabilitation process during the data collection phase and intensifies as goals and expected outcomes are close to being reached. Discharge planning may also be initiated if the patient refuses further treatment or becomes medically or psychologically unstable. If the patient is discharged before outcomes are reached, the reasons for discontinuation of services must be carefully documented. Elements of an effective *discharge plan* are included in Box 1.6.

The therapist should also include the *discharge prognosis,* typically a one-word response such as *excellent, good, fair, or poor*. It reflects the therapist's judgment of the patient's ability to maintain the level of function achieved at the end of rehabilitation without continued skilled intervention.

Implementation of the Plan of Care

The therapist must take into account a number of factors in structuring an effective treatment session. The patient's comfort and optimal performance should be a priority. The environment should be structured appropriately to

Box 1.5 The FITT Equation for Exercise Intervention

Frequency: How often will the patient receive skilled care?

This is typically defined in terms of the number of times per week treatment will be given (e.g., daily or three times per week), or the number of visits before a specific date.

Intensity: What is the prescribed intensity of exercises or activity training?

For example, the POC includes sit-to-stand repetitions, 3 sets of 5 reps each, progressing from high seat to low.

Time (duration): How long will the patient receive skilled care?

This is typically defined in terms of days or weeks (e.g., three times per week for 6 weeks). The duration of an anticipated individual treatment session should also be defined (e.g., 30- or 60-minute sessions).

Type of intervention: What are the specific exercise strategies or procedural interventions used?

Necessary components that should be identified include the following:

- **Posture and activity:** a description of the specific posture and activity the patient must perform (e.g., sitting, weight shifting or standing, modified plantigrade, reaching).
- **Techniques used:** mode of therapist action or intervention used (e.g., guided, active-assisted, or resisted movement), or specific technique (e.g., rhythmic stabilization, dynamic reversals).
- **Motor learning strategies used:** strategies specific to type of feedback (e.g., knowledge of results, knowledge of performance) and scheduling of feedback (e.g., constant or variable), practice schedule (e.g., blocked, serial, or random order), and environment (e.g., closed/structured or open/variable).
- **Additional required elements:** those elements necessary to assist the patient in the exercise or activity (e.g., verbal cues, manual contacts) or equipment (e.g., elastic band resistance, therapy ball, body weight support system with motorized treadmill).

Box 1.6 Elements of the Discharge Plan

Patient, family, or caregiver education: instruction includes information regarding the following:

- Current condition (pathology), impairments, activity limitations, and participation restrictions
- Ways to reduce risk factors for recurrence of condition and developing complications, indirect impairments, activity limitations, and participation restrictions
- Ways to maintain/enhance performance and functional independence
- Ways to foster healthy habits, wellness, and prevention
- Ways to assist in transition to a new setting (e.g., home, skilled nursing facility)
- Ways to assist in transition to new roles

Plans for follow-up care or referral to another agency: patient/caregiver is provided with the following:

- Information regarding follow-up visit to rehabilitation center or referral to another agency (e.g., home care agency, outpatient facility) as needed
- Information regarding community support group and community fitness center as appropriate

Instruction in a home exercise plan (HEP): patient/caregiver instruction regarding the following:

- Home exercises, activity training, ADL training
- Use of adaptive equipment (e.g., assistive devices, orthoses, wheelchairs)

Evaluation/modification of the home environment:

- Planning regarding the home environment and modifications needed to assist the patient in the home (e.g., installation of ramps and rails, bathroom equipment such as tub seats, raised toilet seats, bathroom rails, furniture rearrangement or removal to ease functional mobility)
- All essential equipment and renovations should be in place before discharge

reduce distractions and focus the patient's attention on the task. Patient privacy should be respected, with adequate draping and positioning. The therapist should consider good body mechanics, effective use of gravity and position, and correct application of techniques and modalities. Any equipment should be gathered prior to treatment and be in good working order. All safety precautions must be observed.

The patient's pretreatment level of function or initial state should be carefully examined. General state organization of the CNS and homeostatic balance of the somatic and autonomic nervous systems are important determinants of how a patient may respond to intervention. A wide range of influences, from emotional to cognitive to organic, may affect how a patient reacts to a particular treatment. Patients who are overly stressed may demonstrate altered homeostatic responses. For example, the patient with TBI who presents with high arousal and agitated behaviors can be expected to react to treatment in unpredictable ways, characterized by "fight or flight" responses. Similarly, patients with TBI who are lethargic may be difficult to arouse and demonstrate limited ability to participate in therapy sessions. Responses to treatment should be carefully monitored throughout the episode of care, and treatment modifications should be implemented as soon as needed to ensure successful performance. Therapists develop the "art of clinical practice" by learning to adjust their input (e.g., verbal commands and manual contacts) in response to the patient. Treatment thus becomes a dynamic and interactive process between patient and therapist. Shaping of behavior can be further enhanced by careful orientation to the purpose of the tasks and how they meet the patient's needs, thereby ensuring optimal cooperation and motivation.[10]

Reexamination of the Patient and Evaluation of Expected Outcomes

This last step is ongoing and involves continuous reexamination of the patient and a determination of the efficacy of treatment. Reexamination data are evaluated within the context of the patient's progress toward anticipated goals and expected outcomes set forth in the POC. A determination is made whether the goals and outcomes are reasonable given the patient's diagnosis and progress. If the patient attains the desired level of competence for the stated goals, revisions in the POC are indicated. If the patient attains the desired level of competence for the expected outcomes, discharge is considered. If the patient fails to achieve the stated goals or outcomes, the therapist must determine why. Were the goals and outcomes realistic given the clinical problems and database? Were the interventions selected at an appropriate level to challenge the patient, or were they too easy or too difficult? Were facilitators appropriately identified and the patient sufficiently motivated? Were intervening and constraining factors (barriers) identified? If the interventions were not appropriate, additional information is sought, goals modified, and different treatment interventions selected. Revision in the POC is also indicated if the patient progresses more rapidly or slowly than expected. Each modification must be evaluated in terms of its overall impact on the POC. Thus, the plan becomes a fluid statement of how the patient is progressing and what goals and outcomes are achievable. Its overall success depends on the therapist's ongoing clinical decision making skills and on engaging the patient's cooperation and motivation. Patient involvement in the development and monitoring of the POC should be documented.

PATIENT PARTICIPATION IN PLANNING

A *patient-centered approach* that involves the patient in collaborative planning and evaluation of outcomes is important in a successful POC. The patient is viewed as an active participant and partner who can make informed choices and assume responsibility for his or her own health care. Therapists who place strong emphasis on communicating effectively; educating their patients, families, and caregivers; and teaching self-management skills are able to successfully empower patients. The natural outcomes of this approach are improved therapy outcomes and overall satisfaction with care.[11] Some rehabilitation plans have failed miserably simply because the therapist did not fully involve the patient in the planning process, producing goals or outcomes that were not meaningful to the patient (e.g., for the patient with incomplete SCI, independent wheelchair mobility). That same patient may have established a very different set of personal goals and expectations (e.g., return to walking). For many patients for whom complete recovery is not expected, the overall "goal of any rehabilitation program must be to increase the ability of individuals to manage their lives in the context of ongoing disability, to the greatest extent possible."[11, p. 7] This cannot be effectively done if the therapist assumes the role of expert and sole planner, establishing the rules, regulations, and instructions for rehabilitation. Rather, it is critical to engage the patient in collaborative problem solving and promote lifelong skills in health management. The patient's ability and motivation to participate in planning do vary. The more ill the patient, the more anxiety, and the less likely that he or she will want to be actively involved in planning. As the illness resolves and the patient begins to improve, the more likely he or she will be to want to be engaged in planning the treatment. Also the more difficult the problems encountered, the more likely patients are to put their trust in "the experts" and the less likely they are to trust their own abilities to reach effective decisions. The therapist needs to guard against promoting dependence on the expert (the "my therapist syndrome") to the exclusion of the patient's listening to his or her own thoughts and feelings. The patient's feelings of perceived helplessness are increased while the patient's ability to utilize his or her own decision making abilities is delayed or restricted.

Ozer et al[11] address these issues in an excellent reference titled *Treatment Planning for Rehabilitation—A Patient-Centered Approach*. The authors suggest asking the patient a series of *probing questions* to engage patients in the treatment planning process (Box 1.7). The level of participation in this process may start out limited but can be expected to expand as the collaborative process is continued. A *Levels of Participation Scale* can be used to evaluate and document patient participation in the planning process (Box 1.8). In determining the patient's level of functioning, the therapist starts at the upper end of the scale (free choice) and moves down the scale as necessary. The lowest level of participation is recorded. For most patients, the lowest level of participation is optimally Level B Multiple Choice. Patients with significant cognitive or communication deficits (e.g., the patient with TBI) typically will require lower levels of participation. The goal as the patient recovers and progresses in rehabilitation is to increasingly involve the patient in the planning process, to whatever extent possible. In these situations, the therapist can document improving

Box 1.7 Questions Designed to Engage the Patient in the Treatment Planning Process

1. What are your concerns?
2. What is your greatest concern?
3. What would you like to see happen? What would make you feel that you are making progress in dealing with your chief concern? What are your goals?
4. What is your specific goal?
5. What results have you achieved?
6. What problems do you have? What questions do you have?
7. What would you like to see accomplished that would make you feel that you are making some progress in dealing with your greatest concern?

From Ozer, M, Payton, O, and Nelson, C: Treatment Planning for Rehabilitation—A Patient-Centered Approach. McGraw-Hill, New York, 2000, pp. 37 and 60, with permission.

Box 1.8 Levels of Participation Scale

A = FREE CHOICE: The therapist asks an open-ended question. The patient explores and selects the answer (what) and further specifies where? and to what degree?

B = MULTIPLE CHOICE: The therapist asks questions, provides suggestions (three options). The patient selects one choice from the alternatives presented.

C = CONFIRMED CHOICE: The therapist asks questions, provides a recommendation (one choice), and asks for agreement. The patient puts into own words what has been selected.

D = FORCED CHOICE: The therapist asks questions, provides a recommendation (one option); the patient agrees (or disagrees) with what has been selected.

E = NO CHOICE: The therapist prescribes, does not ask; the patient is compliant (or noncompliant).

From Ozer, M, Payton, O, and Nelson, C: Treatment Planning for Rehabilitation—A Patient-Centered Approach. McGraw-Hill, New York, 2000, p. 44, with permission.

levels of participation as evidence of meeting a goal of improving self-efficacy and self-management.

DOCUMENTATION

Documentation is an essential requirement for timely reimbursement of services and communication among the rehabilitation team members. Written documentation is formally done at the time of admission and discharge, and at periodic intervals during the course of rehabilitation (interim or progress notes). Many facilities require documentation for every treatment session. The format and timing of notes will vary according to the regulatory requirements specified by institutional policy and third-party payers. Data included in the medical record should be meaningful (important, not just nice to have), complete and accurate (valid and reliable), timely (recorded promptly), and systematic (regularly recorded). All handwritten entries should be in ink, legible, and signed with a legal signature. Written charting errors should be corrected by a single line through the error and initialing and dating directly above the error. See Appendix 1.B: Defensible Documentation—General Documentation Guidelines from APTA (American Physical Therapy Association), practice-dept@apta.org.

In the United States, all health care facilities must adhere to the *ICD-9-CM Official Guidelines for Coding and Reporting*.[12] These codes are developed by the Centers for Medicare and Medicaid Services (CMS) and the National Center for Health Statistics (NCHS) and based on the *International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM)*. Adherence to these guidelines is required under the Health Insurance Portability and Accountability Act (HIPAA). Typical billing codes related to the preferred practice patterns are listed in the *Guide to Physical Therapist Practice*.[4]

Electronic Documentation

There is increasing emphasis on using electronic documentation in physical therapy, which can provide a fully integrated and completely paperless workflow for managing patient care. This includes managing referrals, initial intake data, progress and discharge notes, scheduling, and billing. Advantages of electronic documentation include standardization of data entry, increased speed of access to data, and integration of data that can be used for a wide variety of applications (e.g., clinical management of patients, quality control, clinical research). Therapists no longer have to track down medical records to review or input data, because information is readily available from any computer or electronic device with Internet access. Therapists also can receive notification of when the patient arrives or checks in, what notes are due, and scheduled evaluations and POC updates. Software programs typically do not allow notes be filed unless all the required elements are completed. Overall efficiency of practice management is increased with decreased errors in documentation and improved accuracy of reimbursements. Many different companies provide software programs for physical therapy that focus on specific practice settings (e.g., outpatient rehabilitation therapy, home care, private practice). Therapists using documentation software for electronic entry of patient data should ensure that programs comply with appropriate provisions for security and confidentiality.

CLINICAL DECISION MAKING: EXPERT VERSUS NOVICE

There is an accumulating body of evidence on expertise in physical therapy practice, spearheaded by the pivotal work of Jenson and colleagues.[13-15] These researchers have shown that the knowledge, skills, and decision making abilities used by expert clinicians can be identified, nurtured, and taught. Embrey et al[16] suggest that the novice therapist may benefit from a period of active mentoring by expert clinicians early in clinical practice (e.g., clinical residency). This information has important implications for novice therapists and for educators involved in teaching clinical decision making.

Experienced clinicians utilize a *forward reasoning process* (reasoning from data to hypothesis) in which the clinician is able to recognize patient cues and patterns as being similar to previously identified cases. Decisions are formulated based on higher-order (metacognitive) skills and reflective processes. Hypothesis testing is not typically verbalized. Thus, actions are based on a rich experience-based clinical knowledge and pattern recognition. In contrast, a *backward reasoning process* (also termed *hypothetico-deductive process*) involves identifying cues from the patient, proposing a hypothesis (reasoning from hypothesis to data), gathering supporting data for cue interpretation and evaluating the hypothesis, and determining appropriate actions. Experts may use hypothesis-testing methods when routine problem recognition fails (e.g., for an unfamiliar problem) or when they are practicing out of their area of expertise.[15, 17]

Decision making is influenced by knowledge and experience. Experts have more knowledge and experience and are able to organize, integrate, and shape information into a usable format. Their knowledge base is multidimensional; their clinical reasoning is reflective and focused; and they demonstrate increased confidence in evaluating patients and problem solving.[15] Organization of knowledge is specific and highly dependent on the mastery of a particular practice area. Content domains in physical therapy take the form of the specialty areas (orthopedic, neurological, pediatric, and so forth). As expertise increases, master clinicians increase their abilities to categorize information, improving in both mastery of depth and complexity of content. They are able to use collegial knowledge effectively, seeking out mentors and readily consulting their peers on practice issues. Novice therapists, on the other hand, collect data, but do not always recognize important data. Simple review of data and use of book-learned, declarative knowledge

do not allow the novice to recognize meaningful relationships and generate accurate hypotheses within a realistic time frame. New therapists also tend to be rigidly governed by rules for decision making. For example, they adhere to standardized frameworks (protocols), whereas experts easily adapt and refocus their approach if a different direction is indicated. Experts also demonstrate improved intervention skills that are well integrated with their mastery of knowledge and clinical reasoning. Improved skills and expertise are developed through intense, focused, and deliberate practice. Jensen et al point out that experts are highly motivated and are constantly striving to improve their skills, demonstrating a strong inner drive for lifelong learning.[18] The APTA recognizes expertise in a board-certification process for clinical specialists.

The therapist who utilizes a *receptive/systematic data-gathering style* generally suspends judgment until all possible data are gathered. The data are analyzed individually and collectively before a final determination is made of how to organize and use them. A contrasting style is perceptive and intuitive. The individual who utilizes a *perceptive data-gathering style* will seek and respond to ongoing cues and patterns, defining and organizing clinical problems early. Information processing is largely intuitive. Thus, these clinicians are able to respond to a large number of stimuli as they occur and consider initiation of early treatment options.[15] Research suggests that styles may differ by expert group. May and Dennis[19] and Jensen et al[18] found that clinicians with expertise in orthopedics tended to utilize a receptive/systematic style, generating hypotheses only after a methodical and ordered search of data. Embrey et al[16, 20] found that expert clinicians working in pediatric settings tended to utilize a perceptive data-gathering style and process information intuitively. Thus, they responded rapidly to cues and patterns (movement scripts) and changes that occurred within the treatment session. May and Dennis[19] reported that practitioners experienced in cardiopulmonary and neurological physical therapy also tended to respond more favorably to the perceptive/intuitive style. Thus, the differences noted in terms of the types of cognitive strategies reported appear to be evoked by specific problem structure and domain.

Important differences exist between expert and novice clinicians in the area of self-monitoring. Expert clinicians are able to frequently and effectively utilize self-assessment to modify and redefine their clinical decisions. This reflective aspect of practice results in improved improvisational performance, the actions that occur when therapists are actually treating patients. They are better able to control the treatment situation (i.e., constant interruptions, the demands of many scheduled patients, and multiple tasks) and the time allotted. Conversely, novice therapists demonstrate self-monitoring, but are less able to utilize the information effectively to control the situation. They react more to external stimuli and the confusion of competing demands and are less able to offer alternate intervention strategies. Self-monitoring is viewed as a positive experience by the experts twice as often as by novice therapists, an indication that the inexperienced therapists are sensitive to their limitations. The experts are also more willing to take risks and to admit when they did not know something.[15, 21]

Expert clinicians provide patient-centered care. They spend more time with their patients, gathering and evaluating information and involving their patients in collaborative problem solving. Experts maintain as a central goal of care the empowerment of their patients to make autonomous decisions. They affirm the importance of patient education in assisting patients to resolve problems and assume control over their own health care. Teaching strategies therefore focus on maintaining health and preventing the development of indirect impairments, activity limitations, and restrictions to participation. The therapist assumes active roles as coach and teacher.[10] In an era of cost containment and limited services, this is an important value and one that is essential for ensuring successful long-term outcomes. Novice therapists, on the other hand, demonstrate greater interest in mastering hands-on skills and in ensuring the success of their treatments.[17]

Expert clinicians are able to maintain focus on the patient during treatment, as evidenced in their verbal and nonverbal communications. They are able to consistently demonstrate a sense of commitment and caring toward their patients. The experts demonstrate a smooth interplay of hands-on treatment with effective communication that is responsive to the needs of each individual patient.[10, 15] Conversely, novice therapists are influenced by the demands of full-time clinical practice and experience increased challenges in finding adequate time to listen and talk with their patients. They report increased difficulties communicating with "difficult" and "unmotivated" patients.[22] Psychosocial sensitivity is a key factor in directing experienced clinicians during the physical therapy sessions. Novice therapists maintain their focus more on the problems and the mechanics of treatment rather than on the psychosocial needs of the patient.[22]

EVIDENCE-BASED PRACTICE

The analysis of research evidence paired with the physical therapist's experience and expertise provides a powerful tool to guide clinical decision making. There are areas of practice in physical therapy that lack rigorous examination and evidence. Therapists may employ some interventions simply because they are in widespread use. Therapists may also elect to use interventions because they are new and different or because they are the focus of "anecdotal testimonials" in continuing education courses. Harris points out, "The responsibility to deliver evidence-based treatment techniques rests with *all* physical therapists."[23, p. 176] To that end, the APTA developed a *Clinical Research*

Agenda designed to support, explain, and enhance physical therapy clinical practice.[24] The *Research Agenda* was revised in 2011 to be reflective of the rapid changes in health care and in rehabilitation.[25] It identifies broad categories of research and is consistent with the ICF. The APTA's *Hooked on Evidence* project provides links to *Evidence in Practice* (www.ptjournal.org) and provides training programs to assist individuals in this process.

Evidence-based medicine (EBM) is defined as "the integration of best research evidence with our clinical expertise and our patient's unique values and circumstances."[26, p. 1] The term **evidence-based practice (EBP)** encompasses a broader range of health professions.

The essential steps of EBP[26] are as follows:

Step 1: A clinical problem is identified and an answerable question is formulated.
Step 2: A systematic literature review is conducted and evidence collected.
Step 3: The research evidence is critically analyzed for its validity (closeness to the truth), impact (size of the effect), and applicability (usefulness in clinical practice).
Step 4: The critical appraisal is synthesized and integrated with the clinician's expertise and the patient's unique biology, values, and circumstances.
Step 5: The effectiveness and efficiency of the steps in the evidence-based process are evaluated.

A well-built *research question* contains three elements: (1) a specific patient/client group or population, (2) the specific interventions or exposures to be studied, and (3) the outcomes achieved. For example, one study examined interventions commonly applied for low back pain (therapeutic exercise, transcutaneous electrical nerve stimulation [TENS], thermotherapy, ultrasound, massage, E-stim system, traction) using outcomes identified as being important to the patient (pain, function, patient global assessment, QOL, and return to work).[27]

Systematic review (SR) is a comprehensive examination of the literature. The researcher determines key resources to provide the evidence. These include (1) peer-reviewed and evidence-based journals, (2) online services (e.g., Cochrane Reviews, APTA Open Door, PEDro), and (3) search engines (e.g., PubMed). Box 1.9 provides a brief list of electronic medical databases. Specific criteria are developed for the inclusion and exclusion of the research studies selected for review. Studies employing different designs may be analyzed individually or compared qualitatively; studies of similar design may be combined quantitatively (e.g., meta-analysis).

Critical analysis of research findings involves detailed examination of methodology, results, and conclusions. The clinician should be able to answer the following questions: (1) What is the level of evidence? (2) Is the evidence valid? and (3) Are the results important and clinically relevant? Thus, interpretation and synthesis of the evidence must be considered within the context of the specific patient/client problem. Examination begins with the purpose of the study, which should be clearly stated, and the review of literature, which should be relevant in terms of the specific question asked. The

methods/design should be closely examined. Research design varies and can be evaluated in terms of levels of evidence, with grades of recommendation in order of most to least rigorous (Table 1.2). Although a randomized clinical trial (RCT) provides the most rigorous design, there are times when other designs are indicated. For example, there may be ethical issues involving control groups that receive no treatment when treatment is clearly beneficial. In addition, when outcomes are not clearly understood or defined (e.g., quality-of-life issues), designs such as single-case studies may be indicated. The reader is referred to Appendix 1-C: Overview of Evidence-Based Practice Concepts for additional discussion.

Critical Appraisal Tools (CATs) are available to assist the inexperienced clinician in the evaluation of research (see Law, Appendix A: Critical Review Form, Quantitative Studies[28, p. 331]; and Jewell, Appendix B: Evidence Appraisal Worksheets).[29, p. 427] Clinicians also need to utilize effective strategies to organize and store the data and to update data on a regular basis. Reference management systems such as *Endnote* and *Reference Manager* (ISI ResearchSoft, 800 Jones Street, Berkeley, CA 94710) are available to assist the therapist.

Evidence-based clinical practice guidelines (EBCPGs) are defined by the Institute of Medicine as systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances.[30] They are developed through a combination of (1) expert consensus (e.g., the *Guide to Physical Therapist Practice*[5]); (2) systematic reviews and meta-analysis; and (3) analysis of patient preferences combined with outcome-based guidelines. For example, the *Philadelphia Panel* is a multidisciplinary, international panel of rehabilitation experts comprising a group of Clinical Specialty Experts from the United States and the Ottawa Methods Group from Canada. This panel developed a structured and rigorous methodology to formulate evidence-based practice guidelines.[31] For example, the panel analyzed the evidence following a structured and rigorous review of selected interventions for low back pain.[27] The evidence was then translated into EBCPGs by reviewing key outcomes and deciding whether the intervention had clinical benefit. Categories of absolute and relative benefit were used. The panel established a clinical improvement of 15% or more relative to the control as an acceptable level of evidence. Recommendations were graded based on levels (methodological quality) of the studies. Grade A or B recommendations were required to demonstrate clinically important changes and statistical significance. The panel's positive recommendations were then sent to 324 clinical practitioners for their feedback. The panel reviewed practitioners' feedback and revised their recommendations accordingly. In the low back pain study, the panel recommended the following EBCPGs: (1) the use of therapeutic exercises for chronic, subacute, and post-surgery low back pain and (2) continuation of normal activities for acute low back pain. The panel found lack of evidence regarding efficacy for the use of other interventions (e.g., thermotherapy, therapeutic ultrasound, massage, electrical stimulation). EBCPGs have

Table 1.2 Levels of Evidence for Treatment Effectiveness

Level 1	SR[a] of a number of RCTs[b] of studies (meta-analysis) that substantially agree (do not have significant statistical variation)
Level 2	Individual RCT with narrow confidence window (size of treatment effect precisely defined) Observational study with dramatic effect[c]
Level 3	Nonrandomized controlled cohort study[d]
Level 4	Case-control,[e] case-series,[f] or historically controlled studies
Level 5	Mechanism-based reasoning (expert opinion)

a. SR, systematic review: a review in which the primary studies are summarized, critically appraised, and statistically combined; usually quantitative in nature with specific inclusion/exclusion criteria.
b. RCT, randomized controlled trial: an experimental study in which participants are randomly assigned to either an experimental or control group to receive different interventions or a placebo; the most rigorous study design.
c. All-or-none study: a study in which treatment produces a dramatic change in outcomes; all patients die before treatment; none die after treatment.
d. Cohort study: a prospective (forward-in-time) study; a group of participants (cohort) with a similar condition receives an intervention and is followed over time and outcome evaluated; comparison is made to a matched group who do receive the intervention (quasi-experimental with no randomization).
e. Case-control study: a retrospective study in which a group of subjects with a condition of interest are identified for research after outcomes are achieved; e.g., studying the impact of an intervention on level of participation; a comparison group is used.
f. Case series: clinical outcomes are evaluated of a single group of patients with a similar condition.

Adapted from OCEBM Levels of Evidence Working Group—Jeremy Howick, Iain Chalmers (James Lind Library), Paul Glasziou, Trish Greenhalgh, Carl Heneghan, Alessandro Liberati, Ivan Moschetti, Bob Phillips, Hazel Thornton, Olive Goddard, and Mary Hodgkinson: The Oxford 2011 Levels of Evidence. Oxford Centre for Evidence-Based Medicine. Retrieved from www.cebm.net/index.aspx?o=5653.

been published for rehabilitation of patients with the following conditions:

- Low back pain[27]
- Knee pain[32]
- Knee pain and mobility impairments: meniscal and articular cartilage lesions[33]
- Hip pain and mobility impairments: osteoarthritis[34]
- Heel pain: plantar fasciitis[35]
- Neck pain[36]
- Shoulder pain[37]
- Fibromyalgia[38, 39]

According to Rothstein, these studies are clinically important in that they "are not telling us what is known and what is not known, but what is supported by evidence and what is not supported by evidence."[40, p. 1,620] The guidelines provide a summation of best possible evidence for use in clinical practice.

SUMMARY

An organized process of clinical decision making allows the therapist to systematically plan effective treatments. The steps identified in the patient/client management process are (1) examine the patient, and collect data through history, systems review, and tests and measures; (2) evaluate the data and identify problems; (3) determine the diagnosis; (4) determine the prognosis and POC; (5) implement the POC; and (6) reexamine the patient and evaluate treatment outcomes. Patient participation in planning is essential in ensuring successful outcomes. Evidence-based practice allows the therapist to select interventions that have been shown to provide meaningful change in patient's lives. Inherent to the therapist's success in this process are an appropriate knowledge base and experience, cognitive processing strategies, self-monitoring strategies, and communication and teaching skills. Documentation is an essential requirement for effective communication among the rehabilitation team members and for timely reimbursement of services.

Questions for Review

1. What are the key steps in patient/client management?
2. Differentiate between impairments, activity limitations, and participation restrictions. Define and give an example of each.
3. What are the essential elements of goal and outcome statements? Write two examples of each.
4. Differentiate between restorative and compensatory interventions. Give an example of each.
5. What is the FITT equation? Give an example of how is it used in formulating interventions for a POC.
6. What are the advantages of electronic documentation systems? Disadvantages?
7. What are the elements of a well-built research question? Give an example. What is the highest level of evidence available for evidence-based clinical practice guidelines?

CASE STUDY

PRESENT HISTORY

The patient is a 78-year-old woman who tripped and fell at home ascending the stairs outside the front door. She was admitted to the hospital after sustaining a transcervical, intracapsular fracture of the right femur. The patient had an open reduction and internal fixation (ORIF) procedure of the right lower extremity (RLE) to reduce and pin the fracture. After 2 weeks of acute hospital admission, the patient is at home and referred for home care physical therapy.

PAST MEDICAL HISTORY

Patient is a very thin woman (98 pounds) with long-standing problems with osteoporosis (on medication for 5 years). She has a history of falls, three in the last year alone. Approximately 3 years ago she had a myocardial infarction and presented with third-degree heart block, requiring implantation of a permanent pacemaker. She underwent cataract surgery with lens implantation in the right eye 2 years ago; the left eye is scheduled for similar surgery within the next few months.

MEDICAL DIAGNOSES

Coronary artery disease (CAD), hypertension (HTN), mitral valve prolapse, s/p permanent heart pacer, s/p right cataract with implant, osteoporosis (moderate to severe in the spine, hips, and pelvis), osteoarthritis with mild pain in right knee, s/p left elbow fracture (1 year ago), left ankle fracture (2 years ago), urinary stress incontinence.

MEDICATIONS

Fosamax 70 mg weekly
Atenolol 24 mg PO qd
MVI (multivitamin concentrate) with Fe tab PO qd
Metamucil 1 tbs prn PO qd, Colace 100 mg PO bid
Tylenol No. 3 tab prn/mild pain

SOCIAL SUPPORT/ENVIRONMENT

The patient is a retired schoolteacher who was recently widowed after 48 years of marriage. She has two sons, one daughter, and four grandchildren; all live within an hour's driving distance. One of her children visits every weekend. She has a rambunctious black Labrador puppy that is 8 months old and was given to her "for company" at the time her husband died. She was walking the dog at the time of the accident. She is an active participant in a garden club, which meets twice a month, and in weekly events at the local senior center. Previously she was driving her car for all community activities.

She lives alone in a large old New England farmhouse. Her home has an entry with four stairs and no rail. Inside there are 14 rooms on two floors. The downstairs living area has a step down into the family room with no rail. There are 14 stairs to the second floor, with rails on either side. The upstairs sleeping area is cluttered with large, heavy furniture. The second floor bathroom is small, with a high old tub with pedestal feet and a lip. There is no added equipment.

PHYSICAL THERAPY EXAMINATION

1. Mental status
   - Alert and oriented × 3
   - Pleasant, cooperative, articulate
   - No apparent memory deficits
   - Good problem solving and safety awareness about hip precautions
2. Cardiopulmonary status
   - Pulse 74; BP 110/75
   - Endurance: good; min SOB with 20 min of activity
3. Sensation
   - Vision: wears glasses; cloudy vision L eye; impaired depth perception
   - Hearing: WFL
   - Sensation: BLEs intact
4. Skin
   - Incision is healed and well approximated
   - Wears bilateral TEDs q a.m. × 6 wks
5. ROM
   - LLE, BUEs: WFL
   - Affected RLE:
     - Flex 0° to 85°
     - Ext NT
     - Abd 0° to 20°
     - Add NT
     - IR, ER NT
     - Right knee and ankle WFL

6. Strength
   LLE, BUEs: WFL
   Affected RLE:
      Hip flex NT (not tested)
      Hip ext NT
      Hip abd NT
      Knee ext 4/5
      Ankle DF 4/5, PF 4/5
7. Posture
   Flexed, stooped posture: moderate kyphosis, flexed hips and knees
   $^1/_2$-inch leg length shortening on RLE; uses wedge when sitting
   Mild resting head tremor
8. Balance
   Sitting balance: WFL
   Standing balance:
      Eyes open: good; leans slightly to left side
      Eyes closed: unsteady, begins to fall
   Arises from chair without help, some initial unsteadiness; sitting down: safe, smooth motion
   Uses 2-inch foam cushions to elevate seat of kitchen chair and living room chair
9. Functional status
   Patient was completely independent (I) before her fall.
   Results of functional examination:
   I bed mobility
   I transfers; unable to do tub transfers at present
   I ambulation with standard walker × 200 feet on level surfaces, partial weight-bearing RLE
      Increased flexion of knees and dorsal spine
   I one flight of stairs with rail and SBQC
   I dressing; requires minimal assist (MinA) of home health aide for sponge baths
   Requires moderate assistance (ModA) of home health aide for homemaker activities
10. Patient is highly motivated
   "I want to get my life back together, get my dog home again so I can take care of him."

PRIMARY INSURANCE

Medicare

Guiding Questions

1. Develop a prioritized problem list for this patient's POC. Identify and categorize the patient's impairments (direct, indirect, composite). Identify her activity limitations and participation restrictions.
2. What information is available about her functional status within the home in terms of performance versus capacity qualifiers?
3. What is her rehabilitation prognosis?
4. Write two expected outcome and two goal statements to direct her POC.
5. Identify two treatment interventions for her POC.
6. What precautions should be observed?
7. What tests and measures can be used to determine successful attainment of outcomes?

Pattern D: Impaired Integumentary Integrity Associated With Full-Thickness Skin Involvement and Scar Formation

Pattern E: Impaired Integumentary Integrity Associated With Skin

Defensible Documentation—General Documentation Guidelines From APTA

appendix 1.B

Documentation is required for every visit/encounter.

Documentation should include indication of a patient/client's cancellations of appointments and/or refusal of treatment.

All documentation must comply with the applicable jurisdictional/regulatory requirements.

All handwritten entries shall be made in ink, dated, and properly authenticated. Legibility is critical in clinical documentation. If an entry cannot be read, it cannot be understood.

Electronic entries are made with appropriate security and confidentiality provisions.

Documentation must include adequate identification of the patient/client, the physical therapist, and/or physical therapist assistant:

- The patient/client's full name and identification number, if applicable, must be included on all official documents.
- All entries must be dated and authenticated with the provider's full name and appropriate designation (license number and printed name if required by state law).

Charting errors should be corrected by drawing a single line through the error and initialing and dating the error or through the appropriate mechanism for electronic documentation that clearly indicates that a change was made without deletion of the original record. *Example:* Pain in the right shoulder will decrease to 2/10 VAS within 5 4ABD 11/2/06 visits.

Documentation of examination, evaluation, diagnosis, prognosis, plan of care, progress report, and discharge summary must be authenticated by the physical therapist who provided the service.

Documentation of physical therapist service in pediatrics is aligned with family-centered care.

Documentation should emphasize the functional abilities of the child rather than highlight the deficits and should be written in a respectful manner. Therapists often collaborate with the family, child, and other team members on the documentation and record their involvement in the physical therapy services.

Abbreviations should be minimized.

Documentation must be clear about who is providing the service whether it is the physical therapist (PT), the physical therapist assistant (PTA), or both when the PT may perform mobilization and the PTA may perform therapeutic exercises with the same patient/client.

Documentation of intervention in visit/encounter notes must be authenticated by the PT or PTA who provided the service. Medicare requires handwritten signatures or electronic signatures only. Stamp signatures are not acceptable.

Documentation by PTs, PTA graduates, or others pending receipt of an unrestricted license shall be authenticated by a licensed physical therapist, or, when permissible by state law; documentation by PTA graduates may be authenticated by a PTA.

Documentation by students (SPT/SPTA) in PT or PTA programs must be additionally authenticated by the PT or, when permissible by state law, documentation by PTA students may be authenticated by a PTA. The following link provides information regarding student documentation/billing requirements: www.apta.org/Payment/Medicare/Supervision.

Documentation should include the referral mechanism by which physical therapy services are initiated. Examples include the following:

- Direct access when permissible by state law.
- Request for consultation from another practitioner.
- Referral from practitioner authorized to refer per Medicare regulations or state practice act.

From American Physical Therapy Association, with permission. Retrieved November 7, 2011, from www.apta.org/Documentation/DefensibleDocumentation. Last updated March 10, 2011.

1.C

Overview of Evidence-Based Practice Concepts

Prepared by Kevin K. Chui, PT, PhD, GCS, OCS

1. Sensitivity and Specificity

As evidence-based diagnosticians, physical therapists need to consider the accuracy of diagnostic tests.[1] When establishing the accuracy (clinometric properties) of a novel diagnostic test against a reference standard (i.e., the best available examination, which may be a laboratory or clinical test), there are four possible outcomes:

		Reference Standard: Positive	Reference Standard: Negative
Novel Diagnostic Test	Positive	True Positive	False Positive
	Negative	False Negative	True Negative

- A *true positive (TP),* in which the diagnostic test and the reference standard are both positive
- A *false negative (FN),* in which the diagnostic test is negative and the reference standard is positive
- A *true negative (TN),* in which the diagnostic test and the reference standard are both negative
- A *false positive (FP),* in which the diagnostic test is positive and the reference standard is negative

These outcomes are then used to calculate the probability that test results are correct, that is, the sensitivity and specificity of a diagnostic test.

The *sensitivity*, or the TP rate (= TP/TP + FN), refers to the ability of a diagnostic test to identify the condition when it is present. Based on the formula used to calculate sensitivity, there is an inverse relationship between the TP and FN rates. That is, as the TP rate increases (i.e., sensitivity increases), the FN rate will decrease. Therefore, a test that is highly sensitive will have a high TP rate and a low FN rate and can be used to rule out the condition when the test result is negative.

In contrast, the *specificity,* or the TN rate (= TN/TN + FP), refers to the ability of a diagnostic test to identify when the condition is absent. Based on the formula used to calculate specificity, there is an inverse relationship between the TN and FP rates. That is, as the TN rate increases (i.e., specificity increases), the FP rate will decrease. Therefore, a test that is highly specific will have a high TN rate and a low FP rate and can be used to rule in the condition when the test result is positive.

To assist practitioners when selecting and using diagnostic tests, Sackett et al[2] suggested the acronyms "SnNout" and "SpPin." For a highly sensitive (Sn) diagnostic test, a negative (N) finding can be used to rule out (out) the condition, hence SnNout. And for a highly specific (Sp) diagnostic test, a positive (P) finding can be used to rule in (in) the condition, hence SpPin.

2. Likelihood Ratios

The sensitivity and specificity values (i.e., the probability that test results are correct) of a diagnostic test can then be used to calculate likelihood ratios, which quantify the shift in pre-test probability (estimated from other examination findings or prevalence data) to post-test probability that the patient has the condition. Given a positive diagnostic test result, a *positive likelihood ratio* (= sensitivity/1 − specificity) quantifies the increase in pre-test to post-test probability that the patient has the condition. On the other hand, given a negative diagnostic test result, a *negative likelihood ratio* (= 1 − sensitivity/specificity) quantifies the decrease in pre-test to post-test probability that the patient has the condition.

To be clear, whether the diagnostic test is positive or negative and the corresponding positive or negative likelihood ratio is used, the likelihood ratio helps to quantify the probability that the patient has the condition. A likelihood ratio of 1 results in no shift in pre-test to post-test probability (i.e., the probability that the patient has the condition remains the same). As positive likelihood ratios start to exceed 1, the shift in pre-test to post-test probability increases (i.e., the probability that the patient has the condition increases). As negative likelihood ratios start to approach 0, the shift in pre-test to post-test probability decreases (i.e., the probability that the patient has the condition decreases).

Guyatt and Rennie[3] suggest useful guidelines for interpreting likelihood ratios:

- Likelihood ratios >10 or <0.1 result in large and often conclusive shifts in pre-test to post-test probabilities.

- Likelihood ratios of 5–10 or 0.1–0.2 result in moderate shifts in pre-test to post-test probabilities.
- Likelihood ratios of 2–5 or 0.5–0.2 result in small shifts in pre-test to post-test probabilities.
- Likelihood ratios of 1–2 or 0.5–1 result in shifts in pre-test to post-test probabilities that are rarely important.

The nomogram by Fagan[4] can assist practitioners in calculating the post-test probability with knowledge of the pre-test probability and the likelihood ratio.

For example, a study by Wainner et al[5] developed a clinical prediction rule to diagnose cervical radiculopathy. The corresponding positive likelihood ratio for a patient that tested positive on three out of the four items from the cluster is 6.1. Given a pre-test probability of 23% and a positive likelihood ratio of 6.1, the nomogram is then used to calculate a post-test probability of 65% for having cervical radiculopathy.

3. Clinical Decision or Prediction Rules

Clinical prediction (or decision) rules are tools designed to help practitioners with diagnosis and prognosis.[6] These tools identify a parsimonious list of predictor variables from the examination (e.g., history, systems review, and tests and measures) to diagnose a condition or prognosticate which patients are likely to recover, respond to treatment, or become chronic. For example, there are clinical prediction rules to help practitioners identify those at risk for lower and upper extremity deep vein thrombosis, those likely to respond to exercise, and those likely to develop persistent shoulder pain.[7] Furthermore, these clinical prediction rules have documented sensitivity, specificity, and likelihood values to assist the practitioner in interpreting results.

One frequently cited clinical prediction rule, the Wells Clinical Prediction Rule for Lower Extremity Deep Vein Thrombosis, has undergone extensive validation testing and impact analysis.[8,9] For this clinical prediction rule, there are nine criteria:

1. Active cancer (within 6 months of diagnosis or palliative care)
2. Paralysis, paresis, or recent plaster immobilization of lower extremity
3. Recently bedridden 3 days or major surgery within 4 weeks of application of clinical decision rule
4. Localized tenderness along distribution of the deep venous system
5. Entire lower-extremity swelling
6. Calf swelling by 3 cm compared with asymptomatic lower extremity
7. Pitting edema (greater in the symptomatic lower extremity)
8. Collateral superficial veins (non-varicose)
9. Alternative diagnosis as likely or greater than that of deep vein thrombosis

One point is added to the total score for each of the first eight criteria present, and 2 points are deducted from the total score if the ninth criterion is applicable. Low, moderate, and high risks for lower extremity deep vein thrombosis correspond to scores of ≤ 0, 1–2 points, and ≥ 3 points, respectively.

4. Outcome Measures

Outcome measures are standardized tests, measures, or instruments used to measure various aspects of a patient's health status.[10] Results from outcome measures can be used for patient care decisions, research, and quality assurance. Despite the growing body of evidence to support their use, outcome measures remain underutilized by physical therapists.[11,12] What follows is a review of considerations that the evidence-based practitioner must evaluate when selecting an appropriate outcome measure for their patient. These considerations include dimension, type, format, reliability, validity, responsiveness, and feasibility.[13,14]

Dimension

The *dimension* of an outcome measure refers to different aspects of health status, such as body structure and function, activity, and participation, which are examined by the outcome measure. Some outcome measures examine multiple dimensions, whereas others may focus on a particular dimension. Also, many *types* of outcome measures have been developed, such as those that are region specific (e.g., Lower Extremity Functional Scale),[15] disease, or condition specific (e.g., Western Ontario and McMaster Universities Arthritis Index),[16] patient specific (e.g., Patient Specific Functional Scale),[17] or global (e.g., Global Rating of Change).[18]

Format

The *format* of an outcome measure can be either self-reported or performance-based. For self-reported outcome measures, patients respond verbally or in writing about their self-perception of some aspect of their health status. For example, the SF-36 is a questionnaire that includes items addressing physical function, social function, role function, mental health, energy/fatigue, pain, and general health perception.[19] In contrast, performance-based measures require patients to perform a task that is graded by the physical therapist. One example of a performance-based outcome measure is the Functional Independence Measure,[20] which requires the patient to demonstrate self-care activities, transfers, locomotion, and bowel and bladder function.

Reliability

The *reliability* of an outcome measure refers to its consistency or reproducibility.[21] As the reliability increases, the amount of error inherent in the measurement decreases. There are different types of reliability that affect outcome measures. *Test-retest* refers to the stability of measurements over time. Assuming that the patient's health status has not changed, repeated administrations of an outcome measure should result in the same score. *Intratester* and *intertester* reliability refers to consistency of repeated measures obtained by the same practitioner or between two practitioners, respectively. The test-retest, intratester, and intertester reliability of continuous level data is calculated using *intraclass correlation coefficients,* whereas the *kappa coefficient* is used for categorical level data. Last, the *internal consistency* refers to the degree in which similar items on an outcome measure yield similar scores and is represented by *Chronbach's alpha*.

Validity

Validity, in the context of outcome measures, is the degree to which an outcome measure is measuring what it purports to measure,[21] for example, the degree to which the Berg Balance Scale[22] is actually measuring balance. There are four basic types of validity: face, content, criterion-related, and construct. If the instrument appears to reasonably measure what it purports to measure and makes sense to the patient and practitioner, it is said to have *face validity*. *Content validity* refers to the degree to which items on an outcome measure reflect the relevant dimensions of what is being measured. *Criterion-related validity* refers to the relationship between an outcome measure and a criterion test (i.e., another measure that has already been demonstrated to be valid), both of which should be measuring the same thing. *Construct validity* refers to the degree to which a theoretical concept is measured by an outcome measure.

The *responsiveness* of an outcome measure refers to its ability to accurately detect a change or difference when it has occurred.[23,24] Commonly reported indexes of responsiveness include the *standard error of the measurement (SEM), minimal detectable change (MDC),* and *minimal clinically important difference (MCID)*.[25] The SEM is a measure of response stability and is related to measurement error. The SEM is used to calculate the MDC, which is the smallest amount of change that is not likely to be due to error in the measurement. The MCID is the smallest amount of change in an outcome measure that the patient perceives to be beneficial. Practitioners should use these indexes of responsiveness when determining if meaningful change occurred on an outcome measure.

Another important consideration when selecting an outcome measure is its *feasibility*.[13,14] Physical therapists must consider the time, space, equipment, training required, cost (e.g., proprietary issues), and accessibility, among other considerations, associated with administering an outcome measure. Furthermore, practitioners should consider the ease with which scores are calculated for an outcome measure.

In this brief review, evidence-based concepts important to the clinical decision making process and progression through the steps of patient management have been discussed. The concepts of specificity, sensitivity, and likelihood ratios have been explained. Both diagnosis and prognosis can be informed by clinical prediction rules, and outcome measures can be used to measure the health status of patients and the effectiveness of physical therapy interventions.

Chapter 2

Examination of Vital Signs

Thomas J. Schmitz, PT, PhD

LEARNING OBJECTIVES

1. Discuss the rationale for including vital sign measures in the patient examination.
2. Explain the relevance of vital signs data to assigning a diagnostic label, determining the prognosis, and establishing a plan of care.
3. Recognize the importance of vital signs data in determining physiological response to treatment and evaluating patient progress.
4. Describe the procedure for monitoring temperature, pulse, respiration, blood pressure, and hemoglobin oxygenation.
5. Differentiate between normal and abnormal values or ranges for each vital sign.
6. Identify the normative variations in vital signs and the factors that influence these changes.
7. Explain the rationale for using pulse oximetry in the presence of unstable hemoglobin oxygenation levels.
8. Describe the recommended elements for documentation of vital signs data.

CHAPTER OUTLINE

NORMATIVE VITAL SIGN DATA *31*
ALTERATIONS IN VITAL SIGN VALUES: OVERVIEW OF INFLUENTIAL VARIABLES *34*

RESOURCES *79*
SUMMARY *79*

Examination of body temperature, heart (pulse) rate (HR), respiratory rate (RR), and blood pressure (BP) provides the physical therapist with important data about the status of the cardiovascular/pulmonary system. Owing to their importance as indicators of the body's physiological status and response to physical activity, environmental conditions, and emotional stressors, they are collectively referred to as **vital signs**. Because many important clinical decisions are based in part on these measures, accuracy is essential.

The *Guide to Physical Therapist Practice* includes examination of vital signs (HR, RR, and BP) in the cardiovascular/pulmonary systems review for each of the four major categories of practice patterns. Vital signs are also identified among the tests and measures used to characterize or quantify circulatory status. Pulse oximetry is included in the ventilation and respiration/gas exchange category of tests and measures for each of the cardiovascular/pulmonary practice patterns.[1] Although not considered a primary vital sign, **pulse oximetry** is an important related measure that provides information on arterial blood (hemoglobin) oxygen saturation levels. Pulse oximetry data allow the therapist to screen and monitor for *hypoxemia* (decreased oxygen concentrations of atrial blood). Hypoxemia is often associated with pulmonary disorders that impair ventilation of the lungs (e.g., pneumonia, chronic obstructive pulmonary disease [COPD], anemia, respiratory muscle weakness, and circulatory impairments).

Also referred to as *cardinal signs,* vital signs provide quantitative measures of the status of the cardiovascular/pulmonary system and reflect the function of internal organs. Variations in vital signs are a clear indicator that some change in the patient's physiological status has occurred. Taken at rest and during and after exercise, these measures also provide important data on aerobic

capacity and endurance. Together with other examination data, vital sign measures assist the physical therapist in making clinical judgments to do the following:[1]

1. Assign a diagnostic label and classify patient findings within a specific practice pattern.
2. Determine the prognosis and plan of care (POC), including identification of anticipated goals and expected outcomes, and selection of specific interventions.
3. Evaluate patient progress through reexamination at periodic intervals during an episode of care.
4. Evaluate the effectiveness of selected interventions in achieving anticipated goals and expected outcomes (changes in impairment, activity limitations, and disabilities and changes in health, wellness, and fitness).
5. Determine if a referral to another practitioner is warranted.

The physical therapist's clinical decision making will determine which vital signs should be measured and the frequency of measurement for an individual patient within a specific context (e.g., self-paced ambulation on level surfaces vs. stair climbing). Although taking vital sign measures may be delegated to a physical therapist assistant (PTA) or other support personnel, the physical therapist will evaluate and determine the significance of the data.

NORMATIVE VITAL SIGN DATA

Multiple resources provide normal vital signs values across age groups. Normative data are typically presented as averages or as a range of values for the age group from which they were derived; using a range reflects the variability of values designated as normal. Tables 2.1 and 2.2 are examples of normative vital signs data presented by age using ranges (Table 2.1) and a combination of averages and ranges (Table 2.2).[2,3]

Table 2.1 Comparison of Normal Vital Signs for Various Ages Reported as Ranges

Age	Temperature °F (°C)	Pulse Rate	Respiratory Rate	Blood Pressure (mm Hg)
Newborn	98.6-99.8 (37-37.7)	120-160	30-80	Systolic: 50-52 Diastolic: 25-30 Mean: 35-40
3 yr	98.5-99.5 (36.9-37.5)	80-125	20-30	Systolic: 78-114 Diastolic: 46-78
10 yr	97.5-98.6 (36.3-37)	70-110	16-22	Systolic: 90-132 Diastolic: 5-86
16 yr	97.6-98.8 (36.4-37.1)	55-100	15-20	Systolic: 104-108 Diastolic: 60-92
Adult	96.8-99.5 (36-37.5)	60-100	12-20	Systolic: <120 Diastolic: <80
Older adult	96.5-97.5 (35.9-36.3)	60-100	15-25	Systolic: <120 Diastolic: <80

From Dillon,[2] with permission.

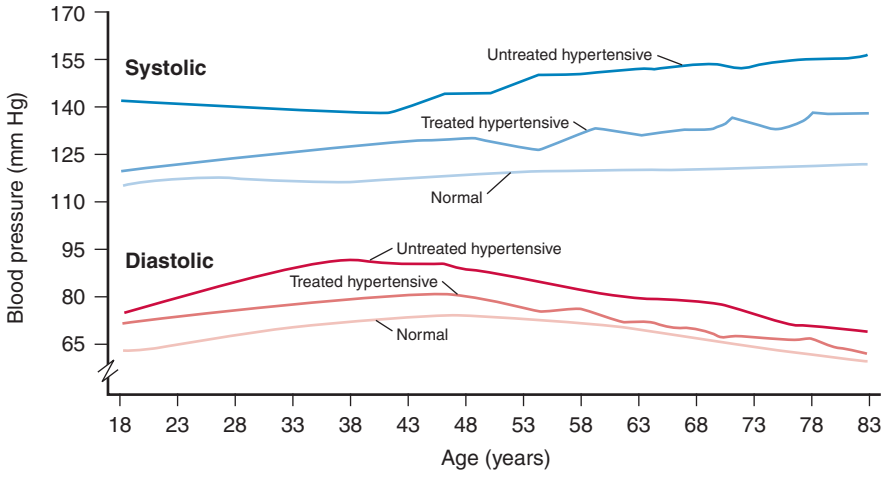
Table 2.2 Comparison of Normal Vital Signs for Various Ages Reported Using a Combination of Averages and Ranges

Age	Temperature Average °F (°C)	Pulse Average (Range) beats per min	Respirations Range breaths per min	Blood Pressure Average mm Hg
Newborn	98.2 (36.8) axillary	120 (70-170)	40-90	80/40
1 to 3 years	99.9 (37.7) rectal	110 (80-130)	20-40	98/64
6 to 8 years	98.6 (37.0) oral	95 (70-110)	20-25	120/56
10 years	98.6 (37.0) oral	90 (70-100)	17-22	110/58
Teen	98.6 (37.0) oral	80 (55-105)	15-20	110/70
Adult	98.6 (37.0) oral	80 (60-100)	12-20	<120/80
Adult older than 70 years	96.8 (36.0) oral	80 (60-100)	12-20	120/80, up to 160/95

From Wilkinson and Van Leuven,[3] with permission.

Clinical Note: Normative vital sign data provide the physical therapist with a *general reference* for comparison during evaluation of clinical findings. It is important to remember that normative values should be used cautiously because some discrepancy exists about the boundaries of normal values.

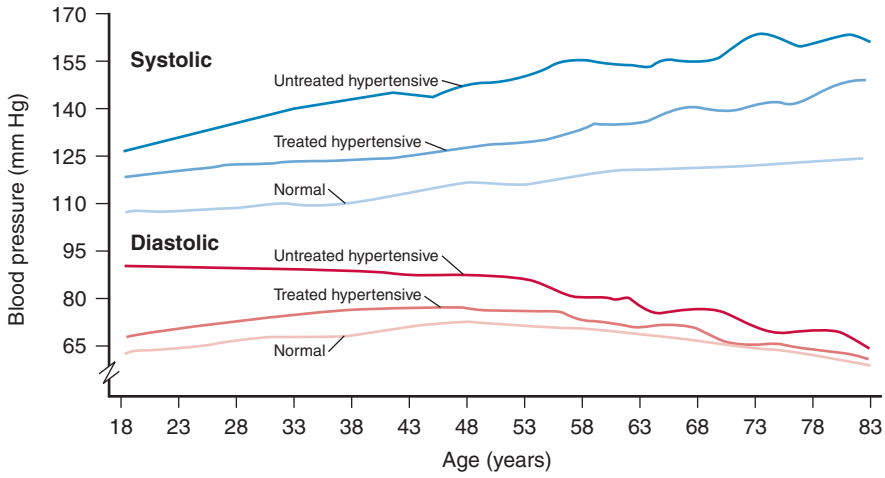
Normative BP and resting HR data are available from the National Center for Health Statistics (NCHS) Division of Health and Nutrition Examination Surveys (DHNES), part of the Centers for Disease Control and Prevention (CDC), which conducts annual National Health and Nutrition Examination Surveys (NHANES) on various health topics.[4] The NHANES 2001–2008 survey provides data on mean BP for 19,921 adults aged 18 and over.[5] Means of systolic blood pressure (SBP) and diastolic blood pressure (DBP) were reported for adults by multiple variables, including sex and hypertension status (normal, treated, and untreated). Data on mean BP values from this analysis are presented in Figure 2.1 for males and in Figure 2.2 for females. Based on the NHANES 1999–2008 survey data, mean resting HR values are also available, reported by several variables including sex and age using a sample of 35,302 people.[6] These resting pulse rate estimates are presented in Table 2.3 for males and Table 2.4 for females.



It is important to note that *normal* values are specific to an individual. Some individuals typically display values different from those represented by normative data. This illustrates the importance of monitoring vital signs as a sequential process for each patient. Vital sign measurements yield the most useful information when performed and recorded at *periodic intervals over time* as opposed to a single measurement taken at a given point in time. Serial recording allows changes in patient status or response to treatment to be monitored over time and can indicate an acute change in physiological status at a specific point in time (e.g., response to an exercise test).

On examination, initial vital sign measures may be well within normal ranges. In these circumstances, Wilkinson and Treas suggest that one should "not become complacent when a client's vital signs are within normal limits. Although stable vital signs *indicate* physiologic well-being, they do not *guarantee* it. Vital signs alone are limited in detecting some important physiologic changes; for example, vital signs may sometimes remain stable in the presence of moderately large blood loss. Vital signs must be evaluated in the context of your overall assessment of the client."[7, p. 305]

At times, an abnormally high or low value for a vital sign may be obtained. In such situations, it is important to maintain a calm professional demeanor and not adversely react to the information. As discussed later in this chapter, multiple factors can alter vital sign values, including those that are patient related (emotion, stress, excessive caffeine ingestion) and/or practitioner related (e.g., faulty positioning and measurement, incorrect blood pressure cuff size). Any abnormal values should be investigated and, if deemed appropriate, repeated to confirm accuracy.



If repeated measures are required, calmly explain to the patient that you want to verify the values obtained. Alfaro-LeFevre[8, p. 75] offers the following guidelines for validating questionable data:

- Double-check information that is extremely abnormal or inconsistent with patient cues.
- Double-check that equipment is functioning correctly.
- Recheck data obtained (e.g., take BP in opposite arm or 10 minutes later).
- Examine for factors that may alter accuracy (e.g., determine if someone with an elevated temperature and no other symptoms has just had a hot cup of coffee).
- When uncertain, ask a more experienced therapist to recheck a vital sign measure.

Figure 2.1 Mean systolic and diastolic pressure for men aged 18 years and over, by age and hypertension status. *(From Wright et al.[5])*

Source: CDC/NCHS, National Health and Nutrition Examination Survey, 2001–2008.

Figure 2.2 Mean systolic and diastolic pressure for women aged 18 years and over, by age and hypertension status. *(From Wright et al.[5])*

- Make a comparison of subjective and objective data to determine if what the patient *states* is consistent with *data obtained* (e.g., compare actual pulse rate with the patient's subjective perceptions of a "racing heart").

Although not a new idea, a *fifth* or even a *sixth* vital sign has been proposed. Perhaps the most common suggestion is adding pain intensity as a fifth vital sign. The American Pain Society (APS) advocates examination of "pain as a fifth vital sign" as a way to increase awareness, to emphasize that pain status is as important as the standard vital signs, and to focus attention on improved management strategies.[9] As part of its National Pain Management Strategy, the Veterans Health Administration (VHA) has embraced the concept of "pain as the fifth vital sign."[10] The principal goal of this strategy is to provide a single, system-wide standard level of care to minimize suffering from preventable pain, thus moving pain management to a top priority within the system. To raise awareness about critical issues, often for specific populations, the designation "5th or 6th vital sign or *newest vital sign*" has also been applied to various lifestyle factors, patient characteristics, and specific tests and measures, such as emotional stress,[11-13] pulse oximetry,[14,15] health literacy,[16,17] functional status,[18] walking speed,[19] dyspnea,[20] smoking status,[21] and continence.[22]

Table 2.3 Resting Pulse Rate Estimates for U.S. Males, by Age Group National Health and Nutrition Examination Survey, 1999–2008

Age Group (years)	*n*	Mean	SE Mean
Under 1	972	128	1.1
1	712	116	0.8
2-3	1,148	106	0.4
4-5	864	94	0.6
6-8	1,212	86	0.5
9-11	1,130	80	0.5
12-15	2,190	77	0.4
16-19	2,411	72	0.4
20-39	3,445	71	0.3
40-59	2,559	71	0.3
60-79	1,147	70	0.5
80 and over	197	71	1.1

n = sample size for each age category; SE: standard error. Data exclude persons with a current medical condition or medication use that would affect the resting pulse rate.

Table 2.4 Resting Pulse Rate Estimates for U.S. Females, by Age Group National Health and Nutrition Examination Survey, 1999–2008

Age Group (years)	*n*	Mean	SE Mean
Under 1	931	130	1
1	633	119	0.8
2-3	1,107	108	0.5
4-5	900	97	0.6
6-8	1,264	88	0.5
9-11	1,236	85	0.5
12-15	2,310	80	0.4
16-19	2,082	79	0.4
20-39	3,061	76	0.3
40-59	2,409	73	0.3
60-79	1,163	73	0.4
80 and over	219	73	0.9

n = sample size for each age category; SE: standard error. Data exclude persons with a current medical condition or medication use that would affect the resting pulse rate.

ALTERATIONS IN VITAL SIGN VALUES: OVERVIEW OF INFLUENTIAL VARIABLES

Lifestyle Patterns and Patient Characteristics

Several lifestyle patterns (modifiable) and patient characteristics (non-modifiable) influence vital sign measures. Lifestyle patterns include, but are not limited to, caffeine intake, tobacco use, diet, alcohol consumption, response to stress, obesity, physical activity level, medications, and use of illegal drugs. Patient characteristics include hormonal status, age, sex, and family history. Other variables that affect vital sign measures include time of day, time of the month (menstrual cycle), general health status, emotional distress, and pain. Information about lifestyle patterns and patient characteristics is gathered from the patient history, the systems review, and tests and measures. Factors identified as modifiable become the focus of patient-related instruction (e.g., current condition, risk factor reduction) and/or health promotion and wellness strategies. Specific factors influencing each vital sign are addressed in greater detail later in the chapter.

Culture and Ethnicity

As with any physical therapy test or measure, the influence of culture and ethnicity on vital sign measures can vary from subtle to marked. For example, a patient who appears anxious or hostile during examination of vital signs may be displaying a response to stress typically shared by others who have a deep-seated distrust of American health care practices. Another example might be a Muslim female patient who exhibits a stress reaction to being examined by a male therapist. These situations can clearly affect the accuracy of the vital sign measures. *Culture* refers to an integration of learned behaviors (not biologically inherited), norms, and symbols characteristic of a society that are passed from generation to generation.[23] It is a set of shared behavioral standards that includes fundamental values, beliefs, attitudes, and customs, including those related to health care and illness.[24-26] *Ethnicity* is defined as an affiliation with a group of people who share a common cultural origin or background, or common racial, national, religious, linguistic, or cultural characteristics.[25] Culture and ethnicity directly affect the attitudes held by an individual toward health care.[27]

Cultural competency in health care can be defined as having the appropriate knowledge and skills to deliver care consistent with a patient's cultural beliefs and practices.[26] Emphasizing the overarching importance of cultural competence, Leavitt proposes that "for physical therapy practitioners, cultural competence is an essential element in making effective and efficient examination, evaluation, diagnosis, prognosis, and intervention possible. Developing rapport, collecting and synthesizing patient data, recognizing personal functional concerns, and developing the plan of care for a particular patient requires cultural competence."[23, p. 4]

Recent demographic changes in the United States have created greater societal diversity and have heightened the need for culturally competent physical therapists. Data from the 2010 Census demonstrate the evolving diversity of cultures and ethnicities that comprise the U.S. population (Table 2.5).[28] Several salient elements of the data report include the following:

- All major race groups increased in population size between 2000 and 2010, but they grew at different rates.
- The Asian population grew faster than any other major race group between 2000 and 2010.
- More than half the growth in the total population of the United States between 2000 and 2010 was due to an increase in the Hispanic population.
- The only major race group to experience a decrease in its proportion of the total population was the "white alone" population (i.e., those reporting only one race). This group's share of the total population fell from 75% in 2000 to 72% in 2010.

Reflective of the importance of cultural competence in understanding and responding effectively to the cultural needs of patients in health care settings, the U.S. Department of Health and Human Service (USDHHS) Office of Minority Health (OMH) published *Recommended Standards for Culturally and Linguistically Appropriate Health Care Services* with input from a national advisory committee. The proposed standards are offered as guidelines for providers, policymakers, accreditation and credentialing agencies, purchasers of health benefits (including labor unions), patients, and advocates (e.g., local and national ethnic, immigrant, and other community-focused organizations), as well as educators and other members of the health care community.[29]

The American Physical Therapy Association (APTA) has addressed cultural competence in a variety of important documents, including the *Blueprint for Teaching Cultural Competence in Physical Therapy Education;*[30] in the evaluative criteria for accreditation of education programs for the preparation of physical therapists[31] and physical therapist assistant[32] education (Commission on Accreditation of Physical Therapy Education [CAPTE]); and in *A Normative Model of Physical Therapist Professional Education*[33] and *A Normative Model of Physical Therapist Assistant Education.*[34]

Burton and Ludwig[35] offer the following suggestions for interaction with a culturally diverse population:

- Address the patient using his or her surname with appropriate title (Mr., Mrs., Ms., or Miss). First names should be used only with the patient's invitation to do so.

Table 2.5 Population by Hispanic or Latino Origin and by Race for the United States: 2000 and 2010

Hispanic or Latino Origin and Race	2000 Number (% of Total Population)	2010 Number (% of Total Population)	Change, 2000 to 2010 Number (%)
Total population	281,421,906 (100.0)	308,745,538 (100)	27,323,632 (9.7)
Hispanic or Latino	35,305,818 (12.5)	50,477,594 (16.3)	15,171,776 (43.0)
Not Hispanic or Latino	246,116,088 (87.5)	258,267,944 (83.7)	12,151,856 (4.9)
• White alone	194,552,774 (69.1)	196,817,552 (63.7)	2,264,778 (1.2)
Race			
Total population	281,421,906 (100.0)	308,745,538 (100)	27,323,632 (9.7)
One race	274,595,678 (97.6)	299,736,465 (97.1)	25,140,787 (9.2)
• White	211,460,626 (75.1)	223,553,265 (72.4)	12,092,639 (5.7)
• Black or African American	34,658,190 (12.3)	38,929,319 (12.6)	4,271,129 (12.3)
• American Indian and Alaska Native	2,475,956 (0.9)	2,932,248 (0.9)	456,292 (18.4)
• Asian	10,242,998 (3.6)	14,674,252 (4.8)	4,431,254 (43.3)
• Native Hawaiian and other Pacific Islander	398,835 (0.1)	540,013 (0.2)	141,178 (35.4)
• Some Other Race	15,359,073 (5.5)	19,107,368 (6.2)	3,748,295 (24.4)
Two or More Races*	6,826,228 (2.4)	9,009,073 (2.9)	2,182,845 (32.0)

From U.S. Census Bureau.[28]

*In Census 2000, an error in data processing resulted in an overstatement of the Two or More Races population by about 1 million people (about 15%) nationally, which almost entirely affected race combinations involving Some Other Race. Therefore, data users should assess observed changes in the Two or More Races population and race combinations involving Some Other Race between Census 2000 and the 2010 Census with caution. Changes in specific race combinations not involving Some Other Race, such as White *and* Black or African American or White *and* Asian, generally should be more comparable. (For information on confidentiality protection, nonsampling error, and definitions, see www.census.gov/prod/cen2010/doc/pl94-171.pdf.)

Sources: U.S. Census Bureau, *Census 2000 Redistricting Data (Public Law 94-171) Summary File,* Tables PL1 and PL2, and *2010 Census Redistricting Data (Public Law 94-171) Summary File,* Tables P1 and P2.

- Respect the individual's beliefs and attitudes regarding health care, traditions, and religion.
- Use common proper English; slang terms should be avoided.
- If a language barrier exists, an interpreter should be used (preferably not a family member).
- Eye contact should be used cautiously; some cultures perceive eye contact as disrespectful or a challenge to authority.
- Direct attention to the patient's facial expressions and nonverbal communication, because this may provide clues that your communication is not being understood.
- Seek clarification if you do not understand something that the patient has said.

Cultural competency is addressed in an expanding body of literature. For further examination of the impact of cultural diversity in health care, the reader is referred to the work of Leavitt,[23] Spector,[27] Purnell and Paulanka,[26,36] Galanti,[37] Perez and Luquis,[38] Srivastava,[39] and Kosoko-Lasaki, Cook, and O'Brien.[40]

PATIENT OBSERVATION

Observation refers to the deliberate use of the senses (vision, hearing, smell) to gather information about the patient.[7,8] Observation alone will not provide definitive diagnostic information, nor will it allow one to draw conclusions or inferences[35]; however, observation may provide clues to underlying problems,[2] inform development of well-structured impairment-specific questions during history taking, guide selection of screening examinations, and assist with prioritizing tests and measurements.[41]

Using a logical, consistent sequence will create a systematic approach to observation (e.g., first facial expression and overall appearance, then any immediate signs of pain or distress, skin condition, and so forth). This will improve efficiency, conserve time,

and help ensure that no areas are overlooked. Several examples follow of the types of information and/or clues to underlying problems that may be gathered via observation.

- Signs of immediate patient distress or discomfort (e.g., pain, grimacing, difficulty breathing) are typically evident by observation of facial expressions, use of accessory muscles for breathing, an irregular or labored breathing pattern, and frequent positional changes. Use of accessory muscles of breathing may be indicative of cardiac or pulmonary impairments.
- Obesity or the presence of **cachexia** (a state of ill health), the appearance of malnutrition, or wasting associated with many chronic diseases may indicate clues about nutritional status. Central obesity (trunk and face) and fat pads near the collarbone and the back of the neck may be associated with Cushing's syndrome.
- *Diaphoresis* (profuse perspiration) may indicate that the body is working to compensate for a reduced cardiac output. It is associated with a variety of potential causes, including myocardial infarct, **hypotension,** and shock; it may also be associated with hyperthermia (e.g., faulty thermoregulation), thyroid hyperactivity, anxiety, and overactive sweat glands. Excessive sweating may also be related to environmental conditions or patient participation in strenuous physical activity prior to visit. The term *hyperhidrosis* also refers to abnormally increased perspiration.
- A disagreeable body odor may suggest poor hygiene (e.g., impaired self-care abilities or lack of resources) or the presence of a wound (e.g., infected drainage) or underlying disease[7]; a fruity breath smell may be suggestive of high blood glucose or diabetic ketoacidosis.[41]
- Various sounds of respiration may be heard, such as wheezing, crackles, or sighs (discussed later in this chapter and in Chapter 12: Chronic Pulmonary Dysfunction). Potential considerations include a narrowed airway (e.g., asthma, congestive heart failure [CHF], tracheal stenosis), COPD, presence of foreign object, or secretions partially blocking an airway.
- The presence of a cough may be caused by a relatively benign airway irritant (e.g., dust particles) or may indicate the presence of a disease such as asthma, bronchitis, COPD, lung cancer, or pneumonia. An acute cough typically resolves within 3 weeks or less (e.g., upper respiratory tract infection). A chronic or persistent cough lasts more than 8 weeks.[42]
- Asymmetry of body parts at rest and during movement may suggest atrophy, hypertrophy, impaired motor function, or underlying disease (e.g., cerebral vascular accident [CVA]). Facial features should also be observed for symmetry.[2,43]
- The skin is the largest organ of the body; observation of skin color provides important preliminary data about the efficiency of the cardiovascular/pulmonary system and may be an indicator of disease, inflammation, and infection.[35,41] **Cyanosis** is a bluish-gray discoloration associated with inadequate oxygenation of the blood (i.e., hemoglobin does not contain normal levels of oxygen). **Central cyanosis** causes diffuse skin color changes in "central" aspects of the body (e.g., trunk, head) as well as color changes in the mucous membranes.[44] These membranes are normally pink and shiny irrespective of skin color. Central cyanosis indicates marked arterial desaturation and occurs when oxygen saturation is less than 80% (normal is 95% to 100%).[2] It is associated with diseases of the cardiovascular/pulmonary system and carbon monoxide poisoning. **Peripheral cyanosis** causes color changes in the nail beds and lips owing to decreased cardiac output, exposure to cold (vasoconstriction), or arterial or venous obstruction. It is frequently transient and is often relieved by warming the area. Common skin color changes with associated causes are presented in Box 2.1.
- The skin should also be observed for changes in texture and hair growth. Patients with diabetes mellitus or atherosclerosis typically lack hair growth on the legs and display thickening of the nails of the fingers and toes. Skin texture also varies with age and poor nutritional status. Skin lesions may be indicative of pathological changes or trauma.
- The color and appearance of fingernails should be noted. With normal circulation and oxygen supply, they should be pink (or light brown in dark-skinned individuals) and free of irregularities. Examples of pathological changes in nails include the following:
  - *Beau's lines* are deep grooved (indented) transverse lines across the nail resulting from disruption of nail growth caused by trauma or disorders such as Raynaud's disease (decreased blood flow to fingers), psoriasis, or infection around the nail plate.
  - *Black nails* are caused by blood under the nail; usually the result of trauma.
  - ***Clubbing*** is a bulbous swelling of fingertips accompanied by a loss of the normal angle between the nail bed and the skin (Fig. 2.3); nails appear bluish-gray (cyanotic) and become soft and boggy (spongy). Clubbing develops gradually over time and is associated with diagnoses imposing long-standing **hypoxia,** such as congenital heart defects and cardiopulmonary diseases.
  - *Half-and-half nails* (also called *Lindsay's nails*) are seen with renal failure; the distal portion of the nail turns red, pink, or brown; there is a distinct line of demarcation between the two halves.
  - *Onycholysis* is detachment of the nail from the nail bed; associated with trauma, fungal infections, psoriasis, and overactive thyroid gland.

Box 2.1 Common Skin Color Changes

- **Cyanosis:** Bluish-gray discoloration of the skin and mucous membranes.
  - **Central cyanosis:** Caused by hypoxia and results in color changes in central aspects of body and mucous membranes; associated with diseases of the cardiovascular/pulmonary system.
  - **Peripheral cyanosis:** Caused by hypoxia with color changes in the nail beds and lips; associated with decreased cardiac output and exposure to cold (extreme vasoconstriction).
- **Ecchymosis:** Caused by bruising (bleeding under the skin) and may be seen anywhere on the body; new bruises appear *bluish-purple* while older bruises are *greenish-yellow*; often caused by trauma (e.g., falls, sports injury, physical abuse); patients on blood thinning agents (e.g., Coumadin) tend to bruise more easily.
- **Erythema:** Reddened area of skin caused by increased blood flow (hyperemia); associated with skin irritation or injury, infection, and inflammation; redness over a bony prominence warns of the potential development of a decubitus ulcer.
- **Flushing:** Diffuse redness of face; may involve other body areas; related to emotions (embarrassment, anger), physical exertion, fever, and increased temperature of environment.
- **Jaundice:** Caused by impaired liver function (e.g., hepatitis, liver cancer), the skin takes on a yellow-orange hue; it is best observed in the sclera, mucous membranes, and palm of hands and sole of the feet.
- **Pallor (pale):** The skin takes on a lighter tone (more white with decreased pink hue) than normal for the individual (a normally "fair" skin color should be ruled out); for darker skin, pallor is apparent by loss of red tones; associated with anemia (low hemoglobin) and impaired circulation; observed in the face, palms, mucous membranes, and nail beds.
- **Petechiae:** Tiny red or purple hemorrhagic spots caused by capillary bleeding with subsequent leakage of blood into the skin; tend to appear in clusters and often seen on the ankles and feet but can occur anywhere on body; may be a sign of thrombocytopenia (low platelet count); as platelets play a critical role in clotting, reduced counts impair clotting and increase the risk of bleeding; low platelet counts are associated with a variety of medications (e.g., anticoagulants, aspirin, steroids, and chemotherapy drugs) and disorders (e.g., acute and chronic infections, leukemia, systemic lupus erythematosus, and scleroderma).

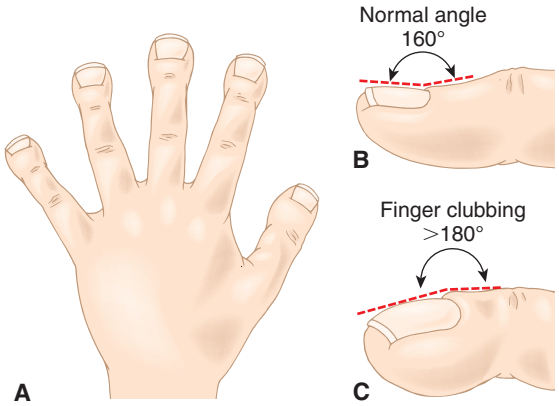

Figure 2.3 **(A)** Clubbing of fingertips is associated with long-term hypoxic states; **(B)** normal nail plate angle of 160°; **(C)** a nail plate angle of 180° or more occurs with clubbing.

- *Mee's lines* are transverse white lines across the breadth of the nail associated with systemic diseases such as renal failure, Hodgkin's disease, malaria, and sickle cell anemia; classically associated with arsenic poisoning.
- *Pitting* is characterized by tiny punctate depressions in the nail caused by systemic diseases such as Reiter's syndrome, psoriasis, and eczema.
- *Splinter hemorrhages* are tiny hemorrhages creating reddish lines of blood under the nail (appears as if a "splinter" is lodged under nail) associated with bacterial endocarditis and trauma.
- Abnormal sitting postures may be suggestive of pain or structural abnormalities of the pelvis (pelvic obliquity), pectoral, or vertebral regions that may also interfere with respiratory patterns.
- Edema may be associated with CHF, liver failure, lymphedema, or venous insufficiency; localized edema may result from varicose veins, thrombophlebitis, or trauma.

TEMPERATURE

Body temperature represents a balance between the heat produced or acquired by the body and the amount lost. Because humans are warm blooded, or *homoiothermic,* body temperature remains relatively constant despite changes in the external environment. This is in contrast to cold-blooded, or *poikilothermic,* animals (such as reptiles), in which body temperature varies with that of their environment.

Thermoregulatory System

The purpose of the thermoregulatory system is to maintain a relatively constant internal body temperature. This system monitors and acts to maintain temperatures that are optimal for normal cellular and vital organ function. The thermoregulatory system consists of three primary components: the thermoreceptors, the regulating center, and the effector organs (Fig. 2.4).[45,46]

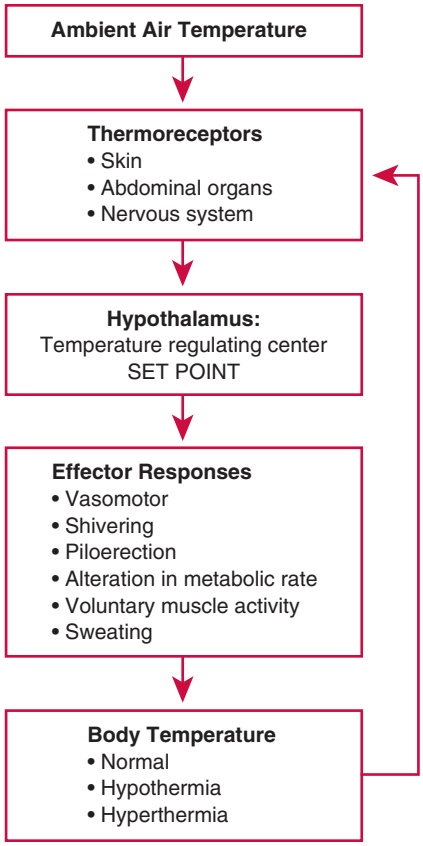

Figure 2.4 Thermoregulatory responses. The thermoreceptors provide input regarding changes in body temperature that signal the preoptic nucleus of the hypothalamus. This physiological thermostat compares incoming signals of actual body temperature with the set point value. If body temperature is lower than the set point value, heat gain mechanisms are implemented. If body temperature is higher than the set point value, heat loss mechanisms are implemented.[45,46]

Thermoreceptors

The thermoreceptors provide input to the temperature-regulating center located in the hypothalamus. The regulating center is dependent on information from thermoreceptors to achieve constant temperatures. Once this information reaches the regulatory center, it is compared with a "set point" standard or optimal temperature value. Depending on the contrast between the "set" value and incoming information, mechanisms may be activated either to conserve or to dissipate heat.[47]

Peripheral and central thermoreceptors provide afferent temperature input to the regulating center. The peripheral receptors (skin temperature), composed primarily of free nerve endings, have a high distribution in the skin. Central thermoreceptors (core temperature) are located in the deep tissues (e.g., abdominal organs), nervous system, and the hypothalamus itself.[47,48] The thermoreceptors located in the hypothalamus are sensitive to temperature changes in blood perfusing the hypothalamus. These cells also can initiate responses to either conserve or dissipate heat. They are particularly sensitive to core temperature changes and monitoring body warmth.[45] The thermoreceptors permit *feed forward* responses to expected changes in core temperature (e.g., change in environmental temperature).

The cutaneous peripheral thermoreceptors demonstrate a larger distribution of cold receptors than warmth receptors and are sensitive to rapid changes in temperature.[45] Signals from these receptors enter the spinal cord through afferent nerves and travel to the hypothalamus via the lateral spinothalamic tract.

Regulating Center

The temperature-regulating center of the body is located in the hypothalamus. The hypothalamus coordinates the heat production and loss processes, much like a thermostat, ensuring an essentially constant, stable body temperature. By influencing the effector organs, the hypothalamus achieves a relatively precise balance between heat production and heat loss. In a healthy individual, the hypothalamic thermostat is set and carefully maintained at 98.6° ± 1.8°F (37° ± 1°C).[45] In situations in which input from thermoreceptors indicates a drop in temperature below the "set" value, mechanisms are activated to conserve heat. Conversely, a rise in temperature will activate mechanisms to dissipate heat. Mechanisms to dissipate heat are particularly important during strenuous exercise. Figure 2.5 summarizes the primary physiological adjustments to exercise or increases in environmental temperature that occur during heat acclimation (physiological adaptations to improve tolerance to heat). These responses are activated through hypothalamic control of the effector organs. Input to the effector organs is transmitted through pathways of both the somatic and autonomic nervous systems.[45,46,49,50]

Effector Organs

The effector organs respond to both increases and decreases in temperature. The primary effector systems include vascular, metabolic, skeletal muscle (shivering), and sweating. These effector systems function either to increase or to dissipate body heat.

Conservation and Production of Body Heat

When body temperature is lowered, mechanisms are activated to conserve heat and increase heat production. The following are descriptions of heat conservation and production mechanisms:

- *Vasoconstriction of Blood Vessels:* The hypothalamus activates sympathetic nerves, an action that results in vasoconstriction of cutaneous vessels throughout the body. This significantly reduces the lumen of the vessels and decreases blood flow near the surface of

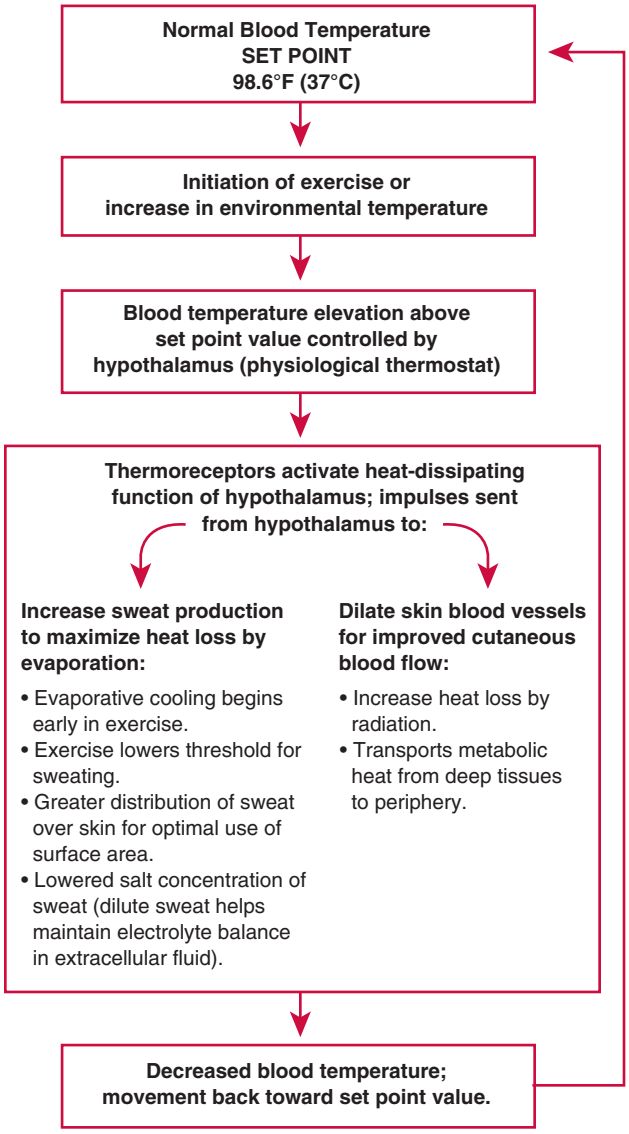

Figure 2.5 Physiological adjustments during heat acclimation. Increased body temperature activities heat (loss) dissipation to maintain normal body temperature.

the skin, where the blood would normally be cooled. Thus, the amount of heat lost to the environment is decreased.

- *Decrease (or Absence) of Sweat Gland Activity:* To reduce or to prevent heat loss by evaporation, sweat gland activity is diminished. Sweating is totally abolished with cooling of the hypothalamic thermostat below approximately 98.6°F (37°C).[45,51]
- *Cutis Anserina or Piloerection*: Also a response to cooling of the hypothalamus, this heat conservation mechanism is commonly described as "gooseflesh." The term *piloerection* means "hairs standing on end." Although of less significance in humans, this mechanism functions to trap a layer of insulating air near the skin and decrease heat loss in lower mammals with greater hair covering.

The body also responds to decreased temperature with several mechanisms, including shivering and hormonal regulation, designed to produce heat. These mechanisms are activated when the body thermostat falls below approximately 98.6°F (37°C).[51] The primary motor center for shivering is located in the posterior hypothalamus. This area is activated by cold signals from the skin and spinal cord. In response to cold, impulses from the hypothalamus activate the efferent somatic nervous system, causing increased tone of skeletal muscles. As the tone gradually increases to a certain threshold level, *shivering* (involuntary muscle contraction) is initiated, and heat is produced. This shivering reflex can be at least partially inhibited through conscious cortical control.[51]

The function of hormonal influence in thermal regulation is to increase cellular metabolism, which subsequently increases body heat. Increased metabolism occurs through circulation of two hormones from the adrenal medulla: *norepinephrine* and *epinephrine*. Circulating levels of these hormones, however, are of greater significance in maintaining body temperature in infants than in adults. Heat production by these hormones can be increased in an infant by as much as 100%, as opposed to 10% to 15% in an adult.[51]

A second form of hormonal regulation involves increased output of *thyroxine* by the thyroid gland. Thyroxine increases the rate of cellular metabolism throughout the body. This response, however, occurs only as a result of prolonged cooling, and heat production is not immediate.[45] The thyroid gland requires several weeks to hypertrophy before increased demands for thyroxine can be achieved.

Loss of Body Heat

Excess heat is dissipated from the body through four primary methods: radiation, conduction, convection, and evaporation.

- *Radiation:* The transfer of heat by electromagnetic waves from one object to another is accomplished by radiation. This heat transfer occurs through the air between objects that are not in direct contact. Heat is lost to surrounding objects that are colder than the body (e.g., a wall or surrounding objects in the room).
- *Conduction:* The transfer of heat from one object to another through a liquid, solid, or gas takes place by conduction. This type of heat transfer requires direct molecular contact between two objects, as when a person is sitting on a cold surface, or when heat is lost in a cool swimming pool. Heat is also lost by conduction to air.
- *Convection:* The transfer of heat by movement of air or liquid (water) is achieved by convection. This form of heat loss is accomplished *secondary to conduction*. Once the heat is conducted to the air, the air is then moved away from the body by convection currents. Use of a fan or a cool breeze

provides convection currents. Heat loss by convection is most effective when the air or liquid surrounding the body is continually moved away and replaced.

- *Evaporation:* Dissipation of body heat by the conversion of a liquid to a vapor occurs by evaporation. This form of heat loss occurs on a continual basis through the respiratory tract and through perspiration from the skin. Evaporation provides the major mechanism of heat loss during heavy exercise. Profuse sweating provides a significant cooling effect on the skin as it evaporates. In addition, this cooling of the skin functions to further cool the blood as it is shunted from internal structures to cutaneous areas. Figure 2.6 illustrates the mechanisms of heat dissipation from the body.

Abnormalities in Body Temperature

Increased Body Temperature

An elevation in body temperature is generally believed to assist the body in fighting disease or infection. *Pyrexia* is the elevation of normal body temperature, more commonly referred to as fever. *Hyperpyrexia* and *hyperthermia* are terms that describe an unusually high fever, generally above 106°F (41.1°C).[51]

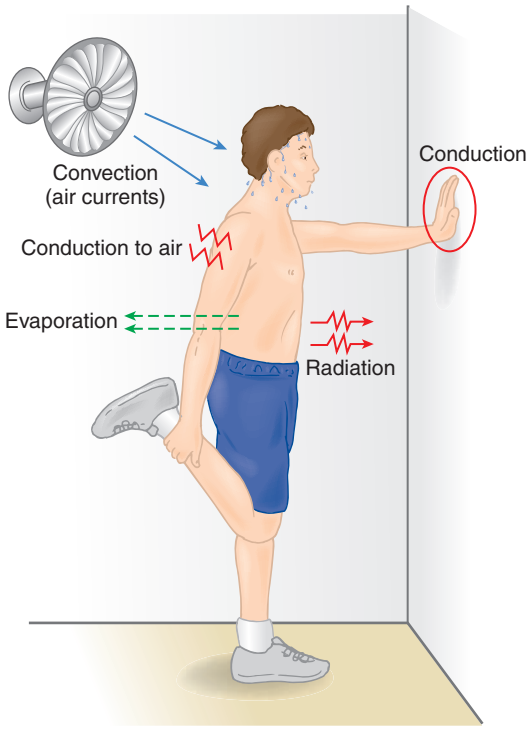

Figure 2.6 Mechanisms of heat dissipation from body. *Conduction* is the transfer of heat by direct contact between two objects (hand on wall), *radiation* occurs through electromagnetic waves between objects not in direct contact with each other (subject's body and wall), heat loss by *convection* is accomplished via air currents (wall fan) after the heat is conducted to air, *evaporation* converts liquid (perspiration) to a vapor.

Pyrexia occurs when the "set" value of the hypothalamic thermostat rises. This elevation is caused by the influence of **pyrogens** (fever-producing substances). Pyrogens are secreted primarily from toxic bacteria or are released from degenerating body tissue.[46] The effects of these pyrogens result in fever during illness. As a result of the new, higher thermostat value, the body responds by activating its heat conservation and production mechanisms. These mechanisms raise body temperature to the new, higher value over a period of several hours. Thus a fever, or febrile state, is produced.

The clinical signs and symptoms of a fever vary with the level of disturbance of the thermoregulatory center, and with the phase of the fever. These signs and symptoms may include general malaise, headache, increased pulse and respiratory rate, chills, piloerection, shivering, loss of appetite (**anorexia**), pale skin that later becomes flushed and hot to the touch, nausea, irritability, restlessness, constipation, sweating, thirst, coated tongue, decreased urinary output, weakness, and insomnia.[35,52] With higher elevations in temperature, disorientation, confusion, convulsions, or coma may occur. These latter symptoms are more common in children younger than 5 years of age and are believed to be related to the immaturity of the nervous system.

The *prodromal phase* is the period just prior to onset of fever; nonspecific symptoms may be experienced, such as a slight headache, muscles aches, general malaise, or loss of appetite. Three phases (stages) have been identified to describe a fever, as follows:

- *Phase 1—Onset:* This is the period from either gradual or sudden rise until the maximum temperature is reached; symptoms include chills, shivering, and pale appearance of skin. As body temperature is raised (e.g., in response to infection), cutaneous vasoconstriction moves blood to the interior of the body to retain heat. The skin becomes cool, and shivering is initiated to produce more heat. Attempts to preserve and produce heat continue until a new, higher temperature is reached.
- *Phase 2—Course:* This is the point of highest elevation of the fever. Once the new higher temperature is reached, it remains relatively stable (fever is sustained); heat production and heat loss are equal and shivering stops; skin may be warm and appear flushed.
- *Phase 3—Termination (defervescence):* This is the period during which the fever subsides and temperatures lower and move toward normal. Cutaneous vasodilation occurs, and sweating is initiated to help cool the body.

Several types of fevers present unique characteristics that are named based on their distinguishing clinical feature: *intermittent, remittent, relapsing,* or *constant* (Box 2.2).

Box 2.2 Types of Fever

Intermittent: Body temperature alternates at regular intervals between periods of fever and periods of normal temperatures.
Remittent: Elevated body temperature that fluctuates more than 3.6°F (2°C) within a 24-hour period but remains above normal.
Relapsing: Periods of fever are interspersed with normal temperatures; each last at least one day; also called *recurrent* fever.
Constant: Body temperature may fluctuate slightly but is constantly elevated above normal.

Decreased Body Temperature

Exposure to extreme cold produces a lowered body temperature called **hypothermia**. With prolonged exposure to cold, there is a decrease in metabolic rate, and body temperature gradually falls. As cooling of the brain occurs, there is a depression of the thermoregulatory center. The function of the thermoregulatory center becomes seriously impaired when body temperature falls below approximately 94°F (34.4°C) and is completely lost with temperatures below 85°F (29.4°C).[47] Therefore, the body's heat regulatory and protection mechanism is lost. Symptoms of hypothermia include decreased HR and RR, cold and pale skin, cyanosis, decreased cutaneous sensation, depression of mental and muscular responses, and drowsiness, which may eventually lead to coma. If hypothermia is left untreated, the progression of these symptoms may lead to death.

Factors Influencing Body Temperature

A statistical average or normal temperature of 98.6°F (37°C) taken orally has been established for body temperature in an adult population. However, a range of values is more representative of normal body temperature because certain everyday circumstances (e.g., time of day) or activities (e.g., exercise) influence the body's temperature. In addition, some individuals typically run a *slightly higher* or *lower* body temperature than the statistical average. Therefore, deviations from the average will be apparent from individual to individual, as well as between measures taken from the same person under varying circumstances.

Time of Day

The term **circadian rhythm** describes a 24-hour cycle of normal variations in body temperature. Certain predictable and regular changes in temperature occur on a daily basis. Body temperature tends to be lowest between 4 and 6 a.m., and highest between 4 and 8 p.m. Both digestive processes and the level of skeletal muscle activity influence these regular changes in body temperature significantly. For individuals who work at night, this pattern is usually inverted.[45,47]

Age

Compared with adults, infants demonstrate a higher normal temperature owing to the immaturity of the thermoregulatory system. Infants are particularly susceptible to environmental temperature changes, and their body temperature will fluctuate accordingly. Young children also average higher normal temperatures because of the heat production associated with increased metabolic rate and high physical activity levels. Elderly populations tend to demonstrate lower than average body temperatures, owing to a variety of factors, including lower metabolic rates, decreased subcutaneous tissue mass (which normally insulates the body against heat loss), decreased physical activity levels, and inadequate diet.

Emotions/Stress

Stimulation of the sympathetic nervous system causes increased production of epinephrine and norepinephrine with a subsequent increase in metabolic rate.

Exercise

The effects of exercise on body temperature are an important consideration for physical therapists. Strenuous exercise significantly increases body temperature because of an increase in metabolic rate. Active muscle contractions are an important and potent source of heat production. During exercise, body temperature increases are proportional to the relative intensity of the workload. Vigorous exercise can increase the metabolic rate by as much as 20 to 25 times that of the basal level.[45]

Menstrual Cycle

Increased levels of progesterone during ovulation cause body temperature to rise 0.5° to 0.9°F (0.3° to 0.5°C). This slight elevation is maintained until just prior to the initiation of menstruation, at which time it returns to normal levels.

Pregnancy

Because of increased metabolic activity, body temperature remains elevated by approximately 0.9°F (0.5°C). Temperature returns to normal after parturition.

External Environment

Generally, warm weather tends to increase body temperature, and cold weather decreases body temperature. Environmental conditions influence the body's ability to maintain constant temperatures. For example, in hot, humid environments the effectiveness of evaporative cooling is severely diminished because the air is already heavily moisture laden. Other forms of heat dissipation are also dependent on environmental factors such as movement of air currents (convection). Clothing also can be an important external consideration because it can function either to conserve and to facilitate release of body heat. The amount and type of clothing is important. To dissipate heat, absorbent, loose-fitting,

light-colored clothing is most effective. To conserve heat, several layers of lightweight clothing to trap air and to insulate the body are recommended.

Measurement Site

Body temperatures vary among body parts. Rectal and tympanic (ear) membrane temperatures are from 0.5° to 0.9°F (0.3° to 0.5°C) higher than oral temperatures; axillary temperatures are approximately 1.1°F (0.6°C) lower than oral temperatures. The normative value for oral temperature in a healthy adult population is generally considered to be 98.6°F (37.0°C), and for rectal and tympanic membrane temperatures the value is 99.5°F (37.5°C). Being an external measure, the axillary normative value is somewhat lower at 97.6°F (36.5°C).

Ingestion of Warm or Cold Foods

Oral temperatures will be affected by oral intake, including smoking. Patients should refrain from smoking or eating for at least 15 minutes (preferably 30 minutes) prior to an oral temperature reading.

Types of Thermometers

Glass Mercury Thermometers

Traditionally, temperatures have been taken using a glass thermometer, which consists of a glass tube with a bulbous tip filled with mercury. Once the bulb is in contact with body heat, the mercury expands and rises in the glass column to register body temperature. A narrowing of the base prevents reflux of mercury down the tube. The device must be shaken vigorously to return the mercury to the bulb before the next use.

Glass thermometers are calibrated in centigrade (Celsius [C]) scale, Fahrenheit (F) scale, or both. The range is from approximately 93° to 108°F (34° to 42.2°C), with slight variations among different manufacturers. The calibrations are in degrees and tenths of a degree. As such, each long line represents a full degree, and each short line indicates 0.1° on the centigrade thermometer and 0.2° on the Fahrenheit thermometer. When recording temperatures, it is common practice to round the fractions of degrees to the nearest whole number (one tenth of a degree on the Fahrenheit scale). If a situation occurs that requires changing a temperature reading from one scale to the other, a conversion formula can be used. To convert centigrade into Fahrenheit, multiply the centigrade value by 9/5 and add 32 ($F = [9/5 \times C°] + 32°$). To change from Fahrenheit into centigrade, subtract 32 from the Fahrenheit value and multiply by 5/9 ($C = [F - 32°] \times 5/9$). Figure 2.7 presents a comparison of Fahrenheit and centigrade temperature values with ranges of normal and altered body temperature.

The distal tip (bulb) of the glass mercury thermometer is used for insertion and is long and slender or has a more blunt, round shape (Fig. 2.8). The long slender shape is used for oral temperatures and is designed with a larger surface area to maximize tissue contact with the oral mucosa. The more blunted, round bulb is used for rectal temperatures and is designed to minimize trauma to the rectal mucosa. The oral thermometer can also be used for axillary temperatures. The tips of mercury glass thermometers may also be color coded (*blue* for oral and *red* for rectal).

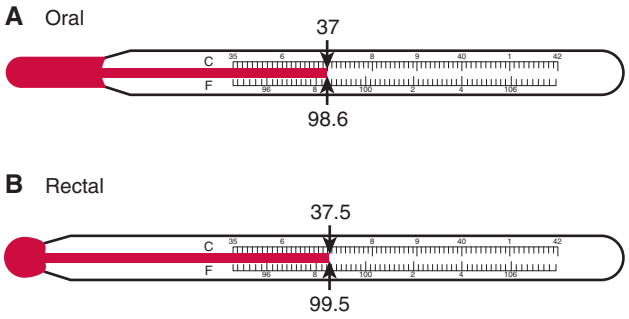

Figure 2.8 Shape of tips (bulbs) on mercury glass thermometers. The long slender shape **(A)** is for oral use and the blunt round shape **(B)** is for rectal measures.

Although glass mercury thermometers may remain in use in the home care setting, automated (electronic) thermometers have largely replaced their use in patient care settings owing to environmental concerns of mercury pollution from breakage and medical waste disposal systems.[43] The U.S. Environmental Protection Agency (EPA) warns against use of mercury thermometers and encourages replacement with non-mercury thermometers wherever possible. Some states have laws restricting the manufacture and sale of mercury thermometers. Many areas also offer collection/exchange programs for mercury-containing devices.[53]

Automated Thermometers

Automated thermometers are widely used in patient care settings. They provide a rapid (several seconds), highly accurate measure of body temperature. Standard clinical automated thermometers consist of a portable battery-operated unit, an attached probe, and plastic disposable probe covers (Fig. 2.9A). The units provide a digital display of body temperature. An important advantage of these thermometers is the low chance of cross-infection, so long as the probe covers are used only once. Other automated devices are designed to monitor more than one vital sign and interface directly with the electronic medical record (EMR), reducing the potential for error associated with manual documentation (Fig. 2.9B).

Oral Thermometers

Handheld automated oral thermometers are readily available commercially. These units are typically about 5 inches in length with a tapered design (Fig. 2.10). One end of the device has a narrow tip and serves as the probe; in some models the tip is flexible. The opposite end is broad and houses the battery. These thermometers also provide a flashed, digital display of body temperature; most models have memory capabilities. Typically these devices are used for a single patient; however, many models allow use with disposable probe covers.

Figure 2.9 **(A)** Hand-held electronic thermometer with disposable probe covers reduces the risk of cross-contamination. **(B)** This device interfaces with the electronic medical record (EMR). By scanning the patient's hospital identification bracelet, two-way wireless communication links ID numbers to patient names for positive identification at the bedside. The unit measures temperature, blood pressure, and oxygen saturation levels (pulse oximetry). The device reduces time required and potential errors of manual documentation as data are relayed directly to the EMR. Manual data may also be entered (e.g., respiratory rate). *(Courtesy of Welch Allyn, Skaneateles Falls, NY 13153-0220.)*

Tympanic Thermometer

Another type of automated thermometer is the tympanic (ear) infrared thermometer. These thermometers measure body temperature through a sensor probe placed in the ear that detects infrared radiation from the tympanic membrane.[54,55] This location provides an important reflection of core temperature because the tympanic membrane receives its blood supply from a tributary of the internal carotid artery, which supplies the hypothalamus (temperature-regulating center). These handheld portable thermometers include an ear probe (used with a single-use disposable cover) and provide a digital display of body temperature within several seconds (Fig. 2.11A). They are particularly useful with infants older than 2 months and children who may have difficulty remaining still during other types of monitoring and in emergency situations where rapid temperature values are required. A tympanic thermometer should never be used in the presence of a draining or infected ear.[55]

Temporal Artery Thermometer

Noninvasive temporal artery thermometers measure body temperature by sliding a probe from the center of the forehead, across the temporal artery area to the hairline (Fig. 2.11B). It detects heat emitting from the skin surface over the temporal artery. The probe can be cleaned with an alcohol swab or used with disposable probe caps. Temporal artery measures have been found to be more precise and more accurate than axillary or ear-based measures.

Figure 2.11 **(A)** Tympanic (ear) thermometer. This thermometer incorporates a sensor that detects infrared radiation from the tympanic membrane (eardrum) and converts the warmth into a digital temperature reading. *(Courtesy of Omron, Inc., Lake Forest, IL 60045.)* **(B)** Temporal artery thermometer. As a measurement site, the temporal artery is easily accessible and poses low risk of injury as there is no contact with mucous membranes. *(Courtesy of Exergen Corporation, Watertown, MA 02472.)*

Box 2.3 Evidence Summary presents studies examining the reliability and validity of measuring body temperature.

Other variations of automated thermometers place the sensor in earlobe clips, finger sleeves, or finger clips, and still others are noncontact. Infrared (IR) noncontact thermometers measure temperature using a surface area, typically the forehead. Because these thermometers do not touch the patient, there is no risk of contamination. Based on manufacturer's specifications, IR thermometers are held several inches from the forehead and provide a body temperature reading with approximately 0.3-degree accuracy. They are frequently used with infants and children and for initial fever screenings. However, their usefulness for fever screening of outpatients has been called into question because the gradient between surface and core temperature is considerably influenced by the patient's age and environmental factors.[56] Some IR thermometers are calibrated to convert the forehead measure into internal (core) temperature. Digital nipple-shaped pacifier designs are also available for monitoring oral temperatures of infants.

Disposable Single-Use Thermometers

Oral Thermometers

These devices are used in a similar fashion to the glass mercury thermometer because they are placed under the tongue. They consist of a thin plastic with a series of raised calibrated dots impregnated with a temperature-sensitive chemical (Fig. 2.12). The dots change color to indicate the temperature. After the thermometer is removed from the mouth, the dots are examined for color changes to determine the temperature reading (Fig 2.13). They are available in both Fahrenheit and Celsius scales and are disposed of after use. Although most commonly used for oral temperatures, disposable thermometers can also be used to obtain axillary temperatures, and some are available with covers (sheaths) containing semirigid stays that allow use for rectal measurements.

Skin Surface Thermometers

Heat-sensitive strips (tape, patches, or disks) provide a general measure of body surface temperature. They also respond to body temperature by changing color and are more frequently used with children. They must be applied to dry skin. The forehead and abdomen are common placement sites. The temperature readings are nonspecific and are usually confirmed with a more precise measuring instrument if deviations are noted.

Hand Hygiene

Hand hygiene plays a critical role in preventing transmission of pathogens in health care settings. According to the World Health Organization (WHO), *health care–associated infection (HCAI)* represents a major patient safety concern, and its prevention should be a top priority in all patient care settings and institutions. WHO states, "The impact of HCAI implies prolonged hospital stay, long-term disability, increased resistance of microorganisms to antimicrobials, massive additional financial burden, high costs for patients and their families, and excess deaths."[57, p. 6]

Hand hygiene is accomplished by *hand washing* using soap and water or *hand rubbing* using an alcohol-based formula. Alcohol-based hand rubs are an efficient and effective way to inactivate a broad spectrum of microorganisms from the hands.[57] The factors on which WHO has based its recommendations for hand rubs are presented in Box 2.4. When using an alcohol-based hand rub, enough product should be used to cover all hand surfaces. The hands are then rubbed together until dry. The hand rubbing technique is illustrated in Figure 2.14.

When one is using soap and water, enough product should be used to cover all hand surfaces. Clean running water assists with removal of microorganisms, and a warm temperature removes less protective oil from the hands than hot water. The force of the water should not cause splashing, which can promote the transfer of microorganisms. Care should be taken not to lean against the sink to avoid contact with a potentially contaminated area. The technique for hand washing is presented in Figure 2.15.

To draw attention to the indications for hand hygiene and its practical application, WHO has developed "My Five Moments for Hand Hygiene." The five moments are (1) before touching the patient; (2) before a clean/aseptic procedure; (3) after body fluid exposure risk; (4) after touching a patient; and (5) after touching patient surroundings.[57]

Box 2.3 Evidence Summary Studies Examining the Reliability and Validity of Measuring Body Temperature

Reference	Method(s)	Subjects/Design	Results	Conclusions/Comments
Rubia-Rubia et al (2011)	To compare the axilla (using Gallium-in-glass[a]), reactive strip, compact electronic, electronic with probe, ear-based (infrared), and frontal forehead scan (infrared) to the pulmonary artery core temperature (Temp) using a Swan-Ganz catheter[b]	Older adults in an intensive care unit (ICU) ($n = 201$). All Temp methods were compared to the core Temp simultaneously.	The Gallium-in-glass in the axilla for 5 and 12 minutes, compact digital, digital with probe and ear-based (infrared, core equivalency) were among the most valid methods. The Gallium-in-glass in the right axilla for 5 and 12 minutes were the most reliable methods. The reactive strip, compact digital, and digital probe were the most accurate methods.	When methods were ranked based on validity, reliability, accuracy, and external influence the Gallium-in-glass in the axilla for 12 minutes attained the highest score. When also considering waste, ease-of-use, speed, durability, security, comfort and cost the compact digital and digital with probe, both in the axilla, scored the highest.
Kelechi et al (2011)	To compare skin Temp 8 cm above the right malleolus using the infrared contact thermometer[c] and the thermistor-type thermometer[d]	Healthy adults ($n = 17$). Temp was taken three times with 10 minutes between each recording.	Strong correlations between the infrared contact thermometer and thermistor-type thermometer were found at baseline ($r = 0.95$), after 10 minutes of rest ($r = 0.97$), and after 10 minutes of cold provocation ($r = 0.87$). There was a reasonable level of agreement between methods at baseline and after 10 minutes of rest, but not after cold provocation.	In summary, the results suggest better agreement between infrared contact and thermistor-type thermometers than within each method except after cold provocation.
Smitz et al (2009)	To compare and correlate two different infrared ear thermometers with a rectal Temp (electronic probe)	Older adult inpatients ($n = 100$). The order of thermometer type and side (right vs. left) used were randomized. Two measures taken for each device and each side. The highest ear Temp from each device used for analysis.	For both infrared ear thermometers: • The mean Temp was significantly higher than the rectal Temp. • There was a high correlation between both ear Temps and the rectal Temp ($r = 0.84$-0.91).	Either infrared thermometer can be used to predict rectal Temps in inpatients who are normothermic and febrile.

Box 2.3 Evidence Summary Studies Examining the Reliability and Validity of Measuring Body Temperature—cont'd

Reference	Method(s)	Subjects/Design	Results	Conclusions/Comments
Duncan et al (2008)	To compare oral and core Temps (temp-sensing urinary catheter) to infrared over the patient's forehead	Adult patients in the emergency department (ED) (oral) ($n = 74$) and ICU (core Temp) ($n = 19$). The three Temps were taken within 2 minutes.	High correlation ($r = 0.94$) between first and second infrared measurements. Between the infrared and oral methods, there was a poor correlation ($r = 0.26$), poor agreement (mean difference between pairs = 0.87°C), and significant difference. Between the infrared and core methods, there was a high correlation ($r = 0.83$); there was also poor agreement and a significant difference between methods.	The infrared method was reliable and easy to use. There was poor agreement between the infrared method and (a) oral and (b) core methods. The infrared method provided lower readings than the oral and core methods.
Giantin et al (2008)	Gallium-in-glass under axilla without nurse assistance was compared to the axilla (electronic thermometer), tympanic (infrared) and Gallium-in-glass under axilla methods with nurse assistance.	Hospitalized older adults ($n = 107$). All temps were taken by the same nurse. All temps were taken at least three times daily at different times and on different days.	There were significant differences between the Gallium-in-glass under axilla with nurse assistance method and Gallium-in-glass under axilla without nurse assistance and tympanic (infrared) methods. There was no significant difference between Gallium-in-glass under axilla with nurse assistance and the tympanic methods and extremely narrow limits of agreement.	The Gallium-in-glass under axilla without nurse assistance method is inadequate for older adults. The tympanic method, however, provides adequate accuracy in this population.
Lawson et al (2007)	To compare oral (electronic), ear-based (infrared tympanic), temporal (infrared scanner), and axillary (electronic) to pulmonary artery (Swan-Ganz catheter[a])	Adult patients in the ICU ($n = 60$). Temps taken in random order within 1 minute. Temp was taken three times every 20 minutes.	Mean (SD) offset with pulmonary artery Temp and confidence limits: • Oral = 0.09°C (0.43°C) and -0.75°C to 0.93°C • Ear-based = -0.36°C (0.56°C) and -1.46° to 0.74°C • Temporal = -0.02°C (0.47°C) and -0.92° to 0.88°C • Axillary = 0.23°C (0.44°C) and -0.64° to 1.12°C	Oral and temporal methods were most precise and accurate. Axillary measurements underestimated pulmonary artery Temp. Ear-based measurements were the least accurate and precise.

Box 2.3 Evidence Summary Studies Examining the Reliability and Validity of Measuring Body Temperature—cont'd

Reference	Method(s)	Subjects/Design	Results	Conclusions/Comments
Moran et al (2007)	To compare tympanic (infrared), urinary (Temp-sensing catheter), and axillary (glass mercury thermometer) to pulmonary artery core Temp (Swan-Ganz catheter)	Older adults in an ICU ($n = 110$). The Temp was measured every 4 hours for the first 72 hours and then every 6 hours for an additional 48 hours.	Concordance of pulmonary artery Temps with tympanic, urinary, and axillary Temps was 0.77, 0.92, and 0.83, respectively.	In critically ill patients, measuring core Temp using a urinary catheter is the most reasonable alternative to the pulmonary artery method.
Fountain et al (2008)	To compare an oral disposable thermometer, tympanic thermometer, and temporal (infrared) thermometer to an oral electronic thermometer	Adults in an inpatient oncology unit ($n = 60$). The order of the oral disposable thermometer, tympanic thermometer, and temporal (infrared) thermometer was randomized. The oral electronic device was always last.	Bias (and precision) was reported as 0.39 (1.01) for the tympanic device, 0.00 (0.92) for the disposable oral device, and 0.68 (0.99) for the temporal artery. Significant differences were found between the oral electronic device and the tympanic and temporal artery devices. No difference was found between the oral electronic and oral disposable thermometers.	Since Temp results are fairly similar, oral disposable thermometers can be used when oral electronic thermometer use is not feasible.

Prepared by Kevin K. Chui, PT, PhD, GCS, OCS.

[a]Gallium-in-glass thermometer: These thermometers are like the mercury thermometers, but have replaced the mercury with galinstan, a liquid alloy of gallium, indium, and tin.

[b]Swan-Ganz catheter: A flexible catheter inserted in the pulmonary artery to measure temperature as well as other hemodynamic characteristics.

[c]Infrared contact thermometer: Is used to detect the energy emitted from the body part.

[d]Thermistor-type thermometer: Is a semiconductor device used to measure temperature.

Figure 2.13 The chemical dots on the disposable single-use thermometers change color from green to black to reflect the temperature (Fahrenheit, *left,* and Centigrade, *right*). The green dots turn black from left to right. The last dot to turn black indicates the temperature. Note there are two grids of dots on each scale (*left* and *right*). Values that fall in the right grid indicate fever is present. In the example on the right, 38.1°C (100.5°F) represents fever. *(Courtesy of Medical Indicators, Inc., Pennington, NJ 08534.)*

Box 2.4 Factors Considered by WHO in Recommending Hand Rubs

WHO recommends alcohol-based hand rubs based on the following factors:

1. Evidence-based, intrinsic advantages of fast-acting and broad-spectrum microbicidal activity with a minimal risk of generating resistance to antimicrobial agents
2. Suitability for use in resource-limited or remote areas with lack of accessibility to sinks or other facilities for hand hygiene (including clean water, towels, and so forth)
3. Capacity to promote improved compliance with hand hygiene by making the process faster and more convenient
4. Economic benefit by reducing annual costs for hand hygiene, representing approximately 1% of extra costs generated by health care–associated infection (HCAI)
5. Minimization of risks from adverse events because of increased safety associated with better acceptability and tolerance than other products

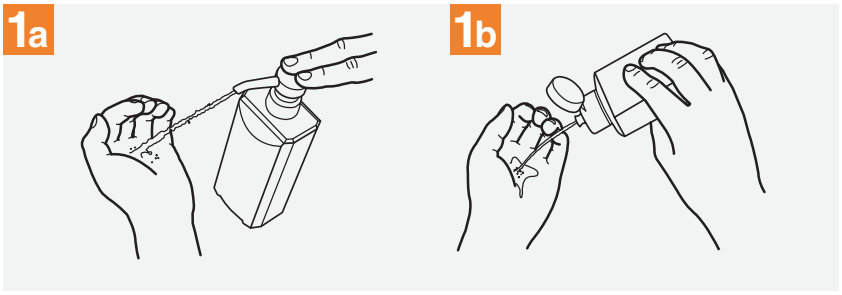
From WHO,[57 p. 57,] with permission.

Clinical Note: Before a vital sign measure is taken, the procedure and its rationale should be explained in terms appropriate to the patient's understanding and confirmation made of patient safety, comfort, and understanding.

Measuring Body Temperature

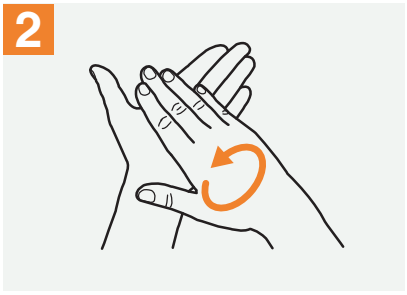
For purposes of establishing baseline data and determining response to treatment, physical therapists generally use oral monitoring. Oral temperatures are contraindicated for patients with *dyspnea* or who are mouth breathers, have had oral surgery, or have a history of epilepsy or are prone to seizures. They also should not be used with infants or small children or patients who are irrational, unconscious, or uncooperative. In situations in which oral temperatures may be contraindicated and an automated unit with an alternative sensor (e.g., earlobe clip, finger sleeve) is unavailable, an axillary measurement may be substituted.

Measuring Oral Temperature: Automated Thermometer



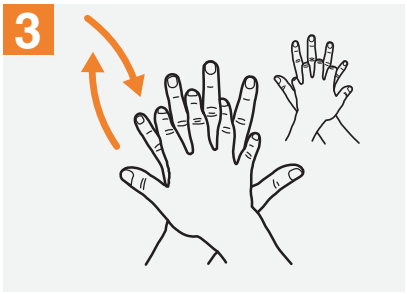
A. Assemble equipment.
   1. An automated thermometer with disposable probe covers or sheaths. Oral temperature can also be taken with a glass mercury thermometer (Appendix 2.A) or a disposable single-use thermometer.
      Note: Hand-held automated oral thermometers are self-contained with an internal battery; the proximal end houses the digital display and battery, and the distal end serves as the temperature probe.
   2. Watch (or wall clock).

B. Wash hands.

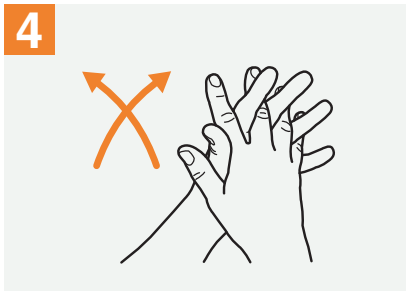


C. Procedure.
   1. Turn on the power.
   2. Grasp the proximal aspect of the thermometer with the thumb and forefinger and attach the disposable cover over the distal probe tip until it snaps or locks in place. (Some units have a proximal button that releases the probe cover after temperature reading is complete.) For a small handheld automated unit, the probe covers are designed as a plastic sheath.
   3. Ask patient to open his or her mouth, and place the covered probe at the posterior base of the tongue to the right or left of the frenulum in the sublingual pocket. This placement positions the tip of the thermometer over superficial blood vessels that reflect core body temperature. Instruct the patient to close the lips (not teeth) around the thermometer. Continue to hold the

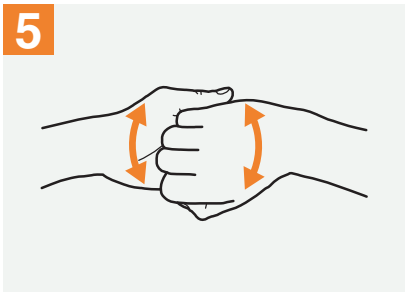
Hand Hygiene Technique with Alcohol-Based Formulation



Duration of the entire procedure: 20-30 seconds

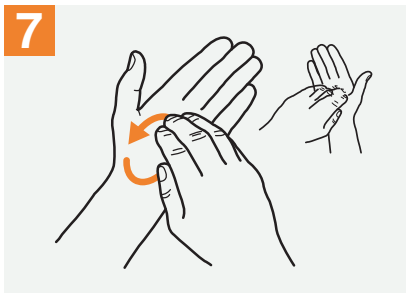


Apply a palmful of the product in a cupped hand, covering all surfaces;

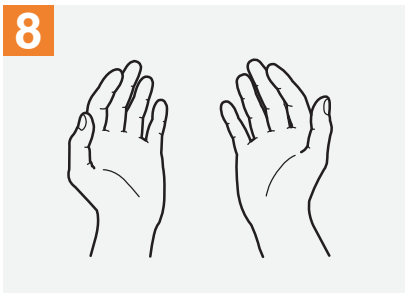


Rub hands palm to palm;

Right palm over left dorsum with interlaced fingers and vice versa;



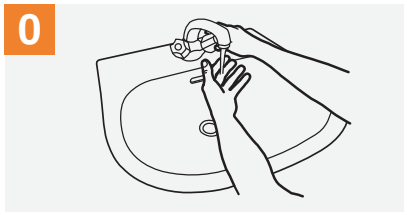
Palm to palm with fingers interlaced;



Backs of fingers to opposing palms with fingers interlocked;

Rotational rubbing of left thumb clasped in right palm and vice versa;

Rotational rubbing, backwards and forwards with clasped fingers of right hand in left palm and vice versa;



Once dry, your hands are safe.

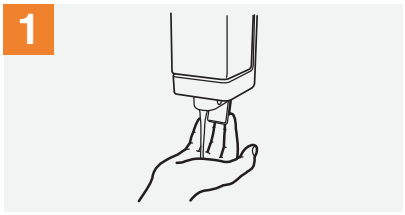


Figure 2.14 Hand rubbing technique. *(From WHO,[57 p. 155], with permission.)*

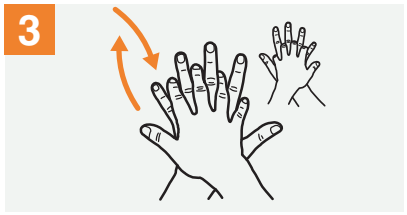
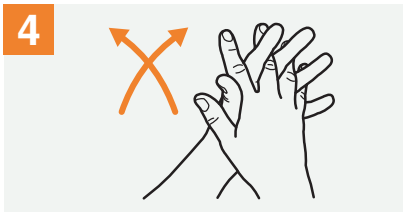
Hand Hygiene Technique with Soap and Water

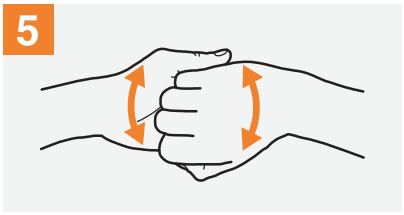
Duration of the entire procedure: 40-60 seconds



Wet hands with water;

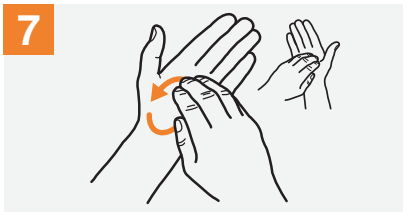


Apply enough soap to cover all hand surfaces;

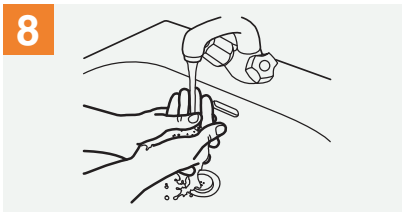


Rub hands palm to palm;

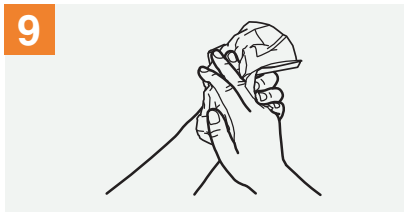
Right palm over left dorsum with interlaced fingers and vice versa;



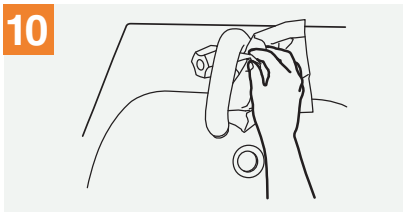
Palm to palm with fingers interlaced;



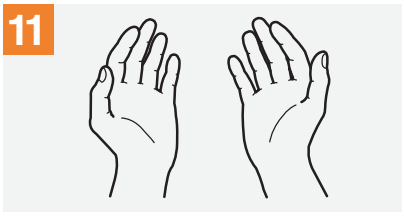
Backs of fingers to opposing palms with fingers interlocked;



Rotational rubbing of left thumb clasped in right palm and vice versa;



Rotational rubbing, backwards and forwards with clasped fingers of right hand in left palm and vice versa;



Rinse hands with water;

Dry hands thoroughly with a single use towel;

Use towel to turn off faucet;

Your hands are now safe.

Figure 2.15 Hand washing technique. *(From WHO,[57 p. 156], with permission.)*

probe in place, because the weight of the probe may displace it from the sublingual pocket.

4. Hold the probe in the sublingual pocket until an audible beep is heard (several seconds). The beep indicates maximum temperature has been reached. Remove the probe from the patient's mouth and note the temperature reading on the digital display for recording.
5. Remove the probe cover over a waste receptacle for disposal. If available on the unit, use the probe release mechanism; if a plastic sheath cover is used, use a clean paper towel for removal. (Cover sheath with paper towel, place thumb and forefinger proximally on probe over paper towel, and slide fingers distally.)
6. Return thermometer to appropriate storage container.
7. Wash hands.

Measuring Axillary Temperature: Automated Thermometer

A. Assemble equipment.

1. An automated thermometer with disposable probe covers or sheaths. Axillary temperatures can also be measured with glass mercury thermometers (Appendix 2.B) as well as disposable single-use thermometers.
2. A towel or gauze pads to dry axillary region. (Moisture will conduct heat.)
3. Watch (or wall clock).

B. Wash hands.

C. Procedure.

1. Expose the axilla, and ensure that area is dry. If any moisture is present, the area should be gently towel dried with a patting motion. (Vigorous rubbing will increase temperature of the area.)
2. Turn on the power.
3. Grasp the proximal aspect of the thermometer with the thumb and forefinger, and attach the disposable cover or sheath over the distal probe tip.
4. With the patient in supine position, place the tip of the thermometer in the center of the axillary region between the trunk and upper arm (Fig. 2.16). The patient's upper extremity (UE) should be placed tightly across the chest to keep the thermometer in place. (Asking the patient to move the hand toward the opposite shoulder is often a useful direction.) If the patient is disoriented or very young, the thermometer must be held in place. Axillary temperature can also be taken in a sitting position, but this carries the risk of the thermometer dropping to the floor.
5. The thermometer is left in place until an audible beep is heard (several seconds). The beep indicates that maximum temperature has been reached. Remove the probe from the patient's axilla, and note the temperature reading on the digital display for recording.
6. Remove the probe cover or sheath over a waste receptacle for disposal.
7. Return thermometer to appropriate storage container.
8. Wash hands.

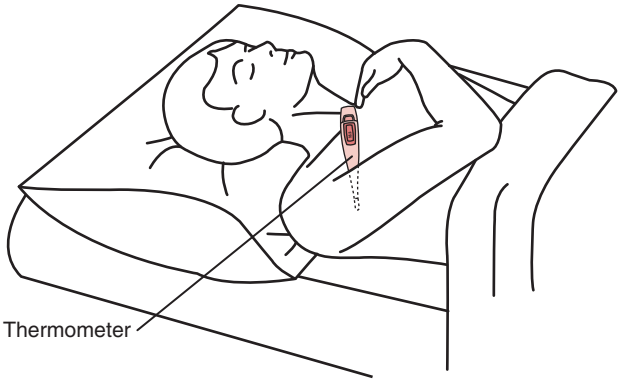


Figure 2.16 Positioning for monitoring axillary temperature. Placing the patient's arm across the chest forces cool air out of the axilla that could potentially result in a lower temperature value. This positioning also places the probe near the vascular supply to the axilla. The proximal portion of the thermometer should be angle toward the patient's head.

Note: Generally, a temperature reading is assumed to be an oral measure unless otherwise noted. Axillary values are designated by a circled A after the temperature or the designation "AT" for *axillary temperature* (e.g., 95°F AT). Similarly, the designation RT (*rectal temperature*) or a circled R after the value indicates a rectal measure (e.g., 99°F ®).

Measuring Tympanic Membrane Temperature: Automated (Ear) Thermometer

A. Assemble equipment.

1. Tympanic (infrared) thermometer. (Many units include a storage base and a protective cap that fits over the probe tip.)
2. Disposable probe covers.

B. Wash hands.

C. Procedure.

1. Attach the disposable cover to the probe, holding it with the thumb and forefinger. (Ensure that the firm circular collar of the cover engages with the base by gently pushing it down; do not touch the plastic film of the probe cover.)
2. Turn the patient's head to one side. For adults, pulling on the pinna (auricle) may help straighten the ear canal and provide better access. For an adult, the pinna is pulled up and back; for a child, it is pulled down and back.[35,55]

3. Insert the probe snugly into the ear canal. A firm gentle pressure should be used; avoid forcing the probe too deeply. The probe should seal the opening of the ear canal. To ensure accurate reading, the probe should be angled anteriorly toward the jawline, as if approaching the patient from behind.
4. Press the button that activates the thermometer. The temperature is displayed within several seconds. Many units emit an audible beep or flashing light when the maximum temperature is reached.
5. Gently remove the probe from the ear. Eject or remove the probe cover over a waste receptacle for disposal. Manual removal of the probe cover should be done using a clean paper towel or tissue.
6. Return tympanic thermometer to protective case.
7. Wash hands.

PULSE

The *pulse* is the wave of blood in the artery created by contraction of the left ventricle during a cardiac cycle (one complete cycle of cardiac muscle contraction and relaxation). With each contraction, blood is pumped into an already full aorta. The inherent elasticity of the aortic walls allows expansion and acceptance of the new supply. The blood is then forced out and surges through the systemic arteries. It is this wave or surge of blood that is felt as the pulse. The strength or amplitude of the pulse reflects the amount of blood ejected with each myocardial contraction (stroke volume).

Peripheral pulses are those located in the periphery of the body that can be felt by palpating an artery over a bony prominence or other firm surface. Examples of peripheral pulses include the radial, carotid, and popliteal pulses. The *apical pulse* is a central pulse located at the apex of the heart that is monitored using a stethoscope.

Pressure changes in the large arteries during the cardiac cycle are reflected in the relatively smooth and rounded appearance of the normal arterial waveform (Fig. 2.17 [top]). The lowest point of pressure occurs during ventricular **diastole,** while the highest point occurs during ventricular systole (peak ejection). The notch on the descending slope of the pulse wave represents closure of the aortic valve and is not palpable.[58] A healthy adult heart beats an average of 70 times per minute, a rate that provides continuous circulation of approximately 5 to 6 liters of blood through the body. The pulse can be palpated wherever a superficial artery can be stabilized over a bony surface. In monitoring the pulse, specific attention is directed toward determining three parameters: *rate, rhythm,* and *quality*.

Rate

The HR is the number of pulsations (peripheral pulse waves) or frequency per minute. **Bradycardia** is an abnormally slow HR, less than 60 beats per minute. **Tachycardia** is an excessively high HR, greater than 100 beats per minute. *Palpitation* refers to the sensation of a rapid or irregular HR perceived by the patient without actually palpating a peripheral pulse. Multiple factors influence the HR, including age, sex, emotional status, stress, and physical activity level. Body size and stature also influence HR. Tall, thin individuals generally have a slower HR than those who are obese or have stout frames.

Rhythm

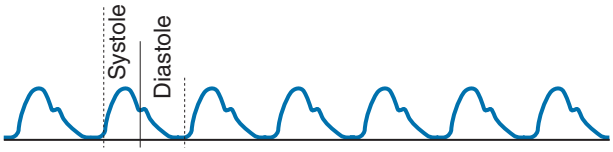
The pulse *rhythm* is the pattern of pulsations and the intervals between them. In a healthy individual, the rhythm is regular and indicates that the time intervals between pulse beats are essentially equal. *Arrhythmia* or *dysrhythmia* refers to an irregular rhythm in which pulses are not evenly spaced. An irregular rhythm may present as premature, late, or missed pulse beats, or random, irregular beats in either a predictable or an unpredictable pattern.[59] Irregular rhythms are often associated with conduction abnormalities or an impulse originating from a site other than the sinoatrial node.[60] See Chapter 13: Heart Disease, for further discussion.

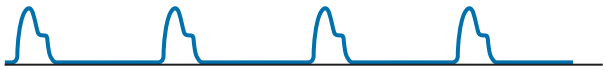
Quality

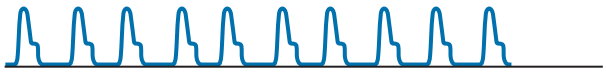
The *quality* (force, volume) of the pulse refers to the amount of force created by the ejected blood volume against the arterial wall during each ventricular contraction. In examining the quality of the pulse, the therapist is determining the feel of the blood as it passes through a vessel. The quantity (volume) of blood within the vessel produces the force of the pulse. Normally, the pulse volume of each beat is the same. The force of the pulse is greater with a higher blood volume, and weaker with a lower blood volume. The volume is examined by noting how easily the pulse can be obliterated. A normal pulse is described as full or strong and can be palpated using moderate pressure of the fingers over a bony landmark. With lower volumes, the pulse is *small,* is easily obliterated, and is termed *weak* or *thready*. With increased volume, the pulse is *large,* is difficult to obliterate, and is termed a *bounding* (or *full*) pulse; a feeling of high tension is noted. A numerical scale is often used to document the quality (strength) of the pulse (Table 2.6).

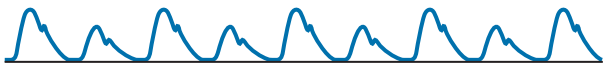
In addition to rate, rhythm, and quality, the feel of the arterial wall under the examiner's fingertips should be determined. Normally, a vessel will feel smooth, elastic, soft, flexible, and relatively straight. With advancing age, vessels may demonstrate sclerotic changes. These changes frequently cause the vessels to feel twisted, hard, or cordlike, with decreased elasticity and smoothness.

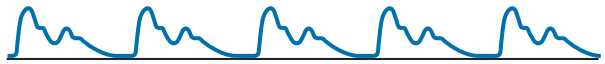
Several other important terms are used to describe variations in pulse. The term *bigeminal* is used to describe an abnormality in pulse rhythm where two beats occur in rapid succession (double systolic peak). *Pulsus alterans* (alternating pulse) is marked by a fluctuation

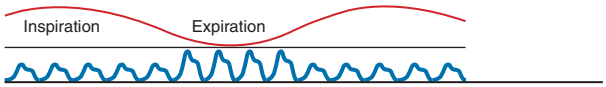












Description	Possible Cause
 **Normal**	
 **Small, Weak Pulse** Decreased pulse pressure with a slow upstroke and prolonged peak	Increased peripheral vascular resistance such as occurs in cold weather or severe congestive heart failure; decreased stroke volume such as occurs in hypovolemia or aortic stenosis
 **Large, Bounding Pulse** Bounding pulse in which a great surge precedes a sudden absence of force or fullness	Increased stroke volume, as in aortic regurgitation; increased stiffness of arterial walls, as in atherosclerosis or normal aging; exercise; anxiety; fever; hypertension
 **Corrigan's (Water-Hammer) Pulse** Increased pulse pressure with a rapid upstroke and downstroke and a shortened peak	Aortic regurgitation, patent ductus arteriosus, systemic arteriosclerosis
 **Pulsus Alternans** Regular pulse rhythm with alternation of weak and strong beats (amplitude or volume)	Left ventricular failure
 **Pulsus Bigeminus** Irregular pulse rhythm in which premature beats alternate with sinus beats	Premature ventricular beats caused by heart failure, hypoxia, or other condition
 **Pulsus Bisferiens** A strong upstroke, downstroke, and second upstroke during systole	Aortic insufficiency, aortic regurgitation, aortic stenosis
 **Pulsus Paradoxus** Pulse with a markedly decreased amplitude during inspiration	Constrictive pericarditis, pericardial tamponade, advanced heart failure, severe lung disease

Figure 2.17 Normal (*top*) and abnormal pulses, as reflected in arterial waveforms. *(From Dillon,[2 p. 477], with permission.)*

in amplitude between beats (a weak and a strong), with minimal change in overall rhythm. A normal pulse beat is followed by a premature beat of diminished amplitude. A *paradoxical* pulse (pulsus paradoxus) is decreased amplitude of the pressure wave detected during quiet inspiration with a return to full amplitude on expiration; it is often associated with obstructive lung disease. Figure 2.17 provides a schematic illustration of normal (top) and common alterations in arterial pulse waveforms.

Table 2.6 Numerical Scale for Grading Pulse Quality (Strength)

Grade	Pulse	Description
0	Absent	No perceptible pulse even with maximum pressure
1+	Thready	Barely perceptible; easily obliterated with slight pressure; fades in and out
2+	Weak	Difficult to palpate; slightly stronger than thready; can be obliterated with light pressure
3+	Normal	Easy to palpate; requires moderate pressure to obliterate
4+	Bounding	Very strong; hyperactive; is not obliterated with moderate pressure

Factors Influencing Heart Rate

Essentially, any factor that alters the metabolic rate will also influence HR. Several factors are of particular importance when considering HR.

Age

Fetal HR averages 120 to 160 beats per minute. The HR for a newborn ranges between 70 and 170, with an average of 120 beats per minute. HR gradually decreases with age until it stabilizes in adulthood (see Tables 2.1 and 2.2). The adult HR range is generally considered to be between 60 and 100 beats per minute; however, in highly trained athletes, the resting value may be considerably lower. This lowered resting value occurs because the effectiveness of each cardiac contraction is 40% to 50% greater in the trained versus untrained individual.[46]

Sex

Men and boys typically have slightly lower HR than women and girls.

Emotions/Stress

Responses to a variety of emotions (e.g., grief, fear, anger, excitement, anxiety, or pain) activate the sympathetic nervous system, with a resultant increase in HR. The stress-inducing effects of moderate to severe pain will also elevate HR.

Exercise

Oxygen demands of skeletal muscles are significantly increased during physical activity. At rest, only 20% to 25% of the available muscle capillaries are open.[45,47] During vigorous exercise, extensive vasodilation causes all capillaries to open. The HR increases to provide additional blood flow to muscles and to meet the increased oxygen requirement. For physical therapists, monitoring a patient's HR is an important method of evaluating response to exercise. Typically, HR will increase as a function of the intensity of the activity (termed *chronotropic competence*). A linear relationship exists between HR and intensity of workload. To use the HR effectively, both the patient's resting and predicted maximal HRs must be determined. Maximum HR values can be determined by a maximal graded exercise test, whenever possible, or by using various published formulas. Common examples are the age-adjusted HR formula (maximum HR [HR_{max}] = 220 minus age), Karvonen formula (target HR = [(HR_{max} − HR_{rest}) × % intensity] + HR_{rest}), and Inbar[61] formula (HR_{max} = 205.8 – [0.685 × age]). However, the age-adjusted HR formula has been called into question. In their discussion of the history of the formula, Robergs and Landwehr[62] indicate it was not developed from original research "but resulted from observation based on data from approximately 11 references consisting of published research or unpublished scientific compilations. Consequently, the formula HR_{max} = 220 – age has no scientific merit for use in exercise physiology and related fields."[62, p. 1] The authors suggest that there is currently no acceptable method to estimate HR_{max}, and, if a determination is needed, population-specific formulas should be used.

Generally, HR during a 15- to 30-minute therapeutic exercise program for a healthy individual should not exceed 60% to 90% of predicted HR_{max}. Lower exercise intensities are indicated for individuals with low fitness levels.[45]

In examining HR response to exercise, level of aerobic fitness also must be considered. Both resting HR and submaximal exercise HR are typically lower in trained individuals. In response to identical exercise intensity, a sedentary person's HR will demonstrate greater acceleration when compared with a trained individual. Although the metabolic requirements of an activity are the same, the lower HR response in a trained individual occurs as a result of a more efficient (increased) stroke volume (SV) owing to greater cardiac strength and efficiency. The linear relationship between HR and workload exists for both trained and untrained individuals. However, the rate of rise will differ. When compared with a sedentary person, the trained individual will achieve a higher work output and greater oxygen consumption before reaching a specified submaximal HR.

Medications

The impact of medications on HR is particularly important for patients with cardiac disease or hypertension. Beta blockers (beta-adrenergic blocking agents) are a category of drugs that blocks the sympathetic beta receptors and decreases both resting HR and HR response to exercise.[45] They are commonly used in the treatment of angina pectoris, arrhythmias, hypertension, and the acute phase of myocardial infarction. Examples of prescribed beta blockers include acebutolol, atenolol,

bisoprolol, metoprolol, nadolol, nebivolol, and propranolol. Patients taking beta blockers typically experience early fatigue with exercise; an alternative to HR monitoring, such as Ratings of Perceived Exertion (RPE scale), should be considered to monitor exercise intensity.[63]

Systemic or Local Heat

During periods of fever, HR will increase. The body will attempt to dissipate heat by vasodilation of peripheral vessels. HR will increase to shunt blood flow to cutaneous areas for cooling. Local applications of thermal modalities (such as a hot pack) may also elevate HR to increase blood flow to cutaneous areas secondary to arteriolar and capillary dilation.

Pulse Sites

A peripheral pulse can be monitored at a variety of sites on the body. A superficial artery located over a bone or other firm surface is easiest to palpate. Table 2.7 identifies common peripheral pulse sites, their locations, and some general indications for their use.[59,60,64] Pulse sites are illustrated in Figure 2.18.

Considered the most accurate,[7] the apical (central) pulse is monitored by auscultation (listening), using a stethoscope directly over the apex (lower portion pointing to the left) of the heart or by placing the hand over the chest to feel the pulsations. In infants, the apical pulse can be felt with the fingertips. Apical pulses are used for weak heartbeats that are imperceptible peripherally when other sites are either inaccessible (e.g., because of medical or surgical contraindications) or difficult to locate and palpate. The apical pulse is typically used to monitor the effects of cardiac medications designed to alter HR and rhythm.[54] Box 2.5 Evidence Summary presents studies examining the reliability and validity of pulse and HR monitoring.

Monitoring Pulse

Peripheral pulses are monitored by palpation using the index and third finger or the first three fingers of one hand.[60] The thumb should not be used because it has

Table 2.7 Pulse Sites, Locations, and Indications for Use

Pulse Site	Location	Indication for Use
Temporal	Over temporal bone; superior and lateral to the eye.	When radial pulse inaccessible; often used with infants; used by anesthesiologists for monitoring during surgical interventions.
Carotid	On either side of the lower neck, below the jaw, fingers over thyroid cartilage between the trachea and medial border of sternocleidomastoid; pressure should not be applied bilaterally or high on the neck to avoid stimulation of the carotid sinus and a subsequent reflex drop in pulse rate.	During shock or cardiac arrest, often used with infants; used to monitor cranial circulation; easily accessible if other peripheral pulses difficult or too weak to locate.
Brachial	Distal medial aspect of the humerus, the biceps can be gently pushed laterally during palpation, or medially in the antecubital fossa; elbow should be slightly flexed and supported to avoid contraction of biceps.	During cardiac arrest; used routinely to monitor blood pressure.
Radial	Distal radius at base of the thumb, lateral to tendon of the flexor carpi radialis.	Most common site for peripheral pulse monitoring; easy to locate and easily accessible.
Femoral	Inferior to the inguinal ligament, midway between the anterior superior iliac spine and the symphysis pubis; typically monitored in supine.	During cardiac arrest; used to monitor lower extremity circulation.
Popliteal	Inferior aspect of popliteal fossa; popliteal artery is deep and at times may be difficult to palpate; typically monitored in prone with knee flexed to relax hamstrings and popliteal fascia; can also be accomplished in supine.	Used to monitor lower extremity circulation; weak or absent popliteal pulse may indicate impaired flow or blockage in femoral artery.
Pedal (dorsalis pedis)	Dorsal, medial aspect of foot, lateral to the tendon of the extensor hallicus longus; ankle should be slightly dorsiflexed; some individuals have congenitally nonpalpable pedal pulses.	Used to monitor circulation to feet; weak or absent pulse may be indicative of arterial disease or occlusion.

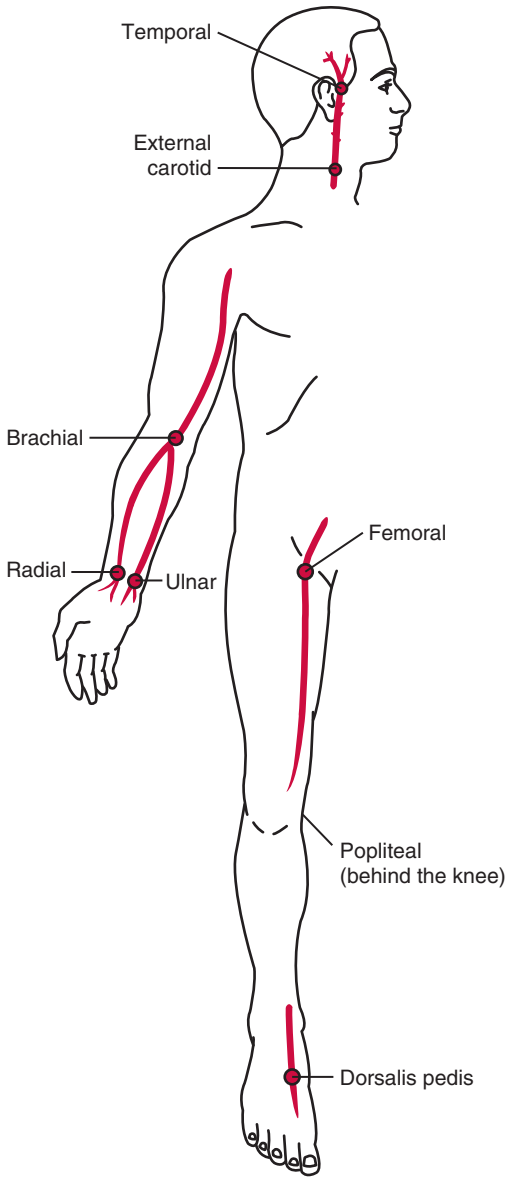


Figure 2.18 Common sites for monitoring peripheral pulses.

its own pulse, which will interfere with monitoring. Generally, a light pressure is used initially to locate the pulse, and then more firm pressure is used when determining the rate, rhythm, and quality. The fingertips should be moved gently over the selected site until the strongest pulsation is found. To monitor resting values, the patient should be resting quietly for at least 5 minutes prior to the pulse measurement.

The radial artery is the most common site for measuring the pulse. With few modifications, the same procedure can be followed for monitoring at other pulse sites.

Measuring Radial Pulse

A. Assemble equipment.
  1. Watch (or wall clock) with a second hand.
B. Wash hands.
C. Procedure.
  1. Explain procedure and rationale in terms appropriate to the patient's understanding.
  2. Ensure patient understanding, safety, and comfort.
  3. Place the patient's wrist in a neutral position relative to flexion and extension, and support the forearm in pronation. If measuring from a supine position, the forearm can be supported across the patient's chest or at his or her side with partial flexion of the elbow. From a sitting position, the forearm can rest across the patient's thigh, supported by a pillow or the therapist's arm. This relaxed positioning of the UE generally facilitates artery palpation.
  4. Place the fingers squarely and firmly over the radial pulse; use only enough pressure to feel the pulse accurately. If the pressure is too great, it will occlude the artery.
  5. Once the strongest pulsation is located, note the position of the second hand on the watch or clock. The first pulsation should be counted as zero to avoid overestimating.[60] Determine the *rate* (number of beats per minute [bpm]) by counting the

Box 2.5 Evidence Summary Studies Examining the Reliability and Validity of Pulse and Heart Rate Monitoring

Reference	Methods	Subjects/Design	Results	Conclusion/Comments
Senduran et al (2011)	Examined the safety and feasibility of early physical therapy in the intensive care unit (ICU).	Case study of a 41-year old male patient in the ICU following implantation of a biventricular assist device. Monitored vital signs before, immediately after, and 5 minutes after treatment.	Data from 15 sessions of physical therapy showed significant differences in pretreatment, immediately after treatment, and 5 minutes after treatment for heart rate (HR) and respiratory rate (RR) only. HR significantly	The findings highlight the importance of monitoring vital signs, such as HR, in order to observe the physiological response of the patient to physical therapy in the ICU.

Box 2.5 Evidence Summary Studies Examining the Reliability and Validity of Pulse and Heart Rate Monitoring—cont'd

Reference	Methods	Subjects/Design	Results	Conclusion/Comments
			increased immediately after treatment and returned to baseline (before) values within 5 minutes.	
Lee et al (2011)	Examined the accuracy of using an infrared light-emitting diode (LED) device to measure HR. Compared HR from an infrared device to electrocardiogram (ECG).	Examined 46 healthy adults (mean age 24.8 ± 5.6 years). Subjects engaged in 4-minute periods of standing (0 mph), walking at 2.0 mph and 3.5 mph, jogging at 4.5 mph, and running at 6.0 mph.	HR measurements from the infrared device and ECG were highly correlated (ICC values provided with 90% confidence interval in parentheses). • 0 mph the ICC = 0.95 (0.94-0.96) • 2.0 mph the ICC = 0.95 (0.94-0.96) • 3.5 mph the ICC = 0.94 (0.92-0.95) • 4.5 mph the ICC = 0.92 (0.90-0.94) • 6.0 mph the ICC = 0.85 (0.81-0.88)	The infrared device used to measure HR was valid for monitoring HR at rest and lower exercise intensities. It becomes less accurate as exercise intensity (speed) increases.
Alexis (2009)	Reviews monitoring pulse rate.	This is a narrative review paper.	Defines pulse and rationales for measuring pulse. Discusses: • Assessment of pulses • Pulse sites • Conditions associated with pulse measurement • Factors influencing the pulse • Reference values • Equipment • Measuring pulses pregnant women, children, and older adults	Accurately measuring, recording, and interpreting pulse rate is critical for assessing the patient's condition and cardiovascular status.
Rawlings-Anderson et al (2008)	Reviews monitoring pulse rate.	This is a narrative review paper.	Defines pulse rate, rhythm, and amplitude. Provides reference values and reasons for tachycardia and bradycardia. Discusses indications, preparing the patient, procedures, and interpreting the results.	Accurately measuring, recording, and interpreting pulse rate is critical for assessing the patient's condition and cardiovascular status.

Box 2.5 Evidence Summary Studies Examining the Reliability and Validity of Pulse and Heart Rate Monitoring—cont'd

Reference	Methods	Subjects/Design	Results	Conclusion/Comments
John et al (2007)	Compared post exercise pulse palpation with electronic (HR) monitoring. Examine the contribution of movement artifact and measurement delay to underestimations of postexercise pulse rate.	Examined 54 female subjects (mean age of 19.9 ± 1.6 years). Subjects palpated their pulse at the midpoint and end point of an exercise period.	It took 17-20 seconds for subjects to obtain their palpated pulse rate after exercise. The palpated pulse rate underestimated HR by 20-27 beats (nearly 20%). The authors calculated and provided correction factors.	Pulse palpation requires teaching and practice. After exercise, applying a correction factor to pulse palpation is recommended.
Lockwood et al (2004)	Examined the best available evidence related to monitoring vital signs, including: • Purpose • Limitations • Optimal measurement frequency • What measures should be considered vital signs	Narrative, systematic review of vital signs. Updated review of Evans et al (2001). Included 124 studies on neonatal, pediatric, and adult patient populations.	There is limited research on pulse rate measurements and its ability to detect serious physiological changes. Measuring pulse rate over 15 seconds will most likely reduce the accuracy.	Pulse rate should be assessed over 30 or 60 seconds. When the pulse rate is rapid or difficult to palpate, the HR should be measured apically using a stethoscope.
Evans et al (2001)	Examined the best available evidence related to monitoring vital signs including: • Measurements that constitute vital signs • Optimal measurement frequency • Limitations of vital signs	Narrative, systematic review of vital signs. Included 69 studies on neonatal, pediatric, and adult patient populations.	There is limited low-level evidence on the frequency with which vital signs should be monitored. There is little research on pulse rate measurement.	Much of current practice of vital sign measurement is not based on research but on tradition and expert opinion.

pulse for 30 seconds and multiplying by 2; if any irregularities are noted, a full 60-second count should be taken to improve accuracy. Note the *rhythm* (time intervals between pulse beats) and the *quality* (force) of the pulse.

6. Wash hands.

Measuring Apical Pulse

A. Assemble equipment.

1. Watch (or wall clock) with a second hand.

2. Stethoscope.

3. Antiseptic wipes for cleaning earpieces and diaphragm of stethoscope before and after use.

B. Wash hands.

C. Procedure.

1. Explain the procedure and rationale in terms appropriate to the patient's level of understanding. Indicate that there will be a request to remain quiet during monitoring to avoid interference with auscultation.

2. Ensure patient understanding, safety, and comfort. Apical pulses are typically monitored with the patient either supine or sitting.
3. Use an antiseptic wipe to clean the earpieces and diaphragm of the stethoscope.
4. Expose the sternum and chest.
5. Locate the site where pulse will be monitored; the apical pulse is located approximately 3.5 inches (8.9 cm) to the left of the midsternum, in the fifth intercostal space, within an inch of the midclavicular line drawn parallel to the sternum (Fig 2.19). These landmarks are guides to locating the apical pulse. In some individuals, a stronger pulse may be noted by altering placement of the stethoscope (e.g., placement in the fourth or sixth intercostal space).
6. Place the earpieces of the stethoscope (tilting slightly forward) into the ears. The tubes of the stethoscope should not be crossed and should hang freely.
7. Place the flat disk diaphragm of the stethoscope over the apex of heart and locate the point where the apical pulse is heard most clearly. This is called the *point of maximal impulse (PMI)*. If the rhythm is regular, count the pulse for 30 seconds and multiply by 2. If any irregularities are noted, a full 60-second count should be taken. The pulse will be heard as a "lub-dub." The "lub" represents closure of the atrioventricular (tricuspid and mitral) valves. The "dub" represents closure of the semilunar (aortic and pulmonic) valves.
8. Wash hands and clean the stethoscope. If the same examiner is using the stethoscope again, it is not necessary to clean the earpieces; the diaphragm should always be cleaned.

Measuring Apical–Radial Pulse

Monitoring the apical–radial pulse involves two examiners simultaneously measuring the pulse at two separate locations: (1) the apical pulse at the apex of the heart; and (2) the radial pulse at the wrist. The values from the two different sites are then compared. Typically, the apical and radial pulse values are the same. However, in some situations (e.g., variations in SV or vascular occlusion), blood pumped from the heart may not be reaching the distal site, causing a weak or imperceptible radial pulse. For example, if the heart contracts prematurely, the ventricles have insufficient time to fill, resulting in a diminished stroke volume and creating an imperceptible pulse in the radial artery.[46] On the other hand, SV may be normal with a weak or imperceptible radial pulse, suggesting a more peripheral problem such as impaired flow or blockage within a vessel. In either situation, there is a deficit in the number of radial pulses when compared with the number of apical pulses.[46] This is called a **pulse deficit,** defined as the difference between the rate of radial and apical pulses. The value of this measure is that it provides important information about the cardiovascular system's ability to perfuse the body.

Automated Heart Rate Monitoring

Advances are continual in the design, features, accuracy, waterproofing, information storage capacity, and computer, tablet, and smartphone interface capabilities of heart rate monitors (HRMs). In addition to monitoring HR, some HRMs provide data on HR variability (calculation of the time between pulses), real-time display of percentage of maximum HR, and estimates of maximal oxygen uptake (VO_{2max}). HRMs with interface capabilities allow data to be downloaded to a computer (tablet or smartphone) for analysis and storage using HR

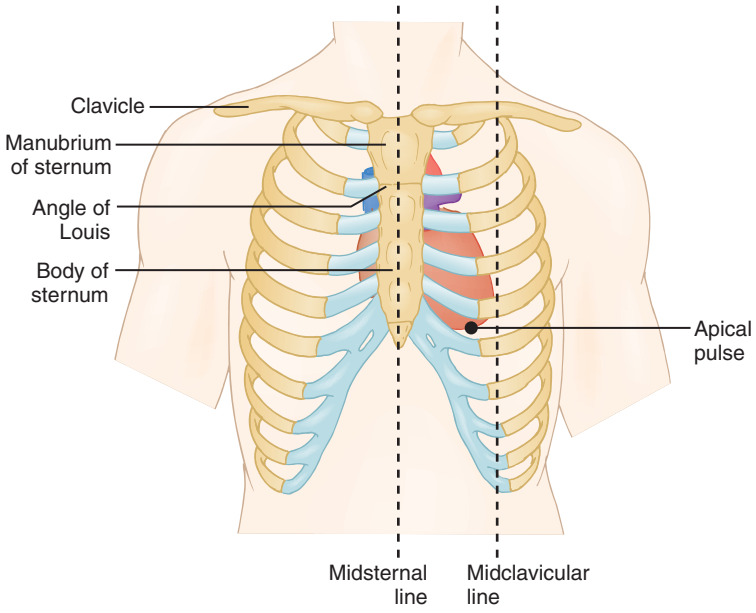

Figure 2.19 The apical pulse is located approximately 3.5 inches to the left of the midsternum, in the fifth intercostal space.

software programs. This provides a permanent record and sequential data on exercise performance. Most models allow programming of a prescribed exercise HR range with an audible and visible warning when the HR is outside the predetermined range. Some models include a talking feature that "speaks" HR information. Memory capabilities allow storage of exercise information over a variable number of exercise sessions.

HRMs consist of two basic elements: (1) a sensor that transmits data; and (2) a monitor that incorporates a receiver, microprocessor, and display. Many HRMs integrate sensors into a chest strap that provides wireless transmission of signals to a monitor worn as a wristwatch (Fig. 2.20A). Another style of HRM replaces the chest strap with fingertip sensors directly on the wristwatch (Fig. 2.20B) or a monitor that is worn around the neck (Fig 2.20C). HR data are recorded when a fingertip is placed in contact with the sensor. On some models, the bezel (ring surrounding the display dial) serves as the sensor. Wireless pulse monitors are available that interface with smartphones (Fig 2.20D) and tablets. HRMs are also available as finger rings. Still other HRMs incorporate a lead wire with a distal sensor housed in an earlobe clip, fingertip cover, or finger sleeve (Fig. 2.20E to H). Some HRMs are equipped with more than one type of sensor. This feature allows selection of the sensor that is most appropriate for the activity and the user.

HRMs are frequently used in prescribed exercise and training programs because they provide a practical, accurate method of pulse monitoring and are lightweight, comfortable, and easy to use. In recent years, many types of exercise training devices (e.g., treadmills, StairClimbers, bicycles, elliptical machines) incorporate HRMs directly into the unit design by means of a metal handgrip sensor device.

Other HRM features are available and differ with the model and manufacturer. Among the more common features are multifunction wrist monitors (consisting of a watch, stopwatch, alarm clock, lap timer, calendar, and data storage), illuminated and large-number LCD displays (some with a zoom feature that doubles the size of information on the screen), bar graph memory displays of previous training sessions, estimates of calories burned and energy expended during exercise, and HR statistics (average, minimum, maximum). Many HRMs interface wirelessly (for data analysis) using infrared signals to transfer data.

Telemetry is the science of remote measurement that includes both gathering data from a distant source and transmitting the data electronically. Telemetric HRMs are not new and have been available since 1983.[65] Since that time, continued research has led to greater and more advanced applications of telemetry in health care. For example, the National Aeronautics and Space Administration (NASA) designed a sophisticated telemetry system to ground monitor astronauts' vital signs data from space. This technology led to the development of the *Patient Monitoring System,* in which the patient continuously wears a small, portable, wireless transmitter that delivers real-time vital sign data to a central location that can monitor multiple patients simultaneously.[45] The Federal Communications Commission (FCC) defines *wireless medical telemetry* as "the measurement and recording of physiological parameters and other patient-related information via radiated bi- or unidirectional electromagnetic signals."[66, p. 1] In 2000, the FCC established the Wireless Medical Telemetry Service (WMTS) by allocating 14 MHz of spectrum for wireless medical telemetry. This networking infrastructure (available in specific geographical areas) was established owing to interference issues created by digital television and protects medical telemetry from interference by other in-band radio-frequency (RF) sources.[66] The FCC has designated the American Society for Healthcare Engineering of the American Hospital Association (ASHE/AHA) as the frequency coordinator for the WMTS.[67]

Gandsas et al[68] applied telemetric technology to examine the efficacy of using a low-cost approach to transmitting vital sign data from an aircraft to a medical ground facility. During an in-flight simulated medical emergency, vital sign data were collected with a monitoring device and transmitted using a laptop computer, an airline seat-back telephone, and the Internet. All data were received without corruption with a maximum delay of 1 second. The authors suggest that during an actual in-flight emergency, patient data could potentially be delivered to an assigned medical facility as well as to the physician's desktop computer anywhere in the world, irrespective of the geographical location of the aircraft.[68] Another area of research involves developing uniform standards of communication for transmission of data from vital sign monitoring equipment directly to clinical information systems currently in use in health care settings.

Doppler Ultrasound and Pulse Oximetry

Doppler Ultrasound

Doppler ultrasound (DUS) is a noninvasive instrument used to examine pulses that are extremely weak or faint or that are obliterated by even slight pressure, or when arterial flow is severely compromised. DUS is based on the principle that high-frequency ultrasound waves directed at a moving interface (i.e., blood flowing through a vessel) will cause a change in the wave frequency reflective of the velocity of the moving interface (called the *Doppler effect*). In essence, the DUS measures how sound waves are reflected off moving blood cells. The resultant frequency change caused by the movement alters the pitch of the sound waves as they are reflected back to the examiner; the pulse is heard as a swooshing sound.[69] The change in pitch heard by the examiner provides important information about the blood flow through a vessel.

Several models of DUS units are available. The essential elements include the ultrasound unit, a handheld probe (piezoelectric crystal) that transmits and receives sound waves, and earpieces that look similar to those on a stethoscope or a small speaker to amplify the sound. Passed gently over the skin surface above an artery using ample coupling gel, the probe transmits high-frequency sound waves to an artery. The waves are disturbed by movement of the red blood cells, reflected back to the probe, and transformed into an amplified audible sound.[70]

The audible sound represents the difference in frequency between the waves directed at the vessel and those reflected back by motion of blood cells; the frequency is proportional to the velocity of the moving red blood cells. The absence of an audible sound indicates no detection of movement and, subsequently, no perfusion.[69] Using a computer interface, the flow measures can be graphically displayed and stored. It should be noted that although the specific characteristics of the reflected sounds are not diagnostic, they can assist in identifying abnormal flow.[71]

Pulse Oximetry

Pulse oximetry provides a measure of arterial blood oxygenation that is updated with each pulse wave.[72] Oxygen is carried in the blood in two forms: (1) dissolved in arterial plasma; and (2) combined with hemoglobin.[45] Arterial plasma transports only about 3% of the oxygen in blood and is measured as PaO_2 (partial pressure of oxygen). The greater amount of oxygen (approximately 97%) is carried by hemoglobin and measured as SaO_2 (arterial hemoglobin oxygen saturation). Pulse oximetry measures arterial blood oxygen saturation as a noninvasive intervention.[73,74] Oxygen saturation via pulse oximetry is reported as SpO_2[75,76] and can be measured at any adequately perfused peripheral pulse.

Normal oxygen saturation levels are between 96% and 100%. In general, saturation levels below 90% are considered significant and warrant additional testing beyond the data provided by pulse oximetry (e.g., arterial blood gas analysis), as well as marking the potential need for administration of supplemental oxygen.[77] *Hypoxemia* is a term used to describe deficient oxygenation of the blood. *Hypoxia* is a diminished supply of oxygen available to body tissues, and *anoxia* is the complete lack of oxygen,[47] a condition that can be sustained for only a very brief period.

Alterations in heart function (e.g., arrhythmias, decreased HR) typically reduce cardiac output and the amount of oxygen delivered to tissues. Examples of other conditions that can affect oxygen saturation levels include impaired ability of the lungs to oxygenate blood, anemia (reduction in number of hemoglobin molecules available to carry oxygen), hypoventilation (e.g., bronchitis, emphysema), and diffusion impairments that affect blood-gas exchange (e.g., alveolar fibrosis, interstitial fluid).[76]

The pulse oximeter provides data on the percent of oxygen that is combined with hemoglobin (SpO_2). The automated units are relatively small (Fig. 2.21A and B), are easy to use and transport, and provide the therapist with immediate information about the patient's saturation levels.[76] The monitor provides a digital percentage of the amount of hemoglobin saturated with oxygen and displays a pulsatile waveform and pulse rate, with an audible signal indicating each pulsation. The patient interface is provided by a lead wire and sensor that attaches to the unit. The sensor is placed over a pulsating arteriolar vascular bed.[75] Several types of sensors are available, including adhesive fingertip and forehead (Fig. 2.22A and B) as well as nasal, earlobe, and foot styles. The sensors contain two light sources (red and infrared) and a photodetector (Fig. 2.23). The dual light source is used because oxygenated and deoxygenated hemoglobin have different patterns of light absorption.[78] The ratio of the amount of each light absorbed during systole and diastole allows quantification of an oxygen saturation measurement (SpO_2).[75-78] Nail polish has been found to interfere with oximetry and should be removed before monitoring.[79] Artificial acrylic fingernails may also interfere with oxygen saturation measurement.[80]

Pulse oximetry contributes to (1) early identification of hypoxemia; (2) monitoring patient tolerance to activity; and (3) evaluating patient response to treatment. Pulse oximetry measures may be done continuously, intermittently to generate a series of values over time, or as a single measure at a given point in time (e.g., as an initial screening tool). The measurement pattern will be determined within the context of the patient history and examination findings. Telemetry oximetry monitoring allows continuous communication of SpO_2 data from remote locations.[75]

RESPIRATION

The primary function of respiration (movement of air into and out of the lungs) is to supply the body with oxygen for metabolic activity and to remove carbon dioxide. The respiratory system consists of a series of branching tubes and brings atmospheric oxygen into contact with the gas exchange membrane of the lungs in the alveoli. Oxygen is then transported throughout the body via the cardiovascular system. *External respiration* is the exchange of oxygen and carbon dioxide between the lungs and the environment. *Internal respiration* is the exchange of oxygen and carbon dioxide between the circulating blood and body tissues.

Respiratory System

The entire pathway that transports air from the environment extends from the mouth and nose down to the alveolar sacs. Figure 2.24 illustrates the structures of the respiratory system. The upper respiratory airways include the nose, mouth, pharynx, and larynx. Air enters the body by way of the nose and mouth and is then moved to the pharynx, where it is warmed, filtered, and humidified. The pharynx serves as a common pathway for both air and food. Inspired air is then moved to the larynx, which contains the epiglottis, vocal cords, and cartilaginous structures. The anatomical arrangement of the larynx and pharyngeal muscles provides the critical function of protecting the lungs from entry of foreign particles, as well as assisting with phonation (production of vocal sounds) and coughing, which is the primary physiological mechanism for clearing the airways. The *laryngopharynx* is the area where solid and liquid food intake is separated from inspired air. It is also the site of bifurcation into the larynx and esophagus. The pharyngeal muscles close the glottis during swallowing to protect the lungs from aspiration. If a foreign body passes the glottis and enters the tracheobronchial tree, the cough reflex is initiated to clear the air passage. Immediately below the thyroid cartilage of the larynx ("Adam's apple") is the site for emergency opening to the tracheal air pathway (*tracheostomy*).[47,76,81,82]

The trachea is approximately 4 to 5 inches (11 to 13 cm) long and continues from the cartilaginous structures of the neck into the thorax. At the level of the carina (Fig. 2.25), the trachea divides into two mainstem bronchi. The carina contains the majority of cough receptors and is located approximately between the sternum and manubrium at the second intercostal space. The right and left mainstem bronchi are asymmetrical in size and shape and continue into the lower respiratory tract, further subdividing into the respiratory bronchioles, where gas exchange begins. However, gas exchange primarily occurs in the alveolar ducts and the large surface area provided by the alveoli. The respiratory

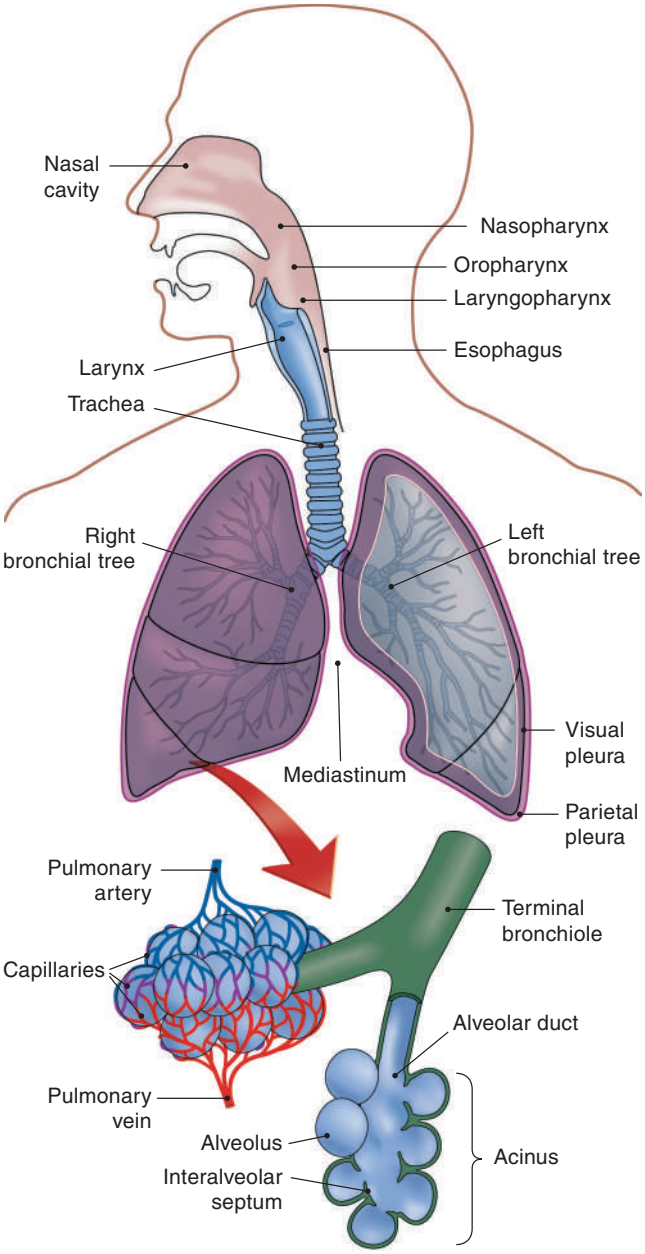

Figure 2.24 Structures of the respiratory system. *(From Dillon,[2 p. 394], with permission.)*

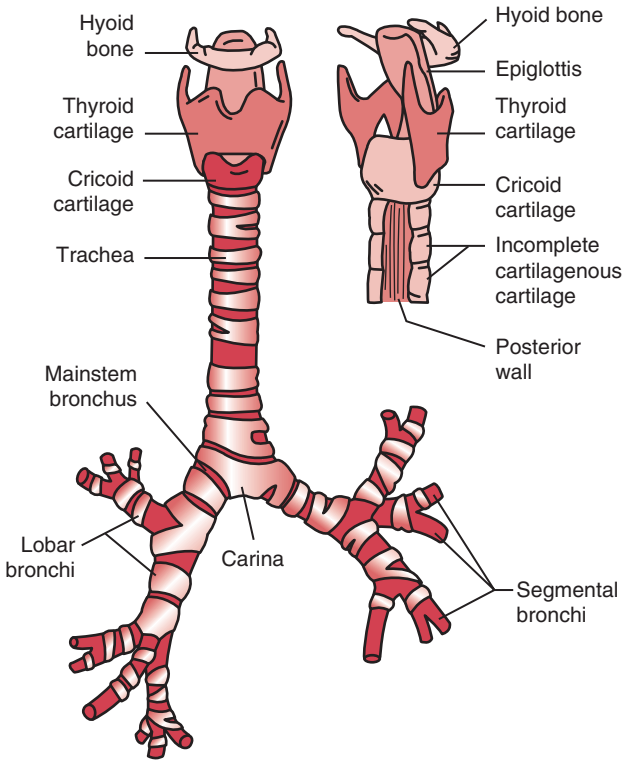

Figure 2.25 Structure of cartilaginous airways, including the trachea and major bronchi. *(From Henderson,[82 p. 388], with permission.)*

bronchioles, alveolar ducts, and alveoli (alveolar sacs) comprise the *respiratory zone* for gas exchange (Fig. 2.26). The *conductive zone* (trachea, bronchi, and terminal bronchioles) provides for continuous movement of air into and out of the lungs; these areas do not contribute to gas exchange.[47,76,78,81]

Inspiration

Inspiration is initiated by contraction of the diaphragm and intercostal muscles. During contraction of these muscles, the diaphragm moves downward and the intercostals lift the ribs and sternum up and outward. The thoracic cavity is thus increased in size and allows for lung expansion. Normal inspiration lasts 1 to 1.5 seconds.[59]

Expiration

During relaxed breathing, expiration is essentially a passive process. Once the respiratory muscles relax, the thorax returns to its resting position, and the lungs recoil. This ability to recoil occurs because of the inherent elastic properties of the lungs. Normal expiration lasts 2 to 3 seconds.[59]

Regulatory Mechanisms

Regulation of respiratory function involves multiple components of both neural and chemical control and is closely integrated with the cardiovascular system. Breathing is controlled by the respiratory center, which lies bilaterally in the pons and medulla. Motor nerves whose cell bodies are located in this area control the respiratory muscles. The respiratory center provides control of both the *rate* and the *depth* of breathing in response to the metabolic needs of the body.[83]

Both *central* and *peripheral* chemoreceptors influence respiration. *Central* chemoreceptors located in the respiratory center are sensitive to changes in either carbon dioxide or hydrogen ion levels of arterial blood. An increase in either carbon dioxide levels or hydrogen ions will stimulate breathing.[46] *Peripheral* chemoreceptors are

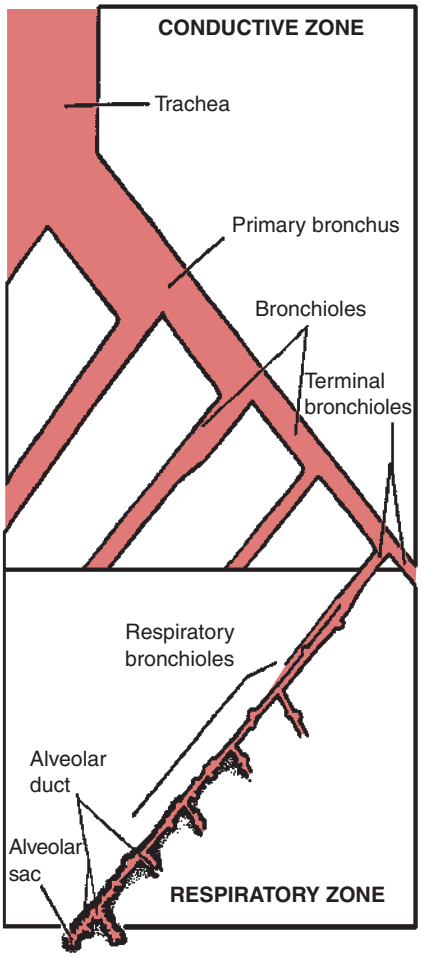

Figure 2.26 Schematic illustration of the functional zones of the respiratory tract. The top area from the trachea to the terminal bronchioles is called the "conductive zone" because these airways transport (conduct) inhaled air to and from the respiratory zone. The bottom area of the illustration represents the areas where air exchange takes place. The air exchange occurs in progressively increasing increments in the respiratory bronchioles, alveolar ducts, and alveolar sacs. Collectively these areas constitute the "respiratory zone." *(From Henderson,[82 p. 389], with permission.)*

located at the bifurcation of the carotid arteries (carotid bodies) and in the arch of the aorta (aortic bodies). These receptors are sensitive to the partial pressure of oxygen (PaO_2) in the arterial blood. When PaO_2 levels in arterial blood drop, afferent impulses carry this information to the respiratory center. Motor neurons to the respiratory muscles are stimulated to increase **tidal volume** (amount of air exchanged with each breath) or, with very low oxygen levels, to increase the respiratory rate as well. These peripheral chemoreceptors cause an increase in respiration only when PaO_2 levels fall to approximately 60 mm Hg (from a normal level of about 90 to 100 mm Hg). This is because the receptors are sensitive only to PaO_2 levels in plasma and not to the total oxygen in blood.[46,83]

Respiration also is influenced by a protective stretch mechanism called the *Hering-Breuer reflex*. Pulmonary stretch receptors throughout the walls of the lungs detect the amount of stretch imposed by entering air.[84] When overstretched, these receptors send impulses to the respiratory center to inhibit further inspiration and increase the duration of expiration. Impulses stop at the end of expiration so that another inspiration can be initiated.[46,76] In adults, this reflex is rarely demonstrated and would likely not be activated until tidal volume reached higher than 1.5 liters.[46] However, evidence suggests that the Hering-Breuer reflex has a significant impact on the breathing pattern of neonates.[85] Respiration is also stimulated by vigorous movements of joints and muscle (exercise) and is strongly influenced by voluntary cortical control.

Factors Influencing Respiration

Multiple factors can alter normal, relaxed, effortless respiration. As with temperature and pulse, any influence that increases the metabolic rate also will increase RR. Increased metabolism and subsequent demand for oxygen will stimulate increased respiration. Conversely, as metabolic demands diminish, respirations also will decrease. Several influencing factors are of particular importance when examining respiration. These include age, body size, stature, exercise, and body position.

Age

The RR of a newborn is between 30 and 90 breaths per minute. The rate gradually slows until adulthood, when it ranges between 12 and 20 breaths per minute. In elderly individuals, the RR increases owing to decreased elasticity of the lungs and decreased efficiency of gas exchange. Other factors associated with normal aging that affect respiratory function include weakening of respiratory muscles, deterioration of alveolar walls, decreased thoracic mobility, and decreased lung volumes.[86]

Body Size and Stature

Men generally have a larger vital capacity than women, adults larger than adolescents and children. Tall, thin individuals generally have a larger vital capacity than stout or obese individuals. With larger lung capacity there is also a lower RR.

Exercise

Respiratory rate and depth will increase with exercise as a result of increased oxygen demand and carbon dioxide production.

Body Position

The recumbent position can significantly affect respiration and predispose the patient to stasis of fluids. Among the influential factors that limit normal lung expansion when lying down are compression of the chest against the supporting surface and pressure from abdominal

organs against the diaphragm. Both of these factors cause increased resistance to breathing. Difficult recumbent breathing is common during the late stages of pregnancy as the fetus shifts the diaphragm upward.[60] Patients with congestive heart failure (CHF) also experience labored breathing when lying flat, which improves when standing or sitting up.

Environment

Exposure to pollutants such as gas and particle emissions, asbestos, chemical waste products, or coal dust can diminish the ability to transport oxygen. Other common offending pollutants include high ozone concentrations, sulfur dioxide, and carbon monoxide.[50] These respiratory irritants typically increase mucus production. High altitudes also affect the respiratory system owing to reduced air mass (i.e., the partial pressure of oxygen in inspired air is low). This means fewer oxygen molecules per liter of air, causing a reduction in arterial blood oxygen levels and triggering shortness of breath (*dyspnea*) and reduced tolerance to activity. Hyperventilation, tachycardia, and pulmonary edema (accumulation of fluid in alveolar walls) can also occur at high altitudes.[50,60,87,88]

Emotions/Stress

Stress as well as emotions can result in an increased rate and depth of respirations owing to stimulation of the sympathetic nervous system.

Pharmacological Agents

Essentially any drug that depresses central nervous system (CNS) function will result in respiratory depression. Narcotic agents (e.g., opioids [morphine], meperidine hydrochloride [Demerol]) will decrease the rate and depth of respirations. Other categories of CNS depressant agents include barbiturates (e.g., phenobarbitol [Nembutal], secobarbital [Seconal]), benzodiazepines (e.g., lorazepam [Ativan], midazolam [generic], diazepam [Valium]), neuroleptics (e.g., chlorpromazine [Thorazine], haloperidol [Haldol], clozapine [generic]) muscle relaxants, tricyclic antidepressants, and anticonvulsants. Conversely, bronchodilators decrease airway resistance and residual volume with a resultant increase in vital capacity and airflow. Common bronchodilator medications include albuterol (AccuNeb, Ventolin, Proventil), bitolterol (Tornalate), epinephrine (EpiPen), formoterol (Foradil), isoproterenol (Isuprel), metaproterenol (Alupent), and terbutaline (generic).[89,90]

Parameters of Respiration

In examining respiration, four parameters are considered: rate, depth, rhythm, and sound. The *rate* is the number of breaths per minute. Either inspirations or expirations are counted, but not both. The normal adult RR is 12 to 20 per minute. The rate should be counted for 30 seconds and multiplied by 2. If any irregularities are noted, a full 60-second count is indicated.

The *depth* of respiration refers to the amount (volume) of air exchanged with each breath. Normally, the depth of respirations is consistent, producing a relatively even, uniform movement of the chest. The normal adult tidal volume is approximately 500 mL of air. The depth of respiration is determined by observation of chest movements and is usually described as *deep* or *shallow,* depending on whether the amount of air exchanged is greater or less than normal. With deep breaths, a large volume of air is exchanged; with shallow respirations, a small amount of air is exchanged, typically with minimal lung expansion or chest wall movement.

The *rhythm* refers to the regularity of inspirations and expirations. Normally, there is an even time interval between respirations. The respiratory rhythm is described as *regular* (normal) or *irregular* (abnormal).

The *sound* of respirations refers to deviations from normal, quiet, effortless breathing. Although some respiratory sounds are audible, accurate identification requires auscultation (listening with a stethoscope placed directly against the chest wall). Normal (*vesicular*) breath sounds are heard primarily during inspiration and sound relatively smooth and soft.[78] Common abnormal (*adventitious*) sounds of breathing include the following:

- **Wheeze** *(Wheezing):* A continuous whistling sound produced by air passing through a narrowed airway such as a bronchi or bronchiole; is often compared to the whistling produced when stretching the neck of a balloon and allowing air to escape slowly through the narrowed passageway. It may be heard on both inspiration and expiration but is more prominent on expiration. Wheezing is a common symptom of asthma, is also seen in CHF, and can result from an airway obstruction.
- **Stridor:** A harsh, high-pitched crowing sound that occurs with upper airway obstructions resulting in narrowing of the glottis or trachea. It is apparent in patients with tracheal stenosis or presence of a foreign object.
- **Crackles** (also called *rales*): Rattling or bubbling sounds that occur owing to secretions in the air passages of the respiratory tract. The sound is often compared to that of rustling a cellophane bag. Crackles may be heard with the ear but are most accurately determined using a stethoscope. Crackles are apparent in patients with CHF.
- **Sigh:** A deep inspiration followed by a prolonged, audible expiration. Occasional sighs are normal and function to expand alveoli; frequent sighs are abnormal and may be indicative of emotional stress.
- **Stertor:** A snoring sound owing to partial obstruction (e.g., secretions) in the upper airway (e.g., trachea, large bronchi).

Patterns of Respiration

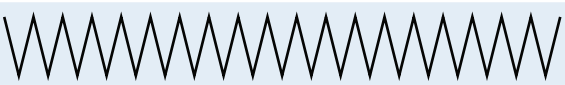
Examination of the rate, rhythm, and depth allows the therapist to determine the *pattern* of respiration. Not all

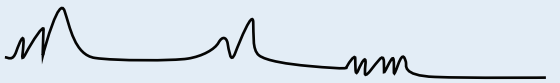
patients will present with a distinct pattern of respiration. However, several patterns occur with sufficient frequency that uniform terminology has been developed for their identification. Common respiratory patterns are presented in Figure 2.27.

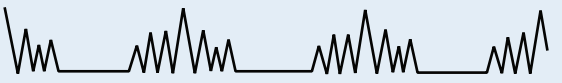
Eupnea is the term used to describe a normal breathing pattern of 12 to 20 times per minute in an adult. **Hyperventilation** is an abnormally fast rate and depth of respiration often associated with anxiety, emotional stress, and panic disorders. A common response to an acute episode is to have the patient rebreathe into a paper bag, which replaces some of the lost carbon dioxide (**hypocapnia**). CNS or pulmonary disorders may cause prolonged hyperventilation. **Hypoventilation** is a reduction in the rate and depth of respirations. This decrease in the amount of air entering the lungs causes an increase in arterial carbon dioxide levels.

Difficult or labored breathing is called **dyspnea**. Patients with dyspnea require increased, noticeable effort to breathe, and often appear as if struggling to get air into the lungs. In an effort to increase effectiveness of respiration, accessory muscles such as the intercostals and abdominals are often active. The intercostals assist in raising the ribs to expand the thoracic cavity; the abdominals assist function of the diaphragm. Additional muscles that may provide accessory functions in respiration are the sternocleidomastoid, pectoralis major and minor, scalenes, and subclavius. Use of accessory muscles to breathe is referred to as **costal** or **thoracic breathing**. Pain and nasal flaring sometimes accompany dyspnea (to bring in more oxygen). Acute episodes may be brought on by blockage of an air passage, infection of the respiratory tract, or trauma to the thorax. Long-standing dyspnea is a hallmark of COPD, such as asthma or bronchitis. Therapists often teach patients with COPD a breathing technique called *pursed-lip breathing* to help prevent small airway collapse. In this technique, air is inhaled slowly through the nose and slowly exhaled through pursed lips.

Orthopnea is difficult or labored breathing (dyspnea) when the patient is lying down that is relieved by moving to a sitting or standing position. The change in positioning causes gravity to lower abdominal organs, allowing increased room for chest expansion. Orthopnea is a characteristic symptom of CHF and also may be seen with asthma, advanced emphysema, and pulmonary edema. **Tachypnea** is an abnormally fast RR, usually greater than 24 breaths per minute. This pattern is seen with respiratory insufficiency and fever as the body attempts to rid itself of excess heat. During fever, RR may increase as much as 4 per minute with each 1°F (0.6°C) increase in temperature.[54] **Bradypnea** is an abnormally slow RR, usually 10 breaths or fewer per minute. Bradypnea is associated with impairment of the respiratory control center, as may occur with increased intracranial pressure (tumor), drug intake (narcotics), or metabolic disorder. **Apnea** is the absence of respirations and is usually transient. If sustained for longer than several minutes, brain damage and death may occur. **Cheyne-Stokes respiration** is characterized by a period of apnea lasting 10 to 60 seconds, followed by gradually increasing depth







TYPE	DESCRIPTION	ILLUSTRATION
Eupnea	Normal respirations, with equal rate and depth, 12–20 breaths/min	
Bradypnea	Slow respirations, <10 breaths/min	
Tachypnea	Fast respirations, < 24 breaths/min, usually shallow	
Kussmaul's Respirations	Respirations that are regular but abnormally deep and increased in rate	
Biot's Respirations	Irregular respirations of variable depth (usually shallow), alternating with periods of apnea (absence of breathing)	
Cheyne-Strokes Respirations	Gradual increase in depth of respirations followed by gradual decrease and then a period of apnea	
Apnea	Absence of breathing	

Figure 2.27 Normal (*top*) and abnormal respiratory patterns. When examining respiratory patterns, consider the *rate*, *rhythm*, and *depth* of breathing and describe what is observed using these terms. *(From Wilkinson and Treas,[7 p. 339], with permission.)*

and frequency of respirations (hyperventilation). It occurs with depression of the cerebral hemispheres (e.g., coma), in basal ganglia disease, and occasionally in CHF. It is associated with a poor prognosis. Box 2.6 Evidence Summary includes studies examining the reliability and validity of measuring respiratory rate.

Respiratory Examination

Because respiration is under both voluntary (cortical) and involuntary control, it is important that the patient is unaware that respiration is being examined. Once aware of the examination, characteristics of the breathing pattern will likely be altered. This is a normal reaction to being observed. It is often recommended that respirations be observed immediately after taking the pulse. After monitoring the pulse, the fingers can remain in place at the pulse site, and respirations can be monitored without drawing the patient's conscious attention to his or her breathing pattern. Ideally, respiration should be examined with the chest exposed. If this is not possible, or if respirations cannot be easily observed through clothing, maintain fingers on the radial pulse site and place the patient's forearm across the chest. This will allow limited palpation without drawing conscious input from the patient. Chapter 12: Chronic Pulmonary Dysfunction, provides a more thorough discussion of the respiratory examination.

Monitoring Respiration

A. Assemble equipment.
  1. Watch (or wall clock) with a second hand.
B. Wash hands.
C. Procedure.
  1. Ensure patient safety and comfort. Respirations are typically monitored with the patient either supine or sitting.
    Note: The patient should be in a quiet resting position for at least 5 minutes prior to monitoring respirations.
  2. Expose chest area; if area cannot be exposed and respirations are not readily observable, place patient's forearm across chest and keep fingers positioned as if continuing to monitor the radial pulse.
  3. As the patient breathes, observe the rise and fall of the chest; note the amount of effort required or audible sounds produced during breathing. (Normally, respiration is effortless and silent.)
  4. Using the second hand of a watch or clock, determine the rate by counting respirations (either inspirations or expirations, but not both) for 30 seconds and multiply by 2.
  5. Identify the rhythm (regularity of inspirations and expirations); note deviations from normal

Box 2.6 Evidence Summary Studies Examining the Reliability and Validity of Measuring Respiratory Rate

Reference	Methods	Subjects/Design	Results	Conclusion/Comments
Smith et al (2011)	To compare an electronic respiratory rate (RR) monitor with the manual counting method. The manual method required the same health professional to place a hand on the patient's chest and count chest excursions for 60 seconds.	A total of 220 patients who required postoperative oxygen via an adult-sized mask were included. RR was measured using the electronic monitor and the manual method simultaneously.	There was a significant correlation ($r = 0.84$) between the two methods for measuring RR. The mean manual RR was 14.32 and the mean monitor RR was 13.46. The mean difference between RR methods was 0.86.	This study showed that the electronic RR monitor was easy to use and safe. In addition, the electronic monitor can provide continuous monitoring, which the manual method cannot provide. The greatest difference between methods was observed in unstable patient populations.
Considine et al (2009)	To predict critical care admissions based on signs (including vital signs) and symptoms.	A retrospective case control design of 386 patients (193 patients in each group). Groups were matched based on age, sex, emergency department diagnosis, and triage category.	Cases (32.3%) had a higher incidence of abnormal RR when compared to controls (22.3%). In fact, RR abnormalities at first nursing assessment (odds ratio = 1.66, 95% CI = 1.05-2.06) increased the odds of critical care admission.	This study indicates factors that may predict critical care admission, such as abnormal RR.

Box 2.6 Evidence Summary Studies Examining the Reliability and Validity of Measuring Respiratory Rate—cont'd

Reference	Methods	Subjects/Design	Results	Conclusion/Comments
Chaboyer et al (2008)	To predict adverse events within 72 hours of discharge from an intensive care unit (ICU). Predictors examined included demographic and clinical characteristics, including vital signs.	This study examined 300 patients admitted to the ICU, of which 208 (69.3%) had no adverse event, 92 (30.7%) had any adverse event, and 17 (5.7%) had a major adverse event.	Based on univariate analyses, an RR < 10 or ≥ 25 was a predictor for: Any adverse event (odds ratio = 4.23, 95% CI = 2.12-8.45) A major adverse event (odds ratio = 5.82, 95% CI = 2.03-16.68) Based on multivariate analysis, an RR < 10 or ≥ 25 was the stronger predictor of any adverse event (odds ratio = 3.22, 95% CI = 1.56-6.66).	Abnormal RR and high HR are commonly used in risk assessment after discharge from an ICU. Both RR and HR are independent predictors of adverse events, with RR being the strongest predictor based on univariate and multivariate analyses.
Lockwood et al (2004)	To examine the best available evidence related to monitoring vital signs, including: • Purpose • Limitations • Optimal measurement frequency • What measures should considered vital signs	Narrative, systematic review of vital signs. Updated review of Evans et al (2001). Included 124 studies on neonatal, pediatric, and adult patient populations.	There is limited research on RR measurements. Studies found focused on accuracy of measuring RR and RR as a marker for dysfunction.	Clinicians should not use RR alone as an indicator of deteriorating physiological function. In children, RR should not be used alone as a measure of serious illness. When measuring RR, count for 60 seconds, use a stethoscope for children and neonates when the RR is rapid, and assess the RR when the patient is at rest. In acute situations, an increasing RR may indicate respiratory dysfunction.
Evans et al (2001)	To examine the best available evidence related to monitoring vital signs, including: • Measurements that constitute vital signs • Optimal measurement frequency • Limitations of vital signs	Narrative systematic review of vital signs. Included 69 studies on neonatal, pediatric, and adult patient populations.	There is limited low-level evidence on the frequency with which vital signs should be monitored. There is little research on RR measurement.	Much of current practice of vital sign measurement is not based on research but on tradition and expert opinion. Several studies have reported inaccurate RR measurements as a function of the technique used. There is also evidence to support the use of pulse oximetry to detect deterioration in physiologic function.

uninterrupted, even spacing. If any irregularities are noted, count for a full 60 seconds to accommodate the fluctuations and ensure an accurate count.

6. Observe the depth of respiration; determine if a small, large, or approximately normal volume of air is inspired. Observe involvement of accessory muscles, which suggests weakness in the primary muscles of breathing (diaphragm and external intercostal muscles); if difficult to observe, palpation of chest wall excursion can be used to identify depth of respiration. Record as shallow, deep, or normal.

   Note: Chest wall excursion can also be determined by circumferential chest measures using a tape measure at specific bony landmarks. Three common landmarks for circumferential chest measures are (1) the sternal angle of Luis; (2) the xiphoid process; and (3) midway between the xiphoid process and the umbilicus.
7. If indicated, determine the sound of breathing using a stethoscope.
8. Return clothing if chest has been exposed.
9. Wash hands.

BLOOD PRESSURE

Blood pressure refers to the force the blood exerts against a vessel wall. It is measured in millimeters of mercury (mm Hg) and recorded in the form of a fraction (e.g., 119/79). The top number indicates systolic pressure, and the bottom indicates diastolic pressure. Because liquid flows only from a higher to a lower pressure, the pressure is highest in the arteries, lower in the capillaries, and lowest in veins.[45,47]

Inasmuch as the heart is an intermittent pulsatile pump, pressure is measured at both the highest and lowest points of the pulse. These points represent the systolic (ventricular contraction) and diastolic (ventricular relaxation) pressures. The **systolic pressure** is the highest pressure exerted by the blood against the arterial walls. The **diastolic pressure** (which is constantly present) is the lowest pressure. The elastic properties of the arterial walls allow for expansion and recoil in response to the changing volume of circulating blood during the cardiac cycle. The mathematical difference between the systolic and diastolic pressures is called the **pulse pressure**. For example, a systolic pressure of 119 mm Hg and a diastolic pressure of 79 mm Hg result in a pulse pressure of 40 mm Hg.

BP is a function of two primary elements: (1) cardiac output (amount of blood flow, CO); and (2) peripheral resistance (impediment to blood flow within a vessel, R) that the heart must overcome. The relationship between BP, CO, and R is expressed in the equation: BP = CO × R. Additional factors that contribute to this relationship include the diameter and elasticity of vessel walls, blood volume, and blood viscosity.[91]

Blood Pressure Regulation

The *vasomotor center* is located bilaterally in the lower pons and upper medulla. It transmits impulses through sympathetic nerves to all vessels of the body. The vasomotor center is tonically active, producing a slow, continual firing in all vasoconstrictor nerve fibers. It is this slow, continual firing that maintains a partial state of contraction of the blood vessels and provides normal *vasomotor tone.*[49] The vasomotor center assists in providing the stable arterial pressure required to maintain blood flow to body tissue and organs. This occurs because of its close connection to the cardiac controlling center in the medulla (because changes in cardiac output will influence BP). In addition, the vasomotor and cardiac controlling centers require input from afferent receptors.

Afferent input regarding BP is provided primarily by *baroreceptors* and *chemoreceptors*. The *baroreceptors* (pressoreceptors) are stimulated by stretch of the vessel wall from alterations in pressure. These receptors have a high concentration in the walls of the internal carotid arteries above the carotid bifurcation and in the walls of the arch of the aorta. Baroreceptors located in the *carotid sinuses* of the carotid arteries monitor BP to the brain. Baroreceptors in the *aortic sinuses* of the aortic arch are responsible for monitoring BP throughout the body.

In response to an increase in BP, the baroreceptor input to the vasomotor center results in an inhibition of the vasoconstrictor center of the medulla and excitation of the vagal center.[47] This results in a decreased HR, decreased force of cardiac contraction, and vasodilation, with a subsequent drop in BP. The baroreceptor input during a lowering of BP would produce the opposite effects.

The *chemoreceptors* are stimulated by reduced arterial oxygen concentrations, increases in carbon dioxide tension, and increased hydrogen ion concentrations. These receptors lie close to the baroreceptors. Those located in the carotid artery are called *carotid bodies,* and on the aortic arch they are termed *aortic bodies*. Impulses from these receptors travel to the brain (cardioregulatory and vasomotor centers) via afferent pathways in the vagus and glossopharyngeal nerves. Efferent impulses from these centers, in response to alterations in BP, will alter HR, strength of cardiac contractions, and size of blood vessels.[46]

Factors Influencing Blood Pressure

Many factors influence pressure. As with all vital signs, BP is represented by a range of normal values and will yield the most useful data when monitored over a period of time. Important influences to be considered when examining BP include blood volume, diameter and elasticity of arteries, cardiac output, age, exercise, and arm position.

Blood Volume

The amount of circulating blood in the body directly affects pressure. Blood loss (e.g., hemorrhage) will cause

pressure to drop, and can result in **hypovolemic shock** from inadequate tissue perfusion. Conversely, an increase in the amount of circulating blood (e.g., blood transfusion) will cause the pressure to rise. Reduced fluid volume, as may occur with diarrhea or inadequate oral intake (dehydration), will also lower BP; excess fluid, as occurs with CHF, will increase pressure.[60] Essentially, any situation causing a shift (increase or decrease) in body fluids (intravascular, interstitial, or intracellular) will alter BP.[60] Bladder distention can also contribute to BP elevation.

Diameter and Elasticity of Arteries

The diameter (size) of the vessel lumen will provide either *increased peripheral resistance* (vasoconstriction) or *decreased resistance* (vasodilation) to cardiac output. The elasticity of the vessel wall also influences resistance. Normally, the expansion and recoil properties of the arterial walls provide a continuous, smooth flow of blood into the capillaries and veins between heartbeats. With age, these properties are diminished; arterial stiffness decreases vessel wall compliance. Thus, there is a higher resistance to blood flow with resultant *increase* in BP.

A characteristic feature of arteriosclerosis is reduced vessel wall compliance in response to fluctuations in pressure. For older adults, elevated BP is often associated with the degenerative effects of arteriosclerosis. As the disease progresses, small arteries and arterioles lose elasticity, the walls become thick and hard and unable to yield to pressure exerted by blood flow, and the lumen gradually narrows and may eventually become blocked. Multiple factors may contribute to hypertension in elders (e.g., smoking, activity level, obesity, diet, comorbidities such as cardiac or vascular disease). In her extensive literature review, Pinto states, "The increase in BP with age is most likely due to complex and varied factors moulded [molded] and influenced by the individual environment and lifestyle."[92, p. 110]

Cardiac Output

When increased amounts of blood are pumped into the arteries, the walls of the vessels distend, resulting in a higher BP. With lower cardiac output, less blood is pushed into the vessel, and there is a subsequent drop in pressure.

Age

BP varies with age. It normally rises gradually after birth and reaches a peak during puberty. By late adolescence (18 to 19 years), adult BP is reached. For many years, the normal adult BP was considered 120/80 mm Hg. New BP guidelines were presented in the Seventh Report of the Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: The JNC 7 Report (Table 2.8).[93] The new recommendations recognize the high prevalence of hypertension that affects millions of individuals in the United States and people worldwide. Hypertension (equal to or greater than 140/90) is a primary risk factor for myocardial infarct, heart failure, stroke, and kidney disease. The former normal adult BP value of 120/80 mm Hg now falls into the new category of prehypertension (systolic pressure: 120 to 139; diastolic pressure: 80 to 89). "Prehypertension is not a disease category. Rather, it is a designation chosen to identify individuals at high risk of developing hypertension, so that both patients and clinicians are alerted to this risk and encouraged to intervene and prevent or delay the disease from developing."[93, p. 12] A BP value of 119/79 mm Hg or below is the new normal adult standard. The JNC 7 Report recommends implementation of measures to prevent further increases in the prevalence of hypertension.[93]

Table 2.8 Classification of Blood Pressure for Adults Ages 18 Years and Older

BP Classification	Systolic BP (mm Hg)	Diastolic BP (mm Hg)
Normal	<120	<80
Prehypertension	120–139	80–89
Hypertension		
• Stage 1	140–159	90–99
• Stage 2	≥160	≥100

From Chobanian et al,[93] with permission.

Clinical Note: Seen more frequently with elders is *white coat hypertension* or *nonsustained hypertension*. This occurs in individuals whose blood pressure is higher in a clinical setting than outside the clinic; it is believed to be associated with the stress and anxiety of seeing a doctor (the "white coat").

Exercise

Physical activity increases cardiac output, with a consequent linear increase in BP. Greater increases are noted in systolic pressure owing to proportional changes in pressure gradient of peripheral vessels. This means that although cardiac output during exercise is high, vasodilation reduces peripheral resistance to maintain a relatively lower diastolic pressure. BP increases are proportional to the intensity of the workload. A drop in SBP of 10 mm Hg or more with increasing exercise intensity is an indication for stopping exercise (per American College of Sports Medicine guidelines).

Valsalva Maneuver

The **Valsalva maneuver** is an attempt to exhale forcibly with the glottis, nose, and mouth closed. It causes an increase in intrathoracic pressure with an accompanying collapse of the veins of the chest wall. There is a subsequent decrease in blood flow to the heart, a decreased venous return, and a drop in BP. This maneuver serves to internally stabilize the abdominal and chest wall

during periods of rapid and maximum exertion such as lifting a heavy object. When the breath is released, the intrathoracic pressure decreases, and venous return is suddenly reestablished as an "overshoot" mechanism to compensate for the drop in BP. In turn, there is a marked increase in HR and BP. This rapid rise in arterial pressure causes vagal slowing of the HR (bradycardia). Although the Valsalva maneuver can temporarily enhance muscle function via internal stabilization, it has an indirect undesirable effect of increasing BP and should be avoided by individuals with cardiac impairment and hypertension.[45,49]

Clinical Note: A common misconception concerning the Valsalva maneuver is that it directly increases HR and BP. As described earlier, it is the body's recovery mechanism of suddenly increasing venous return that causes this increase. The subsequent drop in BP due to the Valsalva maneuver may result in seeing "black dots" and the feeling of dizziness that often accompanies straining while lifting a heavy object.

Orthostatic Hypotension

Associated with prolonged immobility and periods of bedrest, **orthostatic** or **postural hypotension** is a sudden drop in BP that occurs when movement to upright postures (sitting or standing) is initiated. The positional change causes gravitational blood pooling in the lower extremity (LE) veins. Venous return and cardiac outputs are reduced, with resultant cerebral hypoperfusion. This can trigger an episode of light-headedness, dizziness, or even loss of consciousness (syncope). In response to positional changes under normal circumstances, BP is maintained by reflex vasoconstriction (via baroreceptors), which increases HR. After a period of inactivity, postural hypotension should be anticipated; it requires a gradual acclimation to the upright position until normal reflex control returns. Other predisposing factors for postural hypotension include exercise, drugs such as antihypertensives and vasodilators, reduction in baroreceptor response with aging, the Valsalva maneuver, and **hypovolemia** (abnormally low volume of circulating blood).[94,95] Patients with CNS involvement of the autonomic nervous system (e.g., patients with acute cervical spinal cord injury or Parkinson's disease) typically exhibit episodes of orthostatic hypotension with position changes. As a useful precaution, any patient restricted to a recumbent position for even short periods should be considered at risk for postural hypotension. These events can be minimized by use of external pressure supports such as abdominal binders and support or full-length elastic stockings (elastic bandages can also be used effectively) and a very gradual acclimation to upright postures. Should postural hypotension occur during treatment, the patient should be reclined from upright with the legs elevated.

Arm Position

BP may vary as much as 20 mm Hg by altering arm position. For consistency of measurements, the patient should be sitting with the arm in a horizontal supported position at heart level. If patient condition or the type of activity precludes these positions, alterations should be carefully documented. As with other vital signs, factors such as fear, anxiety, or emotional stress also will cause an increase in BP.

Risk Factors

High BP is also associated with a large number of risk factors, including high sodium intake, obesity and being overweight, a sedentary lifestyle, heavy alcohol consumption, pregnancy, sex, and age. In the United States, approximately 76.4 million people aged 20 or older have high BP.[96] Projections suggest that by 2030, another 27 million people could have high BP. Until age 45 years, a greater percentage of men than women have high BP; between 45 and 64 years of age, the percentage of men and women is comparable; and after that a much higher percentage of women than men have high BP.[96] African Americans are at greater risk for high BP than Caucasians. The rate of hypertension among this group is 44%, among the highest in the world.[97] Heredity (parental history of high BP) also places the individual at greater risk. Globally, high systolic BP is seen in 51% of patients with stroke and in 45% of patients with ischemic heart disease.[98]

In addition, some medications can either increase BP or interfere with antihypertensive drugs. These drugs include steroids, nonsteroidal anti-inflammatory agents, diet pills, cyclosporine, erythropoietin, tricyclic antidepressants, monoamine oxidase inhibitors, and some oral contraceptives.

Equipment Requirements

A noninvasive or *indirect* measure of BP is used by physical therapists. In critical care settings, invasive or *direct* measures of BP are obtained by placing a thin catheter directly into an artery. The equipment required for taking BP using the more common noninvasive auscultatory (listening) method includes a *sphygmomanometer* and a *stethoscope*. The sphygmomanometer (frequently referred to as a *blood pressure cuff*) consists of a flat, airtight, inflatable latex bladder. The bladder is covered with a cotton or nylon sleeve that extends beyond the length of the bladder. There are two tubes that extend from the cuff. One is attached to a rubber bulb that has a valve to maintain or to release air from the cuff. The second tube is attached to a pressure manometer (portion of sphygmomanometer that registers the pressure reading). In patient care settings, sphygmomanometers may be wall mounted (Fig 2.28A) or placed on a mobile stand with a wheeled base (Fig 2.28B). Box 2.7 Evidence Summary presents studies examining the reliability and validity of blood pressure measurements.

Box 2.7 Evidence Summary Studies Examining the Reliability and Validity of Blood Pressure Measurements

Reference	Method(s)	Subjects/Design	Results	Conclusions/Comments
Frese et al (2011)	Provide blood pressure (BP) measurement guidelines for physical therapists and physical therapist assistants.	This is a narrative review paper.	Provides information on classification of hypertension, common sources of error, recommended cuff sizes, reference data, and considerations for special situations.	Accurately measuring BP is critical for physical therapists.
Verrij et al (2009)	Examined the effect of elevating the arm overhead for 30 seconds (sec) on the amplitudes of Korotkoff's sounds.	This study examined 46 patients (mean age of 54 years). Compared the amplitudes of Korotkoff's sounds after overhead and usual arm positions.	The amplitude of the first Korotkoff's sound with the arm overhead was significantly (1.82 times) greater than the amplitude of the first Korotkoff's sound with the arm at its usual position.	Korotkoff's sounds can be increased by positioning the arm overhead for 30 sec and then bringing the arm to its usual position before taking BP; positioning the arm overhead does not affect BP.
Scisney-Matlock et al (2009)	Examined the reliability and reproducibility of clinic (manual sphygmomanometer) and home (automated) BP. Compared clinic and home BPs to 24 hour ambulatory BP monitoring.	Middle-aged, racially diverse women ($n = 161$). The mean of the two clinic BPs and the higher of the two home BPs was used.	The correlation between systolic home BP measurements and systolic ambulatory BP monitoring was much stronger for white women than for African-American women.	For both African American and white women, home (automated) BP measurements are reliable when compared to 24-hour ambulatory BP monitoring.
Heinemann et al (2008)	Compared an automated blood pressure (BP) unit with manual sphygmomanometer.	Patients from different departments of a large regional hospital ($n = 63$). BPs taken concurrently using both devices.	There were significant differences between methods. The manual systolic BP (SBP) and diastolic BP (DBP) were significantly higher than the automated SBP and DBP.	The automated machine consistently under-read BPs. The automated machine can be used with some confidence to measure SBP, but caution should be used when measuring DBP.
Nelson et al (2008)	To compare the aneroid manometer, automatic arm monitor, and automatic wrist monitor with the mercury column manometer (used as the gold standard).	A total of 83 participants (age range 19-92 years) participated. Measurements were taken on the left arm with 5 minutes between measurements.	The SBP significantly increased with age but not by device. There was also a significant interaction between age and device.	Difference among monitors depends on the age of the person. The automatic wrist monitors were the most unreliable. The aneroid manometer, automatic arm monitor, and automatic wrist monitor are less accurate than the mercury column manometer.
Eser et al (2006)	Compared the effect of four different body positions on BP:	Measurements were taken on 157 healthy female students, aged 18-24 years. BP was taken on the	For all positions, there was no significant difference in DBP. The SBP in supine was significantly greater than in	The SBP and DBP was the highest in the supine position. There was a significant difference in SBP by posi-

Reference	Method(s)	Subjects/Design	Results	Conclusions/Comments
	(1) sitting, (2) standing, (3) supine, and (4) supine with legs crossed. BP was measured using an automatic arm monitor.	left arm. Measurements were taken in the same order (sitting, standing, supine, and then supine with legs crossed).	the other positions. All changes in SBP between positions were significant except supine and supine with legs crossed.	tion, but not DBP. All of the changes in position significantly changed SBP except for supine and supine with legs crossed.
Fonseca-Reyes et al (2003)	Examined the effect of using a standard cuff on BP in patients with obese arms. Both a standard and large cuff were used.	In this study, 120 individuals with a mean age of 43.1 years and mean arm circumference of 37.9 cm (14.9 inches) were examined. The order of the cuff size used was randomized.	Both the SBP and DBP were significantly greater when the standard cuff size was used.	Using a standard cuff size on an obese arm will overestimate BP. Given the prevalence of obesity, clinics should have different size cuffs for taking BP.

Figure 2.28 In clinical settings, sphygmomanometers may be **(A)** wall-mounted or **(B)** placed on a mobile stand. *(Courtesy of Omron, Inc., Lake Forest, IL, 60045.)*

BP cuffs are typically secured on the patient's extremity by a hook and loop closure. They come in a variety of sizes. In adults, the width of the bladder should be approximately 40% of the arm circumference, and bladder length should be enough to encircle at least 80% of arm circumference.[92,99] Obtaining a cuff of appropriate size is important. Cuffs that are too narrow will show inaccurately high readings; cuffs that are too wide will show inaccurately low readings.[93]

The manometer registers the BP reading. Manometers are either *mercury* or *aneroid* (Fig. 2.29A and B). The mercury manometer registers BP on a mercury-filled calibrated cylinder. At the uppermost portion of the mercury column is a convex curve called the *meniscus*. A reading is obtained by viewing the meniscus at *eye level*. If not observed directly at eye level, an inaccurate reading will be obtained. The aneroid manometer registers BP by way of a circular calibrated dial and needle; automated PB units provide a digital LCD. Owing to environmental concerns, aneroid manometers and automated displays have largely replaced mercury manometers in a majority of patient care settings.

Figure 2.29 Sphygmomanometers. **(A)** Mercury gauge manometers have a vertical glass tube containing liquid mercury with a 300 mm Hg scale marked in 2-mm increments. **(B)** Aneroid manometers consist of a circular glass-covered 300 mm Hg gauge in 2-mm increments with needle marker. *(Courtesy of Omron, Inc., Lake Forest, IL 60045.)*

Figure 2.30 **(A)** Automated clinical sphygmomanometer with **(B)** differently sized cuffs. *(Courtesy of Omron, Inc., Lake Forest, IL 60045.)*

Automated sphygmomanometers (Fig. 2.30A) are self-inflating battery (rechargeable) or electrically powered units; many battery-powered models are also equipped with an AC adapter. Some include the "average mode" feature that performs two or three readings and then averages the total. Devices designed for clinical use often include several cuff sizes (e.g., small, medium, large, and extra-large) (Fig 2.30B).

Personal-sized automated sphygmomanometers are particularly useful and practical for patients requiring frequent self-monitoring. They provide a rapid digital display, monitor pulse (in most cases), allow data storage, and are easy to use. (Place cuff and activate start button.) Automated sphygmomanometers do not require a stethoscope; during automated inflation and deflation, the diastolic and systolic pressures are recorded. These devices monitor BP at the traditional arm location (Fig. 2.31A) or at the wrist (Fig. 2.31B). For both types of cuffs, patients should be instructed that the UE should be supported at heart level.

To monitor BP with a mercury or aneroid sphygmomanometer, an acoustic stethoscope is used to listen to the sounds over the artery as pressure is released from the cuff. By a combination of listening through the stethoscope and watching the manometer, the BP reading is obtained. A stethoscope amplifies and carries body sounds to the examiner's ears. Proximally, it consists of two rubber or plastic earpieces attached to narrow metal tubing that projects laterally from the earpieces about 1 inch (2.5 cm) and then downward about 6 inches (15 cm). The tubes are connected by a flexible, semicircular metal spring mechanism; the total length of a stethoscope is approximately 30 inches. These metal tubes are referred to as *binaurals* (designed for use in both ears). The semicircular spring provides tension to maintain the position of the earpieces in the examiner's ears during use. The metal tubes then either (1) insert into fork-shaped rubber or plastic tubing that joins to form a single lumen and attach to the head distally (Fig. 2.32, left); or (2) insert into two separate rubber or plastic tubes that do not join (Fig. 2.32, right) and lead individually directly to the head of the stethoscope. (The two tubes are held together with small metal clasps.)

Figure 2.31 Personal-size automated sphygmomanometers **(A)** arm cuff and **(B)** wrist cuff. *(Courtesy of Omron, Inc., Lake Forest, IL 60045.)*

There are two types of distal sensing microphones on stethoscopes: a *bell-shape* (Fig. 2.33, left) and a *flat disk diaphragm* (Fig. 2.33, right). Stethoscopes may have only one type of head; others have a combination design with one side bell-shaped and the other a flat disk. The bell shape amplifies low-frequency sounds such as those produced in blood vessels; this type is generally recommended for determining BP. The flat disk diaphragm is more useful for high-frequency sounds such as heart and lung sounds. Another type of sensor incorporates both high- and low-frequency capabilities of the two shapes into a single-sided unit that eliminates the need to turn the head over. To hear low-frequency sound (bell-shape), lighter pressure of the examiner's fingers is used; firmer pressure allows high-frequency sounds to be heard.

Battery-powered stethoscopes (Fig 2.34A) provide higher levels of amplification with volume control, and dual-frequency sound filtering; some are available with interchangeable removable heads. A design variation for prehospital emergency medical service (EMS) personnel provides higher amplification levels by replacing the earpieces with a headset designed to block out noise in a moving ambulance (Fig 2.34B). Disposable stethoscopes are also available for use in high-risk settings where minimizing the risk of cross-infection is essential.

Korotkoff's Sounds

When measuring BP, a series of sounds called **Korotkoff's sounds** are heard through the stethoscope. The bell side of the stethoscope is used for auscultation because Korotkoff's sounds are low frequency. Initially when pressure is applied through the cuff around the patient's arm, the blood flow is occluded and no sound is heard

Figure 2.32 Stethoscopes. Standard acoustic stethoscope with a single tube leading to diaphragm (*left*) and Sprague Rappaport type stethoscope with two separate tubes leading to diaphragm (*right*).

Figure 2.33 Combination design stethoscope head with one side bell-shaped (*left*) to auscultate low-frequency sounds and the opposite side a flat disk diaphragm (*right*) for high-frequency sounds.

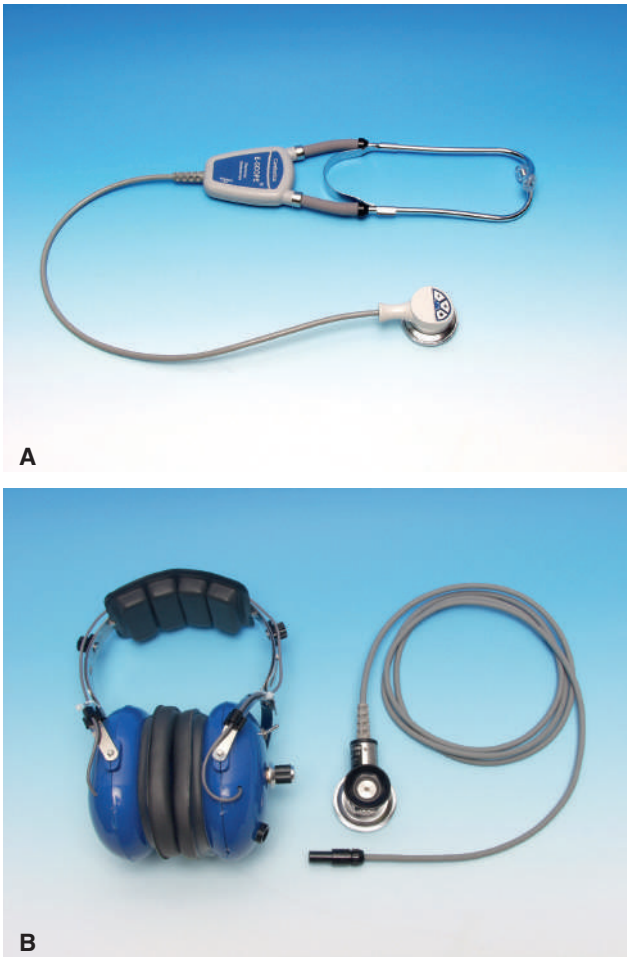

Figure 2.34 Automated stethoscopes. **(A)** Standard automated stethoscope and **(B)** automated stethoscope with headset to block out environmental noise designed for use by emergency medical service (EMS) personnel. *(Courtesy of Cardionics, Inc., Webster, TX 77598.)*

through the stethoscope. As the pressure is gradually released, a series of five phases of sounds can be identified.

The therapist should be alert for the presence of **auscultatory gap**, especially in patients with BP above normal values (hypertension). An auscultatory gap is the temporary disappearance of sound normally heard over the brachial artery between phase 1 and 2 and may cover a range of as much as 40 mm Hg. Not identifying this gap may lead to an underestimation of systolic pressure and overestimation of diastolic pressure.

1. **Phase I:** The first clear, faint, rhythmic tapping sound, which gradually increases in intensity, is heard. The period when blood initially flows through the artery is recorded as *systolic pressure*. This represents the highest pressure in the arterial system during ventricular contraction. *Be alert for an auscultatory gap.*
2. **Phase II:** A murmur or swishing sound is heard as artery widens and more blood flows through artery.
3. **Phase III:** Sounds become crisp, more intense, and louder; blood is now flowing relatively unobstructed.
4. **Phase IV:** Sound is distinct, with abrupt muffling; soft blowing quality.
5. **Phase V:** Last sound is heard; recorded as *diastolic pressure* in adults.

A BP reading with a systolic pressure of 117 and a second diastolic reading of 76 would be recorded as 117/76. An important consideration in determining BP is that it should be done in a minimal amount of time. The BP cuff acts as a tourniquet. As such, venous pooling and considerable discomfort to the patient will occur if the cuff is left in place too long. The brachial artery is the most common site for BP monitoring. A description for monitoring LE BP is also presented.

Measuring Brachial Blood Pressure

A. Assemble equipment.
   1. A stethoscope. A bell-shaped head is preferred.
   2. A sphygmomanometer with a bladder size appropriate for the arm. In adults, the width of the bladder should be about 40% of the arm circumference (measurement can be made using a tape measure midway between the acromion and olecranon processes), and bladder length should be enough to encircle at least 80% of arm circumference.[92,99] In children, the bladder should be long enough to completely encircle the entire arm.[92]
   3. Antiseptic wipes for cleaning earpieces and the head of the stethoscope before and after use.

B. Wash hands.

C. Procedure.
   1. Explain procedure and rationale in terms appropriate to the patient's understanding. Indicate that there will be a request to remain quiet during monitoring to avoid interference with auscultation.

      Note: As with other vital sign measures, BP is monitored after the patient has been in a relaxed quiet setting for a period of time because activity or physical exertion will cause an elevation in measurements.
   2. Guide the patient to the desired position. The sitting position is recommended with the back supported, the legs uncrossed, and feet flat on floor. Placing the chair next to a treatment table will facilitate UE positioning. The UE should be free of clothing. (Rolling up a garment sleeve is not acceptable owing to the tourniquet effect produced and interference with cuff positioning.) The midpoint of the arm should be at heart level with the elbow slightly flexed and the palm up. This can be effectively accomplished by supporting the UE on a treatment table. (If needed, pillows can be used to further adjust height.)

      Note: If a supine position is used, the arm should be at the patient's side and slightly elevated to the middle of the trunk. If measuring BP in standing

position (e.g., monitoring postural hypotension), ensure that the arm is supported at heart level.

3. Ensure patient understanding, safety, and comfort.
4. Use antiseptic wipes to clean the earpieces and head of stethoscope.
5. Wrap the deflated cuff snugly and evenly around the patient's bare arm approximately 1 inch (2.5 cm) above the antecubital fossa; the center of the cuff should be in line with the brachial artery (Fig. 2.35). Some cuffs have markers to guide positioning over the artery.
6. Ensure that the aneroid gauge is easily visible. (A mercury manometer must be on a level surface at eye level.) Check that the sphygmomanometer registers zero.

   Note: The first time a patient's BP is measured, an estimation of the systolic pressure should be made. This will ensure that during the actual measure, an adequate level of cuff inflation is used. The procedure is as follows:

   a. Locate and palpate the radial artery on the distal forearm of the cuffed arm.
   b. Close the valve of the BP cuff (turn clockwise).
   c. While continuing to monitor the pulse, rapidly inflate the BP cuff to 30 mm Hg above the level at which the radial pulse is extinguished.
   d. Note the pressure value on the gauge. (This is the estimate of maximum pressure required to measure systolic pressure for the individual patient.)
   e. Allow air to release quickly.

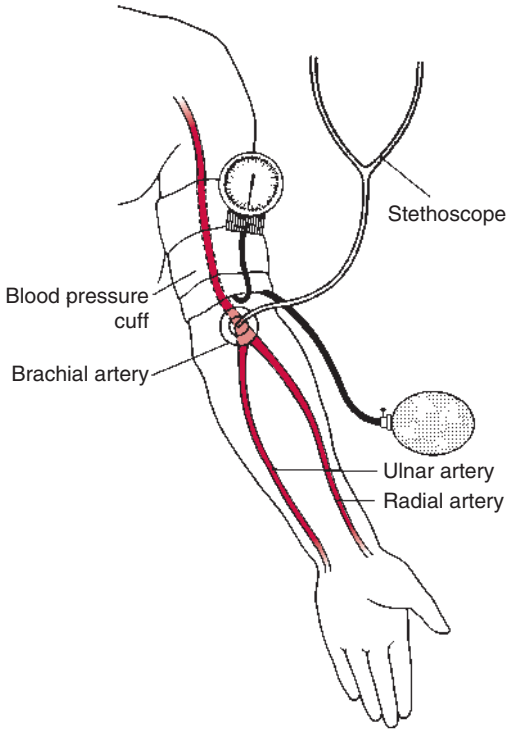

Figure 2.35 Placement of blood pressure cuff and stethoscope for monitoring brachial artery blood pressure.

7. Place the earpieces of the stethoscope (tilting slightly forward) into the ear canals; the tubes of the stethoscope should not be crossed or in contact with each other and should hang freely; use the low-frequency bell side of stethoscope.
8. Locate and palpate the brachial artery slightly above and medial to the antecubital fossa. Place the bell of the stethoscope firmly over the brachial pulse point at the lower border of the BP cuff. Sufficient pressure should be used to avoid gapping between the circumference of the bell and the skin. (In situations in which the pulse is extremely weak and undetectable, Doppler ultrasound may be substituted for use of stethoscope.)
9. Close the valve of the BP cuff (turn clockwise), and rapidly and steadily inflate the cuff to approximately 30 mm Hg above the estimated systolic pressure.
10. Release the thumb valve carefully, allowing air out slowly; air should be released at a rate of 2 mm Hg per heartbeat. Listen for the appearance of Korotkoff's sounds.
11. Watch the manometer closely and note the point at which the first rhythmic tapping sound is heard (a mercury manometer must be viewed at eye level); this is the point when blood first begins to flow through the artery and represents the systolic pressure (Korotkoff phase 1). Deflections in the dial or column of mercury will now be noted.
12. Continue to release air carefully at a rate of 2 mm Hg per heartbeat. Note when the sound first becomes muffled (Korotkoff phase 4) because quickly thereafter the sound will disappear (Korotkoff phase 5); this is recorded as the diastolic pressure.
13. Allow remainder of air to release quickly.
14. Clean the head and earpieces of the stethoscope with antiseptic wipes. If the same examiner is using the stethoscope again, it is not necessary to clean the earpieces. However, the head of the stethoscope should always be cleaned between patients.
15. Wash hands.

Note: It is recommended that at least two BP measurements be taken and the values averaged.[92] At least a 1-minute interval should elapse between repeated measures.

Measuring Popliteal (Thigh) Blood Pressure

Measurement of popliteal BP is indicated in situations in which comparisons between the UE and LE are warranted, such as peripheral vascular disease. They also are used when UE pressures are contraindicated, such as after trauma or

surgery. In comparison to the brachial artery, the popliteal artery normally yields a higher systolic pressure; diastolic values are approximately the same. Essentially, the procedure is the same as that for determining pressure at the brachial artery, with the following variations:

1. The patient is in a prone position; alternatively, the supine position may be used. Expose the LE using appropriate draping procedures.
2. Locate the pulse by palpation in the popliteal fossa. Flexing the knee slightly facilitates pulse location as the artery is deep within the posterior knee. Knee flexion also facilitates stethoscope placement. Because the popliteal pulse is deep, it is often useful to initially palpate it using the first two or three fingers of each hand on either side of the posterior knee. Once a pulse is perceived, attention is then directed to locating the strongest pulse point.
3. Wrap the deflated cuff snugly and evenly around the patient's midthigh. (A wide cuff is used; use guidelines for cuff size described for brachial BP.) The center of the bladder should be directly over the popliteal artery.

   Note: As described for brachial BP, a palpatory estimate of maximum pressure required to measure systolic pressure can be made using the popliteal or dorsalis pedis artery.
4. Proceed with auscultating the pressure as for the brachial artery.

Recording Results

For purposes of physical therapy documentation, many therapists include vital sign data directly within the narrative portion of the note. An important element in recording this information is that it allows easy comparison from one entry to the next. The date, time of day, patient position, examiner's name, and equipment used should all be clearly indicated. Any deviations from standard BP measurement protocol should be documented.

The nursing section of the medical record is an important source of vital sign data and should be checked regularly. Here, data are typically provided in graph form, with time represented on the horizontal axis and the measured values on the vertical axis. Some medical record software programs automatically create graphs from numerical data entries. The visual record allows easy identification of data trends reflective of normal variations or a response to disease or therapeutic intervention.[60] For the therapist practicing in facilities where such forms are used, familiarity with the specific recording system is important. Several methods are used to differentiate vital sign entry; they generally include some variation of open and closed circles, connecting lines, color codes, or other symbols to discriminate among temperature, HR, RR, and BP data.

RESOURCES

Multiple Internet resources are available to enhance patient understanding of the implications of altered vital sign values and the importance of maintaining values within normal ranges, in addition to presenting strategies to prevent, detect, and obtain treatment for the precipitating causes. Many organizations provide a rich source of online information and education for patients and families as well as clinical guidelines and resource materials for health professionals. Several examples are provided in Appendix 2.C: Resources for Patients, Families, and Clinicians.

SUMMARY

Values obtained from monitoring vital signs provide the physical therapist with important information about the patient's physiological status. Results from these measures assist in establishing and maintaining a database of values for an individual patient. They also assist in formulating clinical judgments for determining the diagnosis and prognosis, designing the POC, and establishing and evaluating effectiveness of selected treatment interventions.

The procedure for measuring each vital sign has been presented. Because multiple factors influence vital signs, the most useful data are obtained when measures are taken at periodic intervals rather than as a single measure in time. Sequential measures allow changes in patient status or response to treatment to be monitored over time, as well as indicating an acute change in status at a specific point in time.

For purposes of physical therapy documentation, vital sign data are typically included within the narrative format of the note. Regardless of the system of documentation selected, of critical importance is that it allows easy comparison of serial entries over time.

Questions for Review

1. In monitoring a patient's blood pressure, you obtain values that are markedly higher from those documented by another therapist yesterday. How would you respond to this situation?

2. Prior to a vital signs examination, what preliminary data can be obtained by a careful systematic observation of the patient?
3. Together with other examination data, vital sign measures assist the physical therapist in making clinical decisions about what aspects of patient care?
4. Provide examples of lifestyle patterns (modifiable) and patient characteristics (nonmodifiable) that may influence vital sign measures.
5. What are the mechanisms by which the body conserves and produces heat?
6. What methods are used to dissipate excess heat from the body? Provide a description of each.
7. Hand hygiene plays a critical role in preventing transmission of pathogens. What are the five moments of hand hygiene developed by the World Health Organization to draw attention to its importance and practical application?
8. What is the procedure for measuring oral temperature using a hand-held battery-powered thermometer?
9. What three pulse parameters (characteristics) are considered during monitoring? Describe each.
10. Where is the stethoscope placed to monitor apical pulse?
11. What is a pulse deficit and how is it derived?
12. What medical conditions would alert the therapist to the potential need for monitoring oxygen saturation levels using pulse oximetry?
13. What parameters (characteristics) are considered in examining respiration? Describe each.
14. What is the procedure for measuring brachial blood pressure using a stethoscope and aneroid sphygmomanometer?

CASE STUDY

EMERGENCY ROOM ADMISSION

A 24-year-old man was separated from his skiing group due to an unexpected and violent snowstorm. His being in an unfamiliar area without electronic communication complicated the situation. A 2-day helicopter search located him after approximately 48 hours of exposure to temperatures that ranged between 10° and 20°F (−12.22°C and −6.67°C). The emergency team initiated intravenous fluid replacement (to help restore fluid and electrolyte balance) en route to the hospital.

HISTORY

As reported by his parents, medical history is unremarkable except for the usual childhood diseases. He had recently relocated to the area because of a desire to be a competitive skier (an activity he has enjoyed all his life). He works as an accountant for a local investment firm.

ADMITTING DIAGNOSIS

Hypothermia and frostbite of the toes, thumb, and index and middle fingers, bilaterally.

- **Blood pressure:** Systolic pressure is 45 mm Hg; diastolic not perceptible.
- **Pulse:** Decreased rate, small, weak carotid pulse (12 bpm); peripheral pulses not perceptible.
- **Respiratory rate:** 6 breaths per minute; respirations barely perceptible.
- **Temperature:** 82°F (27.78°C) (rectal).
- **Cognition:** Depressed, unresponsive.
- **Deep tendon reflexes:** Absent.
- **Motor function:** No spontaneous movement.
- **Cutaneous sensation:** Unresponsive to all sensory modalities, including pain.
- **Integument:** Pale, cold on palpation; bluish gray appearance of nail beds and lips.

PHYSICAL THERAPY

The patient is now in the intensive care unit (ICU) and a referral has been made to physical therapy requesting "examination and treatment."

GUIDING QUESTIONS

1. Describe the body system responses to hypothermia.
2. What symptoms of hypothermia are presented by the patient?

3. During the early portion of the patient being stranded, input from thermoreceptors would have indicated a drop in temperature below the "set" temperature value. What mechanisms would have been activated to conserve heat?
4. Considering this patient is unresponsive and cyanotic, what is the most appropriate pulse to monitor? Why?

appendix
2.A

Measuring Oral Temperature: Glass Mercury Thermometer

A. Assemble equipment.

1. Clean oral glass mercury thermometer
2. Clean tissue to wipe thermometer
3. Watch (or wall clock)

B. Procedure

1. Remove the clean thermometer from storage container. If stored in a disinfectant solution, rinse under cold water, and dry with tissue using a firm rotary motion wiping from the bulb toward the fingers.
2. Hold the thermometer between the thumb and forefinger at the end of the stem (opposite the bulb). Holding the thermometer horizontally at eye level (required to obtain an accurate reading), rotate until the column of mercury is clearly visible. Note the level of the column. The reading should be below 95°F (35°C) before placing the thermometer in the patient's mouth. If the value is higher, "shake down" the thermometer until the mercury is below 95°F (35°C). While holding the thermometer securely, use quick, downward snapping motions of the wrist, which will effectively lower the column.
3. Ask the patient to open his or her mouth, and place the bulb of the thermometer at the posterior base of the tongue to the right or left of the frenulum in the sublingual pocket. Instruct the patient to close the lips (not teeth) around the thermometer to hold it in place.
4. Leave the glass mercury thermometer in place for 3 to 5 minutes.
5. Remove the thermometer.
6. Using a clean tissue, wipe the thermometer away from the fingers (toward the bulb) using a firm rotary motion.
7. Hold the thermometer at eye level, rotate until the mercury is clearly visible, and read the highest point on the scale to which the mercury has risen for recording.
8. Wash the thermometer in tepid soapy water and return to the storage container.
9. Wash hands.

Measuring Axillary Temperature: Glass Mercury Thermometer

appendix **2.B**

A. Assemble equipment.

1. Clean the oral glass mercury thermometer
   Note: Axillary temperatures can also be measured with automated thermometers as well as disposable single-use thermometers.
2. Clean tissue to wipe thermometer
3. A towel to dry axillary region (moisture will conduct heat).
4. Watch (or wall clock)

B. Procedure

1. Expose the axilla and ensure area is dry. If any moisture is present, the area should be gently towel dried with a patting motion (vigorous rubbing will increase temperature of the area).
2. Remove the clean thermometer from storage container. If stored in a disinfectant solution, rinse under cold water, and dry with tissue using a firm rotary motion, wiping from the bulb toward the fingers.
3. Hold the thermometer horizontally at eye level and rotate until the column of mercury is clearly visible; note the level of mercury. If necessary, shake the thermometer until the mercury is below 95°F (35°C).
4. Place the bulb of the thermometer in the center of the axillary region between the trunk and upper arm. The patient's upper extremity should be placed tightly across the chest to keep the thermometer in place (asking the patient to move the hand toward the opposite shoulder is often a useful direction). If the patient is disoriented or very young, the thermometer must be held in place.
5. Leave thermometer in place for 10 minutes (more time is required for the mercury to expand when measuring axillary temperature).
6. Remove the thermometer.
7. Using a clean tissue, wipe the thermometer away from the fingers (toward the bulb) using a firm rotary motion.
8. Hold the thermometer at eye level, rotate until the mercury is clearly visible, and read the highest point on the scale to which the mercury has risen for recording.
9. Wash the thermometer in tepid soapy water and return to the storage container.
10. Wash hands.

Examination of Sensory Function

Kevin K. Chui, PT, DPT, PhD, GCS, OCS
Thomas J. Schmitz, PT, PhD

Chapter 3

LEARNING OBJECTIVES

1. Understand the purpose(s) of performing a sensory examination.
2. Understand the relationship between preliminary mental status screening and tests for sensory function.
3. Describe the classification and function of the receptor mechanisms involved in the perception of sensation.
4. Identify the spinal pathways that mediate sensation.
5. Understand the guidelines for administering an examination of sensory function.
6. Describe the testing protocol for each sensory modality.
7. Using the case study example, apply clinical decision-making skills to application of sensory examination data.

CHAPTER OUTLINE

SENSORY INTEGRATION *87*
SENSATION AND MOVEMENT *88*
SENSORY INTEGRITY *88*
CLINICAL INDICATIONS *88*
- Pattern (Distribution) of Sensory Impairment *89*
- Spinal Cord Tracts *92*

AGE-RELATED SENSORY CHANGES *92*
PRELIMINARY CONSIDERATIONS *93*

RELIABILITY *111*
QUANTITATIVE SENSORY TESTING AND SPECIALIZED TESTING INSTRUMENTS *112*
CRANIAL NERVE SCREENING *115*
SENSORY INTEGRITY WITHIN THE CONTEXT OF TREATMENT *116*
SUMMARY *118*

SENSORY INTEGRATION

> If all of the sensory stimuli which enter the central nervous system were allowed to bombard the higher centers of the brain, the individual would be rendered utterly ineffective. It is the brain's task to filter, organize, and integrate a mass of sensory information so that it can be used for the development and execution of the brain's functions.[1, p. 25]—A. Jean Ayers, PhD

The human system is continually inundated with sensory information from a variety of environmental inputs as well as from movement, touch, awareness of the body in space, sight, sound, and smell. "In all higher order motor behaviors, the brain must correlate sensory inputs with motor outputs to accurately assess and control the body's interaction with the environment."[2, p.32] **Sensory integration** is the ability of the brain to organize, interpret, and use sensory information. This integration provides an internal representation of the environment that informs and guides motor responses.[2] These sensory representations provide the foundation on which motor programs for purposeful movements are planned, coordinated, and implemented.[3] Ayers defined *sensory integration* as "the neurological process that organizes sensation from one's own body and from the environment and makes it possible to use the body effectively within the environment."[4, p. 11] In an intact system, sensory integration occurs automatically without conscious effort.

Sensory integration is a theory developed by A. Jean Ayers (1920–1989), an occupational therapist whose work focused on examining the manner in which sensory integration develops, identifying patterns of dysfunction in children with learning disorders, and developing intervention strategies to improve processing of sensory information. The theory purports that disordered sensory integration directly affects both motor and cognitive learning and that interventions designed to enhance sensory integration will improve learning.[1] Bundy and Murray[5] suggest the value of the theory lies in its usefulness in (1) explaining behaviors of individuals with impaired sensory integration functions, (2) establishing a plan of care (POC) to address specific impairments, and (3) predicting expected outcomes of the selected interventions.

SENSATION AND MOVEMENT

Motor learning and motor performance are inextricably linked to *sensation*. As a motor task is practiced, the individual learns to anticipate and correct or modify movements based on sensory input organized and integrated by the central nervous system (CNS). The CNS uses this information to influence movement by both feedback and feedforward control. *Feedback control* uses sensory information received *during the movement* to monitor and adjust output. *Feedforward control* is a proactive strategy that uses sensory information obtained from experience. Signals are sent in *advance of movement* allowing for anticipatory adjustments in postural control or movement.[3,6] The primary role of sensation in movement is to (1) guide selection of motor responses for effective interaction with the environment and (2) adapt movements and shape motor programs through feedback for corrective action. Sensation also provides the important function of protecting the organism from injury. See Chapter 5, Examination of Motor Function: Motor Control and Motor Learning, for a more detailed discussion of CNS control of motor function.

SENSORY INTEGRITY

The term *somatosensation* (somatosensory) refers to sensation received from the skin and musculoskeletal system (as opposed to that from specialized senses such as sight or hearing). Examination of sensory function involves testing *sensory integrity* by determining the patient's ability to interpret and discriminate among incoming sensory information. The sensory examination is based on the premise that within the intact human system, sensory information is taken in from the body and the environment; the CNS then processes and integrates the information for use in planning and organizing behavior. This premise is more aptly termed a *theoretical construct* (a concept that represents an *unobservable* event). We cannot *directly* observe CNS processing, integration of sensory information, or the motor planning process. However, our current knowledge of CNS function and motor behavior provides evidence that these unobservable events do occur. We *can* observe impairments in motor behavior, but can only *hypothesize* that they truly result from faulty sensory integration mechanisms.[5]

The *Guide to Physical Therapist Practice* defines **sensory integrity** as "the intactness of cortical sensory processing, including proprioception, pallesthesia, stereognosis, and topognosis."[7, p. 90] Sensory integrity is included among the list of 24 categories of tests and measures that may be used by physical therapists during patient examination and is included in all practice patterns (i.e., musculoskeletal, neuromuscular, cardiovascular/pulmonary, and integumentary).

Box 3.1 presents examples of pathologies, impairments, activity limitations, disabilities, risk factors, and health, wellness, and fitness needs associated with changes in sensory integrity.

This chapter focuses primarily on examination of somatosensory integrity of the trunk and extremities as well as screening for cranial nerve integrity; testing approaches for examining *cranial nerve integrity* and *reflex testing* are addressed in Chapter 5, Examination of Motor Function: Motor Control and Motor Learning. As the CNS analyzes and uses all sensory input to identify movement errors and initiate corrective responses, examination of sensory function typically precedes examination of motor function. This sequence assists the physical therapist in differentiating the impact of sensory impairments on motor function.

CLINICAL INDICATIONS

Indications for examination of sensory function are based on the history and systems review (including a *sensory screening* described later in this chapter). This includes "information provided by the patient/client, family, significant other, or caregiver; symptoms described by the patient/client; signs observed and documented during the systems review; and information derived from other sources and records."[7, p. 90] These data may indicate the existence of pathology (or risk of pathology) resulting in sensory changes that may impose impairments, activity limitations, participation restrictions, or disability (see Box 3.1).

Sensory dysfunction may be associated with any pathology or injury affecting either the peripheral nervous system (PNS) or CNS, or with a combined involvement of both systems. Deficits may occur at any point within the system including the sensory receptors, peripheral nerves, spinal nerves, spinal cord nuclei and tracts, brainstem, thalamus, and sensory cortex.[8] Examples of conditions that generally demonstrate some level of sensory impairment include pathology, disease, or injury to the peripheral nerves such as trauma (e.g., fracture) that can sever, crush, or damage

Box 3.1 Examples of Pathologies, Impairments, Functional Limitations, Disabilities, Risk Factors and Health, Wellness, and Fitness Needs Associated with Changes in Sensory Integrity (*Note:* ICF terminology has been parenthetically added)

I. Pathology/pathophysiology in the following systems *(ICF: Health conditions)*:
- Cardiovascular (e.g., cerebral vascular accident, peripheral vascular disease)
- Endocrine/metabolic (e.g., diabetes, rheumatological disease)
- Integumentary (e.g., burn, frostbite, lymphedema)
- Multiple systems (e.g., AIDS, Guillain-Barré syndrome, trauma)
- Musculoskeletal (e.g., derangement of joint; disorders of bursa, synovia, and tendon)
- Neuromuscular (e.g., cerebral palsy, developmental delay, spinal cord injury)
- Pulmonary (e.g., respiratory failure, ventilatory pump failure)

II. Impairments in the following categories *(ICF: Body structures/functions [impairments])*:
- Circulation (e.g., numb feet)
- Integumentary integrity (e.g., redness under orthotic)
- Muscle performance (e.g., decreased grip strength)
- Orthotic, protective, and supportive devices (e.g., wears ankle-foot orthosis)
- Posture (e.g., forward head)

III. Functional limitations in the ability to perform actions, tasks, or activities in the following categories *(ICF: Activity/activity limitations)*:
- Self-care (e.g., inability to put on trousers while standing because of loss of feeling in foot)
- Home management (e.g., difficulty with sorting change because of numbness)
- Work (job/school/play) (e.g., inability as a day care provider to change child's diaper because of loss of finger sensation, inability to operate cash register because of clumsiness)
- Community/leisure (e.g., inability to drive car because of loss of spatial awareness, inability to play guitar because of hyperesthesia)

IV. Disability, that is, the inability or restricted ability to perform actions, tasks, or activities of required roles within the individual's sociocultural context, in the following categories *(ICF: Participation/participation restriction)*:
- Self-care
- Home management
- Work (job/school/play)
- Community/leisure

V. Risk factors for impaired sensory integrity *(ICF: Personal Factors and Environment):*
- Lack of safety awareness in all environments
- Risk-prone behaviors (e.g., working without protective gloves)
- Smoking history
- Substance abuse

VI. Health, wellness, and fitness needs *(ICF: Personal Factors)*:
- Fitness, including physical performance (e.g., inadequate balance to compete in dancing competition, limited perception of arms and legs in space during ballroom dancing)
- Health and wellness (e.g., inadequate understanding of role of proprioception in balance)

ICF = International Classification of Functioning, Disability, and Health.

a nerve; metabolic disturbances (diabetes, hypothyroidism, alcoholism); infections (Lyme disease, leprosy, human immunodeficiency virus [HIV]); impingement or compression (arthritis, carpal tunnel syndrome); burns; toxins (lead, mercury, chemotherapy); and nutritional deficits (vitamin B_{12}). Sensory impairments are also associated with injury to nerve roots or spinal cord, cerebral vascular accident (CVA), transient ischemic attack (TIA), tumors, multiple sclerosis (MS), and brain injury or disease. These examples, which are not all-inclusive, indicate the wide spectrum of injuries, disease, and pathologies that may present with some element of sensory deficit.

Pattern (Distribution) of Sensory Impairment

Examination of sensory function contributes critical information to establishing a physical therapy diagnosis and prognosis, identifying anticipated goals and expected outcomes, and developing a POC. A seminal feature of the examination involves determining the *pattern* (specific boundaries) of sensory involvement. Pattern

identification is accomplished using knowledge of skin segment innervation by the dorsal roots and peripheral nerves (Figs. 3.1 and 3.2). The term **dermatome** (or *skin segment*) refers to the skin area supplied by one dorsal root.[9] The graphic illustration of skin segment innervation as presented in Figures 3.1 and 3.2 is referred to as a *dermatome map*. There exist some discrepancies among published dermatome maps based on the methodologies used to identify skin segment innervation. In a clinical commentary, Downs and Laporte[10] discuss the history of dermatome mapping, including the variations in methodologies employed, and the inconsistencies in the dermatome maps used in education and practice. As new technology allows for more precise identification of nerve distribution, the authors suggest that cutaneous spinal nerve distribution be reevaluated.

Clinical Note: Considerable variation exists in the clinical presentation of sensory impairments. This variability is typically associated with the nervous system involved (CNS vs. PNS), the type of injury, pathology, or disease, as well as the severity, extent, and duration of involvement.

During the review of systems, asking the patient to carefully describe the pattern or distribution of sensory

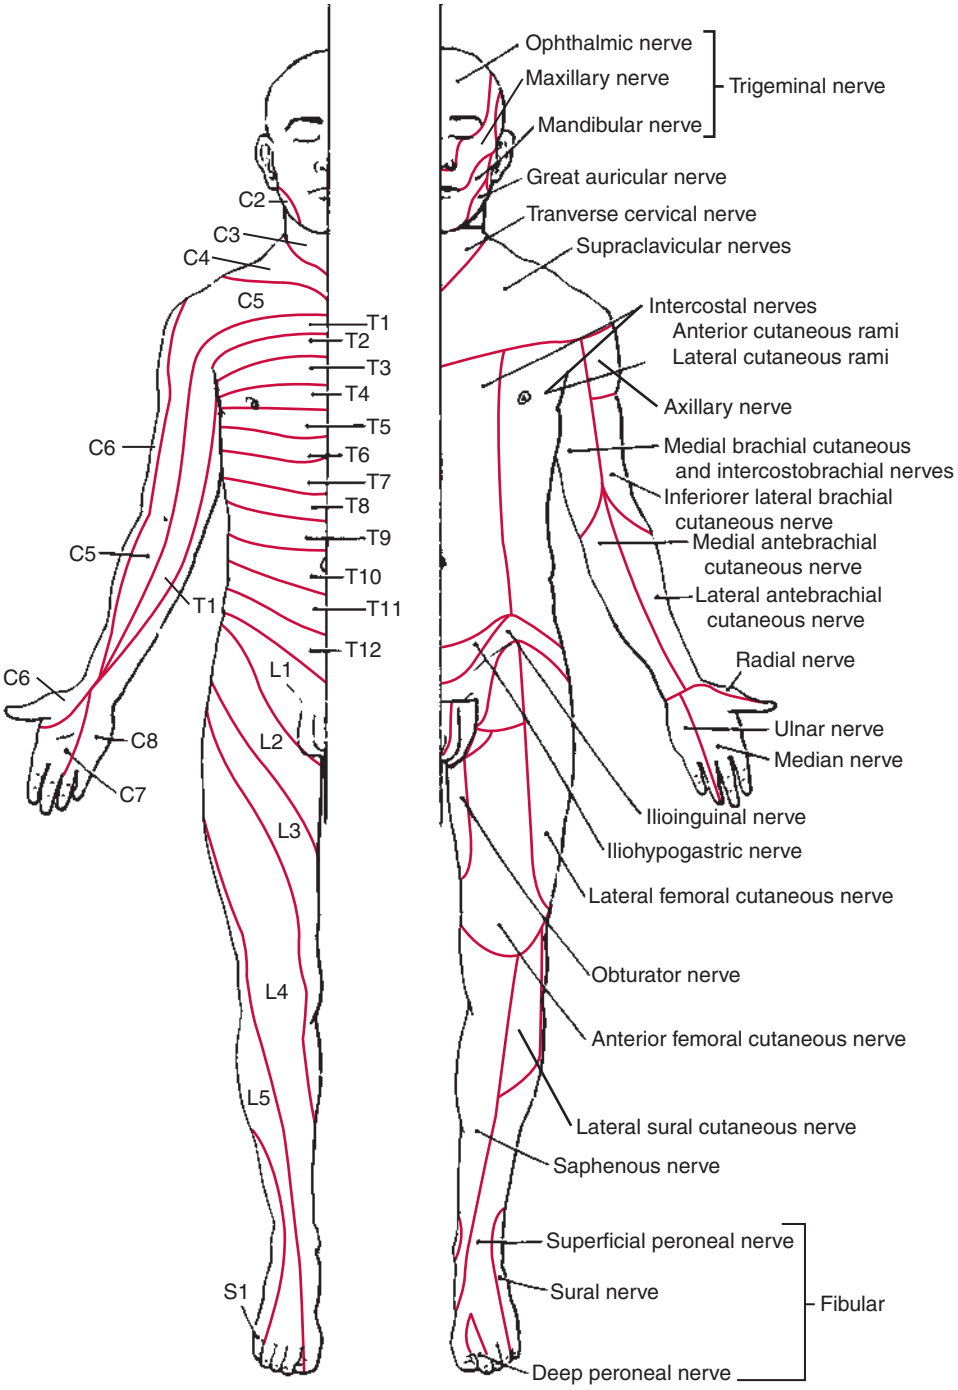

Figure 3.1 Anterior view of skin segment innervation by dorsal roots (*left*) and peripheral nerves (*right*). *(From Gilman and Newman[9, p. 43] with permission.)*

symptoms (e.g., tingling, numbness, diminished, or absent sensation) provides the therapist with preliminary information to help guide the examination and to assist in identifying the dermatome(s) and nerve(s) involved. Peripheral nerve injuries generally present sensory impairments that parallel the distribution of the involved nerve and correspond to its pattern of innervation. For example, if a patient presents with complaints of numbness on the ulnar half of the ring finger, the little finger, and the ulnar side of the hand, the therapist would be alerted to carefully address ulnar nerve (C8 and T1) integrity during the sensory examination. Complaints of sensory disturbances on the palmar surface of the thumb and the palmar and distal dorsal aspects of the index, middle, and the radial half of the ring finger would be indicative of median nerve (C6–8 and T1) involvement.

Other patterns of sensory loss may be associated with specific pathology. For example, with peripheral

neuropathy (e.g., diabetes), sensory loss is often an early symptom and presents in a *glove and stocking* distribution (referring to the typical involvement of the hands and feet). In contrast, MS frequently presents with an unpredictable or scattered pattern of sensory involvement.

Spinal cord injury (SCI) often presents with a more diffuse pattern of sensory involvement below the lesion level that is typically bilateral, although not necessarily symmetrical. Examination of sensory function following SCI provides critical data that reflect the degree of neurological impairment. Together with other tests and measures, sensory data contribute to determining the relative completeness of the injury, the existence of *zones of partial preservation* (areas distal to a complete lesion that retain partial innervation), symmetry or asymmetry of the lesion, and the presence of sacral sensation below the neurological level of lesion (a defining feature of an incomplete lesion).

Spinal Cord Tracts

Examination of sensory function also provides data that reflect the integrity of the spinal cord tracts that carry somatosensory information. For example, contralateral loss or impairment of pain and temperature perception is suggestive of lesions in the anterolateral tracts. Deficits in discriminative sensations such as vibration and two-point discrimination suggest lesions of the dorsal column.

Evidence of both sensory and motor loss is usually indicative of nerve root involvement (recall that the dorsal and ventral roots converge to form the spinal nerves). CNS lesions (e.g., CVA, brain injury) may produce significant sensory impairments characterized by a diffuse pattern of involvement (e.g., head, trunk, and limbs) and can result in significant motor dysfunction (sensory ataxia) and impairment of fine motor control and motor learning, as well as present a significant threat of injury to anesthetic limbs (e.g., an inability to determine the temperature of bath water).

AGE-RELATED SENSORY CHANGES

Alterations in sensory function occur with normal aging and should be clearly differentiated from those associated with specific illness, disease, or pathology. In recent years there has been a gradual expansion of interest in and information about the causes and consequences of age-related sensory changes. This has been evident through the large and expanding body of literature devoted to the neuroscience of aging and its impact on function and quality of life of older adults.[11-34] The topics addressed are specific age-related changes in vision, hearing, and the somatosensory system; treatment, prevalence, and risk factor information; as well as the role of public policy and public health in addressing age-related sensory loss. *Healthy People 2020*,[35] published by the U.S. Department of Health and Human Services, presents a comprehensive health promotion and wellness agenda for the second decade of the 21st century. The overarching goals of *Healthy People 2020* are to (1) attain high-quality, longer lives free of preventable disease, disability, injury, and premature death; (2) achieve health equity, eliminate disparities, and improve the health of all groups; (3) create social and physical environments that promote good health for all; and (4) promote quality of life, healthy development, and healthy behaviors across all life stages. The first goal draws national attention to an expanding population of older adults and the impact of age (including changes in sensation such as vision and hearing) on health improvement and health promotion strategies. Decreased acuity of many sensations occurs and is considered a characteristic finding with aging.[36-40] The exact morphology of diminished sensation with age has not been completely established. However, several neurological changes have been identified and suggest potential explanations.

Over the lifespan neurons are replaced at a declining rate and this may account for the decline of average weight of the brain with aging. Although a feature of Alzheimer's disease, normal aging does not produce a significant loss in the number of cortical neurons.[40] Other changes in the brain include degeneration of neurons with presence of replacement gliosis, lipid accumulation in the neurons, loss of myelin, and development of neurofibrils (masses of small, tangled fibrils) and plaques on the cells.[40-42] There is also a decrease in the number of enzymes responsible for synthesis of dopamine, norepinephrine, and to a lesser degree acetylcholine,[43] as well as depletion of the neuronal dendrites in the aging brain.[43,44]

Electrophysiological studies have identified a gradual reduction in conduction velocity of sensory nerves with advancing age,[45-47] and this may reflect degenerative changes in myelin sheaths or loss or reduction in size of sensory axons.[36,41,45,48] Evoked potentials provide a quantitative measure of sensory function and have been found to decrease in amplitude with age.[49] A reduction in the number of Meissner's corpuscles[50] has also been identified. These corpuscles, responsible for touch detection, are limited to hairless areas, and become sparse, take on an irregular distribution, and vary in size and shape with age.[50] Age-related changes in morphology and decreased concentrations of Pacinian corpuscles, responsive to rapid tissue movement (e.g., vibration), have also been reported.[51]

Degenerative changes in myelin have been documented in both the central and peripheral nervous systems.[40,45,52] In a review of the literature on the effects of normal aging on myelin and nerve fibers, Peters[40] suggests that (1) age-associated cognitive decline is more likely due to widespread damage to myelin sheaths of cortical neuron axons than to actual loss of these neurons and (2) the resulting changes in conduction velocity alter the normal timing of neuronal circuits.

In the PNS, a decrease in the distance between the nodes of Ranvier has been associated with advancing age.[53] This finding may be related to a slowing of saltatory conduction identified by some authors.[41,45] Destruction of myelin sheaths has been linked to a reduced expression of primary myelin proteins, axonal atrophy, and to reduced expression and axonal transport of cytoskeletal proteins.[54] As compared to younger subjects, lower sensory nerve conduction velocities have been documented for both the median[55,46] and sural[46] nerves in older subjects.

Although not an exhaustive list, other documented age-related sensory changes include altered postural stability and control,[15,20,24,26,56,57] diminished response to tactile stimuli,[12,55,58,59] reduced vibratory[51,60] and proprioceptive acuity,[13,31,61] decreased cutaneous temperature thresholds[11] and two-point discrimination,[29,62] and altered ability to adapt sensorimotor responses to task demands.[17]

These changes frequently appear in the presence of age-related visual or hearing losses that impair compensatory capabilities. In addition, some medications may further influence the distortion of sensory input. This combination of sensory impairments may pose a variety of activity limitations for the elderly individual such as postural instability, exaggerated body sway, balance problems, wide-based gait, diminished fine motor coordination, tendency to drop items held in the hand, and difficulty in recognizing body positions in space. Box 3.2 Evidence Summary provides an overview of research exploring age-related sensory changes.

Clinical Note: In addition to age-related sensory changes, activity limitations may be exacerbated by muscle weakness associated with a reduction in the number and size of skeletal muscle fibers and overall cross-sectional area of muscle. See discussion in Chapter 5, Examination of Motor Function: Motor Control and Motor Learning.

PRELIMINARY CONSIDERATIONS

Accuracy of data from examination of sensory function relies on the patient's ability to respond to application of multiple somatosensory stimuli. Use of several easily administered preliminary tests will provide sufficient data to determine the patient's ability to concentrate on, and respond to, the battery of sensory test items. The two general categories of preliminary tests include the patient's (1) arousal level, attention span, orientation, and cognition;[63] and (2) memory, hearing, and visual acuity. These preliminary tests are typically considered with sensory involvement associated with CNS lesions.

Arousal, Attention, Orientation, and Cognition

A necessary first step is to determine the patient's arousal level for participation in the test protocol. **Arousal** is the physiological readiness of the human system for activity.[7] It is described by using traditionally accepted key terms and definitions to identify the patient's level

Box 3.2 Evidence Summary Research Exploring Age-Related Changes in Sensory Function

Tochihara et al[11]	Examined age-related differences in cutaneous temperature (Temp) thresholds for warm thermal sensitivity in "thermoneutral" (28°C [82.4°F]) and "cool" (22°C [71.6°F]) environments. Used a thermal stimulator over the cheek, chest, abdomen, upper arm, forearm, hand, thigh, shin, and foot.	Compared 12 young males (22±1 years) and 13 older male adults (67±3 years) in two different environments. There was a significant difference between groups for mean height, subscapular skinfold thickness, and body mass index (BMI).	Cutaneous Temp (warm) thresholds were significantly great for the elder than the younger men on the hand, shin, and foot in both thermoneutral and cool environments. There were no differences observed for the other body parts.	Older adult males were less sensitive to Temp (warmth) than young males in two environments. Differences in Temp sensitivity were nonuniform on the head and trunk (i.e., cheek, chest, abdomen) and significant on the extremities (i.e., hand, shin, foot).
Davila et al[32]	To determine the prevalence of sensory (hearing or visual)	Examined 1997–2004 data from the National Health Interview	The prevalence of hearing impairment (33.4%) was more	The results of this study highlight the growing need for

	impairment among U.S. workers 65 years and older.	Survey. Of those sampled ($N = 5,590$), the majority were female, 65–69 years old, white, non-Hispanic, married/ living with partner, above the poverty line, had >12 years of education, and had health insurance.	than three times that of visual impairment (10.2%). The highest prevalence of hearing or visual impairment was greatest among farm operators, mechanics, and motor vehicle operators.	workplace accommodations. In addition, there is a need for preventive measures for workers at risk for injury due to their sensory impairments.
Shaffer and Harrison[28]	Reviewed the literature on (1) age-related changes in the proprioceptive and cutaneous systems; (2) the relationship between basic science research and age-related clinical changes; and (3) the relationship between the proprioceptive and cutaneous systems and balance in older adults.	This narrative review included sections on the following: muscle spindle, Golgi tendon organ, proprioception, cutaneous receptors, cutaneous somatosensation, peripheral sensory innervations, and somatosensory integration.	There are age-related declines in various sensory structures and physiology, which accelerates with advancing age. Large myelinated sensory fibers and receptors are preferentially affected with aging. There is evidence that older adults have impaired proprioception, vibration, discriminative touch, and balance. With aging, sensory involvement occurs before motor changes.	This synthesis of the literature provides foundational knowledge about the effects of an aging sensory system on balance. The paper also emphasizes the importance of using reliable and valid methods to examine sensory function. Additional research that examines the relationship between age-related changes in the sensory system and balance is needed.
Laurienti et al[33]	Examined the speed of discrimination responses to the presentation of visual, auditory, or both visual and auditory (multisensory) stimuli. The difference between the visual response time and multisensory response time was examined as an estimate of multisensory gain (i.e., the improvement in performance [reaction time] with additional sensory input).	Compared the speed of discrimination between young ($N = 31$, 28.1±5.6 years) and older adults ($N = 27$, 70.9±5.1 years). The researchers also examined performance accuracy, which was used as a covariate when examining multisensory gain.	When using accuracy as a covariate, the older adults demonstrated a significantly greater multisensory gain when compared to the young group.	Older adults demonstrated greater improvements in performance than younger adults with information from multiple sensory modalities. Despite age-related declines in sensory function, the use of information from multiple senses may compensate for impairment in individual sensory functions.

of consciousness. These terms include *alert*, *lethargic*, *obtunded*, *stupor*, and *coma* and represent a continuum of physiological readiness for activity; they are defined as follows:[63]

- *Alert.* The patient is awake and attentive to normal levels of stimulation. Interactions with the therapist are normal and appropriate.
- *Lethargic.* The patient appears drowsy and may fall asleep if not stimulated in some way. Interactions with the therapist may get diverted. Patient may have difficulty in focusing or maintaining attention on a question or task.
- *Obtunded.* The patient is difficult to arouse from a somnolent state and is frequently confused when awake. Repeated stimulation is required to maintain consciousness. Interactions with the therapist may be largely unproductive.
- *Stupor* (semicoma). The patient responds only to strong, generally noxious stimuli and returns to the unconscious state when stimulation is stopped. When aroused, the patient is unable to interact with the therapist.
- *Coma* (deep coma). The patient cannot be aroused by any type of stimulation. Reflex motor responses may or may not be seen.

Reliable information about the integrity of the somatosensory system can be obtained from patients who are alert. Reliability is proportionally reduced in patients with lethargy and nonexistent in patients who are obtunded, stuporous, or comatose.

Attention is selective awareness of the environment or responsiveness to a stimulus or task without being distracted by other stimuli.[6,9,64] Attention can be examined by asking the patient to repeat items on a progressively more challenging list. These repetition tasks can begin with two or three items and gradually progress to longer lists. For example, the patient might be asked to repeat a series of numbers, letters, or words. Another approach to examining attention is to ask the patient to spell words backwards (e.g., book, fork, bottle, garden). The task can be made more challenging by using progressively longer words. Individuals with a high attention span will be able to perform the task. Attention deficits will be apparent when the order of letters is confused.[64]

Orientation refers to the patient's awareness of time, person, and place. In medical record documentation the results of this mental status screening are often abbreviated "oriented × 3," referring to the three parameters of time, person, and place. If a patient is not fully oriented to one or more domains, the notation would read "oriented × 2 (time)" or "oriented × 1 (time, place)." With partial orientation entries, it is customary to include the *domains of disorientation* within parentheses. Box 3.3 presents sample questions for examining orientation.[9,63,64]

Box 3.3 Sample Questions for Examining Orientation

A series of simple questions is posed to the patient. The questions are designed to determine the patient's understanding of recognition of who he or she is, location including the present facility (the name of hospital or clinic), the present time, and the passage of time.

Person

- What is your name?
- Do you have a middle name?
- How old are you?
- When were you born?

Place

- Do you know where you are right now?
- What kind of a place is this?
- Do you know what city and state we are in?
- What city or town do you live in?
- What is your address at home?

Time

- What is today's date?
- What day of the week is it?
- What time is it?
- Is it morning or afternoon?
- What season is it?
- What year is it?
- How long have you been here?

From Nolan[63, p. 26] with permission.

Cognition is defined as the process of knowing and includes both awareness and judgment.[6] Nolan[63] suggests three areas for testing cognition-dependent functions: (1) fund of knowledge, (2) calculation ability, and (3) proverb interpretation. **Fund of knowledge** is defined as the sum total of an individual's learning and experience in life, which will be highly variable and different for each patient. Detailed information about premorbid knowledge base is often not available. However, a number of general categories of information can be used to test this cognitive function. Sample questions might include the following:[63]

- Who became president after Kennedy was shot?
- Who is the current vice president of the United States?
- Which is more—a gallon or a liter?
- In what country is the Great Pyramid?
- What would you add to your food to make it sweeter?
- In what state would you find the city of Boston?
- What are the elements that make up water and salt?
- Can you name a car made by General Motors?
- Who is Charles Dickens?

Calculation ability examines foundational mathematical abilities.[63,64] Two associated terms are **acalculia**

(inability to calculate) and **dyscalculia** (difficulty in accomplishing calculations).[63] This cognitive screening can be administered either verbally or in written format. The patient is asked to mentally perform a series of calculations when provided with mathematical problems. The test should be initiated with simple problems and progress to the more difficult. Adding and subtracting are generally easier than multiplication and division. An alternative approach is to provide written mathematical problems and ask the patient to fill in the answer (e.g., 4 + 4 = ____; 10 + 22 = ____; 46 × 8 = ____; 13 × 7 = ____; 4 × 3 = ____; 6 × 6 = ____; and so forth.).

Proverb interpretation examines the patient's ability to interpret use of words outside of their usual context or meaning. This is a sophisticated cognitive function. During the screening, the patient should be asked to describe the meaning of the proverb. Sample proverbs include the following:[63,64]

- People who live in glass houses shouldn't throw stones.
- A rolling stone gathers no moss.
- A stitch in time saves nine.
- The early bird catches the worm.
- The dog that trots about finds the bone.
- The empty wagon makes the most noise.
- Every cloud has a silver lining.
- Grass doesn't grow on a busy street.

Memory, Hearing, and Visual Acuity

Also related to the ability to respond during sensory testing is the status of the patient's memory and hearing function as well as visual acuity.

Memory

Both long- and short-term memory should be examined. Impairments of short-term memory will be the most disruptive to collecting sensory information owing to patient difficulties in remembering and following directions. *Long-term (remote) memory* can be examined by requesting information on date and place of birth, number of siblings, date of marriage, schools attended, and historical facts. *Short-term memory* can be addressed by verbally providing the patient with a series of words or numbers. For example, a series of words might include "car, book, cup"; use of numbers could include a seven-digit list; a short sentence could also be used to test short-term memory. To ensure understanding of the task, the patient should repeat the sequence immediately. Individuals with normal memory function should be able to recall the list 5 minutes[9] later and at least two of the items from the list after 30 minutes.[63]

Hearing

Observing the patient's response to conversation can provide a gross assessment of hearing. Note should be made of how alterations in voice volume and tone influence patient response.

Visual Acuity

A gross visual examination can be made by use of a standard Snellen chart mounted on the wall or visual acuity cards for use at bedside. If the patient uses corrective lenses, they should be worn during testing and should be clean. Visual acuity is typically recorded at 20 feet (6 m) from the Snellen chart (standard eye chart). This distance (20 feet [6 m]) is then placed over the size of the type the individual is able to read comfortably. For example, on a continuum of visual acuity 20/20 is considered excellent and 20/200 is considered poor acuity.[9]

Clinical Note: Some diagnoses or co-morbidities directly affect vision such as multiple sclerosis, hypertension, and diabetes. Examining the cranial nerves (CNs) will provide additional information about vision. For example, the oculomotor nerve (CN III) is often affected by diabetes (oculomotor nerve palsy).

Peripheral field vision can be examined by sitting directly in front of the patient with outstretched arms. The index fingers should be extended and gradually brought toward the midline of the patient's face. The patient is asked to identify when the therapist's approaching finger is first seen. Differences between right and left visual field should be noted carefully. Depth perception may be grossly checked by holding two pencils or fingers (one behind the other) directly in front of the patient. The patient is asked to touch or grasp the foreground object.

Because tests of sensory integrity require a verbal response to the stimulus, patients with arousal, attention, orientation, cognitive, or short-term memory impairments generally cannot be accurately tested. However, impairments in vision, hearing, or speech will not adversely affect test results if appropriate adaptations are made in providing instructions and indicating responses (e.g., signaling with either one or two fingers during tests for two-point discrimination, pointing to an area of stimulus contact, mimicking joint position sense or awareness of movement with the contralateral extremity, or object identification by selecting from a group of items during tests for stereognosis).

CLASSIFICATION OF THE SENSORY SYSTEM

Several different schemes have been proposed for categorizing the sensory system. Among the more common is classification by the type (or location) of *receptors* and the *spinal pathway* mediating information to higher centers.

Sensory Receptors

Sensory receptors (sensory nerve endings) are located at the distal end of an afferent nerve fiber. Once stimulated, they give rise to perception of a specific sensation.

Sensory receptors are highly sensitive to the type of stimulus for which they were designed (termed *receptor specificity*). This specificity of nerve fiber sensitivity to a single modality of sensation is called the *labeled line principle*.[65] This means that individual tactile sensations are perceived when specific types of receptors are stimulated. For example, in response to touch, selective activation of Merkel's discs and Ruffini endings generate the sensation of steady pressure in the cutaneous area above the active receptors.[66]

It should be noted that the term *modality* has a specific meaning within the context of sensation. Modality "defines a general class of stimulus, determined by the type of energy transmitted by the stimulus and the receptors specialized to sense that energy."[66, p. 413] Each type of sensation perceived (e.g., vision, hearing, taste, touch, smell, pain, temperature, proprioception) is referred to as a modality of sensation.

The three divisions of sensory receptors include those that mediate the (1) superficial, (2) deep, and (3) combined (cortical) sensations.[9]

Superficial Sensation

Exteroceptors are responsible for the superficial sensations.[67] They receive stimuli from the external environment via the skin and subcutaneous tissue. Exteroceptors are responsible for the perception of pain, temperature, light touch, and pressure.[9,67]

Deep Sensation

Proprioceptors are responsible for the deep sensations. These receptors receive stimuli from muscles, tendons, ligaments, joints, and fascia,[64] and are responsible for position sense[68] and awareness of joints at rest, movement awareness (kinesthesia), and vibration.

Combined Cortical Sensations

The combination of both the superficial and deep sensory mechanisms makes up the third category of combined sensations. These sensations require information from both exteroceptive and proprioceptive receptors, as well as intact function of cortical sensory association areas. The cortical combined sensations include **stereognosis**, **two-point discrimination**, **barognosis**, **graphesthesia**, tactile localization, recognition of texture, and double simultaneous stimulation.

Spinal Pathways

Sensations also have been classified according to the system by which they are mediated to higher centers. Sensations are mediated by either the *anterolateral spinothalamic system* or the *dorsal column-medial lemniscal system*.[41,67,69]

Anterolateral Spinothalamic

This system initiates self-protective reactions and responds to stimuli that are potentially harmful in nature. It contains slow-conducting fibers of small diameter, some of which are unmyelinated. The system is concerned with transmission of thermal and nociceptive information, and mediates pain, temperature, crudely localized touch, tickle, itch, and sexual sensations.

Dorsal Column–Medial Lemniscal System

The dorsal column is the system involved with responses to more discriminative sensations. It contains fast-conducting fibers of large diameter with greater myelination. This system mediates the sensations of discriminative touch and pressure sensations, vibration, movement, position sense, and awareness of joints at rest. The two systems are interdependent and integrated so as to function together.

TYPES OF SENSORY RECEPTORS

The sensory receptors frequently are divided according to their structural design and the type of stimulus to which they preferentially respond. These divisions include (1) *mechanoreceptors*, which respond to mechanical deformation of the receptor or surrounding area; (2) *thermoreceptors*, which respond to changes in temperature; (3) *nociceptors*, which respond to noxious stimuli and result in the perception of pain; (4) *chemoreceptors*, which respond to chemical substances and are responsible for taste, smell, oxygen levels in arterial blood, carbon dioxide concentration, and osmolality (concentration gradient) of body fluids; and (5) *photic (electromagnetic) receptors*, which respond to light within the visible spectrum.[8,9,67,70]

The perception of pain is not limited to stimuli received from nociceptors, because other types of receptors and nerve fibers contribute to this sensation. High intensities of stimuli to any type of receptor may be perceived as pain (e.g., extreme heat or cold and high-intensity mechanical deformation).

The general classification of sensory receptors is presented in Box 3.4.[64,65,71] Note that this list also includes the receptors responsible for electromagnetic (visual) and chemical stimuli.

Cutaneous Receptors

Cutaneous sensory receptors are located at the terminal portion of the afferent fiber. These include free nerve endings, hair follicle endings, Merkel's discs, Ruffini endings, Krause's end-bulbs, Meissner's corpuscles, and Pacinian corpuscles. The density of these sensory receptors varies for different areas of the body. For example, there are many more tactile receptors in the fingertips than in the back. These areas of higher receptor density correspondingly display a higher cortical representation in somatic sensory area I. Receptor density is a particularly important consideration in interpreting the results of a sensory examination for a given body surface. Figure 3.3 illustrates the cutaneous sensory receptors and their respective locations within the various layers of skin.

Box 3.4 Classification of Sensory Receptors

I. Mechanoreceptors
- A. Cutaneous sensory receptors
  - 1. Free nerve endings
  - 2. Hair follicle endings
  - 3. Merkel's discs
  - 4. Ruffini endings
  - 5. Krause's end-bulbs

  - 1. Receptors in hypothalamus

*Extremes of stimuli to other sensory receptors will be perceived as pain.
Adapted from Waxman,[64] Hall,[65] and Fitzgerald et al.[71]

Free Nerve Endings

These receptors are found throughout the body. Stimulation of free nerve endings result in the perception of pain, temperature, touch, pressure, tickle, and itch sensations.[9,64]

Hair Follicle Endings (Hair End-Organs)

At the base of each hair follicle a free nerve ending is entwined. The combination of the hair follicle and its nerve provides a sensitive receptor. These receptors are sensitive to mechanical movement and touch.[72,73]

Merkel's Discs

These touch receptors are located below the epidermis in hairless smooth (glabrous) skin with a high density in the fingertips. They are sensitive to low-intensity touch, as well as to the velocity of touch, and respond to constant indentation of the skin (pressure). They provide for the ability to perceive continuous contact of objects against the skin and are believed to play an important role in both two-point discrimination and localization of touch.[67,73] Merkel's discs are also believed to contribute to recognition of texture.

Ruffini Endings

Located in the deeper layers of the dermis, these encapsulated endings are involved with the perception of touch and pressure. They are slowly adapting and particularly important in signaling continuous skin deformation such as tension or stretch; they are also found in joint capsules and assist with joint position sense.[65,73]

Krause's End-Bulb

The function of these bulbous encapsulated nerve endings is not clearly understood. They are located in the dermis and conjunctiva of the eye. They are believed to be low-threshold mechanical receptors that may play a contributing role in the perception of touch and pressure.

Meissner's Corpuscles

Located in the dermis, these encapsulated nerve endings contain many branching nerve filaments within the capsule. They are low-threshold, rapidly adapting and in high concentration in the fingertips, lips, and toes, areas that require high levels of discrimination. These receptors play an important role in discriminative touch (e.g., recognition of texture) and movement of objects over skin.[41,65,73]

Pacinian Corpuscles

These receptors are located in the subcutaneous tissue layer of the skin and in deep tissues of the body (including tendons and soft tissues around joints). They are stimulated by rapid movement of tissue and are quickly adapting. They play a significant role in the perception of deep touch and vibration. [73,74]

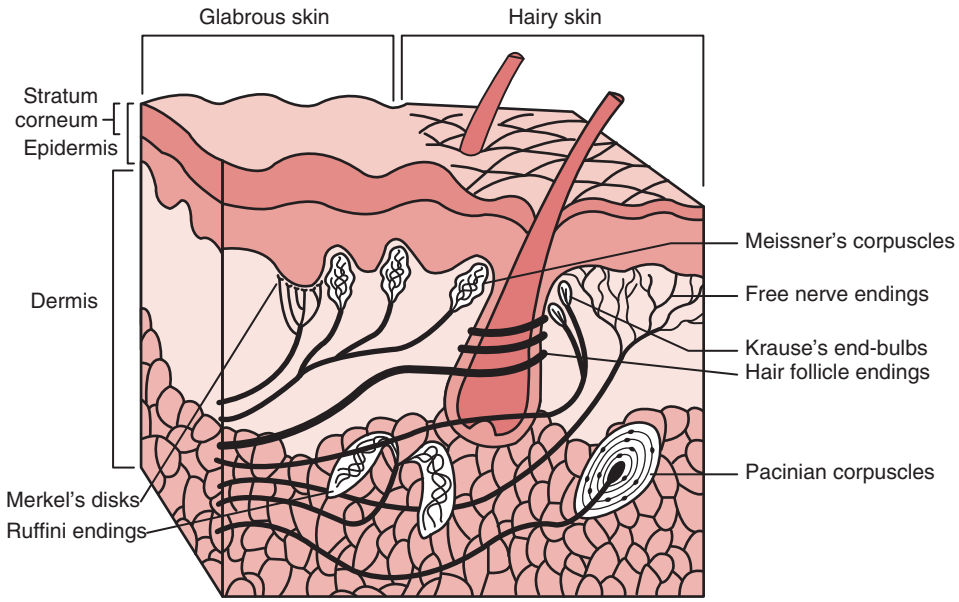

Figure 3.3 The cutaneous sensory receptors and their respective locations within the various layers of skin (epidermis, dermis, and the subcutaneous layer).

Deep Sensory Receptors

The deep sensory receptors are located in muscles, tendons, and joints[64,65,69] and include both muscle and joint receptors. They are concerned primarily with posture, position sense, proprioception, muscle tone, and speed and direction of movement. The deep sensory receptors include the muscle spindle, Golgi tendon organs, free nerve endings, Pacinian corpuscles, and joint receptors.

Muscle Receptors

Muscle Spindles

The muscle spindle fibers (intrafusal fibers) lie in a parallel arrangement to the muscle fibers (extrafusal fibers). They monitor changes in muscle length (Ia and II spindle afferent endings) as well as velocity (Ia ending) of these changes. The muscle spindle plays a vital role in position and movement sense and in motor learning.

Golgi Tendon Organs

These receptors are located in series at both the proximal and distal tendinous insertions of the muscle. The Golgi tendon organs function to monitor tension within the muscle. They also provide a protective mechanism by preventing structural damage to the muscle in situations of extreme tension. This is accomplished by inhibition of the contracting muscle and facilitation of the antagonist.

Free Nerve Endings

These receptors are within the fascia of the muscle. They are believed to respond to pain and pressure.

Pacinian Corpuscles

Located within the fascia of the muscle, these receptors respond to vibratory stimuli and deep pressure.

Joint Receptors

Golgi-Type Endings

These receptors are located in the ligaments, and function to detect the rate of joint movement.

Free Nerve Endings

Found in the joint capsule and ligaments, these receptors are believed to respond to pain and crude awareness of joint motion.

Ruffini Endings

Located in the joint capsule and ligaments, Ruffini endings are responsible for the direction and velocity of joint movement.

Paciniform Endings

These receptors are found in the joint capsule and primarily monitor rapid joint movements.

PATHWAYS FOR TRANSMISSION OF SOMATIC SENSORY SIGNALS

Somatic sensory information enters the spinal cord through the dorsal roots. Sensory signals are then carried to higher centers via ascending pathways from one of two systems: the *anterolateral spinothalamic system* or the *dorsal column–medial lemniscal system*.

Anterolateral Spinothalamic Pathway

The spinothalamic tracts are diffuse pathways concerned with nondiscriminative sensations such as pain, temperature, tickle, itch, and sexual sensations. This system is activated primarily by mechanoreceptors, thermoreceptors, and nociceptors, and is composed of afferent fibers that are small diameter and slowly conducting. Sensory signals transmitted by this system do not require discrete

localization of signal source or precise gradations in intensity.

After originating in the dorsal roots, the fibers of the spinothalamic pathway immediately cross and ascend up the spinal cord through the medulla, pons, and midbrain to the ventroposterolateral (VPL) nucleus of the thalamus (Fig. 3.4). Axons of the VPL neurons project to the somatosensory cortex via the internal capsule.[41,74]

Compared with the dorsal column–medial lemniscal system, the anterolateral spinothalamic pathways make up a cruder, more primitive system. The spinothalamic tracts are capable of transmitting a wide variety of sensory modalities. However, their diffuse pattern of termination results in only crude abilities to localize the source of a stimulus on the body surface, and poor intensity discrimination.[64]

The three major tracts of the spinothalamic system are the (1) *anterior (ventral) spinothalamic tract,* which carries the sensations of crudely localized touch and pressure; (2) the *lateral spinothalamic tract,* which carries pain and temperature; and (3) the *spinoreticular tract*, which is involved with diffuse pain sensations.[64]

Dorsal Column–Medial Lemniscal Pathway

This system is responsible for the transmission of discriminative sensations received from specialized mechanoreceptors. Sensory modalities that require fine gradations of intensity and precise localization on the body surface are mediated by this system. Sensations transmitted by the dorsal column–medial lemniscal pathway include discriminative touch, stereognosis, tactile pressure, barognosis, graphesthesia, recognition of texture, kinesthesia, two-point discrimination, proprioception, and vibration.

This system is composed of large, myelinated, rapidly conducting fibers. After entering the dorsal column the fibers ascend to the medulla and synapse with the dorsal column nuclei (nuclei gracilis and cuneatus). From here they cross to the opposite side and pass up to the thalamus through bilateral pathways called the *medial lemnisci*. Each medial lemniscus terminates in the ventral posterolateral thalamus. From the thalamus, third-order neurons project to the somatic sensory cortex. Projection to sensory association areas in the cortex allows for the perception and interpretation of the combined cortical sensations (Fig. 3.5).[64,65,67,74] Table 3.1 presents a comparison of the most salient features of each ascending pathway.

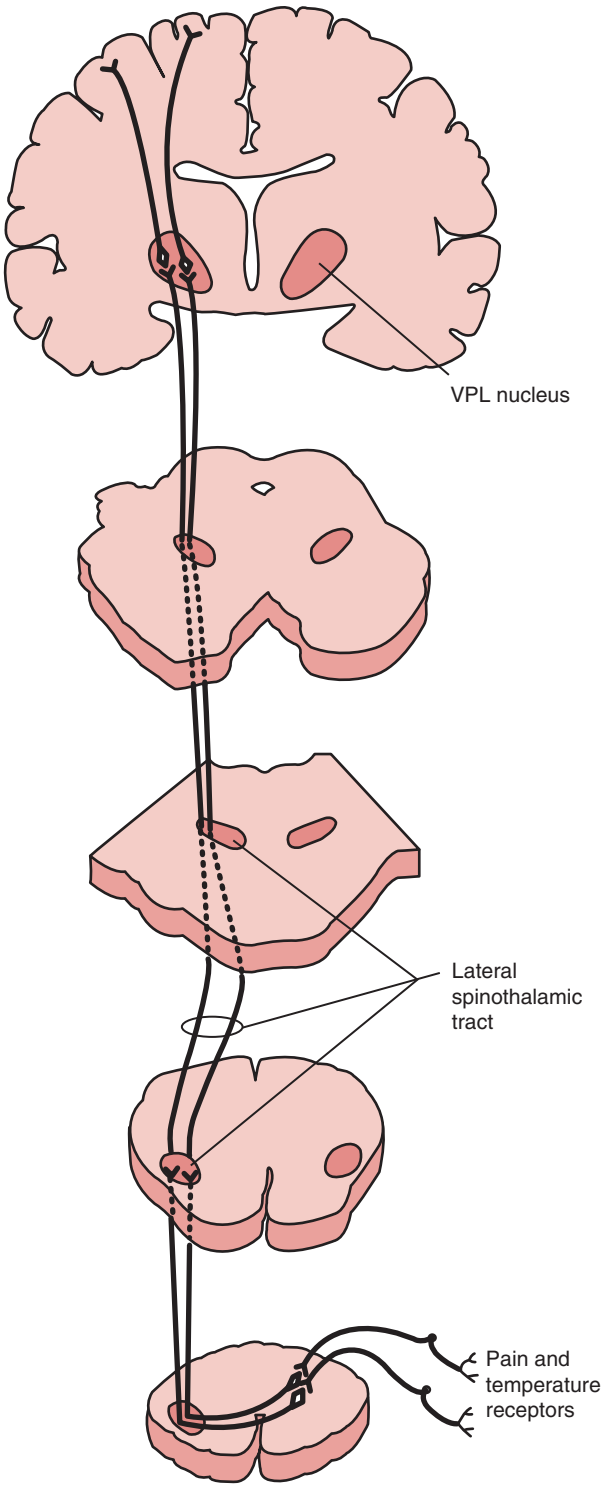

Figure 3.4 Anterolateral spinothalamic tract carrying pain and temperature.

SOMATOSENSORY CORTEX

The most complex processing of sensory information occurs in the somatosensory cortex, which is divided into three main divisions: primary somatosensory cortex (S-I), secondary somatosensory cortex (S-II), and posterior parietal cortex (Fig. 3.6A). The primary somatosensory (S-I) area occupies a lateral strip called the postcentral gyrus (posterior to the central sulcus) and includes four distinct areas: Brodmann's areas 3a, 3b, 1, and 2. S-I neurons identify the location of stimuli as well as discern the size, shape, and texture of objects. At the superior aspect of the lateral sulcus is the secondary somatosensory cortex (S-II), which is innervated by neurons from S-I. S-II projects to the insular cortex that innervates

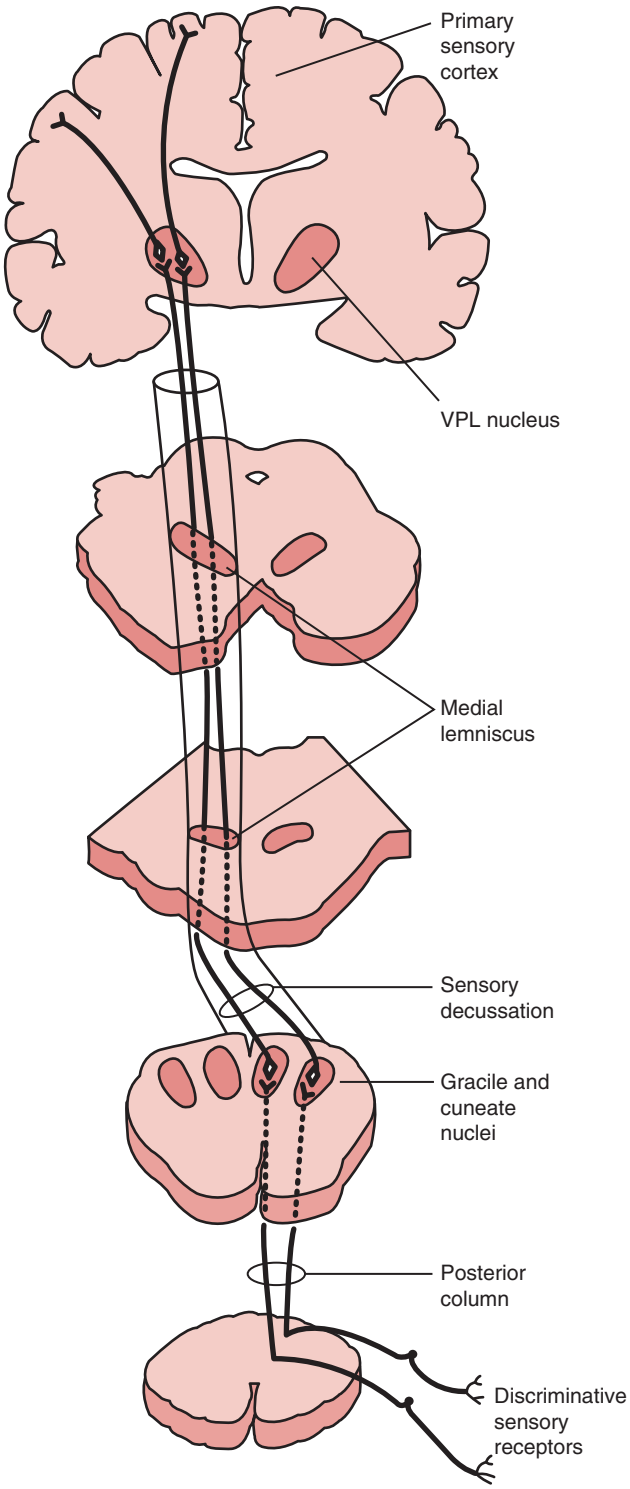

Figure 3.5 Dorsal column–medial lemniscal tract carrying discriminative sensations such as kinesthesia and touch.

the temporal lobe, believed important in tactile memory. The posterior parietal lobe is behind S-I and consists of areas 5 and 7. Area 5 integrates tactile input from mechanoreceptors of the skin with proprioceptive input from muscles and joints. Area 7 integrates stereognostic and visual information from visual, tactile, and proprioceptive input.[69,74,75] These processing areas analyze and integrate somatosensory information and contribute to motor performance by (1) determining the initial position required before a movement occurs, (2) error detection as movement occurs, and (3) identification of movement outcomes, which helps to shape learning.

Animal models have provided considerable insight into the function of the cortical association areas. Complete removal of area S-I of the somatosensory system produces deficits in position sense and the ability to determine the size, texture, and shape of objects. Temperature and pain perception are diminished but not abolished. Owing to reliance on input from S-I, removal of S-II results in severe impairment of the perception of both shape and texture of objects. Animal models have also shown reduced ability to learn new discriminative tasks, which are based on the shape of an object. Insult to the posterior parietal cortex presents profound impairments in attending to sensory input from the contralateral side of the body.[75]

The sensory homunculus (somatotopic map) represents a cross-sectional view through the postcentral gyrus and identifies the relative size of the cortex devoted to specific body parts (Fig. 3.6B). Note that certain areas of the body are exaggerated such as the hand, face, and mouth owing to greater innervation density of the skin. The relative size of body parts represents both the *density* of sensory input from the body region as well as the *importance* of sensory information from the area as it relates to function.[74,75] For example, the relative size of the foot is reflective of its importance in locomotion; the relative size of the index finger reflects its role in fine motor skills. In contrast, cortical areas for the trunk and back are small, implying a lower receptor density and reduced role in sensory perception related to function.

Using two-point discrimination as an example, Bear et al[74] provide an extraordinary illustration of how our ability to perceive a stimulus varies remarkably across the body:

> Two-point discrimination varies at least twenty-fold across the body. Fingertips have the highest resolution. The dots of Braille are 1 mm high and 2.5 mm apart; up to six dots make a letter. An experienced Braille reader can scan an index finger across a page of raised dots and read about 600 letters per minute, which is roughly as fast as someone reading aloud. Several reasons explain why the fingertip is so much better than, say, the elbow for Braille reading: (1) There is a much higher density of mechanoreceptors in the skin of the fingertip than on other parts of the body; (2) the fingertips are enriched in receptor types that have small receptive fields; (3) there is more brain tissue (and thus more raw computing power) devoted to the sensory information

Table 3.1 Features of Pathways for Transmission of Somatic Sensory Signals

Pathway	Type of Sensation	Afferent Fibers	Origin	Projection
Anterolateral spinothalamic	Nondiscriminative (e.g., pain, temperature); broad spectrum of sensory modalities; crude localization; poor intensity discrimination; poor spatial orientation relative to origin of stimulus	Small-diameter, slowly conducting	Skin: mechanoreceptors, thermoreceptors, nociceptors	From dorsal roots of spinal nerves, synapse at dorsal horns, fibers cross and move up spinal cord, through medulla, pons, and midbrain to the ventroposterolateral nucleus of thalamus
Dorsal column–medial lemniscal	Discriminative (e.g., stereognosis, two-point discrimination); precise localization; fine intensity gradations; high degree of spatial orientation relative to origin of stimulus	Large, rapidly conducting	Skin, joints, tendons: specialized mechanoreceptors	From dorsal roots of spinal nerves, ascend to medulla, synapse with dorsal column nuclei, cross to contralateral side and ascend to thalamus; then project to sensory cortex

of each square millimeter of fingertip than elsewhere; and (4) there may be special neural mechanisms devoted to high-resolution discriminations.[74, p. 392]

SCREENING

An important component of physical therapy intervention is to accurately and efficiently meet individual patient needs. Together with information from the history and review of systems, screenings assist the therapist in proficiently identifying the needed tests and measures and setting priorities within the examination process. Screenings consist of a series of brief tests that provide the therapist an "overview" of the system of interest (e.g., musculoskeletal, neuromuscular). Within this context, screenings are conducted to:[7,76]

- Determine the need for further or more detailed examination
- Determine in a timely manner if referral to another health care practitioner is warranted
- Focus the search for the origin of symptoms to a specific location or body part
- Identify system-related impairments that contribute to activity limitations or disability

Clinical Note: The term *screening* is also used in another context. It additionally refers to identification of individuals or groups who are not currently receiving physical therapy services but may be at risk for a health problem.[7] Examples might include identification of risk factors for low back injury, diabetes, obesity, or falls in the elderly. Physical therapy interventions associated with this type of screening typically involve prevention strategies, fitness advocacy, and health promotion and wellness programs designed to meet the needs of an individual client or target population.

To perform a sensory screening, several easily tested (i.e., requiring little or no specialized equipment) modalities of sensation are selected. It is important to select modalities from each of the general categories of sensations. For example, the therapist might select pain and light touch (superficial), kinesthesia and vibration (deep), and two-point discrimination or stereognosis (combined).

Sensory screening is performed by using the selected modalities to test randomly over somewhat large surface areas. For example, several applications of each stimulus might be distributed over the upper and lower extremities and trunk. The information gathered informs the therapist's decision making. For example, if sensory impairments are identified it may (1) indicate the need for more detailed testing, (2) help narrow the origin of symptoms, or (3) provide insight into the cause of activity limitations.

As mentioned earlier, screening tests for mental status (arousal, attention, orientation, cognition, and memory), vision, and hearing acuity should be performed prior to the sensory examination.

PREPARATION FOR ADMINISTERING THE SENSORY EXAMINATION

Before initiating the examination of sensory function, the testing environment should be identified and prepared, needed equipment gathered, and consideration

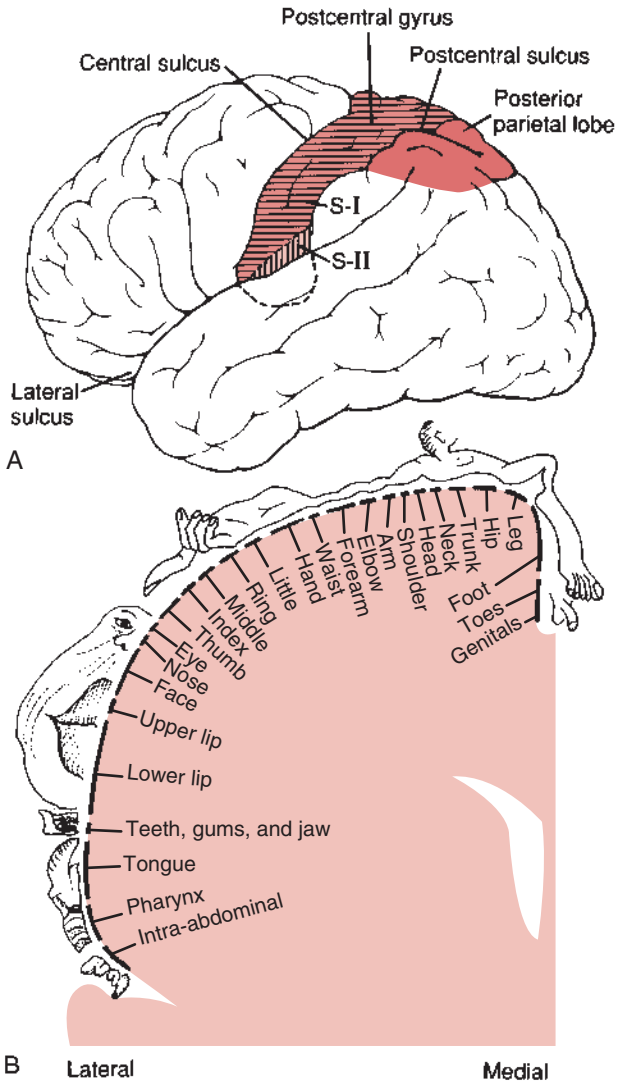

Figure 3.6 **(A)** The somatosensory cortex has three main divisions: The primary (S-I) and secondary (S-II) areas, and the posterior parietal lobe. **(B)** The sensory homunculus. Areas of the body used for tactile discrimination (e.g., lips, tongue, and fingers) are represented by large areas of cortical tissue. Areas with reduced cortical representation, such as the trunk, are reflective of body parts with lesser roles in sensory perception. *(From Kandel, ER, and Jessell, TM: Touch. In Kandel, ER, Schwartz, JH and Jessel, TM: Principles of Neural Science, ed 3. Appleton and Lange, Norwalk, CT, 1991 with permission, pp. 368 [A] and 372[B]).*

given to patient preparation (i.e., what information and instruction will be provided).

Testing Environment

The sensory examination should be administered in a quiet, well-lighted area. Depending on the number of body areas to be tested, either a sitting or recumbent position may be used. If full body testing is indicated, both prone and supine positions will be required and use of a treatment table is recommended to allow examination of each side of the body.

Equipment

To perform a sensory examination the following equipment and materials are used:

1. *Pain*. A large-headed safety pin or a large paper clip that has one segment bent open (providing one *sharp* and one *dull* end). The sharp end of the instrument should not be sharp enough to risk puncturing the skin. If a large-headed safety pin is used, the sharp end may be further blunted by a light sanding. Commercially available single-use protected neurological pins may also be used (Fig. 3.7).
2. *Temperature*. Two standard laboratory test tubes with stoppers.

Clinical Note: The Tip Therm® is an early detection tool for identification of changes in thermal perception designed for monitoring polyneuropathy associated with diabetes (Fig. 3.8). It provides a method for patients to test temperature sensitivity of their feet independently. It provides only a gross estimate of temperature perception; however, its convenience, low cost, and patients' ability to use it are important characteristics. The tool can be used many times, requires no energy, and makes use of the special characteristics of synthetic material and metal. One end is metal and the opposite side is synthetic material. Both materials are essentially at room temperature; however, the metal end takes more heat from the body (metal has a higher

Figure 3.7 Single use protected neurological pin. The image on the *left* shows the pin prior to use with the protective cap intact (although schematically presented to allow visualization of pin location). On the *right*, the protective cap is removed and the pin exposed. On the opposite end of the pin is a smooth rounded surface used to randomly intersperse application of a dull stimulus. After use, the point is destroyed by compressing it against a hard surface and disposed of in a biohazard receptacle. *(Courtesy of US Neurologicals, Kirkland, WA 98033.)*

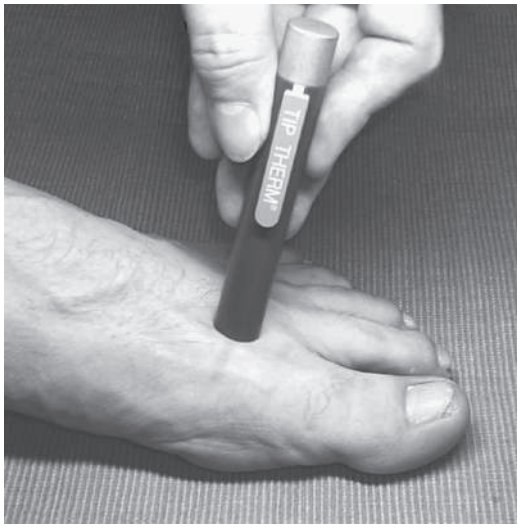

Figure 3.8 The Tip Therm® is a thermal instrument designed for patient monitoring of gross temperature perception of the feet. The instrument is 4 inches (100 mm) long with a .59 inch (15 mm) diameter. *(Courtesy of Tip-Therm® GmbH, Düsseldorf, Germany.)*

conductivity than the synthetic end). As a result, the metal end is perceived as warm and the synthetic end as cooler.

3. *Light touch*. A camel-hair brush, a piece of cotton, or a tissue.
4. *Vibration*. Tuning fork and earphones (if available, to reduce auditory clues). Tuning forks are made of steel or magnesium alloy and grossly resemble a two-pronged fork. When the tines are stuck against a surface (usually the palm of the examiner's hand) the fork resonates at a specific pitch (e.g., 128, 256, or 512 Hz) determined by the length of the two U-shaped prongs (tines).
5. *Stereognosis (object recognition).* A variety of small, commonly used articles such as a comb, fork, paper clip, key, marble, coin, pencil, and so forth.
6. *Two-point discrimination*. Several instruments are available to measure two-point discrimination. A two-point discrimination aesthesiometer (Fig. 3.9) is a small handheld instrument designed to measure the shortest distance that two points of contact on the skin can be distinguished. It consists of a small ruler with one stationary and one moveable (sliding) tip coated with vinyl. The vinyl coverings help to minimize the impact of temperature on perception of contact. Some instruments also have a third tip allowing ease of alternating from two points to a single point of contact during testing. If used on an uneven body surface, care should be taken not to allow the "ruler" portion of the instrument to make contact with the skin. *Note:* The term *aesthesiometer* is not specific to this instrument; it is used to describe any number of instruments designed to examine touch perception.

   For finer gradations in measurement (e.g., fingertips), small circular disks can be used to measure two-point discrimination (Fig. 3.10). These instruments typically allow quantification of two-point discrimination from 1 to 25 mm.

   Electrocardiogram (ECG) calipers[77] with the tips sanded to blunt the ends[78] and a small ruler have also been used to measure two-point discrimination.
7. *Recognition of texture*. Samples of fabrics of various texture such as cotton, wool, burlap, or silk (approximately 4 × 4 inches [10 × 10 cm]).

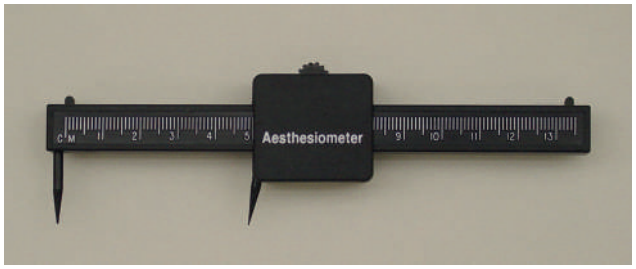

Figure 3.9 A handheld aesthesiometer provides a quantitative measure of two-point discrimination. The two-point threshold is determined by gradually bringing the tips closer together as it is sequentially applied to the patient's skin. The scale is calibrated to the nearest 0.1 cm and measures up to 14 cm.

Patient Preparation

A full explanation of the purpose of the testing should be provided. The patient also should be informed that cooperation is necessary to obtain accurate test results. It is of considerable importance that the patient be requested *not to guess* if uncertain of the correct response.

Figure 3.10 This circular two-point discrimination instrument consists of two joined plastic rotating disks with rounded tips placed at standard testing intervals. *(Courtesy of North Coast Medical, Inc., Morgan Hill, CA 95037.)*

During the examination, the patient should be in a comfortable, relaxed position. Preferably, the tests should be performed when the patient is well rested. Considering the high level of concentration required, it is not surprising that fatigue has been noted to affect results of some sensory tests adversely.[77]

Note: A "trial run" or demonstration of each test should be performed just prior to actual administration. This will orient the patient to the sensation being tested, what to anticipate, and what type of response is required. The importance of this initial trial should not be underestimated. If a practice trial is inadequately or not performed, what appears to be a sensory impairment may in reality only be a reflection of the patient's lack of understanding of the testing protocol or how to respond to a stimulus.

Some method of occluding the patient's vision during the testing should be used (vision should not be occluded during the explanation and demonstration). Visual input is prevented because it may allow for compensation of a sensory deficit and thus decrease the accuracy of test results. The traditional methods of occluding vision are by use of a fabric blindfold (such as those worn by travelers to sleep on an airplane), a small folded towel, or by asking the patient to keep the eyes closed. These methods are practical in most instances. However, in situations of CNS dysfunction, a patient may become anxious or disoriented if vision is occluded for a long period of time. In these situations, a small screen or folder may be preferable as a visual barrier. Whatever method is used, it should be removed between the tests while directions and demonstrations are provided.

THE SENSORY EXAMINATION

The superficial (exteroceptive) sensations are usually examined first, inasmuch as they consist of more primitive responses, followed by the deep (proprioceptive), and then the combined cortical sensations. If a test indicates impairment of the superficial responses, some impairment of the more discriminative (deep and combined) sensations also will be noted and is a contraindication to further testing (e.g., lack of touch sensation would be a contraindication for testing stereognosis). That is, the primary modality of sensation (touch) must be sufficiently intact to permit meaningful testing of cortical sensory function (ability to identify objects placed in the hand).

For each sensory test, the following data will be generated:

- The modality tested
- The quantity of involvement or body surface areas affected (pattern identification)
- The degree or severity of involvement (e.g., absent, impaired, or delayed responses)
- Localization of the exact boundaries of the sensory impairment
- The patient's subjective feelings about changes in sensation
- The potential impact of sensory loss on function (i.e., activity limitation, disability)

Knowledge of skin segment (dermatome) innervation by the dorsal roots and peripheral nerve innervation (see Figs. 3.1 and 3.2) is required for making sound, accurate diagnostic and prognostic judgments. They serve as critical references during testing as well as provide a framework for documenting results.

Sensory tests are typically performed in a distal to proximal direction. This progression will conserve time, particularly when dealing with localized lesions involving a single extremity, where deficits tend to be more severe distally. It is generally not necessary to test every segment of each dermatome; testing general body areas is sufficient. However, once a deficit area is noted, testing must become more discrete and the exact boundaries of the impairment should be identified. A skin pencil may be useful to mark the boundaries of sensory change directly. This information should be transferred later to a sensory examination form, graphically presented on a dermatome chart, and peripheral nerve involvement identified. Figure 3.11 presents a sample Sensory Examination Form. A single documentation form applicable to the variety of patients seen in different practice settings does not exist. Specialized centers or organizations have developed specific forms to examine sensory function (e.g., the American Spinal Injury Association (ASIA) Standard Neurological Classification of Spinal Cord Injury, described in Chapter 20, Traumatic Spinal Cord Injury). However, the following are common elements of sensory examination forms: (1) a dermatome chart to graphically display findings; (2) a grading scale (e.g., 0—absent; 1—impaired; 2—normal; NT—not testable; and so forth) to score patient perception of individual modalities; and (3) a section for narrative comments.

Most often the dermatome charts are completed using a color code (i.e., each color represents a different sensory modality). The colors used to plot each sensation are then coded by the examiner directly on the form (see Fig. 3.11). In many instances hatch marks of varying density are used to represent gradations in sensory impairment (i.e., the closer together, the greater the sensory impairment). With this method, a completely colored-in area indicates no response to a given sensation. With varied or "spotty" sensory loss it is not uncommon that more than one dermatome chart is required to completely depict all test findings. With use of several dermatome charts, the sensation(s) represented should appear in bold print at the top of each page.

Figure 3.11 provides the foundational elements of documentation typically included for sensory examinations. It should be modified or expanded to meet the needs of a given population or facility. It is also not uncommon for therapists to included sensory testing data within the body of a narrative or progress report.

This form provides a record of the type, severity, and location of sensory impairments. It should be used in conjunction with additional dermatome sheets, if needed, to graphically outline the exact boundaries of the impairment. The designations P and D may be added to the grading key to indicate either a proximal (P) or a distal (D) location of the impairment on a limb or body part. The dermatome chart should be color coded and filled in using varying density hatch marks (higher density for more severe areas of impairment). Indicate the color used for documentation in the box titled Color Code (a different color should be used for each sensation). Separate notation should be made for examination of the face and identification of peripheral nerve involvement. Abnormal responses should be briefly described in the comments section.

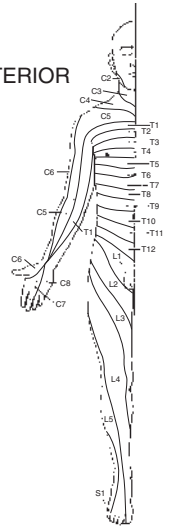
Patient Name: _____ Date: _____

Examiner: _____

Sensations	Upper Extremity		Lower Extremity		Trunk		Comments
	Right	Left	Right	Left	Right	Left	
Pain							
Temperature							
Touch							
Vibration							
Two-Point Disc							
Kinesthesia							
Proprioception							
Stereognosis							

Note: Areas shaded indicate sensation not typically tested for corresponding body part.

Key to Grading



0 = Absent, no response
1 = Decreased, delayed response
2 = Increased, exaggerated response
3 = Inconsistent response
4 = Intact, normal response
NT = unable to test
P = proximal; D = distal

Color Code

Color	Sensation

Indicate Peripheral Nerve Involvement:

ANTERIOR

POSTERIOR

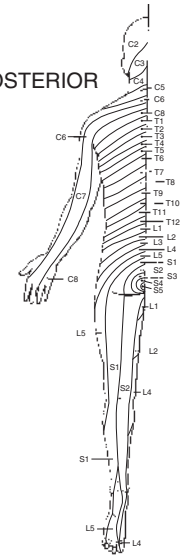


Figure 3.11 Sample Sensory Examination Form.

During testing, the application of stimuli should be applied in a random, unpredictable manner with variation in timing. This will improve accuracy of the test results by avoiding a consistent pattern of application, which might provide the patient with "clues" to the correct response. During application of stimuli, consideration must be given also to skin condition. Scar tissue or callused areas are generally less sensitive and will demonstrate a diminished response to sensory stimuli. Recall that a trial test is performed to instruct the patient in what to expect and how to respond to application of the specific stimuli; and that patient vision is occluded during testing.

The following sections present the individual sensory tests. The tests are subdivided for superficial, deep, and combined cortical sensations. Table 3.2 presents terminology used to describe common sensory impairments.

Clinical Note: Hands should always be washed prior to and after patient contact. "Hand hygiene is a major component of standard precautions and one of the most effective methods to prevent transmission of pathogens associated with health care."[79, p. 1] The World Health Organization (WHO) recommends hand washing with soap and water for 40 to 60 seconds and hand rubbing using an alcohol-based hand rub for 20 to 30 seconds.[80] See Chapter 2, Examination of Vital Signs (section titled Hand Hygiene) for a more detailed discussion and figures illustrating hand hygiene techniques using soap and water and an alcohol-based hand rub.

Superficial Sensations

Pain Perception

This test is also referred to as *sharp/dull discrimination* and indicates function of protective sensation. To test pain awareness, the sharp and dull ends of a large-headed safety pin, a reshaped paper clip (the segment pulled away from the body of the paper clip provides a sharp end), or a single-use protected neurological pin (see Fig. 3.7) are used. The instrument should be carefully cleaned before administering the test and disposed of immediately afterward (owing to the protective cap on the neurological pin, cleaning is not required). The sharp and dull ends of the instrument are randomly applied perpendicularly to the skin. To avoid summation

Table 3.2 Terminology Describing Common Sensory Impairments

Abarognosis	Inability to recognize weight
Allesthesia	Sensation experienced at a site remote from point of stimulation
Allodynia	Pain produced by a non-noxious stimulus
Analgesia	Complete loss of pain sensitivity
Astereognosis	Inability to recognize the form and shape of objects by touch (synonym: tactile agnosia)
Atopognosia	Inability to localize a sensation
Causalgia	Painful, burning sensations, usually along the distribution of a nerve
Dysesthesia	Touch sensation experienced as pain
Hypalgesia	Decreased sensitivity to pain
Hyperalgesia	Increased sensitivity to pain
Hyperesthesia	Increased sensitivity to sensory stimuli
Hypesthesia	Decreased sensitivity to sensory stimuli
Pallanesthesia	Loss or absence of sensibility to vibration
Paresthesia	Abnormal sensation such as numbness, prickling, or tingling, without apparent cause
Thalamic syndrome	Vascular lesion of the thalamus resulting in sensory disturbances and partial or complete paralysis of one side of the body, associated with severe, boring-type pain; sensory stimuli may produce an exaggerated, prolonged, or painful response
Thermanalgesia	Inability to perceive heat
Thermanesthesia	Inability to perceive sensations of heat and cold
Thermhyperesthesia	Increased sensitivity to temperature
Thermhypesthesia	Decreased temperature sensibility
Thigmanesthesia	Loss of light touch sensibility

of impulses, the stimuli should not be applied too close to each other or in too rapid a succession. To maintain a uniform pressure with each successive application of stimuli, the pin or reshaped paper clip should be held firmly and the fingers allowed to "slide" down the pin or paper clip once in contact with the skin. This will avoid the chance of gradually increasing pressure during application. The instrument used to test pain perception should be sharp enough to deflect the skin, but not puncture it.

Response

The patient is asked to verbally indicate *sharp* or *dull* when a stimulus is felt. All areas of the body may be tested.

Temperature Awareness

This test determines the ability to distinguish between warm and cool stimuli. Two test tubes with stoppers are required for this examination; one should be filled with warm water and the other with crushed ice. Ideal temperatures for cold are between 41°F (5°C) and 50°F (10°C) and for warmth, between 104°F (40°C) and 113°F (45°C). Caution should be exercised to remain within these ranges, because exceeding these temperatures may elicit a pain response and consequently inaccurate test results. The side of the test tube should be placed in contact with the skin (as opposed to only the distal end). This technique provides sufficient surface area contact to determine the temperature. The test tubes are randomly placed in contact with the skin area to be tested. All skin surfaces should be tested.

Response

The patient is asked to reply *hot* or *cold* after each stimulus application.

Clinical Note: The clinical usefulness of thermal testing may be problematic. Nolan[77] points out that the tests are extremely difficult to duplicate on a day-to-day basis owing to rapid changes in temperature once the test tubes are exposed to room air. Although it is a simple test to perform, determining changes over time is not practical unless a method of monitoring the temperature of the test tubes is used.[77]

Touch Awareness

This test determines perception of tactile touch input. A camel-hair brush, piece of cotton (ball or swab), or tissue is used. The area to be tested is lightly touched or stroked. Examination of finer gradations of light touch can be quantified using monofilaments (see later section titled Quantitative Sensory Testing and Specialized Testing Instruments).

Response

The patient is asked to indicate when he or she recognizes that a stimulus has been applied by responding "yes" or "now."

Note: A quantitative score for pain perception, temperature, and light touch awareness can be obtained by dividing the number of *correct responses* by the *number of stimuli* applied (normal response would be 100%).[81] Also, inability to verbally communicate does not necessary preclude obtaining accurate data. For example, having the patient hold up one or two fingers might be used for dichotomous responses (yes/no; hot/cold). Other options might include nodding the head, pointing to index cards containing printed responses; or using hand gestures to indicate recognition of a stimulus.

Pressure Perception

The therapist's fingertip or a double-tipped cotton swab is used to apply a firm pressure on the skin surface. This pressure should be firm enough to indent the skin and to stimulate the deep receptors. This test can also be administered using the thumb and fingers to squeeze the Achilles tendon.[77]

Response

The patient is asked to indicate when an applied stimulus is recognized by responding "yes" or "now."

Deep Sensations

The deep sensations include **kinesthesia**, **proprioception**, and **vibration**. Kinesthesia is the awareness of movement. Proprioception includes position sense and the awareness of joints at rest. Vibration refers to the ability to perceive rapidly oscillating or vibratory stimuli. Although these sensations are closely related, they are examined individually.

Kinesthesia Awareness

This test examines *awareness of movement.* The extremity or joint(s) is moved passively through a relatively small range of motion (ROM). Small increments in ROM are used as joint receptors fire at specific points throughout the range. The therapist should identify the range of movement being examined (e.g., initial, mid-, or terminal range). As discussed, a trial run or demonstration of the procedure should be performed prior to actual testing. This will ensure that the patient and the therapist agree on terms to describe the direction of movements.

Response

The patient is asked to describe verbally the direction (up, down, in, out, and so forth) and range of movement in terms previously discussed with the therapist while the extremity is *in motion*. The patient may also respond by simultaneously duplicating the movement with the contralateral extremity. This second approach, however, is impractical with proximal lower extremity

joints, owing to potential stress on the low back. During testing, movement of larger joints is usually discerned more quickly than that of smaller joints. The therapist's grip should remain constant and minimal (fingertip grip over bony prominences), to reduce tactile stimulation.

Proprioceptive Awareness

This test examines *joint position sense* and *the awareness of joints at rest*. The extremity or joint(s) is moved through a ROM and held in a static position. Again, small increments of range are used. The words selected to identify the range of movement examined should be identified to the patient during the practice trial (e.g., initial, mid-, or terminal range). As with kinesthesia, caution should be used with hand placements to avoid excessive tactile stimulation.

Response

While the extremity or joint(s) is held in a static position by the therapist, the patient is asked to describe the position verbally or to duplicate the position of the extremity or joint(s) with the contralateral extremity (position matching). This test may also be performed unilaterally using the same extremity or joint(s); first held in position by the examiner, then returned to resting position, followed by active duplication of position by patient using the same limb.

Clinical Note: Based on a series of position matching studies conducted in the Motor Control Laboratory at the University of Michigan, Goble[82] presents several important factors to assist clinicians in making informed decisions about proprioceptive matching test outcomes:

- For position matching tests, there are different memory influences and different interhemispheric communication requirements between use of the ipsilateral extremity (same arm positioned by examiner is used to actively replicate the joint angle[s]) versus contralateral limb (patient moves opposite extremity from that used by examiner).
- Likely owing to the enhanced role of the right hemisphere in proprioceptive feedback processing, the left arm appears to have an advantage in matching tasks.
- The magnitude of the reference joint angle (larger magnitudes associated with greater error) and how reference positions are established (fewer errors noted when active movement used to establish position versus passive movement by examiner) will influence performance.
- Proprioceptive acuity must be considered within the context of anticipated changes occurring over the lifespan or that are diagnosis specific (e.g., stroke).
- Task workspace (area in which activities of daily living are typically performed) appears to influence joint position matching performance. During position matching experiments, greater performance occurred to the left of body midline with the fewest errors in the far left of the workspace.

Vibration Perception

This test requires a tuning fork that vibrates at 128 Hz.[77] The ability to perceive a vibratory stimulus is tested by placing the base of a vibrating tuning fork on a bony prominence (such as the sternum, elbow, or ankle). The tuning fork base (the "handle" of the fork) is held between the examiner's thumb and index finger without making contact with the tines. The tines are then briskly hit against the open palm of the examiner's opposite hand to initiate the vibration. Care must be taken not to touch the tines, as this will stop the vibration. The base of the fork in then placed over a bony prominence. If vibration sensation is intact, the patient will perceive the vibration. If there is impairment, the patient will be unable to distinguish between a vibrating and non-vibrating tuning fork. Therefore, there should be a random application of vibrating and non-vibrating stimuli.

Auditory clues can pose a challenge in obtaining accurate test results. Typically it is easy to hear the sound of the tines making vigorous contact with the examiner's hand to initiate the vibration. If the sound is not heard, it provides an easy indicator to the patient that the next application will be non-vibrating. To minimize this effect, the vibration can be initiated for *every* stimulus application; however, when a non-vibrating stimulus is desired, brief contact of the therapist's fingers on the tines will stop the vibration prior to placement on the skin. This, though, does not solve the problem of the auditory cues generated during application of a vibrating stimulus. The best solution is use of sound occlusive earphones (the type worn by airport ground workers). Unfortunately, such earphones are seldom available in a clinic setting.

Response

The patient is asked to respond by verbally identifying or otherwise indicating if the stimulus is vibrating or non-vibrating each time the fork makes contact.

Combined Cortical Sensations

Stereognosis Perception

This test determines the ability to recognize the form of objects by touch (stereognosis). A variety of small, easily obtainable, and culturally familiar objects of differing size and shape are required (e.g., keys, coins, combs, safety pins, pencils, and so forth). A single object is placed in the hand, the patient manipulates the object, and then identifies the item verbally. The patient should be allowed to handle several sample test items during the explanation and demonstration of the procedure.

Response

The patient is asked to name the object verbally. For patients with speech impairments, sensory testing shields can be used (Fig. 3.12). Alternatively, the item manipulated can be identified from a group of images presented after each test.

Tactile Localization

This test determines the ability to localize touch sensation on the skin (topognosis). The patient is asked to identify the specific point of application of a touch stimulus (e.g., tip of ring finger, lateral malleus, and so forth) and not simply the perception of being touched. Tactile localization is typically not tested in isolation and frequently examined in combination with similar tests such as pressure perception or touch awareness. Using a cotton swap or fingertip, the therapist touches different skin surfaces. After each application of a stimulus the patient is given time to respond.

Response

The patient is asked to identify the location of the stimuli by pointing to the area or by verbal description. The patient's eyes may be open during the response component of this test. The distance between the application of the stimulus and the site indicated by the patient can be measured and recorded. Accuracy of localization over various parts of the body may be compared to determine the relative sensitivity of different areas.

Figure 3.12 A sensory testing shield can be used for examining stereognosis in the presence of speech or language impairments. In this simulation, the subject manipulates the object without the use of visual input. Following manipulation, the subject points to the matching object pictured on the ledge of the testing shield. *(Courtesy of North Coast Medical, Inc., Morgan Hill, CA 95037.)*

Two-Point Discrimination

This test determines the ability to perceive two points applied to the skin simultaneously. It is a measure of the smallest distance between two stimuli (applied simultaneously and with equal pressure) that can still be perceived as two distinct stimuli. Two-point discrimination values vary for different individuals and body parts. As this sensory function is most refined in the distal upper extremities, this is the typical site for testing. It is believed to contribute to precision grip movements and instrumental activities of daily living (IADL).[83]

Two-point discrimination is among the most practical and easily duplicated tests for cutaneous sensation. Some years ago, a series of classic two-point discrimination studies were conducted by Nolan.[84–86] The purpose of his research was to establish normative data on two-point discrimination for young adults. His sample consisted of 43 college students ranging in age from 20 to 24 years. Values from Nolan's studies for the upper and lower extremities as well as the face and trunk are presented in Appendix 3.A. The results from these studies should be used cautiously, inasmuch as they relate to a specific population. They should not be generalized for interpreting data from older or younger patients. Normative data for two-point discrimination have been documented by several authors including van Nes et al,[29] Kaneko et al,[62] and Vriens and van der Glas.[87]

As mentioned earlier, the aesthesiometer (see Fig. 3.9) and the circular two-point discriminator (see Fig. 3.10) are among the most common devices used for measurement. Two reshaped paper clips can also be used; however, this requires the assistance of a second examiner to measure the distance between the two points using a small ruler. During the test procedure the two tips of the instrument are applied to the skin simultaneously with tips spread apart. To increase the validity of the test, it is appropriate to alternate the application of two stimuli with the random application of only a single stimulus (the purpose of the third tip on some aesthesiometers). With each successive application, the two tips are gradually brought closer together until the stimuli are perceived as one. The smallest distance between the stimuli that is still perceived as two distinct points is measured.

Response

The patient is asked to identify the perception of "one" or "two" stimuli.

Double Simultaneous Stimulation

This test determines the ability to perceive simultaneous touch stimuli (double simultaneous stimulation [DSS]). The therapist simultaneously (and with equal pressure)

touches: (1) identical locations on opposite sides of the body, (2) proximally and distally on opposite sides of the body, and/or (3) proximal and distal locations on the same side of the body. The term *extinction phenomenon* is used to describe a situation in which only the proximal stimulus is perceived, with "extinction" of the distal.

Response

The patient verbally states when he or she perceives a touch stimulus and the number of stimuli felt.

Several additional tests for the combined (cortical) sensations include graphesthesia (traced finger identification), recognition of texture, and barognosis (recognition of weight). However, these tests are usually not performed if stereognosis and two-point discrimination are found to be intact.

Graphesthesia (Traced Figure Identification)

This test determines the ability to recognize letters, numbers, or designs "written" on the skin. Using a fingertip or the eraser end of a pencil, a series of letters, numbers, or shapes is traced on the palm of the patient's hand. During the practice trial, agreement should be reached about the orientation of the tracings. (For example, the bottom of the traced figures will always be oriented toward the base of the patient's hand [wrist].) Between each separate drawing the palm should be gently wiped with a soft cloth to clearly indicate a change in figures to the patient. This test is also a useful substitute for stereognosis when paralysis prevents grasping an object.

Response

The patient is asked to identify verbally the figures drawn on the skin. For patients with speech or language impairments, the figures can be selected (pointed to) from a series of line drawings.

Recognition of Texture

This test determines the ability to differentiate among various textures. Suitable textures may include cotton, wool, burlap, or silk. The items are placed individually in the patient's hand. The patient is allowed to manipulate the sample texture.

Response

The patient is asked to identify the individual textures as they are placed in the hand. They may be identified by name (e.g., silk, cotton) or by texture (e.g., rough, smooth).

Barognosis (Recognition of Weight)

This test determines the ability to recognize different weights. A set of discrimination weights consisting of small objects of the same size and shape but of graduated weight is used (Fig. 3.13). The therapist may choose to place a series of different weights in the same hand one at a time, place a different weight in each hand simultaneously, or ask the patient to use a fingertip grip to pick up each weight.

Figure 3.13 Discrimination weights are identical in size, shape, and texture. The only distinguishing feature is their variation in weight. *(Courtesy of Lafayette Instruments, Lafayette, IN 47903.)*

Response

The patient is asked to identify the comparative weight of objects in a series (i.e., to compare the relative weight of the object with the previous one); or when the objects are placed (or picked up) in both hands simultaneously the patient is asked to compare the weight of the two objects. The patient responds by indicating that the object is "heavier" or "lighter."

Clinical Note: Impaired sensation is a contraindication to or precaution for use of some physical agents because the end range of intensity or duration is frequently associated with the patient's subjective report of how the intervention feels (i.e., patient tolerance).

RELIABILITY

Reliability is an important parameter of any test or measure. However, few systematic reports addressing the reliability of traditional sensory tests appear in the literature. This is likely due to the inability to accurately quantify test results. In an important early reliability study by Kent[88] the upper limbs of 50 adult patients with hemiplegia were tested for sensory and motor deficits. Three sensory tests were administered and then repeated by the same examiner within 1 to 7 days. Results revealed a high reliability for both stereognosis ($r = 0.97$) and position sense ($r = 0.90$). A lower reliability was reported for two-point discrimination, with correlation coefficients ranging from 0.59 to 0.82, depending on the body area tested.

More recently, Moloney et al[89] examined the interrater reliability of thermal quantitative sensory testing in young healthy adults. The interrater reliability for cold detection threshold (ICC = 0.27–0.55), warm detection threshold (ICC = 0.38–0.69), cold pain threshold (ICC = 0.88–0.94), and heat pain threshold (ICC = 0.52–0.86) ranged from poor to high. Juul-Kritensen et al[90] examined proprioception of the elbow in healthy subjects. The test-retest reliability (of the absolute error) of joint position sense (ICC = 0.59) and threshold to detection of a passive motion (ICC = 0.69) ranged from fair to good, respectively. Khamwong et al[91] examined the vibration sense of two upper extremity sites on healthy male volunteers. The test-retest reliability of vibration sense over the lateral epicondyle (ICC = 0.94) and belly of the carpi radialis brevis muscle (ICC = 0.93) was excellent. Byl et al[92] examined the reliability of a new test of stereognosis on patients with hand problems and controls and reported excellent interrater reliability (ICC = 0.99). Their new test also moderately correlated (r = 0.41–0.53) with other tests of stereognosis and graphesthesia. In a similar study, Rosen[93] examined the properties of a recently introduced test for the assessment of tactile gnosis (stereognosis). Good interrater reliability (kappa = 0.66) was reported using the test for patients with serve upper extremity nerve injuries.

Although limited published data are available related to reliability measures, several approaches can be used to improve this aspect of the tests, including (1) use of consistent guidelines for completing the tests; (2) administration of the tests by trained, skillful examiners; and (3) subsequent retests performed by the same individual. It also should be noted that the patient's understanding of the test procedure and the patient's ability to communicate results further influence the reliability of sensory tests. As developing advances in technology (see discussion below) provide tools for quantitative sensory testing, greater emphasis on reliability will follow. Additional research related to standardization of testing protocols and identification of normative data for various age groups will improve the overall reliability and interpretation of test results.

QUANTITATIVE SENSORY TESTING AND SPECIALIZED TESTING INSTRUMENTS

With the expanding availability of specialized testing systems and instruments, quantitative sensory testing (QST) has gained considerable clinical and research interest. This is clearly evident from the expanding body of literature on this topic.[94–104] QST allows quantification of the level of stimuli required for perception of a sensory modality. Although sufficient data are not available to predict the ultimate integration of QST instrumentation into clinical practice, preliminary information suggests its potential usefulness. This section provides a brief overview of selected QST devices and is certainly not all-inclusive. The Internet provides a rich source of information on this developing technology and instrumentation.

TSA-II Thermal Sensory Analyzer + VSA 3000 (Medoc, Ltd., Durham, NC)

This computer-controlled system (Fig. 3.14) is capable of generating and recording a response to repeatable vibratory and thermal stimuli (i.e., warmth, cold, heat- or cold-induced pain). For testing thermal sensation, a "thermode" capable of heating or cooling is placed on the patient's skin (Fig. 3.15). The patient is asked to respond to the stimulus by pushing a response button. A sensory threshold is recorded and a computer comparison to age-matched normative data is generated. The system includes hand and foot (Fig. 3.16) support vibratory stimulators as well as a handheld vibrating device (see Fig 3.14). A variety of report formats can be generated; a sample is presented in Figure 3.17. Several examples of clinical applications include neuropathies (e.g., diabetic, metabolic, cancer), compression injuries, and pharmacological trials.

von Frey Aesthesiometer (Somedic Sales AB, Hörby, Sweden)

Monofilaments are not new to examination of sensory function and are actually considered a classic tool

Figure 3.14 TSA-II Thermal Sensory Analyzer + VSA 3000. This system provides quantitative measures of both thermal and vibratory stimuli using a variety of patient interfaces. Note the small handheld vibratory device on the far left. *(Courtesy of Medoc, Ltd., Durham, NC 27707.)*

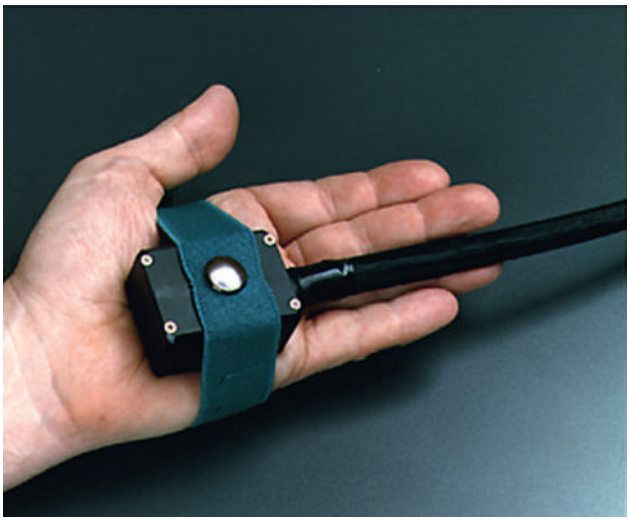

Figure 3.15 Thermode placed in hand for measuring perception of thermal stimuli. *(Courtesy of Medoc, Ltd., Durham, NC 27707.)*

Figure 3.16 Foot support vibratory stimulator. *(Courtesy of Medoc, Ltd., Durham, NC 27707.)*

for measuring touch-evoked potentials (Fig. 3.18). They are designed to detect very small changes in touch threshold. The filaments are available as sets, in various sizes (i.e., thicknesses), with each mounted on a handle. The force required for bending the monofilament increases from 0.026 g for the first handle to 100 g for the last (pressure range of between 5 g/mm^2 and 178 g/mm^2). The filaments are applied individually to the patient's skin until it bends; each filament providing a specific amount of force (thicker filaments are used if the thinner are not perceived). With vision occluded, the patient responds "yes" when a stimulus is felt. The filaments are held perpendicular to the skin and application is usually repeated three times at each testing site.[81] Monofilaments are frequently used in hand rehabilitation clinics; other examples of clinical applications include neuropathies (e.g., diabetic) and peripheral nerve injuries.

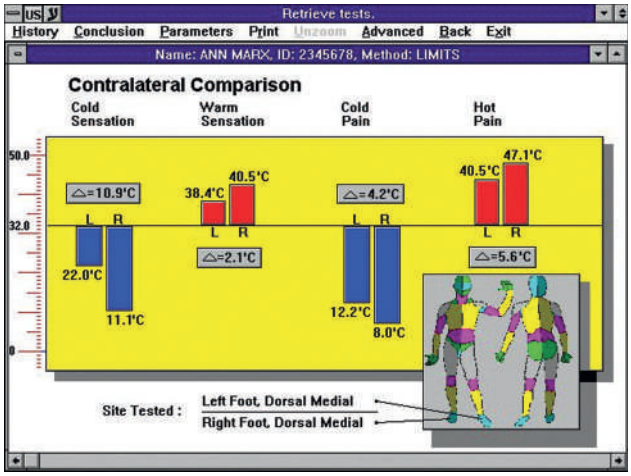

Figure 3.17 Computer-generated data from thermal testing that presents a comparison between the two sides of the body. Note the data for the right foot presents consistently higher threshold values than that of the left. Values are generated for each foot as well as the total difference between the feet. All values are in Celsius. Conversions for the temperature scale on the left border are 32°C = 89.6°F and 50°C = 122°F. *(Courtesy of Medoc, Ltd., Durham, NC 27707.)*

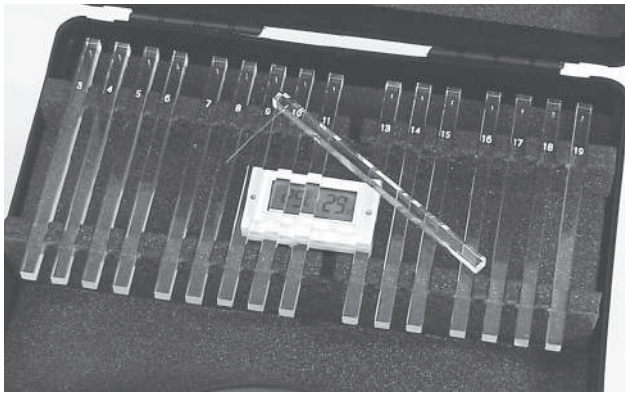

Figure 3.18 von Frey aesthesiometer. This set contains 17 monofilaments mounted on Plexiglas handles. *(Courtesy of Somedic Sales AB, Hörby, Sweden.)*

Touch-Test Sensory Evaluator (North Coast Medical, Inc., Morgan Hill, CA)

Individual monofilaments are also available in increments ranging from 0.008 to 300 g (Fig. 3.19). These instruments are convenient and can be carried in a pocket. The handle opens to a 90° angle for testing; when folded it protects the monofilament when not in use.

Rydel-Seiffer 64/128 Hz Graduated Tuning Fork (US Neurologicals, Kirkland, WA)

This quantitative tuning fork contains small scaled weights on the distal ends of the two prongs converting

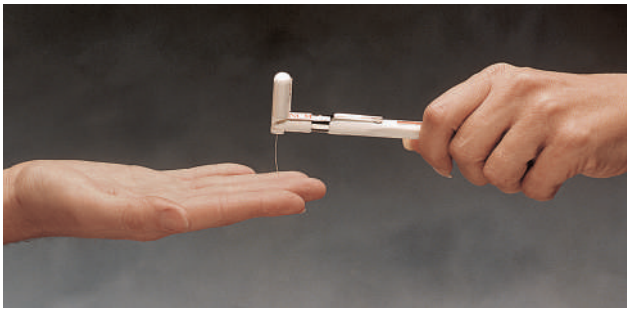

Figure 3.19 Individual monofilament. *(Courtesy of North Coast Medical, Inc., Morgan Hill, CA 95037.)*

it from 128 to 64 Hz (Fig. 3.20). The two triangles move closer together and their intersection moves upward as the intensity of vibration decreases. The intensity where the patient no longer perceives the vibration is recorded as the number adjacent to the intersection of the triangles. This instrument allows more sensitive and specific testing for detecting sensory changes as compared to qualitative tuning forks and has demonstrated high intertester and intratester reliability.[105]

Rolltemp (Somedic Sales AB, Hörby, Sweden)

This instrument is used as a screening tool for determining changes in perception of thermal sensation (Fig. 3.21). The rollers are housed in a storage unit to maintain temperature. The individual rollers are placed in contact with the skin to provide a gross estimate of temperature perception.

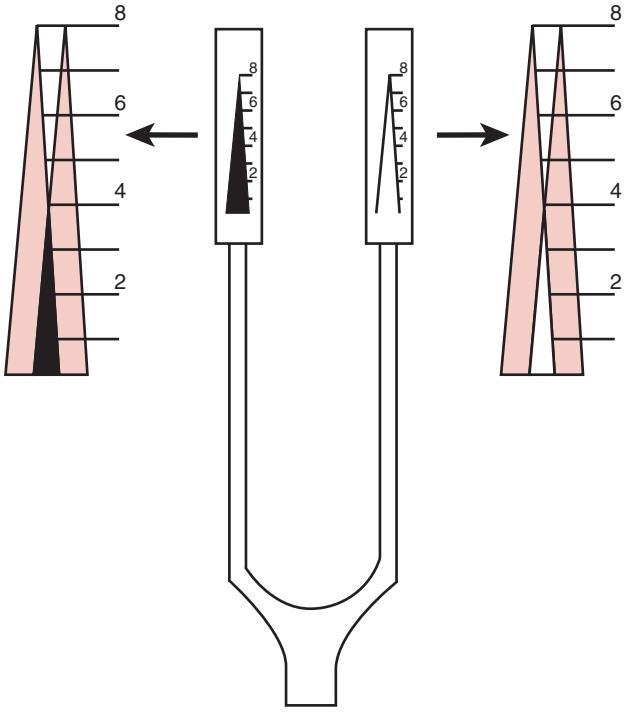

Figure 3.20 Schematic illustration of the Rydel-Seiffer tuning fork. *(Courtesy of US Neurologicals, Kirkland, WA, 98033.)*

Figure 3.21 The Rolltemp provides a quick screening tool for thermal sensation. The rollers are mounted on handles and stored upright in the two square insertion points on the storage unit. One roller is maintained at 40°C (104°F); the other at 25°C (77°F). *(Courtesy of Somedic Sales AB, Hörby, Sweden.)*

Bio-Thesiometer (Bio-Medical Instrument Co, Newbury, OH)

This instrument is designed to quantitatively measure threshold perception of a vibratory stimulus (Fig. 3.22). The stimulus is applied using a handheld device applied to the skin. Intensity of stimulation can be preset or gradually increased until the threshold is reached (or gradually lowered until no longer felt).

Vibrameter (Somedic Sales AB, Hörby, Sweden)

The Vibrameter also quantitatively measures the perception of vibration (Fig 3.23). Standardized test points have been identified for use with this instrument. The test points (e.g., dorsum of the metacarpal bone of index finger, first metatarsal, and on tibia) allow for ease of comparison and interpretation of results. The sites also represent relatively long neural pathways for transmission to the CNS. Stimulus is applied using the handheld device.

SENSEBox (Somedic Sales AB, Hörby, Sweden)

This instrument measures pain thresholds (**algometer**) and touch evoked potentials (von Frey transducer). It determines the relationship between the intensity of controlled mechanical stimuli and patient response.

Figure 3.22 Bio-Thesiometer for measuring perception of vibratory stimulus. *(Courtesy of Bio-Medical Instrument Co., Newbury, OH, 44065.)*

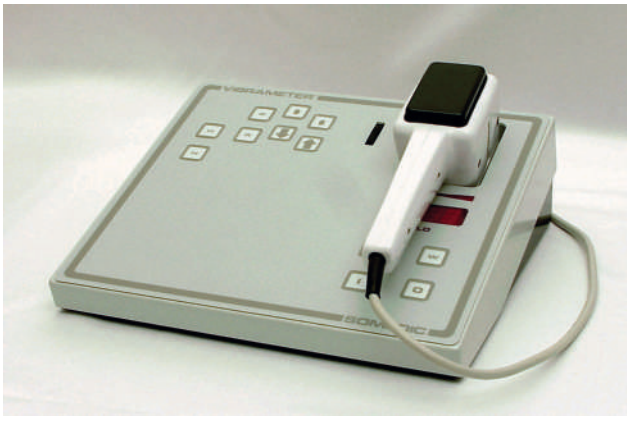

Figure 3.23 Vibrameter for measuring perception of vibratory stimulus *(Courtesy of Somedic Sales AB, Hörby, Sweden.)*

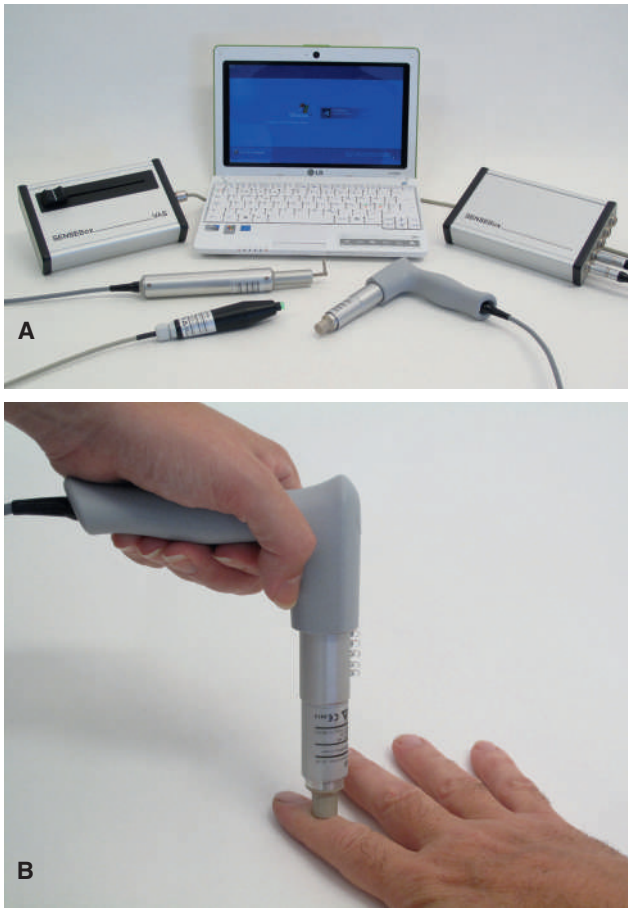

Figure 3.24 **(A)** SENSEBox. Viewing counterclockwise, to the left of computer is the electronic patient response visual analog scale (VAS), von Frey transducer for touch evoked potentials, pushbutton patient response device, algometer transducer for measuring sensitivity to pain, and data collection unit. **(B)** Algometer transducer for SENSEBox. *(Courtesy of Somedic Sales AB, Hörby, Sweden.)*

Handheld transducers are used to apply the stimuli (Fig. 3.24A and B). Patient responses are recorded using a handheld pushbutton device or a continuous electronic visual analog scale (VAS). During examination, data are automatically stored in a computer database.

MSA (Modular Sensory Analyzer) Thermotest (Somedic Sales AB, Hörby, Sweden)

The MSA Thermotest (Fig. 3.25) measures response to thermal (warm and cold) stimuli. Thermodes of different sizes allow testing of various anatomical locations. A computer interfaces using SenseLab software that sets up and runs the Thermotest, and allows for analysis and storage of data. Temperatures range from 41° to 125.6°F (5° to 52°C).

Figure 3.25 MSA Thermotest. In the right foreground is a 1 × 2 inch (25 × 50 mm) standard thermode for application of thermal stimuli.

CRANIAL NERVE SCREENING

Screening tests for the cranial nerves provide information about location of dysfunction within the brainstem as well as identification of cranial nerves that require more detailed examination. Data generated may in-

clude function of muscles innervated by the cranial nerves; visual, auditory, sensory, and gag reflex integrity; perception of taste; swallowing characteristics; eye movements; and constriction and dilation patterns of the pupils.

Table 3.3 provides a summary of the functional components of the cranial nerves. Box 3.5 presents screening tests for each cranial nerve. Impairments noted during the screening indicate that a more comprehensive examination is warranted. See Chapter 5, Examination of Motor Function: Motor Control and Motor Learning, for additional information on cranial nerve examination.

SENSORY INTEGRITY WITHIN THE CONTEXT OF TREATMENT

Learning a motor behavior is dependent on the patient's ability to take in sensory information from the body and the environment (sensory intake), process it (sensory integration), and use it to plan and organize behavior (output). When patients experience impairment in processing

Table 3.3 Functional Components of the Cranial Nerves

Number	Name	Components	Function
I	Olfactory	Afferent	Olfaction (smell)
II	Optic	Afferent	Vision
III	Oculomotor	Efferent	
		Somatic	Elevates eyelid
			Turns eye up, down, in
		Visceral	Constricts pupil
			Accommodates lens
IV	Trochlear	Efferent (somatic)	Turns the adducted eye down and causes intorsion (inward rotation) of eye
V	Trigeminal	Mixed	
		Afferent	Sensation from face
			Sensation from cornea
			Sensation from anterior tongue
		Efferent	Muscles of mastication
			Dampens sound (lensor tympani)
VI	Abducens	Efferent (somatic)	Turns eye out
VII	Facial	Mixed	
		Afferent	Taste from anterior tongue
		Efferent (somatic)	Muscles of facial expression
			Dampens sound (stapedius)
		Efferent (visceral)	Tearing (lacrimal gland)
			Salivation (submandibular and sublingual glands)
VIII	Vestibulocochlear	Afferent	Balance (semicircular canals, utricle, saccule)
			Hearing (organ of Corti)
IX	Glossopharyngeal	Mixed	
		Afferent	Taste from posterior tongue
			Sensation from posterior tongue
			Sensation from oropharynx
		Efferent	Salivation (parotid gland)
X	Vagus	Mixed	
		Afferent	Thoracic and abdominal viscera
		Efferent	Muscles of larynx and pharynx
			Decreases heart rate
			Increases GI motility
XI	Spinal accessory	Efferent	Head movements (sternocleidomastoid and trapezius)
XII	Hypoglossal	Efferent	Tongue movements and shape

From Nolan[63,p. 44] with permission. GI, gastrointestinal.

Box 3.5 Screening Tests for Cranial Nerves[9,63]

Cranial nerve I: Examine olfactory acuity using non-noxious odors such as lemon oil, coffee, cloves or tobacco.
Cranial nerve II: Examine visual acuity using a Snellen chart; both central and peripheral vision is tested.
Cranial nerves III, IV, and VI: Determine equality and size of pupils; reaction to light; presence of strabismus (loss of ocular alignment); ability of eyes to follow a moving target without head movement; presence of ptosis of eyelid.
Cranial nerve V: Sensory tests of face (sharp/dull discrimination, light touch); open and close jaw against resistance; jaw jerk reflex.
Cranial nerve VII: Examine any asymmetry of face at rest and during voluntary contraction.
Cranial nerve VIII: Test auditory acuity using a vibrating tuning fork (Weber test) placed on vertex of skull or forehead, patient indicates on which side the tone is louder; rub fingers together at a distance and gradually bring toward patient, note distance when first heard; alter volume of conversation; Rinne test (conductive hearing loss) vibrating tuning fork placed on mastoid process, then near external ear canal, note hearing acuity.
Cranial nerve IX: Examine taste on posterior one-third of tongue; examine gag reflex.
Cranial nerve X: Examine swallowing; observe uvula and soft palate for any asymmetry (tongue depressor).
Cranial nerve XI: Examine strength of the sternocleidomastoid and trapezius muscles.
Cranial nerve XII: With tongue protruded, examine ability to move tongue rapidly from side to side.

sensory intake, deficits typically occur in planning and organizing behavior. This produces behaviors that may interfere with successful motor learning and motor function.

The POC designed for a patient with impaired sensation is typically guided by one of two approaches, the *Sensory Integration Approach* and the *Compensatory-Approach*. The selection of a treatment model is based on a complete data set of information from all examinations together with the established prognosis and diagnosis. The treatment approach depicted in Figure 3.26 is based largely on the Sensory Integration Model developed by Ayers.[1,106–110] The basic premise of this approach is that specific treatment techniques can enhance sensory integration (CNS processing) with a resultant change in motor performance.

Using the Sensory Integration Approach, data obtained from the examination of sensory function informs development of a POC to enhance opportunities for *controlled* sensory intake within a framework of meaningful functional skills. During treatment, the patient is provided guided practice in planning and organizing motor behaviors using both *intrinsic* feedback (from the movement itself) and *augmented* feedback (cues planned by the therapist). This approach is designed to improve the ability of the CNS to process and integrate information and promote motor learning. The reader is referred to the work of Ayers[1,106–110]) and Bundy and Murray[5] for a detailed presentation of both the theory and practice of the Sensory Integration Model.

The Compensatory Approach is a more traditional intervention that focuses on patient education to accommodate to the limitations imposed by the sensory deficit. The therapist's role is to assist the patient in achieving optimum functional capacity, minimizing activity limitations, protecting anesthetic limbs, and creating appropriate environmental adaptations to enhance safety and function. Guided by this approach, the therapist instructs the patient in practical strategies

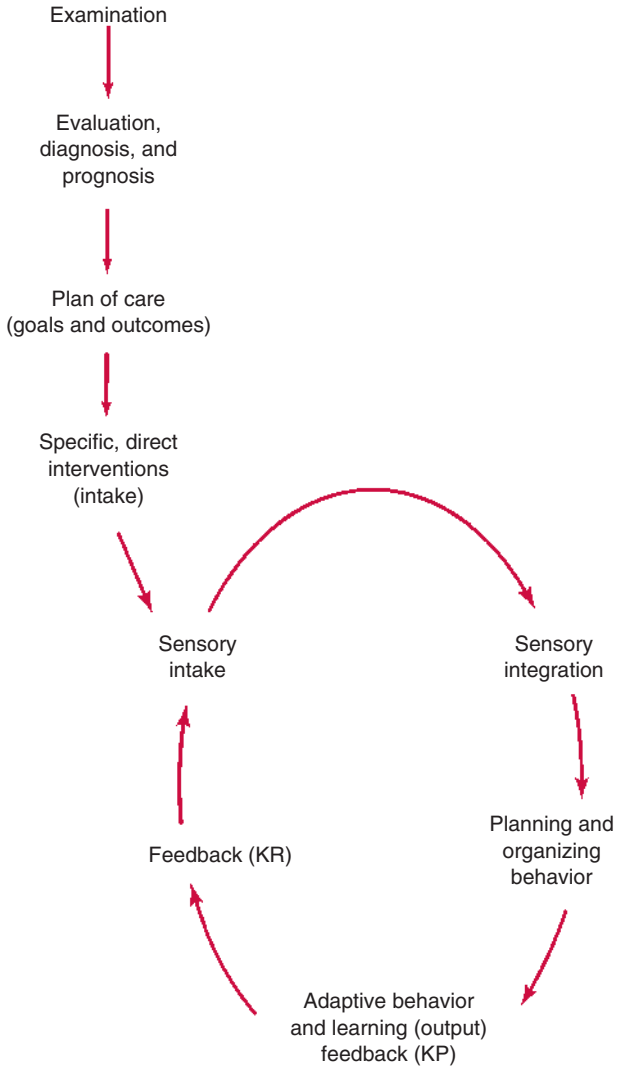

Figure 3.26 Elements of patient management for sensory impairment. KP refers to knowledge of performance (feedback about the quality of movement produced) and KR refers to knowledge of result (feedback about the end result or outcome of the movement). *(Adapted from Bundy and Murray.[5, p. 5])*

such as testing bath water with a thermometer or body part with intact sensation before entering; not going barefoot; regularly checking insensitive skin areas for cuts or bruises (particularly important for patients with diabetes); adaptations ("compensations" for the sensory loss) that can include substituting vision for absent tactile cues when carrying objects; wearing heat-resistant gloves when working in the kitchen; using a rolling cart in kitchen or other work space to transport items from one area to another; and arranging kitchen supplies to eliminate need for access to storage areas directly over the stove.

SUMMARY

Examination of sensory function provides important information about the integrity of the somatosensory system. Findings from the examination assist in making clinical judgments about diagnosis, prognosis, anticipated goals and expected outcomes, and establishing the POC. Periodic reexamination provides critical data on changes in patient status and in determining progress toward goals and outcomes. Individual tests for each sensory modality have been presented. Reliability of these test procedures can be improved by careful adherence to consistent guidelines, administration of tests by trained individuals, and subsequent retests performed by the same examiner. Documentation of test results should address the type(s) of sensation affected, the quantity, and degree of involvement, and localization of the exact boundaries of the sensory deficits. Finally, it should be emphasized that additional research related to sensory testing is warranted. Further development of QST techniques, standardized protocols, reliability measures, and additional normative data will significantly improve the clinical applications of data obtained from the examination of sensory function.

Questions for Review

1. Define a dermatome and describe a precaution with using published dermatome maps.
2. Identify six pathologies or health conditions that would warrant (or indicate the need for) examination of sensory function.
3. Describe the five terms used to document a patient's level of consciousness.
4. Which type of sensory receptor is responsible for position sense and awareness of joints at rest, during movement, and vibration? How would you comprehensively examine this sensory receptor?
5. Which type of muscle receptor senses tension and how does it affect the muscle when under extreme tension?
6. For a suspected localized lesion, in which direction would you conduct your examination of sensory function and why?
7. Describe four purposes of screening the sensory system.
8. Describe how the data from the examination of sensory function is used by the physical therapist.
9. Describe equipment (items) that can be used to assess stereognosis.
10. What type of findings from an examination of sensory function would indicate that a referral is warranted?
11. Explain why impaired sensation is a contraindication to or precaution for use of some physical agents.
12. What information would you provide to the patient prior to administration of sensory tests to obtain informed consent?
13. Which muscles would you test to assess the spinal accessory cranial nerve?
14. Describe the variables you would use to record the results of sensory testing.

CASE STUDY

A 68-year-old woman presents for outpatient physical therapy with an improperly fitted cane. You escort her to the examination room while observing her gait pattern, which is characterized by a slower self-selected walking speed, wide base of support, and increased time spent in double limb support. She has a long-standing history of hypertension (15 years), hypercholesterolemia (10 years),

and diabetes (25 years). In addition to reporting several falls in the past 6 months, none of which resulted in injury serious enough to be hospitalized, the patient describes increasing pain in her lower extremities that is deep, sharp, and burning, that is symmetrical, and occasionally wakes her up at night. The patient lives alone in a one-bedroom apartment in a building with an elevator and level entrance to the lobby.

GUIDING QUESTIONS

1. Of all the senses, which one is most often affected by the patient's medical conditions and how would you assess it?
2. Given her history of falls, which sensory systems should you examine? Why? How?
3. How would you examine pain sensation and what findings would you expect given the long-standing history of diabetes? Why is it important to examine pain sensation?
4. How would you quantitatively measure touch awareness (touch-evoked potentials) in this patient?
5. The test findings indicate mild loss of proprioception and vibration in the lower extremities (distal more than proximal). What receptors are responsible for these sensory modalities? Where are the receptors located? Identify the ascending pathway that mediates proprioception and vibration.

3.A

Two-point Discrimination Values for Healthy Subjects 20 to 24 Years of Age

Two-Point Discrimination Values for the Upper Extremities of Healthy Subjects 20 to 24 Years of Age ($N = 43$)

Skin Region	X (mm)	s
Upper—lateral arm	42.4	14.0
Lower—lateral arm	37.8	13.1
Mid—medial arm	45.4	15.5
Mid—posterior arm	39.8	12.3
Mid—lateral forearm	35.9	11.6
Mid—medial forearm	31.5	8.9
Mid—posterior forearm	30.7	8.2
Over first dorsal interosseous muscle	21.0	5.6
Palmar surface—distal phalanx, thumb	2.6	0.6
Palmar surface—distal phalanx, long finger	2.6	0.7
Palmar surface—distal phalanx, little finger	2.5	0.7

Two-Point Discrimination Values for the Lower Extremities of Healthy Subjects 20 to 24 Years of Age ($N = 43$)

Skin Region	X (mm)	s
Proximal—anterior thigh	40.1	14.7
Distal—anterior thigh	23.2	9.3
Mid—lateral thigh	42.5	15.9
Mid—medial thigh	38.5	12.4
Mid—posterior thigh	42.2	15.9
Proximal—lateral leg	37.7	13.0
Distal—lateral leg[a]	41.6	13.0
Medial leg	43.6	13.5
Tip of great toe	6.6	1.8
Over 1–2 metatarsal interspace	23.9	6.3
Over 5th metatarsal	22.2	8.6

[a] $n = 41$

Two-Point Discrimination Values for the Face and Trunk of Healthy Subjects 20 to 24 Years of Age ($N = 43$)

Skin Region	X (mm)	s
Over eyebrow	14.9	4.2
Cheek	11.9	3.2
Over lateral mandible	10.4	2.2
Lateral neck	35.2	9.8
Medial to acromion process	51.1	14.0
Lateral to nipple	45.7	12.7[a]
Lateral to umbilicus	36.4	7.3[b]
Over iliac crest	44.9	10.1[c]
Lateral to C7 spine	55.4	20.0[b]
Over inferior angle of scapula	52.2	12.6[b]
Lateral to L3 spine	49.9	12.7[b]

[a] $n = 26$
[b] $n = 42$
[c] $n = 33$

Chapter 4

Musculoskeletal Examination

D. Joyce White, PT, DSc, MS

LEARNING OBJECTIVES

1. Identify the purposes of performing a musculoskeletal examination.
2. Discuss the components of a musculoskeletal examination.
3. Identify questions that should be included in a patient interview.
4. Describe the procedures used to selectively test specific tissue types in a musculoskeletal examination.
5. Identify additional procedures that often complement a musculoskeletal examination.
6. Using the case study examples, apply clinical decision making skills in evaluating musculoskeletal examination data.

CHAPTER OUTLINE

PURPOSES OF THE MUSCULOSKELETAL EXAMINATION *124*
EXAMINATION PROCEDURES *125*
- Patient History and Interview *125*
- Mental Status *132*
- Vital Signs *132*
- Observation/Inspection *132*
- Palpation *133*
- Anthropometric Characteristics *134*
- Range of Motion *134*
- Accessory Joint Motions *143*
- Muscle Performance *144*
- Special Tests *151*
- Additional Tests and Measures *152*

EVALUATION OF EXAMINATION FINDINGS *152*
SUMMARY *155*

The musculoskeletal system includes bones; muscles with their related tendons and synovial sheaths; bursa; and joint structures such as cartilage, menisci, capsules, and ligaments. Acute injuries or chronic conditions that disrupt the anatomy or physiology of musculoskeletal tissues can greatly affect a patient's function by causing direct impairments such as pain, inflammation, swelling, structural deformity, restricted joint movement, joint instability, and muscle weakness. Examples of diagnoses that result in direct impairment of the musculoskeletal system include fracture, rheumatoid arthritis (RA), osteoarthritis (OA), joint dislocation, tendinitis, bursitis, muscle strain/rupture, and ligament sprain/rupture.

Many pathological conditions that initially affect other body systems such as the neurological, cardiovascular, or pulmonary systems can result in secondary or indirect impairment of the musculoskeletal system. This often occurs when patients' activities are restricted by the condition—perhaps as a result of confinement for a period of time to a bed or wheelchair—or the patient moves the upper extremities (UEs)or lower extremities (LEs) in an inefficient or stress-causing pattern. Diagnoses that can cause indirect impairments of the musculoskeletal system include traumatic brain injury (TBI), cerebral vascular accident (CVA), cerebral palsy (CP), spinal and peripheral nerve injury, burns, and myocardial infarction (MI), just to name a few.

Both direct and indirect musculoskeletal impairments can contribute to activity limitations and participation restrictions and disability that affect a patient's ability to perform certain tasks and roles in society. By considering the few examples of diagnoses that cause direct and indirect musculoskeletal impairments provided in the previous paragraph, one can appreciate how often physical therapists and other health professionals encounter clinical problems affecting the musculoskeletal system. Administering specific tests and measures is almost always a major component of an initial patient examination.

This chapter discusses the purposes of, and provides a general framework for, conducting a musculoskeletal examination. The principles and components of a musculoskeletal examination, together with how to organize and integrate the data with those of other body systems, are emphasized. Other resources are available that provide detailed musculoskeletal testing procedures of specific body regions.[1-5]

PURPOSES OF THE MUSCULOSKELETAL EXAMINATION

Evaluation of data from the musculoskeletal examination contributes to establishing a diagnosis and prognosis, setting anticipated goals and expected outcomes, and

developing and implementing a plan of care (POC). A musculoskeletal examination is also an important component of evaluating treatment outcomes both periodically during the treatment process and at the conclusion of the episode of care. The purposes of performing a musculoskeletal examination include the following:

1. To determine the presence or absence of impairments, activity limitations, and disability involving muscles, bones, and related joint structures.
2. To identify the specific tissues that are causing/contributing to the impairment, activity limitation, or disability.
3. To determine baseline status.
4. To help formulate appropriate anticipated goals, expected outcomes, and plan of care.
5. To evaluate the effectiveness of rehabilitation, medical, or surgical management.
6. To identify risk factors to prevent the development or worsening of impairments, activity limitations, or disabilities.
7. To determine the need for orthotic and adaptive equipment necessary for functional performance of activities of daily living (ADL), occupational, and/or recreational activities.
8. To motivate the patient.

EXAMINATION PROCEDURES

Patient History and Interview

Before beginning the physical examination, it is important to gain as much information as possible about the patient's current condition and past medical history. This information will help to direct and focus the physical examination to an area and system of the body. Information on symptoms and functional ability will help to establish a baseline against which treatment effectiveness can be judged. It will also help ensure that the examination and subsequent treatment are conducted safely.

Typically, most of this information is obtained while interviewing the patient. However, utilizing other information sources can be very efficient and provide objectivity and details to supplement interview data. If the patient is hospitalized in an acute care or rehabilitation setting, the medical records, including admission reports, progress notes, medication sheets, surgical summaries, body imaging reports, and laboratory test results, should be available and sought out. Referral summaries from previous medical care settings that review prior treatment approaches and discuss functional status may also be included. Other members of the health care team can be consulted for their input.

Outpatients often arrive with only a general diagnosis from a referring physician, or may be self-referred. In such cases it will be helpful to ask the patient to complete a medical history questionnaire before the examination process. A medical history questionnaire should include space for the patient to note the chief problem and date of onset; diagnostic tests performed for the problem; name and date of all surgeries; all medications currently being taken; past or current treatment for the problem (including those initiated by patient); a checklist of common medical conditions the patient may have experienced; brief family medical history; and patient's age, occupation, and lifestyle questions pertaining to smoking, alcohol use, and exercise. Figure 4.1 provides an example of a medical history questionnaire. The Guide to Physical Therapy Practice also includes a detailed template for a patient self-administered health questionnaire.[6]

A thorough understanding of the patient's medical background is critical for selection and safe application of examination and treatment procedures. For example, a history of an MI would cause the therapist to limit and more closely monitor the patient during muscle performance testing. A history of diabetes mellitus (DM) would cause the therapist to suspect and test for potentially compromised peripheral vascular and peripheral nervous systems, and to possibly avoid the use of heat modalities during treatment.

Patient self-administered health questionnaires have been shown to be generally accurate when conducted in a general medicine[7] and orthopedic outpatient settings.[8] However, even if a patient completes a medical history questionnaire, it is important for the therapist to review and clarify the information with the patient. Sometimes important medical background and medication data are inadvertently forgotten as the patient focuses on current problems. Verbally reviewing the information with the patient may jog the patient's memory.

After reviewing the information gained from medical records, other health care providers, and the patient-completed medical history questionnaire, the therapist is ready to begin the patient interview. Ideally, the patient interview should be conducted in a quiet, well-lit room that offers a measure of privacy. To encourage good communication, the therapist and patient should be at a similar eye level, facing each other, with a comfortable space between them—about 3 feet (91.44 cm) apart is customary in the United States. The patient should have the therapist's undivided attention; telephone calls and other interruptions should be avoided. The therapist may wish to have paper and pen available to record particular dates and information that is easily forgotten, but the interview should flow as an active conversation, not a dictation session. Repeated practice greatly improves the therapist's ability to listen, direct the interview, and establish a positive working relationship with the patient.

Over the course of the interview the therapist gains information about the patient's current complaints including onset, location, type and behavior of symptoms, current medications, previous treatments, secondary medical problems, medical history, and goals for

The purpose of this questionnaire is to assist us in providing you with quality care by obtaining a better understanding of your total health status. This questionnaire is part of your confidential medical record.

the physical therapy episode of care. The patient's age and gender should be noted; some conditions are more common in particular age groups and genders. Often, detailed information about a patient's occupation, recreational activities, and social/living situation are required to understand the cause of the impairments, activity limitations, and to develop a relevant POC that focuses on the patient's goals. Open-ended, objective questions that do not promote biased answers should be used. For example, instead of asking "Is your right knee painful?" the therapist should ask, "Where are your symptoms located?" The therapist should carefully guide the interview to keep it focused on pertinent information and conclude in a timely manner. All questions should use conversational language rather than medical terminology so the patient easily understands the questions. The therapist should ask one question at a time and be sure to obtain a response before proceeding to other questions. Follow-up inquiries may be needed to clarify initial answers. It is important for the therapist to keep an open mind during the interview and not rush to conclusions about the patient's symptoms and diagnosis.

The following sequence is suggested as a way of organizing the interview. Similar information on general patient

interviewing, that includes slight variations in format, can be found in texts by Talley and O'Connor,[9] Hertling and Kessler,[1] Paris,[10] and Coulehan and Block.[11]

Opening Question

The interview should begin with a general question such as "What brings you to physical therapy today?" or "What seems to be the problem?" If the patient is hospitalized the question may need to be rephrased to avoid having the patient retell the medical history to every health care provider. "I see from your medical chart that you fractured your hip and underwent a surgical repair yesterday. Is that what happened?" The patient should be given the opportunity to present the story. After the patient has concluded his or her statement, it is appropriate to say, "That's good. Now I have an idea of the problem. I have some other questions I need to ask to help me understand your problem better." Depending on the information provided by the patient, some of the following questions may be asked.

Onset of Symptoms

"How did this pain (swelling, limitation, problem, etc.) begin?" The therapist must know if the onset was sudden (e.g., caused by trauma such as a fall, blow, or skiing or motor vehicle accident). Specific information about the patient's body or body segment position at the time of trauma and the mechanism of injury will help to identify the structures involved. If the onset was more gradual or insidious, a systemic condition or chronic biomechanical problem may be more likely. A congenital onset is also a possibility.

Location of the Symptoms

"Where is your pain? Can you point to the location?" A body chart (Fig. 4.2) can be used to help identify and document the specific location of symptoms. The patient (or therapist with the patient's direction) can darken the involved area on the body chart using a pen or pencil. Often the location of the symptoms coincides with the location of the lesion. This is more likely if the lesion is in superficial and distal tissues. For example, a lesion in a superficial tendon near the ankle will usually cause pain over the tendon site. Lesions in deeper, more proximal tissues can refer pain distally following sclerotome (Fig. 4.3) or dermatome patterns. (Refer to Chapter 3, Examination of Sensory Function.)

Referred pain may be perceived as originating from any or all tissues innervated by the same segmental spinal level in which the lesion is located. For example, pain due to OA of the hip is often felt in the anterior groin and thigh along the sclerotomes or dermatomes for L2 and L3. Considerable individual variation has been noted in dermatome and sclerotome patterns.[12]

"Has the pain changed in location? Spread to other areas? Become more focused?" Pain that is spreading usually indicates a worsening condition, whereas more focused symptoms indicate improvement. Changes in symptoms in relationship to varying body positions, activities, and treatments should be noted.

Quality of the Symptoms

"How severe is the pain? Is the pain sharp? Dull? Throbbing?" A simple yet effective way to document pain severity is to ask the patient to rate his or her pain from 0 (no pain) to 10 (most severe pain imaginable) as illustrated in the numerical pain rating scale presented in Figure 4.4. A visual analog scale (Fig. 4.5) or thermometer pain scale (Fig. 4.6) can also be used if preferred. A checklist of adjectives like that found in the McGill Pain Questionnaire[13] can clarify symptoms further (Fig. 4.7).

The adjectives used to describe pain may have diagnostic implications. Dull, aching pain may indicate muscle or joint lesions. Numbness, tingling, shooting pain, or burning sensations may indicate nervous system involvement. Deep, throbbing pain, or coolness in a body region may indicate vascular problems. Weakness, clumsiness,

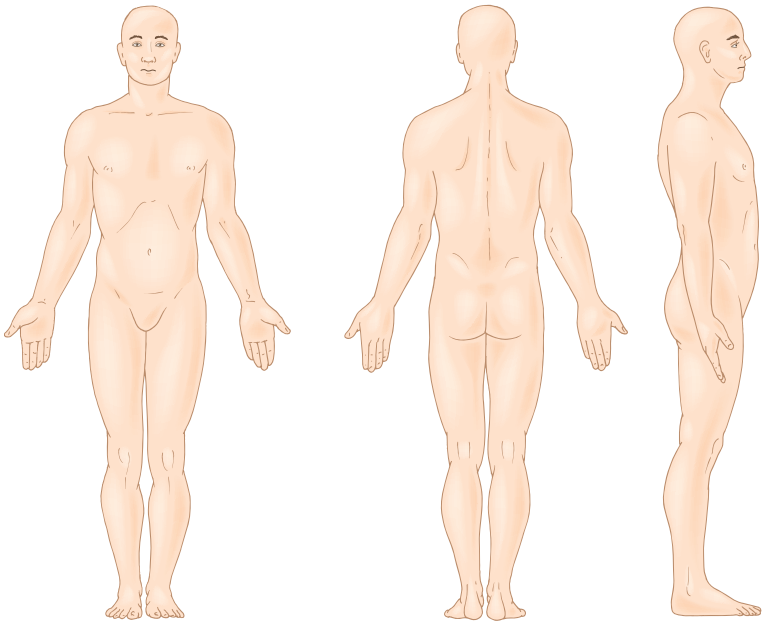

Figure 4.2 This body chart can supplement the patient's verbal description of the location of the pain.

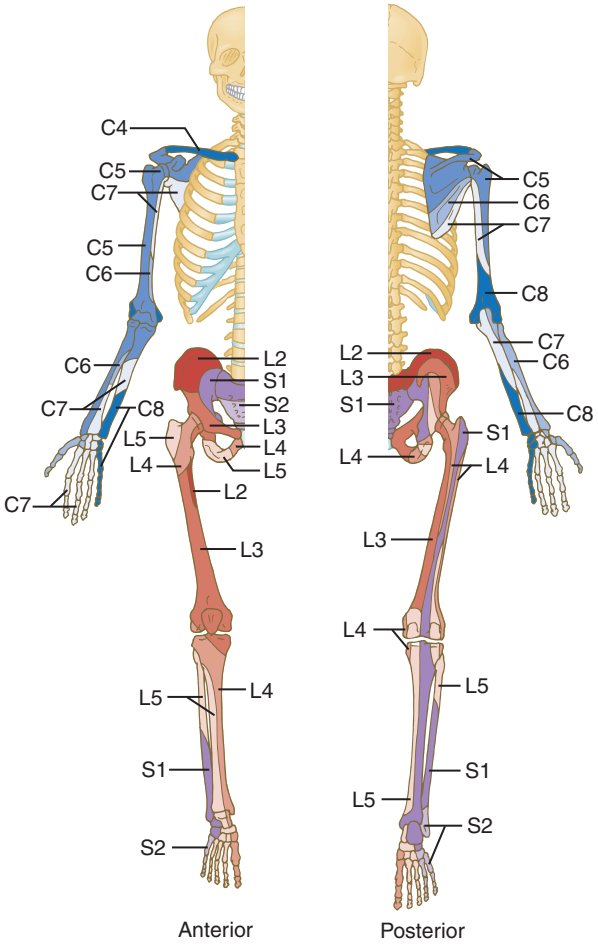

Figure 4.3 Sclerotomes from the anterior and posterior aspects of the body. *(From Hertling and Kessler,[1, p. 52] with permission.)*

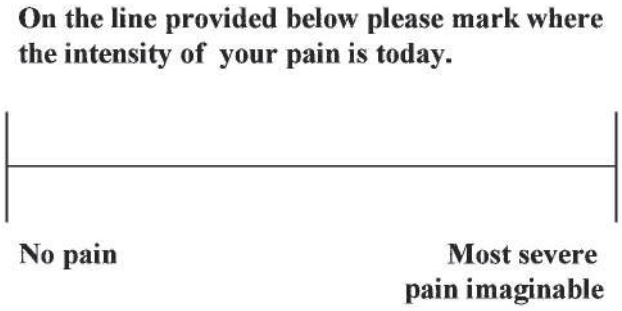

Figure 4.5 Visual analog pain rating scale. The line is usually 10 cm in length. The patient's mark is measured from the left (no pain) end of the scale and is recorded in centimeters.

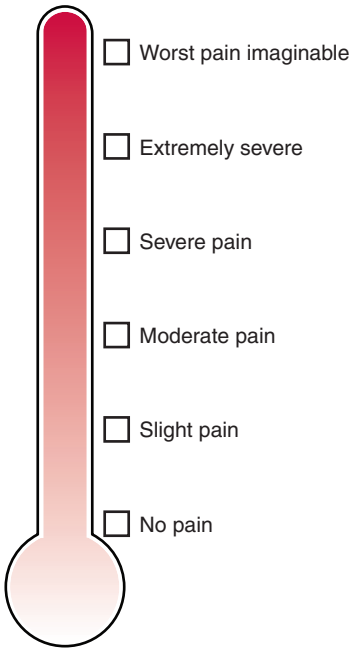

Figure 4.6 Thermometer pain rating scale. *(From Brodie, DJ, et al: Evaluation of low back pain by patient questionnaires and therapist assessment. J Orthop Sport Phys Ther 11:528, 1990, with permission.)*

or incoordination may suggest muscle and possibly peripheral or central nervous system dysfunction.

Behavior of the Symptoms

"What makes your symptoms increase? Decrease?" Symptoms from musculoskeletal conditions typically vary in response to rest, activity, and body positions that either increase or decrease mechanical stress placed on the involved tissue. The behaviors of the symptoms help to establish a diagnosis and determine which treatment techniques are more likely to be effective. For example, pain from overuse syndromes such as tendonitis will decrease with rest, whereas joint stiffness caused by OA often increases following rest. If a patient reports that the sitting position reduces back pain, then the therapist will probably have more success in relieving the pain using back flexion rather than extension exercises.

Circle the number below which best represents the intensity of your pain today.

Annoying	Spreading	Tight	Cool	Nagging
Troublesome	Radiating	Numb	Cold	Nauseating
Miserable	Penetrating	Drawing	Freezing	Agonizing
Intense	Piercing	Squeezing		Dreadful
Unbearable		Tearing		Torturing

Figure 4.7 The McGill Pain Questionnaire. The first 10 groups of words are somatic (describing what the pain feels like), 11–15 are affective, 16 is evaluative, and 17–20 miscellaneous.[13]

Symptoms that do not vary with a change in activity or body position are rarely due to musculoskeletal lesions, and in fact are a "red flag" for more serious conditions such as space-occupying tumors and pathologies involving internal organs. Often patients will report that "nothing helps the pain." This statement should be fully explored with follow-up questions such as "Is your pain better or worse in the morning when you wake up from sleeping? Does your pain vary if you sleep on your back versus on your stomach?"

Behavior of Symptoms During the Last 48 Hours

It is important to understand the behavior of the symptoms during the past few days, not just at the current moment. Sometimes symptoms suddenly worsen or disappear at the time of the physical examination. A more accurate picture of the situation is told if the time frame spans 48 hours. "Are the symptoms getting better, worse, or staying the same?" The answer to this question will help inform the therapist about the effectiveness of future treatment. If the patient's pain has been steadily worsening over the last 48 hours and treatment stabilizes the pain, then the treatment may be deemed helpful. However, if the patient reports that the pain has been steadily improving over the last 48 hours and treatment stabilizes the pain, then the treatment may be deemed as detrimental.

Previous Care of this Problem

"What previous care has been sought for the problem? Who else (e.g., physician, therapist, athletic trainer, chiropractor) has treated the problem? What tests and treatments did they perform? What have you done to relieve the problem?" From these and similar questions, all previous exercises, physical modalities, manual treatments, medications, injections, orthotics, and surgical procedures should be delineated. The answers to these questions help the therapist decide if further medical referrals are needed, and focus on the most effective treatment for the condition. For example, a patient who fell 3 days ago is experiencing severe ankle pain and swelling. The patient borrowed a friend's crutches and has been self-treating the ankle with ice and elevation. The therapist would recommend that the patient be examined by a physician and have radiographs taken to rule out a fracture before physical therapy intervention. In another scenario, if a patient with adhesive capsulitis of the shoulder has been treated previously by a physical therapist with ultrasound and pendulum exercises without improvement, then other physical therapy interventions should be considered.

Specific Medical History

"Has this problem occurred before? How was it treated? How was it resolved?" Many musculoskeletal problems tend to recur with continued occupational, recreational, and daily activities if underlying biomechanical abnormalities, weaknesses, joint laxity, or tightness persists. Information about previous successful and unsuccessful treatments for similar past problems can help in treatment planning for the current problem.

General Medical History

A brief history should be obtained concerning medical problems and prior surgeries involving other body regions and systems. Conditions involving the cardiac, respiratory, neurological, vascular, metabolic, endocrine, gastrointestinal, genital urinary, visual, and dermatological systems should be noted. Having a patient complete a medical history questionnaire before the examination is an efficient means of obtaining this information, but the information should also be verified during the interview. Therapists also need to be aware of other conditions that mimic signs and symptoms often attributable to the musculoskeletal system. For example, inflammation of the gallbladder (cholecystitis) may result in right shoulder pain. However, shoulder pain related to cholecystitis typically will not increase with shoulder movements or resisted isometric testing of shoulder musculature, as would occur in the presence of musculoskeletal conditions. Patients with cholecystitis would likely have additional symptoms such as upper abdominal discomfort, bloating, belching, nausea, and intolerance of fried foods. Knowledge of systemic human pathology allows the therapist to recognize conditions requiring additional physician evaluation and intervention. Boissonnault[14] and Goodman and Snyder[15] have provided useful information to assist physical therapists in screening for medical conditions.

Medications

The type, frequency, dose, and effect of medications the patient is taking should be noted. The use of analgesic or anti-inflammatory medications may reduce the intensity of symptoms at the time of the examination. Changes in the use of these medications may make it difficult to determine the effects of physical therapy treatment. The secondary effects of some medications may necessitate the modification of examination and treatment techniques. For example, prolonged use of corticosteroids is associated with osteopenia (reduced bone mass) and reduced tensile strength of ligaments. The therapist may need to limit manual force applied through the lever of long bones to prevent fracture or ligament tear. The use of anticoagulants may make the patient susceptible to contusions and **hemarthrosis**. Such patients should be closely monitored for bruising and joint swelling. The amount of force used in exercise and manual therapies may need to be reduced.

Social History and Occupational, Recreational, and Functional Status

Questions in this area might include the following: "What type of work do you do in and outside of the home? How has this problem affected your ability to perform your job? Care for your children? Play golf? Dress? Bathe?" Certain occupational and recreational activities may contribute to the problem or interfere with recovery. Strategies such as joint preservation techniques and use of assistive devices may need to be considered to allow performance of necessary tasks. Medical insurance companies often make treatment reimbursement decisions based on a patient's functional status as related to the medical problem. Figure 4.8 presents sample questions that can be used to quantify the impact of the problem on function. Detailed assessment instruments, such as the Katz Index of Independence in Activities of Daily Living, Outcome and Assessment Information Set (OASIS), and SF-36 have also been developed to quantify a patient's functional status. See Chapter 8, Examination of Function, for additional information on examination of function.

"Do you have to climb stairs to get into your house? To reach the bedroom? Bathroom?" Characteristics of the home environment may determine whether a patient who uses an ambulatory assistive device requires instruction in stair activities before returning home. The condition of floors, size of halls and doorways, placement of furniture, and bathroom facilities will need to be considered for a patient using a wheelchair. A more detailed discussion of examination of the environment including the home, workplace, and community can be found in Chapter 9, Examination of the Environment.

"Do you live alone?" It is helpful to understand the patient's living situation to determine if others are available to assist with exercise programs, ambulation, and transfer activities. Some patients have responsibility for the care of children, elderly parents, or a disabled spouse or sibling. These responsibilities may need to be restructured to allow time for rest and recovery.

"Do you use tobacco products? Alcohol? Recreational drugs?" Cigarette smoking has been associated with decreased bone density, delayed bone healing after fractures, greater spinal disk degeneration, increased low back pain, and increased UE and LE musculoskeletal disorders. Use of alcohol and recreational drugs can lead to risk-taking behaviors resulting in increased incidence of injuries, or difficulty in safely performing functional activities and home exercise programs (HEPs). Therapists may wish to advise a patient to reduce the use of these substances and refer the patient to appropriate social services or self-help organizations for counseling.

Anticipated Goals, Expected Outcomes, and Time Frame of Recovery

Ask the following types of questions, as appropriate: "What do you hope will be the outcome of physical therapy treatment? When do you anticipate returning home? To work? To playing football?" These questions enable the therapist and patient to discuss and determine mutually agreed upon anticipated goals and expected outcomes. The therapist should not presume to know what issues are important to the patient. Answers to these questions help the therapist to determine

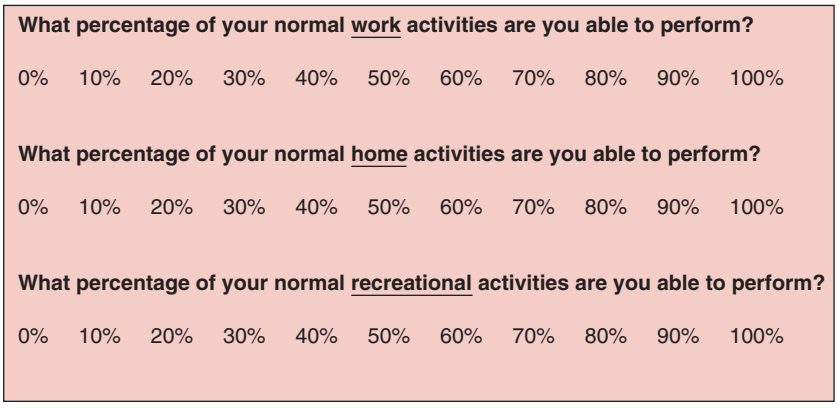

Figure 4.8 Questions used to rate a patient's function. The patient circles the percent of activity that he or she is able to perform.

whether the patient has realistic expectations or will need further patient education concerning his or her condition and typical recovery. For example, an elderly patient who suffered a fractured hip yesterday and is currently hospitalized may expect to remain in the acute care hospital for 2 weeks until he or she can independently ambulate and be independent in self-care. More realistic goals given current health insurance practices may need to be discussed, such as discharge from the hospital in 3 or 4 days to a rehabilitation or extended care facility for further nursing care, physical and occupational therapy, or discharge home with home health aides, visiting nurses, and home care physical and occupational therapists.

Concluding Question

When the therapist has finished obtaining the above information, one final type of open-ended question needs to be asked: "Is there anything else you wish to tell me?" or "Is there anything else you think I should know concerning your condition that I have not asked about?" Most likely the patient will respond by saying that he or she has no further information to offer and believes you understand the problem clearly. Sometimes, though, a patient may take this opportunity to clarify a previous point or share a concern that is adding stress to his or her life. Without this type of question at the conclusion of the interview, important information that may affect treatment and recovery may be lost.

The information elicited with the questions discussed above may be supplemented with additional questions based on the specific region of the body being examined and suspected etiologies. The physical therapist's knowledge of anatomy, kinesiology, pathokinesiology, physiology, and pathophysiology, as well as the physical presentation and progression of musculoskeletal conditions, provide the appropriate background on which to base and develop patient interview questions.

Mental Status

During the interview, the patient's orientation to person, place, and time as well as general arousal state and cognitive and communication abilities should be noted (see section titled Arousal, Attention, Orientation, and Cognition in Chapter 3, Examination of Sensory Function). If deficits in these areas are present, the examination may need to be modified to gain accurate information. The use of simple words, concise instructions, and task demonstrations may be helpful. Distractions in the environment should be kept to a minimum. Communication difficulties may be overcome through the use of foreign language interpreters, gestures, drawings, and language boards. Changes in medications, upright positioning, and access to natural light via windows and skylights may improve patient arousal and orientation to time. Depending on the type of deficit, the patient may benefit from an evaluation by a neurologist, neuropsychologist, speech-language pathologist, and/or occupational therapist.

Vital Signs

If a patient's medical record or interview suggests a compromised cardiovascular system, then heart rate, blood pressure, and respiratory rate should be determined before beginning other physical examination procedures (see Chapter 2, Examination of Vital Signs). Patients who are getting out of bed for the first time following recent surgery or prolonged bedrest should routinely have vital signs taken to establish baseline values before movement.

Observation/Inspection

Observation begins with the therapist's first contact with the patient, whether at bedside in the case of hospitalized patients, or in the waiting room for outpatients. The patient's general posture and ability to perform functional activities—change bed position, transfer from sitting to standing, ambulate to the examining room—provides information about the severity of symptoms, willingness to move, range of joint motion, and muscle strength. This information, although preliminary, helps to focus and individualize the physical examination. For example, a patient with a shoulder disorder who uses the UE to push off from a chair during transfers, stands with level bilateral shoulder height, and has an alternating arm swing during gait, would be expected to have milder symptoms, tolerate a more extensive examination, and have a greater range of motion (ROM) and muscle function than a patient who stands with an elevated scapula and protectively cradles the UE during transfers and gait. If functional difficulties and gait abnormalities were noted, detailed functional status and gait examinations would be performed later. See Chapter 8, Examination of Function, and Chapter 7, Examination of Gait, for additional information about these examination procedures.

To perform the physical examination and inspect specific areas of the body, the patient must be suitably dressed. Observation of the shoulders, elbows, or spine will require males to remove their shirt and females to wear only a bra or loose hospital gown that can be draped to expose the UE and back. To observe the LEs, patients should undress from the waist down, wearing only undergarments or shorts.

Once the patient is in the privacy of an examining room and appropriately disrobed, the therapist begins a careful inspection of the body region implicated in the interview as well as biomechanically related areas. The LEs and lumbar region, being intricately involved in weight-bearing activities, should be inspected as a functional unit. Likewise, conditions involving the shoulder require the examination of the cervical and thoracic regions, and vice versa. Visual inspection should focus on bone, soft tissue structures, skin, and nails. The therapist should view the body region anteriorly, posteriorly, and

laterally. Often palpation, which is discussed in the next section, is combined with observation.

Bone shafts and joints are judged against normative models for symmetry, comparing one side of the body to the other. Contour and alignment should be considered. Common causes of changes in bone contour include acute fractures, callus formation or bone angulation owing to healed fractures, congenital variations, or bone hyperplasia at tendon insertions, and arthritis. Alignment differences can be due to the above conditions as well as muscle and soft tissue tightness, muscle weakness, muscle and ligament laxity, and joint dislocation.

For patients with musculoskeletal involvement, an examination for postural alignment is often indicated. From an *anterior* view both eyes, shoulders (acromion processes), iliac crests, anterior superior iliac spines, greater trochanters of the femur, patellae, and ankle medial malleoli should be horizontally level. Waist angles should be symmetrical. Patellae and feet should face anteriorly. *Laterally* the line of gravity should bisect the external auditory meatus, acromion process, greater trochanter, lie just posterior to the patella and approximately 2 inches (5 centimeters) anterior to the lateral malleolus (Fig. 4.9).[16]

The cervical and lumbar spine should exhibit normal lordotic curves, and the thoracic spine a normal kyphotic curve. From a *posterior* view the ear lobes, shoulders, inferior angles of the scapula, iliac crests, posterior superior iliac spines, greater trochanters, buttock and knee creases, and malleoli should be level.

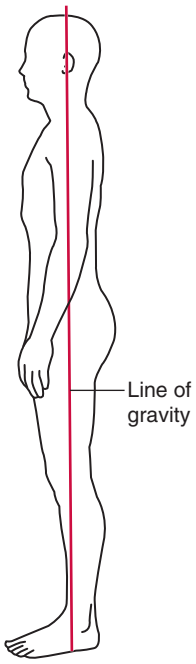

Figure 4.9 The location of the line of gravity from the lateral view. *(From Levangie and Norkin,[16] with permission.)*

The spine should be straight, with the medial borders of the scapula equidistant from the spine bilaterally. Varus and valgus deformities of the knee and calcaneus should be noted.

The size and contour of soft tissue structures should be inspected and compared bilaterally. An increase in size may indicate soft tissue edema, joint effusion, or muscle hypertrophy. A decrease in size often indicates muscle atrophy. A loss of soft tissue continuity can suggest a muscle rupture. Cysts, rheumatoid nodules, ganglia, and gouty tophi can all change soft tissue contour. *Clubbing,* in which the distal finger and nail become rounded (bulbous), is believed to be caused by chronic hypoxemia and is typically associated with cardiovascular and respiratory diseases or neurovascular abnormalities.[9] Clubbing may also occur in the toes. Skin color and texture provide important clues to pathological conditions. *Cyanosis,* a blue discoloration of the skin and nail bed, indicates a lack of oxygen and excessive carbon dioxide in superficial blood vessels.[9] Inspection of the tongue for cyanosis helps determine if the poor perfusion is due to central or peripheral causes. *Pallor* is noted with a decrease in blood flow or blood hemoglobin—for example, in situations such as peripheral vasoconstriction, shock, internal bleeding, and anemia. *Erythema,* a localized redness, usually indicates increased blood flow and inflammation. Generalized redness can suggest fever, sunburn, or carbon monoxide poisoning. Yellow skin tone may be due to increased carotene intake, or liver disease. Brown, highly pigmented, hairy areas sometimes overlay bony defects such as spina bifida. Open wounds should be measured and diagrammed in patient records. New scars will be red, and older scars will be white in color. Skin tissue thickenings such as *calluses* can indicate chronic overloading and stress. Thin, glossy skin with decreased elasticity and hair loss is often found with peripheral nerve lesions or neurovascular disorders.

Palpation

It is suggested that palpation immediately follow or be integrated with observation and occur before other testing procedures. Other procedures may aggravate the patient's condition, making it more difficult to localize tenderness if palpation is performed later. The information gained from palpation will also help guide decision making about the need for additional test and measurements.

Palpation requires detailed knowledge of anatomy and a systematic approach. All structures on one body surface should be palpated before proceeding to another surface. For example, all structures on the anterior surface of the patient should be palpated before beginning to palpate structures on the posterior surface. The uninvolved side is palpated first to acquaint the patient with the procedure and, in some cases, to serve as a normative model for comparison. The therapist should develop a system of moving from superior to inferior structures, medial to lateral, or superior and then inferior from a

joint line. Which direction the therapist moves is not important, but the palpation process should be consistent and thorough.

Palpation of bone, soft tissue structures, and the skin is performed by varying the therapist's tactile pressure and using various parts of the hands. Light tactile pressure allows palpation of superficial tissues like the skin, whereas more pressure is needed to palpate deeper structures such as bone. Usually the fingertips are used for palpation, but large, deeper structures such as the greater trochanter of the femur or borders of the scapula are easier to locate using the entire surface of the hand. Rolling the skin and soft tissue between the fingertips and thumb helps the therapist judge myofascial mobility. Changes in skin temperature may be easier to detect using the posterior surface of the therapist's hand. When moving from one area to another, the therapist's hand should stay in firm contact with the skin whenever possible to prevent a tickling sensation. The fingers should not "crawl" or "walk" across the skin.

During palpation the therapist seeks feedback from the patient to help localize painful structures. Some lesions in deep or proximal structures will refer symptoms to other body areas, but localized tenderness often helps to implicate particular structures. Localized skin temperature should be noted: cool temperatures suggest reduced circulation, whereas warmth indicates increased circulation and often inflammation. Skin and soft tissue density and extensibility should be considered. Often muscle spasms and adhesions in skin and connective tissue can be found with palpation. The quality (amplitude) of peripheral pulses will provide gross information on arterial blood supply. Bilateral edema in the ankles and legs that forms pits with tactile pressure (termed *pitting edema*) can indicate cardiac failure, liver, or renal conditions. Unilateral pitting edema is typically associated with obstruction of returning circulation.

Anthropometric Characteristics

Abnormalities noted during observation and palpation may be further documented with anthropometric measurements. Using a cloth or flexible plastic tape measure, limb lengths are measured from one bony landmark to another and compared bilaterally. For example, true leg length is commonly measured from the anterior superior iliac spine to the medial malleolus.

Circumferential measurements help substantiate joint effusion, edema, and muscle hypertrophy and atrophy. Typically, these measurements are taken at specified distances (inches or centimeters) above or below a bony landmark so they can be reliably reproduced during subsequent measurements. For example, circumference measurements of the upper arm should be taken at noted distances distal to the acromion process of the scapula or proximal to the olecranon process of the ulna. If measurements are needed of the hands or feet, volumetric measurements can be taken by submerging the distal extremity in a container of water and noting the volume of water that is displaced.

Range of Motion

Joints and their related structures are examined by performing active and passive joint motions. Joint motion is a necessary component of most functional tasks. Numerous studies have identified the ROM needed in the LE to walk on level surfaces,[17-21] ascend and descend stairs,[21-23] rise from a chair,[24-26] as well as squat, kneel, and sit cross-legged.[27,28] The ROM needed in the UE to eat with a spoon[29,30] and perform many UE activities[31-33] has been examined. Careful examination of joint movement for ROM, end-feel, effect on symptoms, and pattern of restriction help identify and quantify impairments causing activity limitations, and determine which structures need treatment.[34]

Active Range of Motion

The examination of joint motion begins by testing **active range of motion** (**AROM**). Active motion is the unassisted voluntary movement of a joint. The patient is asked to move a body part through the osteokinematic motions at the involved and other biomechanically related joints. **Osteokinematics** refers to the gross angular motions of the shafts of bones. These motions are described as occurring in the three cardinal planes of the body: flexion and extension in the sagittal plane, abduction and adduction in the frontal plane, and medial and lateral rotation in the transverse plane. For example, in an examination of the hip the patient would be asked to move the hip into flexion, extension, abduction, adduction, and medial and lateral rotation. Often flexion and extension of the knee, as well as flexion, extension, rotation, and lateral flexion of the lumbar spine, are tested, because knee and spine motions can affect hip function. Some therapists prefer to have the patient move in functional, combined motions rather than straight plane motions. For example, a patient would be asked to reach a hand behind the head to test shoulder abduction and medial rotation simultaneously rather than perform isolated, individual motions.

Active motion is a good musculoskeletal screening procedure to further focus the physical examination. The amount, quality, and pattern of motion, as well as the occurrence of pain and crepitus, should be noted. For purposes of musculoskeletal screening, AROM can be visually estimated to determine if motion is within functional limits (WFL); however, use of a goniometer is required for the more objective and accurate measurements needed to establish a pathological baseline and to evaluate treatment response. Normal ROM varies among individuals and is influenced by factors such as age and gender,[35-44] as well as measurement methods.[45-50] Ideally, to determine if ROM is impaired, the ROM values should be compared with those obtained with the same measurement methods

from people of the same age and gender. Studies that provide normative values by age and gender have been summarized by Norkin and White.[34] However, when particular values are not available, the therapist may need to compare ROM values to those of the patient's contralateral extremity or to average adult values from sources such as the *American Academy of Orthopedic Surgeons*[51,52] and the *American Medical Association*.[53] If the patient can complete AROM easily, without presenting pain or other symptoms, then further passive testing of that motion is usually unnecessary.

If, however, the amount of active motion is less than normal the therapist will not be able to isolate the cause without further testing. Capsule, ligament, muscle and soft tissue tightness, joint surface abnormalities, and muscle weakness are all capable of causing limitations in AROM. Pain during AROM may be due to the contracting, stretching, or pinching of contractile tissues such as muscles, tendons, and their attachments to bone, or due to the stretching or pinching of non-contractile tissues such as ligaments, joint capsules, and bursa.[54] Variations in the quality and pattern of active motion can result from central and peripheral nervous system disorders and metabolic conditions, in addition to disorders involving musculoskeletal structures. So, although active motion is an effective screening procedure, positive findings require a variety of additional tests to identify the underlying etiology and thus enable effective treatment.

Passive Range of Motion

Passive motions are movements performed by the therapist without the assistance of the patient. The term **passive range of motion** (**PROM**) typically refers to the amount of osteokinematic motion available when the patient's joint is moved without the patient's assistance. Normally, PROM is slightly greater than AROM because joints have a small amount of motion at the end of the range that is not under voluntary control. This additional range helps to protect joint structures by allowing the joint to absorb extrinsic forces. Passive ROM is examined not only for amount of motion, but also for the motion's effect on symptoms, the type of tissue resistance felt by the therapist at the end of the motion (end-feel), and pattern of limitation.

Passive range of osteokinematic motions depends on the integrity of joint surfaces and the extensibility of the joint capsule, ligaments, muscles, tendons, and soft tissue. Limitations in PROM may be due to bone or joint abnormalities or tightness of soft tissue structures. Because the therapist provides the muscle force needed to perform PROM, rather than the patient, PROM (unlike AROM) does not depend on the patient's muscle strength and coordination.

Pain during PROM is often due to moving, stretching, or pinching of non-contractile structures. Pain occurring at the end of PROM may be due to stretching contractile structures, as well as non-contractile structures. Pain during PROM is not due to the active shortening (contracting) of muscle and the resulting pull on tendon and bone attachments. By comparing active and passive motions that cause pain, and noting the location of the pain, the therapist gains important information about which injured tissues are involved.

For example, on examination a patient is found to have limited and painful active knee flexion. This pain and limitation may be due to a lesion in the hamstring muscles (including tendons and bone attachments), the quadriceps muscles (including patella tendon and bone attachments), tibiofemoral and patellofemoral joint surfaces, meniscus, joint capsule, collateral and cruciate ligaments, or various anterior and posterior bursa. If the patient had similar pain and limitation during passive ROM, the quadriceps muscles, tibiofemoral and patellofemoral joint surfaces, meniscus, joint capsule, collateral and cruciate ligaments, or various anterior bursa may be involved. The hamstring muscles would not be implicated as these structures are put on slack and relieved of tension during passive knee flexion. Careful consideration of patient history, observation and palpation findings, and the results of additional tests and measurements such as end-feel determination, capsular versus non-capsular joint limitation patterns, accessory joint motion tests, and ligament stress tests will help to isolate the involved structures. These additional tests are discussed later in this chapter. If, however, passive knee flexion ROM were now normal and pain free as compared to painful during active flexion, a lesion in the hamstring muscles would be likely. The performance of resisted isometric muscle contractions would be used to confirm the presence of a lesion in the hamstring muscles.

In the clinical setting, PROM is usually measured with **universal goniometers** (Fig. 4.10) or less frequently with **inclinometers** (Fig. 4.11A and B), tape measures, and flexible rulers. With the exception of screening examinations, visual estimates are not used because they are less accurate than measurements taken with goniometers.[55,56] Both the beginning and the end of the motion are measured to identify the "range" of movement and are recorded using both the start and end values (e.g., 0°–110°) (Fig. 4.12).

Using the most common notation system, the 0° to 180° system, all motions except rotation begin in anatomical position at 0° and progress toward 180°. For example, a motion that begins at 0° and ends at 135° would be recorded as 0°–135°. A ROM that does not start with 0° or ends prematurely indicates joint **hypomobility**. Joint **hypermobility** at the beginning of the range is noted by the inclusion of a zero (the normal starting position) between the starting and ending measurements. For example, if the elbow joint has 5° of hypermobility in extension and 140° of flexion, it would be recorded as 5°–0°–140°. Hypermobility at the end of the ROM is denoted by an ending value higher than normal. Measurement results are incorporated

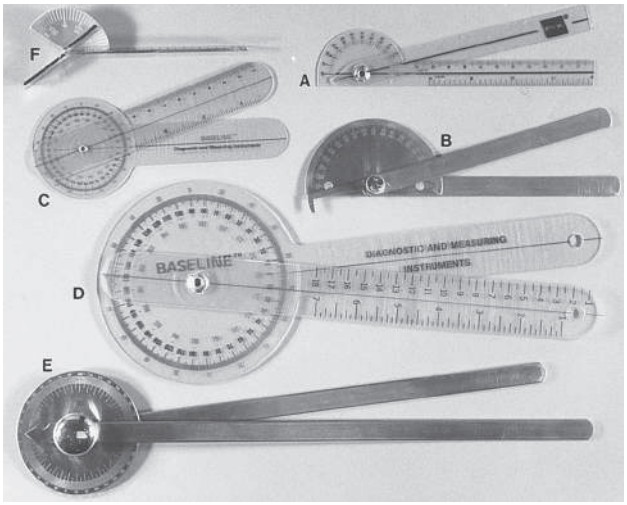

Figure 4.10 A variety of metal and plastic universal goniometers in different sizes and shapes. All universal goniometers have a central "body" with a protractor and fulcrum to center over the patient's joint, as well as two "arms" to align with the patient's body parts. *(From Norkin and White,[34] with permission.)*

into narrative reports or recorded on specialized forms. Specialized ROM recording forms typically have joints and motions listed centrally, with multiple columns on the left and right sides to record the date, examiner's initials, and ROM values of serial measurements (Fig. 4.13). These forms readily allow comparison of serial measurements to assess patient progress. Norkin and White,[34] Clarkson,[57] and Reese and Bandy[58] provide detailed descriptions of goniometric measurement procedures.

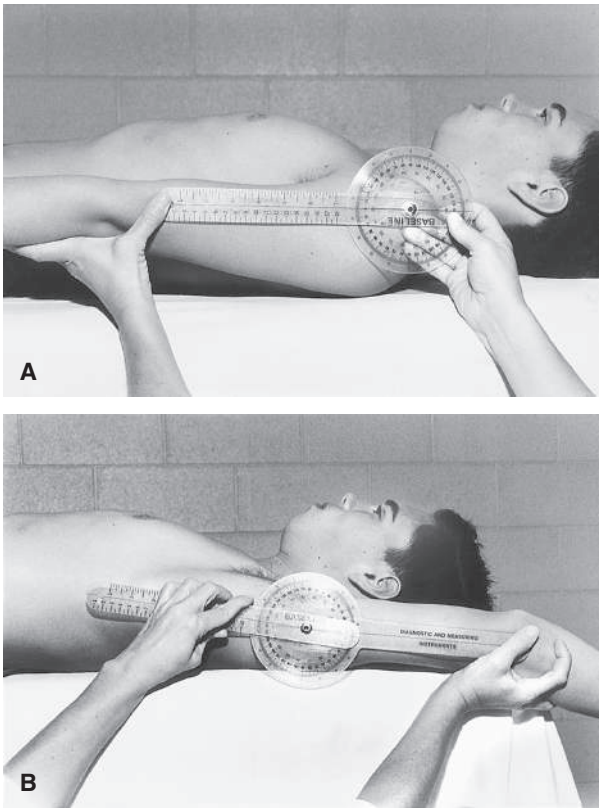

Figure 4.12 Measurement of the beginning (A) and end (B) of shoulder flexion ROM with a universal goniometer. The universal goniometer is moving from 0° toward 180° during the motion. *(From Norkin and White,[34, p. 63] with permission.)*

ROM measurements taken with a universal goniometer of the extremity joints generally have good to excellent reliability. Reliability does vary depending on the joint and motion being measured. Reliability studies that include ROM measurements of elbow motions with a universal goniometer are presented in Box 4.1 Evidence Summary. ROM measurements of UE joints have been found to be more reliable than measurements of the LE[46,60,66] and spine.[67-69] In an often cited study, Boone et al[60] found the average standard deviation between measurements made on the same subjects by different testers to be 4.2° for UE motions and 5.2° for LE motions. These differences in reliability have been attributed to difficulties in measuring complex as compared to simple hinged joints, in palpating bony landmarks, and in moving heavy body parts.[60,70] The use of standardized positions, stabilization of the body part proximal to the joint being tested, use of bony landmarks to align the goniometer, and repeated testing conducted by the same therapist (rather than multiple therapists) all help to improve the validity and reliability of goniometric measurements.[46,56,71]

End-Feel

The end of each motion at each joint is limited from further movement by particular anatomical structures. The type of structure that limits a joint motion has a characteristic feel, which may be detected by the therapist performing the passive ROM. This feeling, which is experienced by the therapist as resistance, or a barrier to further motion, is called the **end-feel**. Cyriax and Cyriax,[54] Kaltenborn,[72] and Paris[73] have described a variety of normal (physiological) and abnormal (pathological) end-feels. A summary of the types of end-feels has been adapted from the work of these authors. Normal end-feels are generally described as *soft, firm,* or *hard* (Table 4.1). A soft end-feel has a gradual increase in resistance as muscle, skin, and subcutaneous tissues are compressed between body parts.[74] A firm end-feel has a more abrupt increase in resistance as compared to a soft end-feel. Firm end-feels include varying amounts of creep, or give, depending on whether the barrier to the end of the motion is the stretching of muscle, capsule, or ligamentous tissue. The firm end-feel with the most creep would be the rubbery resistance offered by the stretch of muscle tissue, and the least amount of creep would be provided by the stretch of ligamentous tissue. The firm end-feel created by the stretch of a joint capsule usually has a moderate amount of creep. A hard end-feel is abrupt; there is an immediate stop to movement as when bone contacts bone.

End-feels are considered to be abnormal when they occur sooner or later in the ROM than is typical, or if they are not the type of end-feel that is normally found for that joint motion. Abnormal end-feels have been associated with more pain than normal end-feels.[75] Many abnormal, pathological end-feels have been described, but most can be categorized as variations of soft, firm, and hard end-feels (Table 4.2). An abnormal end-feel that cannot be categorized as soft, firm, or hard, is an *empty end-feel*. This term describes the inability of the therapist to detect any anatomical barrier to the end of the ROM. Rather, the patient through verbal or nonverbal cues indicates that no further motion should occur, usually because of pain.

The ability to determine the type of end-feel is important in helping the therapist identify the limiting structures and choose a focused and effective treatment. Developing this ability takes practice and sensitivity. Passive ROM, particularly toward the end of the motion, must be performed slowly and carefully. Secure stabilization of the bone proximal to the joint being tested is critical in preventing multiple joints and structures from moving and interfering with determination of the end-feel.[76,77]

Capsular Patterns of Restricted Motion

Cyriax and Cyriax[54] initially described characteristic patterns of restricted joint ROM due to diffuse, intra-articular inflammation involving the entire joint capsule. These patterns of restricted motion, which usually involve multiple motions at a joint, are called **capsular patterns**. The restrictions do not involve the loss of a fixed number of degrees, but rather the loss of a proportion of one motion relative to another. Capsular patterns vary from joint to joint. Table 4.3 presents common capsular patterns as described by Cyriax and Cyriax[54] and Kaltenborn.[72] Although therapists have been using capsular patterns in clinical decision making for many years, studies are needed to test the hypotheses regarding the cause of capsular patterns and to determine the capsular pattern for each joint.[78,79]

Hertling and Kessler,[1] expanding on Cyriax's work, have suggested that capsular patterns are due to one of two general situations: (1) joint effusion or synovial inflammation or (2) relative capsular fibrosis. Joint effusion or synovial inflammation results in a capsular pattern of limitation by distending the entire joint capsule, causing the joint to maintain a position that allows the greatest intra-articular volume. Pain triggered by stretching the capsule, and muscle spasms that protect the capsule from further stretch, inhibit movement and cause a capsular pattern of restricted motion. The other general situation that causes capsular patterns is relative capsular fibrosis, seen in the resolution of acute capsular inflammation, chronic low-grade capsular inflammation, and immobilization of a joint. These conditions cause a decrease in the extensibility of the entire capsule owing to an increase in collagen content of the capsule relative to the mucopolysaccharide content, or from internal changes in the collagen tissue.

To plan an effective treatment, the therapist must determine whether the capsular pattern is caused by joint effusion/synovial inflammation or capsular fibrosis. If joint effusion or synovial inflammation is present,

Reference	Subjects	Design/Intervention/ Duration	Results	Comments
Fish and Wingate,[62] 1985	1 healthy adult	Repeated measures design, blinded 46 PT student testers measured with 2 instruments: plastic and steel goniometers 3 conditions: ALIGN = elbow in fixed position with landmarks noted, ASSIGN = elbow in fixed position with no landmarks, PROM = full range of passive flexion	ALIGN plastic SD = 1.8° – 2.1° ALIGN steel SD = 2.0° – 2.6° ASSIGN plastic SD = 2.5° – 3.0° ASSIGN steel SD = 2.5° – 3.4° PROM plastic SD = 3.4° – 3.8° PROM steel SD = 3.9° – 4.2°	Variability of scores increased as standardization of measurements decreased
Greene and Wolf,[64] 1989	20 healthy adults (10 males, 10 females) 18–55 years	Repeated measures design. AROM 1 PT tester 2 instruments: universal goniometer and pendulum goniometer 3 trials per instrument in a session 3 sessions within 2 weeks	Universal goniometer within-sessions: Flexion: ICC = .94; SD = 1.2°; 95% CI = 3.0°; Extension: ICC = .95; SD = 1.0°; 95% CI = 1.9°; Both instruments had sig difference between sessions. Low correlation (r =.11 – .21) and sig difference between instruments within-sessions	High intratester reliability with universal goniometer in one session. 95% of time reliability within 2–3° if taken by same tester in one session. Different instruments should not be used interchangeably.
Goodwin et al,[63] 1992	23 healthy females, 18–31 years	Repeated measures design. AROM 3 experienced testers. 3 instruments: universal goniometer, fluid goniometer, electrogoniometer. Landmarks noted on skin. 3 trials per instrument by each tester in a session. 2 sessions 4 weeks apart.	Universal goniometer intra-tester reliability between sessions: r = .61 – .92 ICC = .56 – .91. Difference in means between sessions = 0.9°; Average difference in means between testers = 5.1°; Sig differences and interactions between goniometers, testers, and sessions	Moderate to high intra-tester reliability between 2 sessions 4 weeks apart, depending on tester. Differences between sessions smaller than differences between testers. Different instruments should not be used interchangeably.

Box 4.1 Evidence Summary Outcome Studies on Reliability of Using Universal Goniometer to Measure Elbow Range of Motion—cont'd

Reference	Subjects	Design/Intervention/ Duration	Results	Comments
Armstrong et al,[65] 1998	38 patients with history of surgery for upper extremity injury. 19 males, 19 females 14–72 years	Repeated measures design. AROM 5 testers of varying experience. 2 instruments: universal goniometer and electrogoniometer. 2 trials per instrument by each tester on same day	Universal goniometer: Intratester reliability for flexion: ICC = .55 – .98, mean difference between trials = 3.2°; 95% CI = 5.9° Extension: ICC = .45 – .98, mean difference = 3.5°; 95% CI = 6.6° Intertester reliability for flexion: ICC = .58 – .62, mean difference = 6.4°; 95% CI = 9.2°; Extension: ICC = .58 – .87, mean difference = 7.0°; 95% CI = 8.9°	Moderate to high intra-tester reliability. Moderate intertester reliability. 95% of time reliability within 6.7° if taken by same tester, and 9° if taken by different testers.

AROM = active range of motion; CI = confidence interval; ICC = intraclass correlation coefficient; PROM = passive range of motion; PT = physical therapist; *r* = Pearson's correlation coefficient; sig = significant.

Table 4.1 Normal End-Feels

End-Feel	Structure	Example
Soft	Soft tissue approximation	Knee flexion (contact between soft tissue of posterior leg and posterior thigh)
Firm	Muscular stretch	Hip flexion with the knee straight (passive elastic tension of hamstring muscles
	Capsular stretch	Extension of metacarpophalangeal joints of fingers (tension in the anterior capsule)
	Ligamentous stretch	Forearm supination (tension in the palmar radioulnar ligament of the inferior radioulnar joint, interosseous membrane, oblique cord)
Hard	Bone contacting bone	Elbow extension (contact between the olecranon process of the ulna and the olecranon fossa of the humerus)

From Norkin and White,[34] with permission.

Table 4.2 Abnormal End-Feels

End-Feel		Examples
Soft	Occurs sooner or later in the ROM than is usual, or in a joint that normally has a firm or hard end. Feels boggy, with fluid shift.	Soft tissue edema Synovitis
Firm	Occurs sooner or later in the ROM than is usual, or in a joint that normally has a soft or hard end.	Increased muscular tonus Capsular, muscular, ligamentous shortening

Continued

Table 4.2 Abnormal End-Feels—cont'd

End-Feel		Examples
Hard	Occurs sooner or later in the ROM than is usual, or in a joint that normally has a soft or firm end. A grating or bony block is felt.	Chondromalacia Osteoarthritis Loose bodies in joint Myositis ossificans Fracture
Empty	No real end because pain prevents reaching end of ROM. No resistance is felt except for patient's protective muscle splinting or muscle spasm.	Acute joint inflammation Bursitis Abscess Fracture Psychogenic disorder

From Norkin and White,[34] with permission.

Table 4.3 Capsular Patterns of Extremity Joints

Shoulder (glenohumeral joint)	Maximum loss of external rotation Moderate loss of abduction Minimum loss of internal rotation
Elbow complex	Flexion loss is greater than extension loss
Forearm	Full and painless Equally restricted in pronation and supination in presence of elbow restrictions
Wrist	Equal restrictions in flexion and extension
Hand Carpometacarpal joint I Carpometacarpal joints II-V	 Abduction and extension restriction Equally restricted in all directions
Upper extremity digits	Flexion loss is greater than extension loss
Hip	Maximum loss of internal rotation, flexion, abduction Minimal loss of extension
Knee (tibiofemoral joint)	Flexion loss is greater than extension loss
Ankle (talocrural joint)	Plantarflexion loss is greater than extension loss
Subtalar joint	Restricted varus motion
Midtarsal joint	Restricted dorsiflexion, plantarflexion, abduction, and medial rotation
Lower extremity digits Metatarsalphalangeal joint I Metatarsalphalangeal joints II-V Interphalangeal joints	 Extension loss is greater than flexion Variable, tend toward flexion restriction Tend toward extension restriction

Capsular patterns are from Cyriax and Cyriax[54] and Kaltenborn.[72]

treatment methods typically focus on resolving the acute inflammation with rest, cold modalities, compression, elevation, joint mobilization using grade 1 sustained and grade 1 and 2 oscillations, gentle ROM exercise, and anti-inflammatory medications. Capsular fibrosis, a more chronic condition, can be treated with heat modalities, joint mobilization using grade 3 sustained stretch and grade 3 and 4 oscillations, passive stretching procedures, and more vigorous ROM exercises. Patient history, observation, palpation, and careful determination of end-feels will help establish the cause of the capsular pattern.

Noncapsular Patterns of Restricted Motion

Restricted passive ROM that is not proportioned similarly to a capsular pattern is called a **noncapsular pattern** of restricted motion.[1,54] Noncapsular patterns usually involve only one or two motions of a joint, in contrast to capsular patterns, which involve all or most motions of a joint. Noncapsular patterns are caused by conditions

involving structures other than the entire joint capsule. Internal joint derangement, adhesion of a part of a joint capsule, and extracapsular lesions such as ligament shortness, muscle strain, and muscle shortness are examples of conditions that can result in noncapsular patterns. For example, shortness of the iliopsoas muscle will result in the noncapsular pattern of limited passive hip extension; the passive range of other hip motions will not be affected. This is in contrast to the capsular pattern of the hip caused by diffuse joint effusion or capsular fibrosis, in which there is loss of passive internal rotation, flexion, and abduction.

The sole recognition of a noncapsular pattern is not enough to direct appropriate treatment. Information gained from the patient history, observation, palpation, active and passive ROM, end-feels, resisted isometric muscle tests, joint mobility tests, and special tests must be integrated to determine the most likely cause of the noncapsular pattern. For example, both chronic shortness and acute strain of the iliopsoas muscle may result in a noncapsular pattern of limited passive hip extension. However, those conditions will present differently in terms of patient history, pain during active and passive ROM, end-feel, and resisted isometric muscle tests, and will require different treatment approaches.

Accessory Joint Motions

If passive ROM is found to be limited or painful, an examination of arthrokinematic motions in indicated. **Arthrokinematics** refers to the motion of joint surfaces. These motions, often called **accessory** or **joint play motions**, are used to determine joint mobility and integrity. Accessory joint motions are typically described as slides (or glides), spins, and rolls. A **glide** (**slide**) is a linear motion of one surface sliding over another (Fig. 4.14). A **roll** is a rotary motion similar to the bottom of a rocking chair rolling over the floor or a tire rolling over a road (Fig. 4.15). A **spin** is a rotary motion around a fixed point or axis (Fig. 4.16).

Accessory motions usually occur in combination with each other and result in angular movement of the bone shaft, or osteokinematic motion. Kaltenborn[72] refers to the combination of translatory glide and the rotary motion of rolling as **roll-gliding**. The combination of a roll and glide allows for increased ROM by postponing the joint compression and separation that would occur at either side of the joint during a pure rolling motion. The direction of the rolling and gliding components of roll-gliding depends on whether a concave or convex joint surface is moving. If a concave joint surface is moving, the gliding component occurs in the same direction as the rolling or angular movement of the shaft of the bone (Fig. 4.17). For example, during flexion of the knee with the femur fixed, the shaft of the tibia rolls posteriorly while the joint surface of the tibia also glides posteriorly. If a convex joint surface is moving, the gliding component occurs in the direction opposite to the rolling or

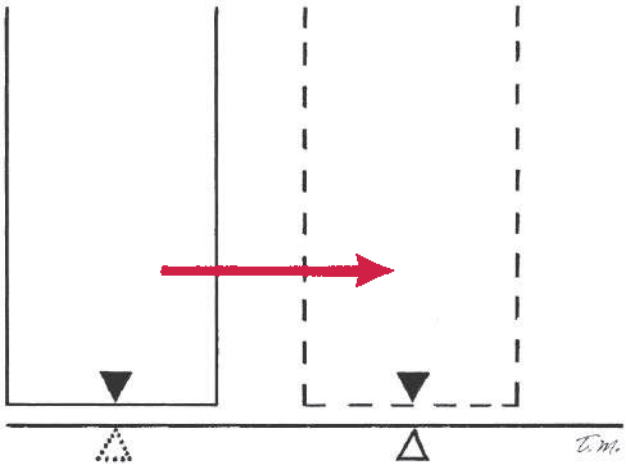

Figure 4.14 A glide (slide) is a type of linear accessory joint motion in which points on a moving joint surface comes in contact with new points on the opposing joint surface. *(From Norkin and White,[34] with permission.)*

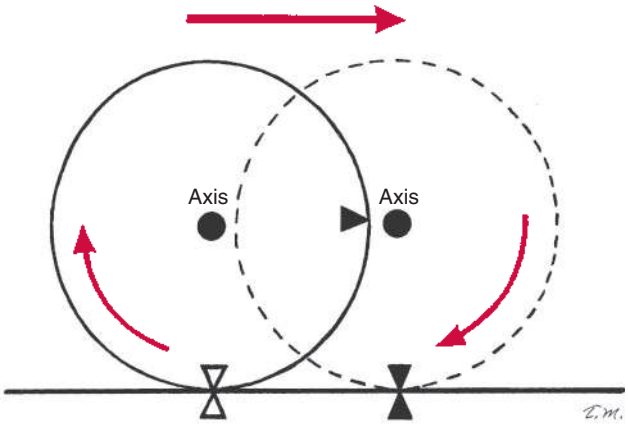

Figure 4.15 During a roll, new points on the moving joint surface come in contact with new points on the opposing surface. The axis of rotation also moves, in this case to the right. *(From Norkin and White,[34] with permission.)*

angular movement of the shaft of the bone. As an example, during abduction of the glenohumeral joint, the shaft and humeral head roll cranially, while the contacting articular surface of the humeral head glides caudally. In the human body, roll-gliding is by far the most frequently occurring arthrokinematic motion, although there are several instances of pure spin motions. An example of a spin joint motion would be supination and pronation of the radius at the humeroradial joint.

Normal arthrokinematic (accessory) motions are necessary for full and symptom-free osteokinematic motions. The careful examination of accessory motions helps to more specifically locate and treat the source of impaired osteokinematic motions. The patient cannot perform accessory motions actively because these

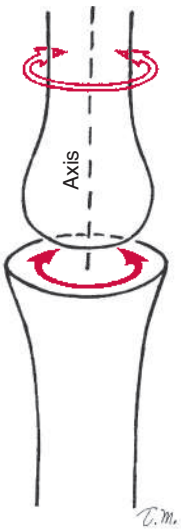

Figure 4.16 A spin is an accessory joint motion in which all the points on the moving surface rotate around a fixed axis. *(From Norkin and White,[34, p. 4] with permission.)*

motions are not under voluntary control. Rather, the therapist tests them passively. The accessory motions most commonly tested are translatory motions: glides that are parallel to the joint surfaces, and *distractions* and *compressions* that are perpendicular to the joint surfaces. Kaltenborn,[72] Kisner and Colby,[80] Edmund,[81] and Hertling and Kessler[1] describe specific testing and treatment techniques that focus on accessory motions—usually under the topic of **joint mobilization**. Careful attention must be given to general patient positioning, specific joint positioning, relaxation of surrounding muscles, stabilization of one joint surface, and mobilization of the other joint surface.

Accessory joint motions are examined for amount of motion, effect on symptoms, and end-feel. The ranges of accessory motions are very small and cannot be measured with goniometers or standard rulers. Rather, they are typically compared to the same motion on the contralateral side of the patient's body, or compared to the therapist's past experience in testing people of similar age and gender as the patient. Accessory motions are assigned a joint play mobility grade of 0 to 6.[72] These mobility grades have implications for treatment (Table 4.4).[1,81]

The testing accessory motions put stress on specific anatomical structures. A change in symptoms during the performance of an accessory motion helps to implicate particular structures. Distraction stresses the entire joint capsule and numerous ligaments surrounding and supporting the joint. Glides stress a specific part of the joint capsule and particular ligaments, depending on the direction of the glide and joint. Compression applies force to intracapsular structures such as meniscus, bone, cartilage, and projections of the synovial lining of the joint capsule into the joint space. Accessory motions are of such a small magnitude that they do not stress surrounding muscles. Angular changes in joint position that typically occur during osteokinematic ROM movements more effectively change the length of muscle tissue. Normal and abnormal end-feels noted during passive accessory motions are characterized as soft, firm, and hard. Similar to end-feels noted during passive osteokinematic motions, they help determine the limiting structures and guide treatment planning.

Muscle Performance

Muscle performance is the ability of a muscle to do work.[6] **Linear work** is defined as force multiplied by distance, and **rotational work** is defined as torque (force multiplied by perpendicular distance from the axis of rotation) multiplied by arc of movement. Usually during a

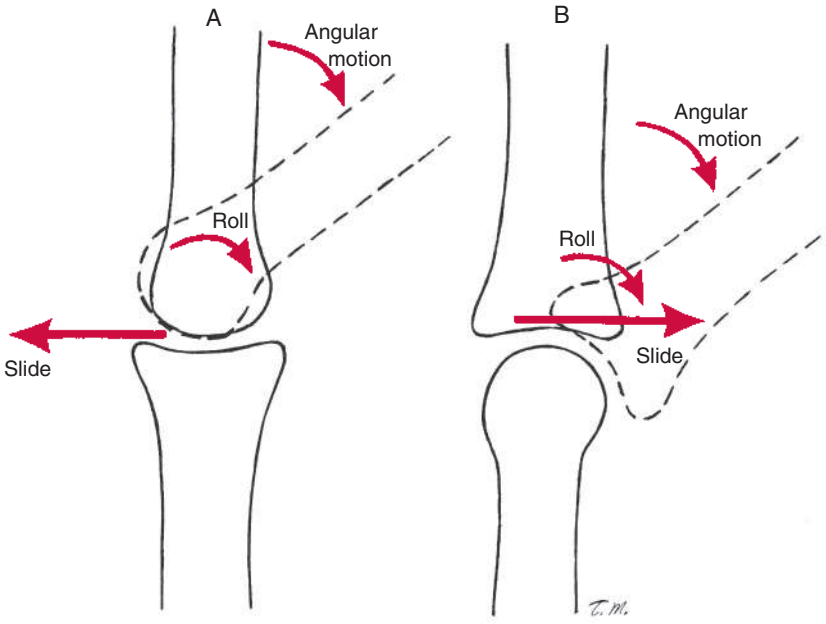

Figure 4.17 Diagrammatic representation of the concave-convex rule. **(A)** If the joint surface of the moving bone is convex, gliding is in the opposite direction of the angular movement of the bone. **(B)** If the joint surface of the moving bone is concave, gliding is in the same direction as the angular movement of the bone. *(From Norkin and White,[34, p. 5] with permission.)*

Table 4.4 Accessory Joint Motion Grades and Implications for Treatment

Grade	Joint Status	Implications for Treatment
0	Ankylosed	Joint mobilization is not indicated; surgery should be considered.
1	Considerable hypomobility	*Grades 1 and 2*: Joint mobilization to increase the extensibility of joint structures is indicated. Heat modalities before mobilization and ROM exercises after mobilization should be considered.
2	Slight hypomobility	
3	Normal	Joint mobilization is not needed, because findings are normal.
4	Slight hypermobility	*Grades 4 and 5*: Joint mobilization to increase joint extensibility is not indicated. Taping, bracing, strengthening exercises, and education regarding posture and positions to be avoided should be considered.
5	Considerable hypermobility	
6	Unstable	Joint mobilization is not indicated; surgery should be considered.

musculoskeletal examination, a component of muscle performance—muscle strength—is tested. **Muscle strength**, as described in the *Guide to Physical Therapist Practice*,[6] is the force exerted by a muscle or group of muscles to overcome a resistance in one maximal effort. Clinical methods of determining muscle strength include manual muscle testing (MMT), handheld dynamometry, and isokinetic dynamometry. Depending on the patient, other characteristics related to muscle performance may also be tested. ***Muscle power*** is work produced per unit of time, or the product of strength and speed. **Muscle endurance** is the ability of the muscle to contract repeatedly over time. In addition to these quantitative measures, the patient's qualitative response in terms of changes in pain during resisted isometric testing is important in identifying musculotendinous lesions.

Resisted Isometric Testing

During the performance of active and passive ROM testing, a patient may complain of pain. The patient history, location of pain, and the pattern of painful motions may suggest a lesion in contractile tissues such as muscle or tendons and their insertions into bone, or involvement of inert tissues such as the joint surfaces, joint capsule, or ligaments. Resisted isometric testing can be used to further clarify which type of tissue, contractile or inert, is involved. *Increased pain* during a resisted isometric contraction, caused by shortening of the muscle and pulling on the tendon, helps to confirm the involvement of contractile tissues. Sometimes more pain is felt when the contraction is released and lengthening occurs; this would still be considered a positive finding for a lesion in contractile tissues. The *lack of pain* during resisted isometric testing, pain noted with limited accessory joint motions, a capsular pattern of joint restriction, or particular end-feels during PROM and accessory joint motions help to confirm the involvement of inert tissues. For example, bicipital tendinitis would be painful during resisted isometric testing of elbow flexion and shoulder flexion. An adhesive capsulitis of the glenohumeral joint would be painless during these same resisted isometric maneuvers.

Resisted isometric testing must be performed carefully to stress particular contractile tissue while avoiding stress to surrounding inert tissue. The therapist should place the patient's joint in a position midway through the ROM, so that minimal tension is put on inert structures. The body part proximal to the joint being tested must be well stabilized by the therapist to minimize extraneous muscle substitutions. The patient is then asked to hold the position while the therapist gradually applies resistance. Joint movement is strictly avoided. Although some compression of articular surfaces will occur during the isometric contraction, this does not usually present a problem in interpreting the results. However, a bursa located deep to the musculotendinous tissue will also be compressed. Although bursae are not considered to be connective tissue, pain will be felt during the isometric contraction if a bursa is inflamed. Fortunately, treatment for bursitis is similar to treatment for musculotendinous strains and inflammation.

In addition to determining the absence or presence of pain during the resisted isometric testing, the therapist should also note the strength of the muscle contraction. If weakness is found, more extensive testing of muscle strength should be performed using MMT or dynamometers. Muscle weakness may be due to many causes, including pathologies involving upper motor neurons, peripheral nerves, neuromuscular junctions, muscles, and tendons. Pain, fatigue, and disuse atrophy can also cause weakness. The pattern of muscle weakness will help to identify the site of the pathology and direct treatment. The patient history and the results of sensory, coordination, motor control, cardiopulmonary, and electromyography (EMG) testing will help clarify findings as well.

Several authors[1,2,54] have suggested using the results of resisted isometric testing to determine the type of pathology. The strength of the muscle contraction (strong or weak) and the presence or absence of pain (painful or painless) are used to implicate possible pathologies (Table 4.5). Franklin et al[82] have suggested that a resisted isometric test finding of "weak and painful" warrants expansion to include not only serious pathologies, but also relatively minor muscle damage and inflammation such as that induced by eccentric isokinetic exercise. Intratester and intertester reliability of resisted isometric testing have been examined to determine types of pathology in the shoulder and knee.[83,84]

Manual Muscle Testing

Manual muscle testing was developed by Wright[85] and Lovett[86] beginning in 1912 as a means of testing and grading muscle strength based on gravity and manually applied resistance. Over the years others have described various MMT methods, but the two methods most frequently used in the United States are those proposed by Daniels and Worthingham[87] and Kendall et al.[88] Both methods, based on the works by Wright and Lovett, use arc of motion, gravity, and manually applied resistance by the therapist to test and determine muscle grades. Generally, the patient is positioned so that the muscle or muscle group being tested has to move or hold against the resistance of gravity. If this is well tolerated, the therapist applies manual resistance gradually to the distal end of the body part in which the muscle inserts, and in a direction opposite to the torque produced by the muscle(s) being tested.

In recent editions, both methods recommend applying manual resistance in the form of a **break test** in which the patient holds a joint position until the therapist gradually overpowers the patient and an eccentric contraction begins to occur. Both methods suggest that the break test occurs at the end of the ROM when testing one-joint muscles, and at mid-range when testing two-joint muscles. In addition, many therapists apply manual resistance while the patient moves through the ROM, in what is called a **make test**, or an **active resistance test**, so that the muscle's ability to contact concentrically against maximal resistance can also be determined. In the case of weaker muscles that cannot hold or move well against gravity, the patient is repositioned and attempts to move the body part through a gravity-minimized (horizontal) plane of motion. During all testing, stabilization of the body part on which the muscle originates and careful avoidance of substitution by other muscle groups are emphasized.

Although there are many similarities, there are some differences between these two popular MMT methods. Kendall et al[88] propose to examine individual muscles insofar as practical, whereas the Daniels and Worthingham method[87] examines muscle groups that perform particular joint motions. Some testing positions are similar but others vary between the two methods, with Daniels and Worthingham providing more instruction and emphasis on gravity-minimized positioning for weaker muscle groups. Daniels and Worthingham recommend that the patient move through the arc of motion when testing both against gravity and with gravity minimized. Kendall et al have the patient move through an arc of motion only when testing with gravity minimized; otherwise the patient is positioned against gravity at the middle or end of the ROM and asked to hold the position.

Both methods use a grading system based on the work of Lovett with categories of Normal, Good, Fair, Poor, Trace, and Zero. However, Kendall et al suggest a 0% to 100% or a 0 to 10 scale; Daniels and Worthingham suggest a 0 to 5 scale (Table 4.6). If numerical scoring is used, it is important to clarify which scale is being used by following the score with a slash indicating the maximal value of the scale. For example, a grade of *Fair* strength should be noted as 3/5 if using a 0 to 5 scale, or 5/10 if using a 0 to 10 scale. Results can be noted in a narrative report or on standardized recording forms (Fig. 4.18).

It is important to note that these numerical scales indicate ordinal data, because the intervals between the numbers do not represent equal units of measure. The MMT grades of *Good* and *Normal* typically encompass a large range of muscle strength, whereas the grades of *Fair, Poor,* and *Trace* include a much narrower range. Sharrard,[89] counting alpha motor neurons in spinal cords of individuals with poliomyelitis at the time of autopsy, found that muscles previously receiving a grade of *Good* had 50% of their innervated motor neurons, whereas muscles graded as *Fair* had only 15% of their motor neurons. Beasley[90] noted that patients with

Table 4.5 Results of Resisted Isometric Testing

Findings	Possible Pathologies
Strong and painless	There is no lesion or neurological deficit involving the tested muscle and tendon.
Strong and painful	There is a minor lesion of the tested muscle or tendon.
Weak and painless	There is a disorder of the nervous system, neuromuscular junction, a complete rupture of the tested muscle or tendon, or disuse atrophy.
Weak and painful	There is a serious, painful pathology such as a fracture or neoplasm. Other possibilities include an acute inflammatory process that inhibits muscle contraction, or a partial rupture of the tested muscle or tendon.

Table 4.6 Manual Muscle Testing Grades

Grades	Grade Abbreviations	0–5 Scale	0–10 Scale	Criteria
Normal	N	5	10	Full available ROM, against gravity, strong manual resistance
Good plus	G+	4+	9	Full available ROM, against gravity, nearly strong manual resistance
Good	G	4	8	Full available ROM, against gravity, moderate manual resistance
Good minus	G–	4–	7	Full available ROM, against gravity, nearly moderate manual resistance
Fair plus	F+	3+	6	Full available ROM, against gravity, slight manual resistance
Fair	F	3	5	Full available ROM, against gravity, no resistance
Fair minus	F–	3–	4	At least 50% but not full ROM, against gravity, no resistance
Poor plus	P+	2+	3	Full available ROM, gravity minimized, slight manual resistance
Poor	P	2	2	Full available ROM, gravity minimized, no resistance
Poor minus	P–	2–	1	At least 50% but not full ROM, gravity minimized, no resistance
Trace plus	T+	1+		Minimal observable motion (less than 50% ROM), gravity minimized, no resistance
Trace	T	1	T	No observable motion, palpable muscle contraction, no resistance
Zero	0	0	0	No observable or palpable muscle contraction

poliomyelitis were graded as having *Good, Fair,* and *Poor* knee extension when they had on average only 43%, 9%, and 3% of the knee extension force of normal subjects, respectively. Andres et al,[91] in a study of four muscle groups in patients with amyotrophic lateral sclerosis (ALS), found that the muscles were often graded as *Normal* until up to 50% of strength was lost.

The concurrent validity of MMT with muscle strength measured by handheld dynamometers (described in the following section) and strain gauges have been supported by many research studies. Schwartz et al[92] studied 24 muscle groups in 122 patients with spinal cord injury (SCI) and noted correlation coefficients ranging from .59 to .94 between strength measured with MMT grades and handheld dynamometry. Other investigators have reported similar findings.[91,93,94] However, several researchers have noted a wide range of strength values within a MMT grade and an overlap in strength values between adjacent MMT grades, especially in the grades of *Good* and *Normal.*[92,94-96] Manual muscle testing has been shown to be less sensitive in detecting strength deficits in stronger muscles than in weaker muscles. Although more costly and time consuming than MMT, handheld dynamometry can be used to improve objectivity and sensitivity as needed. When muscles are strong enough to move against gravity and the dynamometer's lever arm, isokinetic dynamometry may also be used.

Generally, intratester reliability of MMT has been found to be good among trained therapists using established methods, with correlation coefficients ranging from .63 to .98.[96-98] The results of studies on intertester reliability of MMT vary more widely. Several investigators[98-102] report complete agreement in MMT grades between testers who examined the same patient to be the lowest, ranging from 28% to 75%. Using a 0–5 scale, agreement between testers within a half grade (plus or minus) was better, ranging from 50% to 97%. Using a 0–10 scale, agreement between testers within plus or minus one full grade was high, ranging from 89% to 100%. Correlation coefficients for intertester reliability

ranged from .11 to .94.[92,98,99,103] Training to standardize testing positions, stabilization, and grading criteria resulted in higher agreement and correlation coefficients between testers. Global strength scores that average MMT results from multiple muscle groups also resulted in higher reliability.[98,103]

Grade definitions modified from Kendall et al[88] and Daniels and Worthingham[87] are presented in Table 4.6 with additional criteria as to the amount of motion completed by the patient to delineate the grades of *Fair minus*, *Poor minus*, and *Trace plus*. The grades *Fair plus* through *Normal* depend on the therapist's interpretation of what is minimal, moderate, and maximal resistance. A *Normal* grade is typically equated with the normal strength for that muscle given the patient's age, gender, and body size. It should be noted that there is considerable variability in the amount of resistance that *Normal* muscles can be expected to hold against. For example, large muscles in the LE will normally hold against considerable force and be difficult to overpower during a break test, while small muscles of the hand will normally hold against less force and be easily overpowered during a break test. The application of resistance throughout the arc of motion (**make test** or **active resistance test**) in addition to resistance at only one point in the arc of motion (**break test**) may help in accurately judging a muscle's strength.

Handheld Dynamometry

Handheld dynamometers (HHDs) are portable devices, placed between the therapist's hand and the patient's body, that measure mechanical force at the point of application (Fig. 4.19). Patients are typically asked to push against resistance in a maximal isometric contraction (make test), or hold a position until the resistance overpowers the muscle producing an eccentric contraction (break test). The force measured by the dynamometer will vary depending on the method of applying the resistance (make or break test), the patient's body position in relationship to gravity, joint angle, dynamometer placement on the patient (lever arm), stabilization to prevent muscle substitution, and the therapist's strength.[104-106] Although force values determined with make and break tests are highly correlated, break tests usually result in greater force values than make tests,[107,108] so they should not be used interchangeably.

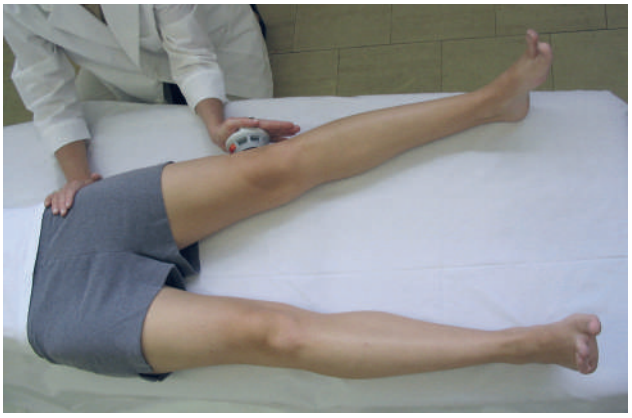

Figure 4.19 Measurement of the strength of the left hip abductors with a handheld dynamometer. The handheld dynamometer measures force at the point of application, which should be converted to torque by multiplying the force by the distance from the joint axis.

To reduce the effect of moving a body segment's weight on force measurements, it is recommended that muscle groups be tested in gravity-minimized positions. For example, to test the strength of the hip abductors the patient would be positioned supine so that the muscle action would pull in a horizontal plane relative to the ground (see Fig. 4.19). Soderberg[106] provides detailed information on recommended positions and procedures for HHD. The joint should also be positioned at an easily reproducible angle so that muscle length remains constant. The dynamometer is applied perpendicular to the body segment at an established location on the patient's body. When muscles contract they produce **torque** that creates angular joint motion. The therapist must apply sufficient resistance to oppose the patient's torque to ensure an isometric (make test), or an eccentric contraction (break test). To provide greater resistance than what can be achieved manually, the dynamometer can be attached to a fixed surface[109,110] or an isokinetic dynamometer can be used with the speed set to 0°/sec.

Normative force values for particular muscle groups by age and gender have been reported;[111-115] however, attention must be directed to replicating methods used in the normative studies to ensure appropriate comparisons. Some authors have also included regression equations to take into account body weight and height.[111,112] Most normative studies have reported results in units of force such as pounds, newtons, or kilogram-force. However, these force values will vary depending on the length between the dynamometer's location on the patient's body to the joint axis of motion, or lever arm. A better method of comparison across people would be to use torque.[105,115,116] To determine torque, the measured force is multiplied by the distance between the dynamometer's location and the joint axis. Examples of units of torque are foot-pounds, newton-meters, or kilogram-force (kgf) meters.

For patients with unilateral conditions, it may be helpful to compare results to that of the uninvolved extremity. Andrews et al[112] found no statistically significant difference in force between the dominant and nondominant LEs using a HHD, but did find a difference between the dominant and nondominant UEs. In general, differences were between 0 and 4.5 pounds or between 0% and 11.2% of the average forces generated. Phillips et al[111] found statistically significant differences in force between sides in a variety of upper and LE muscle groups ranging

from 0.2% to 8.0%. Sapega[117] has recommended that a difference in muscle force between sides of greater than 20% *probably* indicates abnormality, while a difference of 10% to 20% *possibly* indicates abnormality.

Muscle forces measured with HHD have been compared to forces measured with isokinetic dynamometers to evaluate concurrent validity. Most studies have found good to excellent validity with correlation coefficients ranging from .78 to .98.[118-120] Several investigators have reported that HHD underestimates strength in large muscle groups such as the knee extensors,[121,122] or when forces are greater than 196 to 250 newtons.[118,123]

Depending on the study, HHDs have demonstrated good to excellent intratester reliability, and poor to excellent intertester reliability.[107,122,124-130] Several reviews of such reliability studies are available.[106,131,132] Reliability seems to be better when testing the UEs than when testing the LEs and trunk,[125,127] in particular, the measurements of ankle dorsiflexion and hip abduction.[111,112,122,125] Agre et al[124] found the standard deviation of the repeated measurements expressed as a percentage of the mean force measurements (coefficient of variation of replication) to be 5.1% to 8.3% for the UE muscle groups, and 11.3% to 17.8% for the LE muscle groups. Wang et al[128] reported coefficient of variation of replication ranging from 4.2% to 7.4% for three LE muscle groups. Researchers believe some of the error in using HHDs is due to off-center loading of the dynamometer, difficulties in positioning and stabilization, and limitations in the strength and experience of the examiners.

Isokinetic Dynamometry

Isokinetic dynamometers are stationary, electromechanical devices that control the velocity of a moving body segment by resisting and measuring the patient's effort so that the body segment cannot accelerate beyond the preset angular velocity (Fig. 4.20). For example, the velocity of a Cybex Humac Norm (Computer Sports Medicine, Inc., Stoughton, MA 02071) isokinetic dynamometer can be set from 0° to 500°/sec; the resistance, measured in torque, can be monitored up to 500 ft-lb, or 680 newton-meters.[133] Speeds of 60°, 120°, and 180°/sec are commonly tested in relatively sedentary patients, whereas faster speeds may be warranted in trained individuals. Isokinetic dynamometers can be used to measure the torque produced during isometric (if the velocity is set to 0°/sec), concentric, and eccentric contractions. Isokinetic dynamometers, although expensive and cumbersome, are especially helpful in examining the performance of large, strong muscle groups. In such situations, MMT and HHDs are often insensitive to muscle performance abnormalities.[90,105] Muscle groups acting at the knee, shoulder, back, and to a lesser extent the elbow and ankle are those most frequently tested with isokinetic devices.

Isokinetic dynamometers measure torque and ROM as a function of time. Muscle performance characteristics

Figure 4.20 An isokinetic dynamometer is being used to measure muscle performance characteristics of the right knee extensors (quadriceps). Peak torque is the most frequently noted characteristic. *(Courtesy of Biodex Medical Systems, Inc., Shirley, NY 11967.)*

most often noted are peak (maximal) torque, and less frequently peak torque/body weight (Nm/kg), and average torque. Work measurements can be derived from the angular displacement and torque values. Power, which is work per unit time, also can be determined. Endurance (muscle fatigue) can be assessed by measuring the time required for peak torque to decrease by 50%.[117] Other approaches to examining endurance include determining: the sum of work performed for 25 repetitions of a motion; and a ratio of the work performed in the last 5 repetitions divided by the work performed in the first 5 repetitions.[134,135]

Peak torque ratios of reciprocal (agonist-antagonist) muscle groups such as the hamstrings/quadriceps and external/internal rotators of the shoulder have been documented. However, careful corrections for the weight of the limb (gravity effects) are necessary to arrive at an accurate relationship.[136-139] If gravity corrections are not utilized, the muscles assisted by gravity will exhibit erroneously high torque values, whereas the muscles that resist gravity will exhibit erroneously low torque values.

It has been suggested that submaximal patient effort can be detected by the increased variability of repeated measures of peak torque, average torque, and slope to peak torque in isometric and concentric contractions.[140-142] However, research in this area has produced conflicting findings and demonstrated large errors in classifying effort into maximal and submaximal categories.[138,143-145] Many factors such as patient pain, fear, or fatigue, and damp settings, preload forces, mechanical artifact, and acceleration and deceleration ramping can affect the variability of torque measurements. The use of isokinetic dynamometer records to form clinical opinions of patient effort is not advised.

To ensure the validity of isokinetic dynamometry measurements, calibration of the equipment is necessary and should be performed each day of testing, at the same speed and damp setting to be used during testing.[138] Proper alignment of joint axis and machine axis, stabilization of proximal body parts, and gravity correction are needed. Several practice trials of the motion to acquaint the patient with the equipment and testing protocol is helpful, and at least one to three maximal test repetitions should be performed before recording measurements.[146,147] It is important to note that torque values will vary with type of muscle contractions (isometric, concentric, eccentric) and changes in velocity settings, joint angle, patient position, test trials, rest intervals, patient feedback, and preload, damp, and ramping machine settings. For example, isometric contractions will result in higher torque values than concentric contractions in the same muscle group, whereas eccentric contractions will result in higher torque values than isometric contractions. Faster velocity settings during concentric contractions will result in lower torque values than slower velocity settings. All of these factors must be kept constant in order to effectively use repeat testing data to judge patient progress. Keating and Matyas,[148] Rothstein et al,[138] Davies et al,[149] and Gaines and Talbot[150] have presented information to improve the validity and reliability of isokinetic testing. Peak torque and work measurements in a variety of healthy and patient populations have shown good to excellent reliability for concentric contractions, and poor to good reliability for eccentric contractions.[146,151-161] Reciprocal (agonist–antagonist) ratios have shown less reliability than peak torque measurements.[161]

Normative data on adults[161-168] and children[169-174] can provide a reference for evaluating and interpreting patient data. However, comparisons with published data are appropriate only when identical procedures and equipment are used, and tested populations are similar. Patient age, gender, weight, height, and athletic participation can affect recorded values. Out of necessity, the involved extremity is often compared to the contralateral extremity. Generally, studies have found no statistically significant difference between dominant and nondominant sides in torque measurements for muscles surrounding the knee joint,[165,169,175-177] elbow,[170,174] and shoulder.[170,178] Alternatively, some studies have found differences due to side dominance for certain motions at the elbow and shoulder especially in highly skilled male athletes.[174,179-182] A difference of at least 10% in torque values between opposing sides of the body has been suggested as an indicator of impairment.[183,184] Others have noted imbalances of more than 10% between sides of the body in healthy populations. Further research is needed to establish the magnitude of difference between opposite limbs that would indicate impairment. At the present time it seems appropriate to use the guidelines provided by Sapega,[117] suggesting that a difference in muscle force between sides of greater than 20% *probably* indicates abnormality, whereas a difference of 10% to 20% *possibly* indicates abnormality.

Special Tests

After completing the patient interview, observation, palpation, and examination of ROM, accessory motions, and muscle performance, the therapist may suspect the nature of the pathology. Special tests, designed to focus on specific conditions in a particular region of the body, may be helpful in confirming the diagnosis. A therapist would ordinarily choose to perform only those tests indicated by previous findings that are relevant to the area of the body being examined. False-positive and false-negative results are possible. However, a positive test finding in conjunction with other aspects of the examination would be highly suggestive of pathology. There are many special tests presented in the work of Hoppenfeld,[3] Magee,[2] Starky et al,[5] and Konin et al.[185]

One category of special tests is used to determine the integrity of ligaments in supporting a joint. The therapist performs these **ligamentous instability tests**, also called *ligament stress tests,* on a relaxed, passive joint. These maneuvers are often similar to tests of accessory or joint play motions. Although these tests focus on ligament integrity, capsular integrity as well as dynamic muscle support may influence the results. If possible, results should be compared with those from the uninvolved, contralateral joint. The amount of laxity is usually graded from I to IV (Table 4.7).[186] Examples of ligamentous instability tests include the *Lachman test,* which examines injury to the anterior cruciate ligament; the *posterior drawer test,* which examines damage to the posterior cruciate ligament of the knee; and the *varus and valgus stress tests,* which examine the integrity of collateral ligaments at the elbow and knee.[2,3]

In addition to ligament instability tests, there are more general tests that examine joint subluxation and dislocation. These tests are often called **apprehension tests** because the patient is placed in a vulnerable joint position while being monitored for apprehension. For example, to test for a history of an anterior subluxation or dislocation of the glenohumeral joint, the shoulder is positioned in 90° of abduction and moved toward external rotation. These provocative tests are considered positive and should be stopped if they begin to elicit patient discomfort.

Table 4.7 Grading of Ligamentous Instability Tests

Grades	Amount of Movement
I	0–5 mm
II	6–10 mm
III	11–15 mm
IV	>15 mm

The length of muscles that cross and act at one joint can usually be examined in the process of testing PROM. However, some muscles cross and act at two or more joints. Some special tests examine the length of these multi-joint muscles. The *Thomas test*,[34,88] which examines the length of one and two joint hip flexors; the *Ober test*,[34,88] which focuses on the length of the tensor fascia lata; and the *Bunnel-Littler test*,[3] which determines the role of the lumbricles, interossei, extensor digitorum, and joint capsule in limited flexion of the proximal interphalangeal joints of the hand, are examples of special muscle length tests.

Numerous special tests address common conditions affecting the integrity of muscle and tendon structures. These tests typically stretch or contract the inflamed or injured structure, resulting in pain if the tests are positive. For example, the *Finkelstein test*[3] is used to examine inflammation of the tendons of the abductor pollicis longus and extensor pollicis brevis by stretching these structures over the wrist and thumb. The *tennis elbow test*[3] has the patient isometrically contract the extensor carpi radialis muscles against manual resistance. Often the therapist will have previously noted pain, limitation, and possibly weakness during tests for ROM and muscle performance; special tests are used to clarify these earlier findings.

Another category of special tests reproduces the symptoms caused by irritation, compression, or restricted mobility of peripheral nerves. For example, the *Tinnel test* that involves manual tapping over superficial nerve sites is positive for nerve irritation and possible neuroma when pain, numbness, burning, or tingling sensations are elicited. The *Phalen test* for carpal tunnel syndrome places the wrist in full flexion for 60 to 90 seconds to reproduce pain and paresthesia due to compression of the median nerve by the transverse carpal ligament.[2,3] Neurodynamic tests utilize sequential positioning of two or more joints to lengthen and mobilize neural tissue independent from surrounding non-neural structures.[186-188] The ability to complete the sequence of joint positions is compared to the uninvolved side. Once symptoms are provoked, the examiner moves one of the joints out of the nerve lengthening position to determine if the symptoms are relieved and confirm the involvement of neural tissue. However, before conducting neurodynamic testing all joints in the sequence should be tested and cleared for joint and non-neural soft tissue limitations so as not to confound the results.[189] An example of a neurodynamic test is the *slump test* which requires the sequential motions of thoracic, lumbar, and cervical spine flexion, hip flexion, ankle dorsiflexion, and knee extension to assess the mechanosensitivity of the spinal cord, cervical and lumbar nerve roots, and sciatic nerve.[2,80,186] Additional neurodynamic tests have been developed to test the sciatic, femoral, obturator, and peroneal nerves in the LE, and median, radial, and ulnar nerves in the UE.[2,80,186,187,189-192]

In addition to palpating for the quality of arterial blood flow at the brachial, radial, femoral, popliteal, tibial, and dorsalis pedius pulses, special tests can be performed to examine the peripheral circulation of particular body regions. For example, the *Allen test* examines blood flow from the radial and ulnar arteries to the hand.[2,3] *Homan's sign* utilizes ankle dorsiflexion, knee extension, and deep palpation to elicit calf pain, which would be suggestive of deep vein thrombophlebitis; however diagnostic reliability is limited.[2,3]

Additional Tests and Measurements

Depending on findings, other tests and measurements may be indicated. Many of these additional examination procedures are discussed in detail in other chapters of this book. For example, patient complaints of paresthesia or difficulty in muscle performance often indicate neurological involvement that calls for testing of superficial, deep, and proprioceptive sensations (see Chapter 3, Examination of Sensory Function), reflexes and motor tone (see Chapter 5, Examination of Motor Function: Motor Control and Motor Learning), and coordination and balance (see Chapter 6, Examination of Coordination and Balance). Data from these tests together with muscle performance results help to identify conditions affecting peripheral nerves, spinal nerve roots, and the CNS. Therapists must distinguish peripheral nerve versus nerve root patterns of sensory and motor innervation. Manual muscles testing textbooks, such as those by Kendall et al[88] and Hislop and Montgomery,[87] provide extensive information on innervation patterns. Figure 4.21 presents muscle testing recording forms that are helpful in recognizing impaired innervation patterns. Myotomes that are often included as parts of a musculoskeletal examination are shown in Table 4.8, and deep tendon reflexes are presented in Chapter 5, Examination of Motor Function: Motor Control and Motor Learning. Upper motor neuron lesions usually result in hyperreflexia, whereas lower motor neuron lesions involving the spinal nerve root or peripheral nerves usually cause hyporeflexia of deep tendon reflexes.

Impairments in ROM, accessory joint motions, and motor performance may affect activities of daily living (ADL) and occupational and recreational activities. In such cases the examination of gait (see Chapter 7, Examination of Gait), functional abilities (see Chapter 8, Examination of Function), and environmental surroundings (see Chapter 9, Examination of the Environment) is often appropriate. Sometimes findings indicate the need for additional testing by other health professionals such as physician specialists, psychologists, speech-language pathologists, and occupational therapists.

EVALUATION OF EXAMINATION FINDINGS

At the conclusion of the musculoskeletal examination, all pertinent historical, subjective, and physical findings are evaluated to establish a physical therapy diagnosis on which treatment is based. A *diagnosis* has been defined

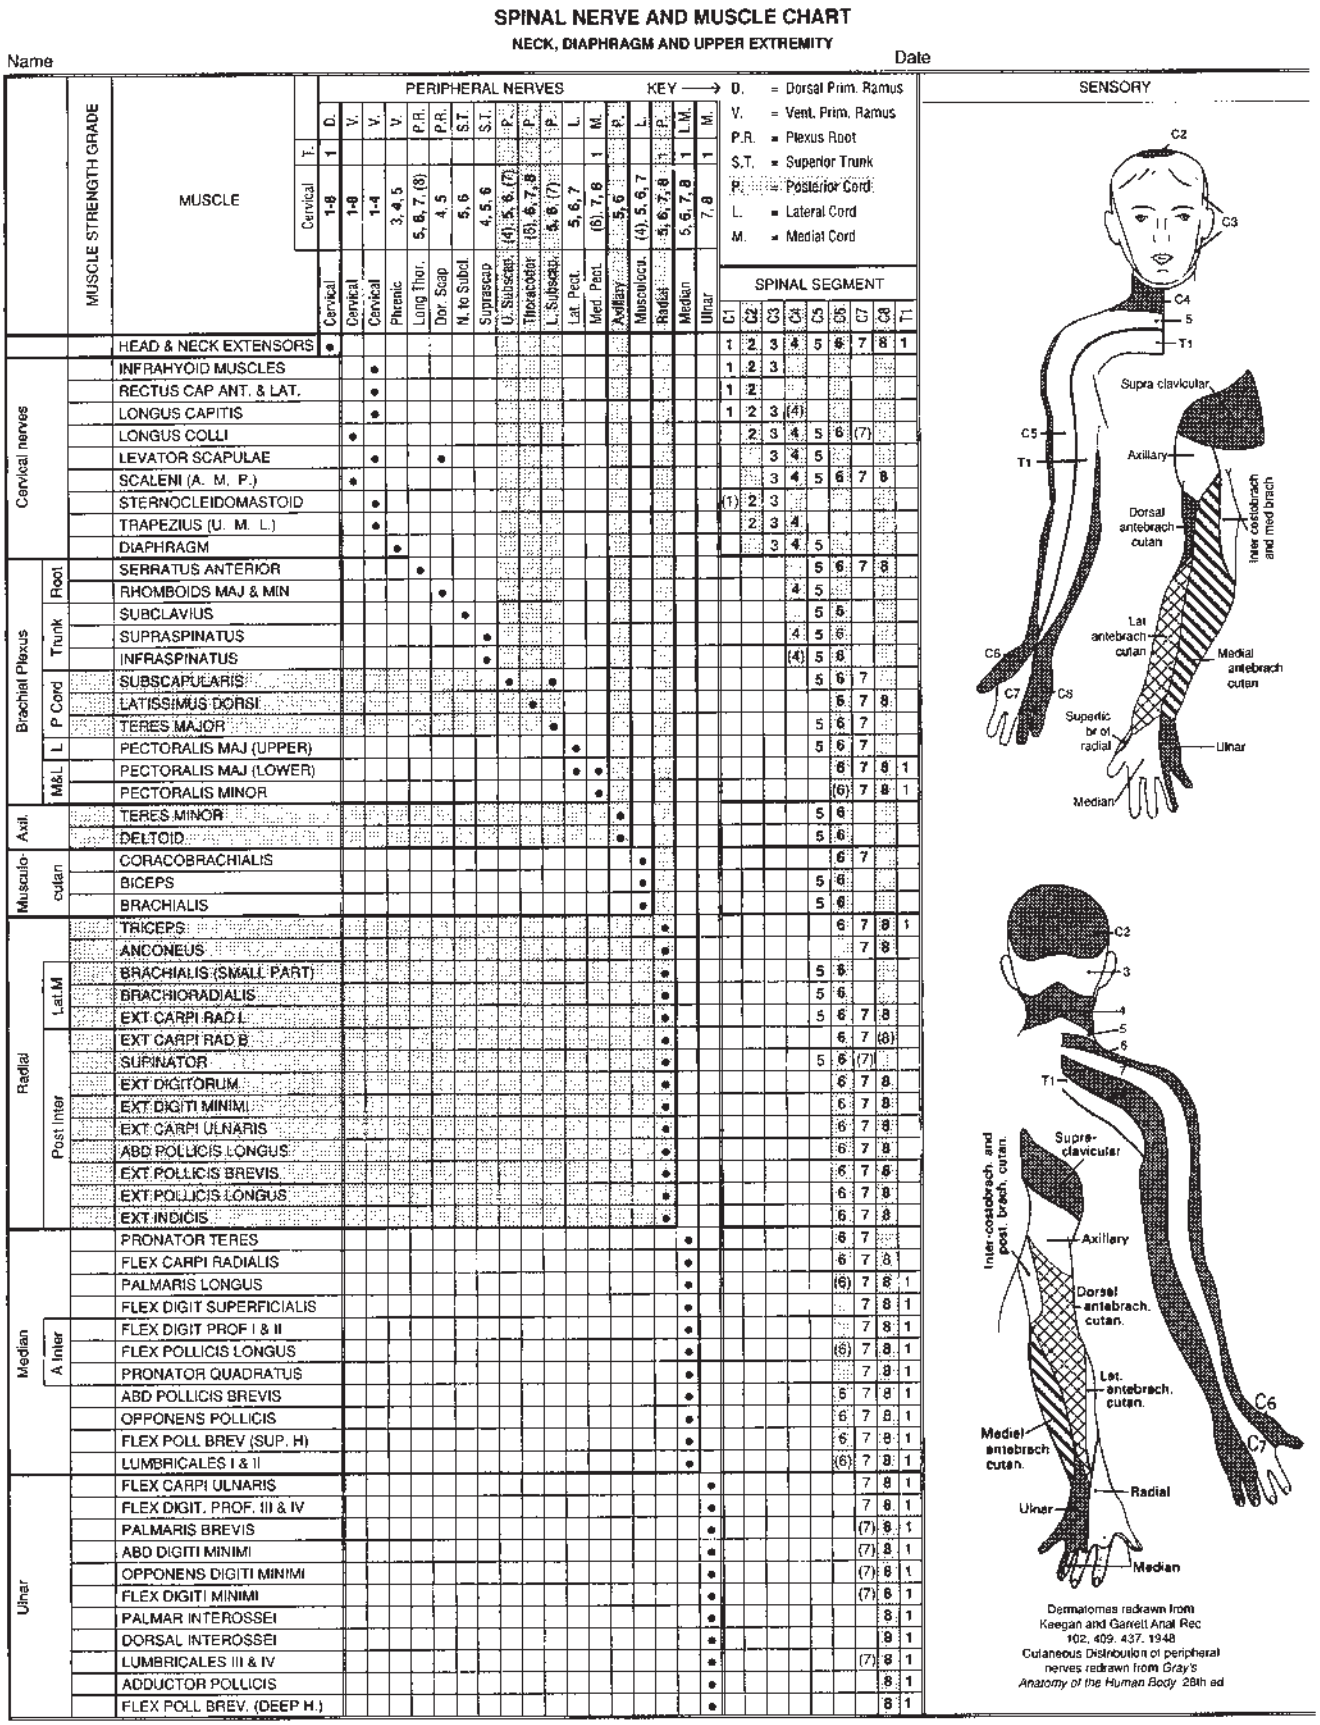

Figure 4.21 Manual muscle testing recording forms that aids in determining the site or level of a nerve lesion. *(From Kendall et al,[88] with permission.)*

Table 4.8 Myotomes[2,3]

Level	Upper Quarter Myotomes	
	Action to Be Tested	*Muscle*
C5	Shoulder abduction, shoulder flexion	Deltoid
C5, C6	Elbow flexion	Biceps
	Wrist extension	Extensor carpi radialis longus Extensor carpi radialis brevis
C7	Elbow extension	Triceps
	Wrist flexion	Flexor carpi radialis Flexor carpi ulnaris
C8	Ulnar deviation	Flexor carpi ulnaris Extensor carpi ulnaris
T1	Digit abduction/adduction	Interossei
Level	**Lower Quarter Myotomes**	
	Action to Be Tested	*Muscle*
L2, L3	Hip flexion	Iliopsoas
L2, L3, L4	Knee extension	Quadriceps
L4	Ankle dorsiflexion	Anterior tibialis
L5	Extension of great toe	Extensor hallicus longus
S1	Plantarflexion	Gastrocnemius
	Ankle eversion	Peroneus longus Peroneus brevis

as a label encompassing a cluster of signs and symptoms, syndromes, or categories.[6] The specific tissues causing the impairments should be identified so that treatment can be focused and effective. The therapist must have a thorough understanding of the pathologies commonly affecting the body segment under consideration. The symptoms and clinical manifestations of these pathologies are compared to the current examination findings to establish a diagnosis. Musculoskeletal Practice Patterns listed in the *Guide to Physical Therapist Practice*[6] can assist in categorizing diagnoses into common clusters, and provide information on prognosis, anticipated goals and expected outcomes, POC, and intervention strategies (see Appendix A in Chapter 1, Clinical Decision Making).

Sometimes the evaluation process does not yield a clearly identifiable diagnosis. In such cases, a provisional diagnosis and the alleviation of symptoms and impairments become the basis for treatment. In other instances, the evaluation may indicate the presence of two or more conditions. The therapist should then prioritize and focus initially on the condition causing the most serious impairments, activity limitations, and disability.

The evaluation should clearly determine the baseline for the patient's symptoms, impairments, activity limitations, and participation restrictions. This information becomes the basis of the clinical problem list and guides development of anticipated goals and expected outcomes. The results of future examinations can be compared to this baseline to evaluate the effectiveness of treatment.

In addition to establishing a diagnosis and baseline data, the evaluation of findings should ascertain etiological factors. Unless the underlying causes of the condition are recognized and treated, chronic problems can be expected.[1] The therapist must not only direct attention to the specifically involved tissues, but must also think more broadly of physiological units of function and biomechanics. For example, a patient with a sprain of the medial collateral ligament of the knee may initially respond well to treatment consisting of compression elastic wrapping, ice, elevation, reduced activity, and a protective non–weight-bearing crutch gait. However, if the condition is partially due to abnormal foot pronation, the resumption of normal weight-bearing activities may cause reinjury unless the alignment of the foot and leg is improved with orthotics. Similarly, a patient with supraspinatus tendinitis may react well to rest, modalities applied to the tendon, and gentle glenohumeral ROM exercises, but often also requires eventual strengthening of the rotator cuff, middle and lower trapezius, and serratus anterior muscles, as well as lengthening of the posterior and inferior glenohumeral capsule to restore normal scapulohumeral rhythm and prevent

recurrent subacromial impingement of the supraspinatus tendon.

Other information that affects the prognosis and course of treatment should be determined during the evaluation process. The mode and mechanism of onset must be established. Was the onset sudden, gradually acquired, or congenital? Generally, the prognosis is better for a condition caused by a well-defined event than for a congenital condition or one with an insidious, gradual onset. The mode and mechanism of onset also provide clues to help develop strategies for prevention of reoccurring episodes of the injury or condition.

Finally, an analysis of the examination findings should establish the stage of the patient's condition. The stage, whether acute, subacute, or chronic, can indicate how well the patient will tolerate mechanical loads such as those imposed by daily activities or by a therapist during treatment. The **acute stage** is usually defined as occurring up to the first 48 to 72 hours after onset. The **subacute stage** may continue up to 2 weeks to several months after onset. Typically, conditions are considered in the **chronic stage** after 3 to 6 months. Another way of defining the stages, which is probably more relevant to treatment planning, focuses on tissue inflammation and the repair process.[1] Conditions in an *acute inflammation stage* will show signs and symptoms of inflammation associated with hyperemia, increased capillary permeability with protein and plasma leakage, and an influx of granulocytes and other defensive cells. These signs and symptoms include swelling, elevated skin temperature at the lesion site, and pain at rest that worsens with ROM and resisted isometric contractions that even minimally stress the involved tissues. The *chronic inflammation stage* produces signs and symptoms associated with attempts at tissue repair, including an increase in the number of fibrocytes and the presence of granulation tissue; the patient will now have minimal or no swelling and elevated temperature at the lesion site. Pain tends to occur only at the extremes of ROM when the end-feel is reached, or with a moderate to maximal amount of isometric resistance. Tissues in an acute stage will often not tolerate mechanical loading from daily, recreational, occupational, or therapeutic activities. The force, frequency, and duration of treatment procedures must be monitored closely so as not to increase inflammation and worsen the condition. In contrast, tissues in the chronic stage will usually tolerate and require treatment procedures involving more mechanical loading, frequency, and duration to effect positive changes in the tissues. The stage of the condition also adds prognostic information. Typically, an acute condition will show more spontaneous improvement over a shorter period of time than a chronic condition. A chronic condition usually requires a longer period of treatment to promote a smaller improvement in status.

SUMMARY

The musculoskeletal examination provides important information concerning the status of bones, articular cartilage, joint capsules, ligaments, and muscles. The examination process begins with a review of the patient's medical records and a detailed interview. Careful observation, palpation, and ROM, accessory joint motion, and muscle performance tests are typically performed. Depending on the findings, special tests particular to the body region under examination may need to be included. Examination of the peripheral and central nervous systems, gait, functional ability, and the environment is often required. At the conclusion of this process, all findings must be evaluated to determine the diagnosis, baseline status, etiological factors, mode of onset, and stage (acute, subacute, or chronic) of the condition. At this point the prognosis, anticipated goals, expected outcomes, and plan of care can be developed.

Questions for Review

1. What are the purposes of a musculoskeletal examination?
2. What information about the patient's symptoms should be obtained during a patient interview?
3. What are the three types of normal end-feels? What types of tissue contribute to these end-feels?
4. Compare capsular versus noncapsular patterns of restricted motion.
5. Give at least three examples of osteokinematic and arthrokinematic motions. How do arthrokinematic motions combine to produce osteokinematic motion in a typical synovial joint in which the moving joint surface is concave? Convex?
6. Distinguish between muscle performance, strength, endurance, work, and power.
7. Discuss the implications of a finding of *pain* versus *no pain*, and *strong* versus *weak* during the performance of resisted isometric testing.

8. What three factors are important in determining manual muscle testing grades? What would be the criteria for manual muscle testing grades of *Good*, *Fair,* and *Poor*?
9. What are the advantages and disadvantages of using manual muscle testing, handheld dynamometers, and isokinetic dynamometers to determine muscle strength?
10. What would a positive finding on an apprehension test indicate?
11. What summary information should be determined from evaluation of the musculoskeletal examination findings to develop a clinical problem list, goals, expected outcomes, prognosis, and plan of care?

CASE STUDY 1

A 45-year-old man enters the outpatient physical therapy department with a complaint of right shoulder pain of 1 week's duration. The pain began Monday morning following a weekend of scraping and painting his house. The patient describes his pain as aching and troublesome; his pain is a 6 on a pain scale of 0 to 10. He reports that he is married, and having difficulty in home maintenance activities such as lawn mowing. He is able to perform only 30% of his normal home and recreational activities. The therapist decides to conduct a musculoskeletal examination.

While palpating the shoulder region, increased tenderness and skin temperature in the region of the bicipital groove of the right anterior shoulder is noted. Active ROM of the right shoulder reveals increased pain and some limitations during shoulder flexion, abduction, and extension; all other active motions are pain free and within normal ROM limits. Passive shoulder motions are pain free with normal ROM, except for shoulder extension, which is limited and causes an increase in pain toward the end of motion.

GUIDING QUESTIONS

1. What additional information should be gathered during the interview?
2. What is a capsular pattern of limitation? Does this patient have a capsular pattern of limitation for the glenohumeral joint?
3. The therapist suspects the presence of bicipital tendinitis. Do the findings during testing of active and passive ROM support this diagnosis? Explain.
4. What additional tests should be performed to selectively examine contractile tissue and help to support or repudiate the diagnosis of bicipital tendinitis? Provide a rationale for your selection.

CASE STUDY 2

A 14-year-old girl is referred for outpatient physical therapy 12 weeks after sustaining midshaft fractures of her left tibia and fibula from a bicycle accident. Her long leg cast was removed yesterday. The fracture is well healed. The patient reports her left knee and ankle are stiff and painful when she tries to bend them. She also describes her left leg as weak. At this time she is ambulating with two crutches, weight-bearing as tolerated, with hopes of progressing off the crutches as soon as possible.

GUIDING QUESTIONS

1. On observation, the patient's left thigh and calf appear to be thinner than the right. How can this observation be objectively measured and documented? Why might the patient's left leg be thinner than the right?
2. Passive ROM for left knee flexion is 10° to 70°. The end-feel for left knee flexion is firm. What is an end-feel? What are the three general types of normal end-feels? What tissues could be causing a firm end-feel for knee flexion in this patient?
3. What accessory joint motion should be examined considering the limitation in passive knee flexion ROM? Apply the concave–convex rules for determining the direction of the glide given the shape of the joint surfaces. The accessory joint motion was found to be very hypomobile. What grade should the accessory joint motion be given?
4. In addition to observing, palpating, and testing active ROM, passive ROM, accessory joint motions, and muscle performance, what other testing procedures would be important to include in the examination of this patient?

Examination of Motor Function: Motor Control and Motor Learning

Susan B. O'Sullivan, PT, EdD
Leslie G. Portney, PT, DPT, PhD, FAPTA

Chapter 5

LEARNING OBJECTIVES

1. Identify the purposes and components of the examination of motor function: motor control and motor learning.
2. Describe the examination process and specific tests and measures of various components of motor function.
3. Discuss the implications of common deficits associated with disorders of motor function for goal setting and treatment planning.
4. Discuss factors that influence the complexity of the motor examination and evaluation process.
5. Describe the instrumentations systems and general methodology used to perform an electromyography (EMG) and nerve conduction velocity (NCV) examination.
6. Describe the characteristics of normal and abnormal EMG and NCV findings.
7. Discuss the implications of clinical EMG and NCV findings for goal setting and treatment planning.
8. Discuss factors that influence determination of the physical therapy diagnosis with disorders of motor function.
9. Analyze and interpret patient data, formulate realistic anticipated goals and expected outcomes, and identify appropriate interventions when presented with a clinical case study.

SUMMARY *201*

OVERVIEW OF MOTOR FUNCTION

Motor control evolves from a complex set of neural, physical, and behavioral processes that govern posture and movement. Some movements have a genetic basis and emerge through processes of normal growth and development. Examples of these include the largely reactive reflex patterns that predominate during much of early life and in some patients with brain damage. Other movements, termed *motor skills*, are learned through interaction and exploration of the environment. Practice and feedback are important variables in defining motor

learning and motor skill development. Sensory information about movement is used to guide and shape the development of motor programs. A **motor program** is defined as "an abstract representation that, when initiated, results in the production of a coordinated movement sequence."[1, p. 497] Examples include the complex neural circuitry in the spinal cord known as central pattern generators (CPGs) that control locomotion and gait. Higher-level motor programs can be viewed as abstract rules or code for coordinated actions that are stored (*generalized motor programs [GMPs]*). GMPs contain information about the order of events, the timing of events (temporal structure), the overall force of contractions, and the muscle(s) or limb(s) used in the movements.[1] Sensory feedback from the responding limbs, as well as from the environment, modifies the resulting movements.[1] A **motor plan** (*complex motor program*) is an idea or plan for purposeful movement that is made up of several component motor programs. **Motor memory** (*procedural memory*) involves the recall of motor programs or subroutines and includes information on (1) initial movement conditions; (2) how the movement felt, looked, and sounded (sensory consequences); (3) specific movement parameters (knowledge of performance); and (4) outcome of the movement (knowledge of results).

The cooperative actions of multiple systems allow for accommodation of movement to match the specific demands of the task and the environment. This is defined by *systems theory,* a distributed model of motor control. The central concept is that many systems interact to produce coordinated movement, not just the nervous system. For example, mechanical factors of the musculoskeletal system (body mass, inertia, and gravity) contribute to the overall quality of the movement produced. Cognition (attention, memory, learning, judgment, and decision making) and perception (interpretation of sensation) are also critical. Impairments in any of these interacting systems can significantly alter the quality of the movement produced and the level of function achieved.[2] Another concept is that units of the central nervous system (CNS) are organized around specific task demands (termed *task systems*). The entire CNS may be necessary for complex tasks, whereas only small portions may be needed for simple tasks. Command levels vary depending on the specific task executed. Thus, the highest level of command may not be required in the execution of some simple movements.[2,3] Lateral pathways are involved in voluntary movement of distal musculature and are under direct cortical control (i.e., corticospinal and rubrospinal tracts). Ventromedial pathways are involved in control of posture and locomotion and are under brainstem control (i.e., vestibulospinal tracts, tectospinal tract, and pontine and medullary reticulospinal tracts). The neurons of the ventral horn of the spinal cord are the final common pathway to engage the peripheral muscles for function.

Motor skills are acquired and modified by actions of the CNS through processes of motor learning. **Motor learning** is defined as "a set of internal processes associated with practice or experience leading to relatively permanent changes in the capability for skilled behavior."[1, p. 497] The CNS organizes and integrates vast amounts of sensory information. **Feedback** is response-produced information received during or after the movement and is used to monitor output for corrective actions. **Feedforward**, the sending of signals in advance of movement to ready the sensorimotor systems, allows for anticipatory adjustments in postural activity. Processing of information by the CNS is both serial and parallel, leading to the production of coordinated movement. **Coordination** is the ability to execute smooth, accurate, and controlled motor responses. **Coordinative structures** (synergistic units) are the functionally specific units of muscles that are constrained by the nervous system to act cooperatively to produce relatively stable movement patterns but are scaled to the environment.[1]

Recovery of function is the reacquisition of movement skills lost through injury. The movements recovered may be performed exactly as before. In the patient with neurological damage, it is more often the case that the movements are modified and not performed exactly as before. A determination then needs to be made as to whether the movements are of sufficient quality and efficiency to permit return of function (e.g., the patient with stroke learns to dress using the involved upper extremity [UE]). **Compensation** refers to the adoption of alternative behavioral strategies to complete a task. Movements utilize different muscles and strategies to substitute for the loss function (e.g., the patient with stroke dresses using the less involved UE). The term **neuroplasticity** refers to the ability of the brain to change and repair itself. Neuroplasticity includes "a continuum from short-term changes in the efficiency or strength of synaptic connections to long-term structural changes in the organization and numbers of connections among neurons."[2, p. 84] As learning progresses there is a shift from short-term to long-term memory processes. Memory allows for continued access of this information for repeat performance or modification of existing patterns of movement.

Damage to the CNS interferes with motor function processes. Lesions affecting areas of the CNS can produce specific, recognizable deficits that are consistent among patients (e.g., patients with upper motor neuron syndrome). Individual differences in neural plasticity, recovery, and functional outcomes can be expected. In conditions with widespread damage to the CNS (e.g., traumatic brain injury [TBI]) the resultant problems in motor function are numerous, complex, and difficult to delineate. An accurate picture of the scope of deficits may not be readily apparent on initial examination. A process of reexamination over time will generally yield an understanding of the patient's performance

capabilities and deficits. The comprehensive examination focuses on delineation of impairments, activity limitations, and participation restrictions. Those impairments that directly affect motor function and motor learning should be clearly identified. Anticipated goals, expected outcomes, and plan of care (POC) can then be effectively developed.

This chapter will review essential components of examination, factors that may constrain the motor function examination (preliminary examinations), and elements of the motor function examination (with the exception of the examination of coordination and balance, which is discussed in Chapter 6, Examination of Coordination and Balance). Required elements of motor learning and examination are also discussed.

COMPONENTS OF THE EXAMINATION

An examination of motor function involves three components: (1) patient history, (2) a review of relevant systems, and (3) specific tests and measures that allow formulation of the diagnosis, prognosis, and POC.[4]

Patient History

During the patient/client history, information is gathered on (1) general demographics; (2) social history; (3) employment/work (job/school/play); (4) living environment; (5) general health status; (6) social/health habits; (7) family history; (8) medical/surgical history; (9) current condition(s)/chief complaint(s); (10) functional status and activity level; (11) medications; and (12) other clinical tests. Information is obtained from the patient and other interested persons (family members, significant others, and caregivers). If the patient is unable to communicate accurate and meaningful information, as is frequently the case with injury to the brain, data must be gathered from other sources (e.g., family members, caregivers). A review of the medical record can be used to verify and triangulate data obtained from personal communications. Often, the medical record of a patient with pronounced deficits in motor function (e.g., the patient with traumatic brain injury [TBI]) is filled with extensive volumes of data that can be unwieldy and difficult to sort through. The therapist can benefit from the application of a framework to identify and classify problems. The International Classification of Functioning, Disability and Health (ICF) model,[5] focusing on impairments, activity limitations, and participation restrictions, provides a useful framework and is discussed fully in Chapter 1, Clinical Decision Making.

Systems Review

A systems review serves the purpose of a screening examination; that is, a brief or limited examination of body systems. The physical therapist can then use this information to identify potential problems that will require more extensive testing. For example, screening examinations for posture and tone may reveal significant impairments. More detailed tests and measures are then required to delineate the exact nature of the problems uncovered. Sometimes screening examinations reveal problems in communication and/or cognition that preclude further testing. For example, a patient with stroke and severe communication and cognitive impairments will be unable to follow directions and cooperate with many individual tests of physical function. The therapist will document this in the medical record as *unable to test at the present time due to severe communication/cognitive deficits.*

Tests and Measures

Specific parameters of dyscontrol should be closely examined using appropriate tests and measures. If the test accurately measures the parameter of performance being examined, it is said to have **validity**. Validity can be established through construct, content, and criterion-based validity (concurrent, predictive, and prescriptive). The **reliability** of an instrument is reflected in the consistency of results obtained by a single examiner over repeat trials (intrarater reliability) or among multiple examiners (interrater reliability). **Sensitivity** refers to the proportion of times that a method of analysis correctly identifies an abnormality as being present (true positive). **Specificity** refers to the proportion of times that a method of analysis correctly identifies an abnormality as being absent (true negative). Therapists should select standardized methods and instruments with established validity and reliability, consistent with the American Physical Therapy Association's goal of evidence-based practice (EBP).

An examination of motor function is a multifaceted process that requires a number of different specific tests and measures. Instruments can be qualitative, utilizing observations of complex aspects of performance. Insights and understanding of patterns of movement or postures are developed from inductive reasoning (formulating generalizations from specific observations). The experienced therapist or expert clinician is far more efficient in reaching decisions about qualitative performance than the novice therapist. Quantitative instruments use objective measurement as a way of examining performance. Documentation constraints imposed by the health care system and third-party payers increasingly emphasize objective instruments as proof of the need for services and the effectiveness of services. However, many aspects of motor function are not easily measured. For example, motor learning is not directly measurable but rather is inferred from measures of performance, retention, generalizability, and adaptability. Thus, these constructs are used to infer changes in the CNS that occur with learning. The therapist must be sensitive to the nature of the variables being examined and identify appropriate measures that provide a meaningful analysis

of patient function. It is not likely that any one measure will provide all of the data needed for the examination of motor function.

Reexaminations are performed to determine if goals and outcomes are being met and if the patient is benefiting from the plan of care (POC). Interventions can then be modified or redirected as appropriate. Successful achievement of anticipated goals and expected outcomes is an indication for discharge and referral for follow-up or additional services. Reexamination is also an important quality assurance measure.

FACTORS THAT MAY CONSTRAIN THE MOTOR FUNCTION EXAMINATION

Patients who sustain brain damage either through trauma or disease may present with a number of cognitive, perceptual, or communication deficits that can significantly affect how they experience the environment and interact with others. Impairments in sensation and sensory integrity can also profoundly influence a patient's movement responses. It is important to understand how the examination of motor function can be influenced by these factors. Using tests and directions that confuse a patient during an examination or are clearly beyond the capabilities of the patient will only yield inaccurate information about a patient's movement behaviors.

Consciousness and Arousal

Examination of consciousness and arousal is important in determining the degree to which an individual is able to respond. The *ascending reticular activating system* (ARAS) includes core neurons in the brainstem, the locus coeruleus, and raphe nuclei that synapse directly on the thalamus, cortex, and other brain regions. It functions to arouse and awaken the brain and control sleep–wake cycles. High levels of activity are associated with extreme excitement (high arousal), whereas lesions in the brainstem are associated with sleep and coma. The *descending reticular activating system (DRAS)* is composed of the pontine and medullary reticulospinal tracts. The pontine (medial) reticulospinal tract enhances spinal cord antigravity reflexes and extensor tone of lower limbs. The medullary (lateral) reticulospinal tract has the opposite effect, reducing antigravity control.[6]

Five different levels of consciousness have been identified. **Consciousness** refers to a state of arousal accompanied by awareness of one's environment. A conscious patient is awake, alert, and oriented to his or her surroundings. **Lethargy** refers to altered consciousness in which a person's level of arousal is diminished. The lethargic patient appears drowsy but when questioned can open the eyes and respond briefly. The patient easily falls asleep if not continually stimulated and does not fully appreciate the environment. Attempts to communicate with the patient are difficult owing to deficits in maintaining focus. The therapist should speak in a loud voice while calling the patient's name. Questions should be simple and directed toward the individual (e.g., How are you feeling?). **Obtunded state** refers to diminished arousal and awareness. The obtunded patient is difficult to arouse from sleeping and once aroused, appears confused. Attempts to interact with the patient are generally nonproductive. The patient responds slowly and demonstrates little interest in or awareness of the environment. The therapist should shake the patient gently as if awakening someone from sleep and again use simple questions. **Stupor** refers to a state of altered mental status and responsiveness to one's environment. The patient can be aroused only with vigorous or unpleasant stimuli (e.g., painful stimuli such as flexion of the great toe, sharp pressure or pinch, or rolling a pencil across the nail bed). The patient demonstrates little in the way of voluntary verbal or motor responses. Mass movement responses may be observed in response to painful stimuli or loud noises. The unconscious patient is said to be in a **coma** and cannot be aroused. The eyes remain closed and there are no sleep–wake cycles. The patient does not respond to repeated painful stimuli and may be ventilator dependent. Reflex reactions may or may not be seen, depending on the location of the lesion(s) within the CNS.[7]

Clinically the patient can progress from one level of consciousness to another. For example, with an intracranial bleed, the swelling and mass effect compresses the brain, resulting in decreasing levels of consciousness. The patient progresses from consciousness, to lethargy, to stupor, and finally to coma. If medical interventions are successful, recovery is evidenced by a reverse progression. True coma is generally time limited. Patients emerge into a *minimally conscious (vegetative) state,* characterized by return of irregular sleep–wake cycles and normalization of the so-called vegetative functions—respiration, digestion, and blood pressure control. The patient may be aroused, but remains unaware of his or her environment. There is no purposeful attention or cognitive responsiveness. The term *persistent vegetative state* is used to describe individuals who remain in a vegetative state 1 year or longer after TBI and 3 months or more for anoxic brain injury. This state is caused by severe brain injury.

The *Glasgow Coma Scale (GCS)* is a gold standard instrument used to document level of consciousness in acute brain injury. Three areas of function are examined: eye opening, best motor response, and verbal response. Total GCS scores range from a low of 3 to a high of 15. A total score of 8 or less is indicative of severe brain injury and coma, a score between 9 and 12 is indicative of moderate brain injury, and a score from 13 to 15 is indicative of mild brain injury.[8] The Rancho Los Amigos Scale, or Levels of Cognitive Functioning (LOCF), is widely used in rehabilitation

facilities to examine the return of the person with brain injury from coma (Level I, no response) to consciousness (Level VIII, Purposeful–Appropriate). Different levels of behavioral function are described (e.g., confused states, automatic states).[9] See Chapter 19, Traumatic Brain Injury, for a complete discussion of both these instruments.

Examination of the pupillary size and reaction can also reveal important information about the unconscious patient. Pupils that are bilaterally small may be indicative of damage to the sympathetic pathways in the hypothalamus or metabolic encephalopathy. Pinpoint pupils are suggestive of a hemorrhagic pontine lesion or narcotic overdose (e.g., morphine, heroin). Pupils that are fixed in mid-position and slightly dilated are suggestive of midbrain damage, whereas large bilaterally fixed and dilated pupils suggest severe anoxia or drug toxicity (e.g., tricyclic antidepressants). If only one pupil is fixed and dilated, temporal lobe herniation with compression of the oculomotor nerve and midbrain is likely.[7]

Whereas an appropriate level of arousal allows for optimal motor performance, very low or high levels of arousal can cause deterioration in motor performance. This is referred to as the **inverted-U principle** (Yerkes-Dodson law).[10,11] Patients at either end of the arousal continuum (either very high or very low) may not respond at all or may respond in an unpredictable manner. This phenomenon may explain the reactions of patients with brain damage who are labile and lack homeostatic controls for normal function. Under conditions of severe stress, performance can become severely disrupted.

Therapists need to be cognizant of *autonomic nervous system (ANS)* responses. The ANS has two main divisions; the actions of the ANS are typically widespread with multiple systems engaged (Table 5.1) and two main divisions. The *sympathetic nervous system (SNS)* allows actions to be initiated to protect the individual during conditions of stress (*the alarm system*). Motor systems become engaged in carrying out defensive commands, producing *fight or flight responses* (e.g., the aroused patient with TBI may hit or bite). The *parasympathetic nervous system (PNS)* is activated continuously to maintain *homeostasis*. It shuts down when the SNS is activated and works to restore homeostasis afterward.[6]

Critical components for baseline examination include (1) a representative sampling of ANS responses, including heart rate (HR), blood pressure (BP), respiratory rate (RR), pupil dilation, and sweating; (2) a determination of patient reactivity, including the degree and rate of response to stimulation; and (3) a determination of physiological stressors (e.g., environmental factors). Careful monitoring during a motor performance examination assists in defining homeostatic stability. Specific guidelines for the examination of vital functions can be found in Chapter 2, Examination of Vital Signs.

Table 5.1 Effects of Autonomic Nervous System Stimulation

SNS Stimulation	PNS Stimulation
Fight or Flight Response	*Maintains Homeostasis*
Hypervigilance; increased awareness of environment	Decreased awareness of environment
Pupils dilate	Pupils constrict
Heart rate (HR) increases	Heart rate slows
Blood pressure (BP) increases	Blood pressure slows
Respiration increases and quickens	Respiration slows, becomes shallow
Blood flow to muscles increases; blood flow to skin and gastrointestinal track decreases	Blood flow returns to viscera/GI tract
Digestion slows; release of insulin and digestive enzymes slows	Digestion returns
Glucose production and release increases	
Activation of mass muscles	Relaxation of most muscle groups
Sweating increases	Sweating ceases

PNS = parasympathetic nervous system; SNS = sympathetic nervous system.

Autonomic dysregulation is characteristic of certain diseases and conditions and can be seen in patients with TBI, Parkinson's disease, multiple sclerosis (MS), and spinal cord injury (SCI) (particularly injury above T5). Examination of baseline ANS parameters should, therefore, precede other elements of the motor examination in the patient suspected of autonomic instability. Ongoing monitoring is also critical to ensuring that accurate data are collected, as well as to safeguard the patient.

Cognition

A screening examination of cognitive abilities should include orientation, attention, and memory; communication; and executive or higher-order cognition (e.g., calculating abilities, abstract thinking, constructional ability). Abnormalities can occur with neurological disease (e.g., frontal lobe disease, TBI) or psychiatric illness (e.g., panic attacks, depression following stroke). Impaired cognitive function deficits can range from orientation and memory deficits to poor judgment; distractibility; and difficulties in information processing, abstract reasoning, and learning, to name just a few.

Patients with deficits across many or all areas of cognitive function demonstrate diffuse or multifocal pathology (e.g., Alzheimer's disease, chronic brain syndrome). Patients with deficits in only one or a few areas of testing typically demonstrate focal deficits (e.g., stroke).[12] The physical therapist may be one of the first professionals to interact with the patient and should be able to screen for cognitive deficits and initiate appropriate referrals. A referral for a detailed examination by an occupational therapist and/or speech-language pathologist is typically necessary to obtain a complete and accurate picture of these deficits. The reader is referred to Chapter 27, Cognitive and Perceptual Dysfunction, and Chapter 28, Neurogenic Disorders of Speech and Language, for detailed descriptions of examination procedures and deficits.

Orientation

Orientation is the ability to comprehend and to adjust oneself with regard to time, location, and identity of persons. It is examined with respect to (1) *time* (What day/month/season/year is it? What is the time of day?); (2) *place* (Where are you? What city/state are we in? What is the name of this place?); and (3) *person* (What is your name? How old are you? Where were you born? What is the name of your wife/husband?). The therapist records the accuracy of the patient's responses. Findings are documented in the medical record as follows: Patient is alert and oriented × 3 (time, person, place) or × 2 (person, place) depending on the domains correctly identified. An additional domain that can be examined is *circumstance* (What happened to you? What kind of a place is this? Why do people come here?). To answer these last questions correctly, the individual must be able to take in, store, and recall new information. This may be severely disrupted in the patient with TBI. Disorientation is also common in the patient with delirium or advanced dementia.

Attention

Attention is the directing of consciousness to a person, thing, perception, or thought. It is dependent on the capacity of the brain to process information from the environment or from long-term memory. An individual with intact *selective attention* is able to screen and process relevant sensory information about both the task and the environment while screening out irrelevant information. The complexity and familiarity of the task determine the degree of attention required. If new or complex information is presented, concentration and effort are increased. Patients who are inattentive will have difficulty concentrating. Attention deficits are typically seen in individuals with delirium, brain injury, dementia, mental retardation, or performance anxiety.

Selective attention can be examined by asking the patient to attend to a particular task. For example, the therapist asks the patient to repeat a short list of numbers forward or backward (*digit span test*). The therapist documents the number of digits the patients is able to recall. Normally individuals can recall seven forward and five backward numbers. For patients with communication impairments, the therapist can read a list of items while the patient is asked to identify or signal each time a particular item is mentioned. *Sustained attention* (or vigilance) is examined by determining how long the patient is able to maintain attention on a particular task (time on task). *Alternating attention* (attention flexibility) is examined by requesting the patient to alternate back and forth between two different tasks (e.g., add the first two pairs of numbers, then subtract the next two pairs of numbers). Requesting the patient to perform two tasks simultaneously is used to determine *divided attention.* For example, the patient talks while walking (*Walkie–Talkie Test*), or walks while locating an object placed to the side (simulated grocery shopping). Documentation should include the specific component of attention examined, any slowness or hesitation in the response (latency), the duration and frequency of episodes of inattention, the environmental conditions that contribute to or hinder attention abilities, and the amount of required redirection (verbal cueing) to the task.

Memory

Memory is the process of registration, retention, and recall of past experience, knowledge, and ideas. *Declarative (explicit) memory* involves the conscious recollection of facts, past events, experiences, and places. **Motor memory (procedural memory)** involves recall of movements or motor information and storage of motor programs, subroutines, or schema as well as perceptual and cognitive skills. Patients with brain injury and deficits in the medial temporal lobe areas and hippocampus demonstrate profound deficits in explicit memory while they may retain implicit memory, which is more broadly distributed in the CNS motor areas (striatum, cerebellum, premotor cortex).

The length of time required from initial acquisition into memory also distinguishes types of memory. *Immediate memory* (immediate recall) refers to the immediate registration and recall of information after an interval of a few seconds (e.g., repeat after me). *Short-term memory (STM)* (recent memory) refers to the capability to remember current, day-to-day events (e.g., what was eaten for breakfast, date), learn new material, and retrieve material after an interval of minutes, hours, or days. *Long-term memory (LTM)* (remote memory) refers to the recall of facts or events that occurred years before (e.g., birthdays, anniversary, historic facts). It includes items an individual would be expected to know.

A simple test for memory involves presenting the patient with a short list of words of unrelated objects (e.g., pony, coin, pencil) and asking the patient to repeat those words immediately after presentation (immediate recall) and again 5 minutes after presentation (STM).

LTM can be determined by having the patient recall events or persons from his or her past (Where were you born? Where did you go to school? Where do/did you work?). The patient's fund of general knowledge can also be examined (Who is the president? Who was president during World War II?). The questions selected should represent sensitivity to the cultural and educational background of the patient. It is important to consider that memory may be influenced by attention, motivation, rehearsal, fatigue, and other factors.[11] The *Mini-Mental Status Examination (MMSE)* provides a valid and reliable quick screen of cognitive function.[13]

Patients with **amnesia** experience partial or total, permanent or transient loss of memory. *Anterograde amnesia (post-traumatic amnesia [PTA])* refers to the inability to learn new material acquired after a brain insult. *Retrograde amnesia* refers to the inability to remember previous learning acquired before the occurrence of a brain insult. Patients with *delirium (acute confusional state)* typically demonstrate impairments in immediate memory and STM along with confusion, agitation, disorientation, and usually illusions or hallucinations. Patients with *dementia* demonstrate broad-based memory impairments and learning. Significant memory deficits are also seen in patients with diffuse encephalopathies, bilateral temporal lesions, and Korsakoff's psychosis (thiamine deficiency). Certain drugs can improve memory (e.g., CNS stimulates, cholinergic agents) whereas other drugs can degrade memory (e.g., benzodiazepines, anticholinergic drugs).[7] Patients who demonstrate difficulty in retrieving information will often relate that the information is on the "tip of their tongue" (the *tip of the tongue phenomenon*). Various different strategies can be used to facilitate recall of information (e.g., prompting, rehearsal, and repetition). If attention and memory are impaired, instructions during the examination should be kept simple and brief (one-level commands vs. two- or three-level commands). The therapist should structure or choose an environment in which distractions are reduced (i.e., a closed environment) to ensure maximum performance during the examination. Demonstration and positive feedback can assist the patient to understand what is expected, and can be used to motivate and improve performance. Use of any memory-enhancing strategies during an examination should be carefully documented in the patient's chart. It is also important to remember that diffuse declarative memory deficits can persist while procedural memory for well-learned motor tasks can be retained (e.g., the patient with brain injury remembers how to pedal a bicycle). Documentation should include delineation of declarative versus procedural memory deficits.

Communication

The patient's grasp of information and ability to communicate should be ascertained. The physical therapist should listen carefully to spontaneous speech during the initial examination sessions. The patient's understanding of spoken language can be determined using simple tests. Word comprehension can be determined by varying the difficulty of commands, from one- to two- or three-stage commands (Point to your nose; Point to your right hand and lift your left hand). Repetition and naming can be tested (Repeat after me: Name the parts of a watch). Problems with articulation (*dysarthria*) are evidenced by speech errors, such as difficulties with timing, vocal quality, pitch, volume, and breath control. Problems of *fluency,* word flow without pauses or breaks, should be noted. Speech that flows smoothly but contains errors, neologisms (nonsense words), misuse of words, and circumlocutions (word substitution) is indicative of *fluent aphasia* (i.e., Wernicke's aphasia). The patient typically demonstrates deficits in auditory comprehension with well-articulated speech marked by word substitutions. Speech that is slow and hesitant with limited vocabulary and impaired syntax is indicative of *nonfluent aphasia* (i.e., Broca's aphasia). Articulation is labored and word-finding difficulties are apparent. In some settings, especially the acute hospital setting, the physical therapist may be the first to become aware of communication deficits. Referral to a speech-language pathologist is indicated for comprehensive examination and evaluation (see Chapter 28, Neurogenic Disorders of Speech and Language).

To ensure the validity of the physical therapy examination, it is necessary to identify an appropriate means of communicating with the patient. Consultation with the speech-language pathologist is essential. This may include simplifying instructions, using written instructions, or using alternative forms of communication such as gestures, pantomime, or communication boards. A common error is to assume that the patient understands the task at hand when he or she really has no idea what is expected. To ensure accuracy of testing, frequent checks for comprehension should be performed throughout the examination. For example, the use of message discrepancies (saying one thing and gesturing another) can be used to test the patient's level of understanding.

Executive functions included under this heading include awareness, reasoning, judgment, intuition, and memory. The patient with brain injury may demonstrate an inability to plan, manipulate information, initiate and terminate activities, recognize errors, problem-solve, and think abstractly. The presences of any of these deficits can have a significant impact on learning and performance. Referral to an occupational therapist is indicated for comprehensive examination and evaluation (see Chapter 27, Cognitive and Perceptual Dysfunction). Recognition and understanding of these deficits can improve the validity of the motor function examination and the effectiveness of the rehabilitation POC. Collaboration and consistency of team members can go a long way toward alleviating potential frustrations and inappropriate expectations.

Sensory Integrity and Integration

Sensory information is a critical component of motor function. It provides the necessary feedback for determination of initial position before a movement, error detection during the movement, and movement outcomes necessary to shape further learning. A *closed-loop system* of motor control is defined as "a control system employing feedback, a reference of correctness, computation of error, and subsequent correction in order to maintain a desired state."[1, p. 462] A variety of feedback sources are used to monitor movement including visual, vestibular, proprioceptive, and tactile inputs. The term *somatosensation* (or *somatosensory inputs*) is sometimes used to refer to sensory information received from the skin and musculoskeletal systems. The CNS analyzes all available movement information, determines error, and institutes appropriate corrective actions as necessary. Thus, a thorough sensory examination of each of these systems is an important first step in the examination of motor function. See Chapter 3, Examination of Sensory Function, for a complete discussion of this topic. The primary role of closed-loop systems in motor control appears to be the monitoring of constant states such as posture and balance, and the control of slow movements, or those requiring a high degree of precision or accuracy. Feedback information is also essential during learning of new motor skills. Patients who have deficits in any movement-monitoring sensory system may be able to compensate with other sensory systems. For example, the patient with major proprioceptive losses can use vision as an error-correcting system to maintain a stable posture. When vision is also impaired, however, postural instability becomes readily apparent. Significant sensory losses and inadequate compensatory shifts to other sensory systems may result in severely disordered movement responses. The patient with proprioceptive losses and severe visual disturbances such as diplopia (commonly seen in the patient with multiple sclerosis) may be unable to maintain a stable posture at all. An accurate examination, therefore, requires that the therapist not only look at each individual sensory system but also at the overall sensory interaction and integration and the adequacy of compensatory adjustments. Postural tasks, balance, slow (ramp) movements, tracking tasks, or new motor tasks provide the ideal challenge in which to test feedback control mechanisms and closed-loop processes.

An **open-loop system** of motor control is a "control system with preprogrammed instructions to a set of an effectors; it does not use feedback information and error-detection processes."[1, p. 497] Movements emerge from learned motor **schema** that contain "a rule, concept, or relationship formed on the basis of experience."[1, p. 499] Rapid and skilled movement sequences or well-learned movements can thus be completed without the benefit of sensory feedback. In reality, most movements have elements of both closed- and open-loop control processes (hybrid control system). Absence of sensation degrades movement quality (e.g., the patient with sensory neuropathy and sensory ataxia).

Joint Integrity, Postural Alignment, and Mobility

Joint range of motion (ROM) and soft tissue flexibility are important elements of motor function. Limitations restrict the normal coordinated action of muscles and alter the biomechanical alignment of body segments and posture. Long-standing immobilization results in contracture, a fixed resistance resulting from fibrosis of tissues surrounding a joint, and restricted movement. The resultant compensatory movement patterns are frequently dysfunctional, producing additional stresses and strains on the musculoskeletal system. They are also more energy costly and can significantly limit functional mobility. For example, shortening of the gastrocnemius muscles results in a toe-walking gait pattern; tightness of the hip adductors results in a scissoring gait pattern. Changes in alignment secondary to muscle tightness alter postural control. For example, in standing, anterior pelvic tilting and flexion of the hips and knees are typically the result of hip flexor tightness. Posterior pelvic tilting is associated with kyphosis and forward head in sitting and is typically the result of hamstring tightness. Abnormalities in alignment that alter the center of mass (COM) within the base of support (BOS) place increased demands on the postural control system. For example, the patient with stroke will stand with the weight displaced over the sound leg and away from the affected limb. This patient will be limited in the use of normal postural control strategies. Thus, an examination of the musculoskeletal system is important to complete before an examination of motor function.

ELEMENTS OF THE MOTOR FUNCTION EXAMINATION

Tone

Tone is defined as the resistance of muscle to passive elongation or stretch. It represents a state of slight residual contraction in normally innervated, resting muscle, or steady-state contraction. Tone is influenced by a number of factors, including (1) physical inertia, (2) intrinsic mechanical-elastic stiffness of muscle and connective tissues, and (3) spinal reflex muscle contraction (tonic stretch reflexes). It excludes resistance to passive stretch from fixed soft tissue contracture. Because muscles rarely work in isolation, the term *postural tone* is preferred by some clinicians to describe a pattern of muscular tension that exists throughout the body and affects groups of muscles. Tonal abnormalities are categorized as *hypertonia* (increased above normal resting levels), *hypotonia* (decreased below normal resting levels), or *dystonia* (impaired or disordered tonicity).

Hypertonia

Spasticity

Spasticity is a motor disorder characterized by a velocity-dependent increase in muscle tone with increased resistance to stretch; the larger and quicker the stretch, the stronger the resistance of the spastic muscle. During rapid movement, initial high resistance (spastic catch) may be followed by a sudden inhibition or letting go of the limb (relaxation) in response to a stretch stimulus, termed *clasp-knife response*. Chronic spasticity is associated with contracture, abnormal posturing and deformity, functional limitations, and disability.

Spasticity arises from injury to descending motor pathways from the cortex (pyramidal tracts) or brainstem (medial and lateral vestibulospinal tracts, dorsal reticulospinal tract) producing disinhibition of spinal reflexes with hyperactive tonic stretch reflexes or a failure of reciprocal inhibition. The result is hyperexcitability of the alpha motor neuron pool. It occurs as part of **upper motor neuron (UMN) syndrome** (Table 5.2). Increased tonic contraction of muscles is seen at rest, evidenced by abnormal typical resting postures. When movements are attempted, the result is action-induced abnormal movement patterns (stereotyped movement synergies or spastic dystonia). Additional signs include **associated reactions**, defined as involuntary movements resulting from activity occurring in other parts of the body (e.g., sneezing, yawning, squeezing the hand). **Clonus** is characterized by cyclical, spasmodic alternation of muscular contraction and relaxation in response to sustained stretch of a spastic muscle. Clonus is common in the plantarflexors, but may also occur in other areas of the body such as the jaw or wrist. The *Babinski sign* is dorsiflexion of the great toe with fanning of the other toes on stimulation of the lateral sole of the foot.[14-16]

Table 5.2 Positive and Negative Features of Upper Motor Neuron Syndrome

Negative Features	Positive Features
Paresis and paralysis	Spasticity
Loss of dexterity	Stereotyped movement synergies; spastic dystonia
Fatigue	Spasms (flexor, extensor/adductor)
	Spastic co-contraction
	Extensor plantar response (Babinski sign)
	Clonus
	Exaggerated deep tendon reflexes (DTR)
	Associated reactions
	Disturbances in movement efficiency and speed; mass movements

Rigidity

Rigidity is a hypertonic state characterized by constant resistance throughout ROM that is independent of the velocity of movement (*lead-pipe rigidity*). It is associated with lesions of the basal ganglia system (*extrapyramidal syndromes*) and is seen in Parkinson's disease. Rigidity is the result of excessive supraspinal drive (upper motor neuron facilitation) acting on alpha motor neurons; spinal reflex mechanisms are typically normal. Patients demonstrate stiffness, inflexibility, and significant functional limitation. *Cogwheel rigidity* refers to a hypertonic state with superimposed ratchet-like jerkiness and is commonly seen in upper extremity movements (e.g., wrist or elbow flexion and extension) in patients with Parkinson's disease. It may represent the presence of tremor superimposed on rigidity. Tremor, bradykinesia, and loss of postural stability are also associated motor deficits in patients with Parkinson's disease.

Decorticate and Decerebrate Rigidity

Severe brain injury can result in coma with decorticate or decerebrate rigidity. **Decorticate rigidity** refers to sustained contraction and posturing of the upper limbs in flexion and the lower limbs in extension. The elbows, wrists, and fingers are held in flexion with shoulders adducted tightly to the sides while the legs are held in extension, internal rotation, and plantarflexion. **Decerebrate rigidity** (abnormal extensor response) refers to sustained contraction and posturing of the trunk and limbs in a position of full extension. The elbows are extended with shoulders adducted, forearms pronated, and wrist and fingers flexed. The legs are held in stiff extension with plantarflexion. Decorticate rigidity is indicative of a corticospinal tract lesion at the level of diencephalon (above the superior colliculus), whereas decerebrate rigidity indicates a corticospinal lesion in the brainstem between the superior colliculus and vestibular nucleus. *Opisthotonus* is characterized by strong and sustained contraction of the extensor muscles of the neck and trunk, resulting in a rigid, hyperextended posture. Extensor muscles of the proximal limbs may also be involved. These postures are considered exaggerated and severe forms of spasticity.

Dystonia

Dystonia is a prolonged involuntary movement disorder characterized by twisting or writhing repetitive movements and increased muscular tone. *Dystonic posturing* refers to sustained abnormal postures caused by co-contraction of muscles that may last for several minutes,

for hours, or permanently. Dystonia results from a CNS lesion commonly in the basal ganglia and can be inherited (primary idiopathic dystonia), associated with neurodegenerative disorders (Wilson's disease, Parkinson's disease on excessive l-dopa therapy), or metabolic disorders (amino acid or lipid disorders). Dystonia can affect only one part of the body (*focal dystonia*) as seen in spasmodic torticollis (wry neck) or isolated writer's cramp. *Segmental dystonia* affects two or more adjacent areas (e.g., torticollis and dystonic posturing of the arm).[17]

Hypotonia

Hypotonia and *flaccidity* are the terms used to define decreased or absent muscular tone. Resistance to passive movement is diminished, stretch reflexes are dampened or absent, and limbs are easily moved (floppy). Hyperextensibility of joints is common. **Lower motor neuron (LMN) syndrome** results from lesions that affect the anterior horn cell and peripheral nerve (e.g., peripheral neuropathy, cauda equina lesion, radiculopathy). It produces symptoms of decreased or absent tone, decreased or absent reflexes, paresis, muscle fasciculations and fibrillations with denervation, and neurogenic atrophy. Mild decreases in tone along with asthenia (weakness) can also be seen in cerebellar lesions. Acute UMN lesions (e.g., hemiplegia, tetraplegia, paraplegia) can produce temporary hypotonia, termed *spinal shock* or *cerebral shock* depending on the location of the lesion. The duration of CNS depression and hypotonia that occurs with shock is highly variable, lasting days or weeks. It is typically followed by the development of spasticity and classic UMN signs.

Examination of Tone

An examination of tone consists of (1) initial observation of resting posture and palpation, (2) passive motion testing, and (3) active motion testing. Variability of tone is common. For example, patients with spasticity can vary in their presentation from morning to afternoon, day to day, or even hour to hour depending on a number of factors, including (1) volitional effort and movement, (2) anxiety and pain, (3) position and interaction of tonic reflexes, (4) medications, (5) general health, (6) ambient temperature, and (7) state of CNS arousal or alertness. In addition, urinary bladder status (full or empty), fever and infection, and metabolic and/or electrolyte imbalance can also influence tone. The therapist should therefore consider the impact of each of these factors in arriving at a determination of tone. Repeat (serial) testing and a consistent approach to examination is necessary to improve the accuracy and reliability of test results.[17]

Initial observation of the patient can reveal abnormal posturing of the limbs or body. Careful inspection should be made regarding the position of the limbs, trunk, and head. With spasticity, posturing in fixed, antigravity positions is common; for example, a spastic upper extremity is typically held fixed against the body with the shoulder adducted, elbow flexed, forearm supinated with wrist/fingers flexed. In the supine position, the lower extremities are typically held in extension, adduction with plantarflexion, and inversion (Table 5.3).[18] Limbs that appear floppy and lifeless (e.g., a lower extremity [LE] rolled out to the side in external rotation) may indicate hypotonicity. *Palpation* of the muscle belly may yield additional information about the resting state of muscle. Consistency, firmness, and turgor should all be examined. Hypotonic muscles will feel soft and flabby, whereas hypertonic muscles will feel taut and harder than normal.

Passive motion testing reveals information about the responsiveness of muscles to stretch. Because these responses should be examined in the absence of voluntary control, the patient is instructed to relax, letting the therapist support and move the limb. During a passive motion test, the therapist should maintain firm and constant manual contact, moving the limb in all motions. When tone is normal, the limb moves easily and the therapist is able to alter direction and speed without feeling abnormal resistance. The limb is responsive and feels light. Hypertonic limbs generally feel stiff and resistant to movement, whereas flaccid limbs feel heavy and

Table 5.3 Typical Patterns of Spasticity in Upper Motor Neuron Syndrome

Upper Limbs	Actions	Muscles Affected
Scapula	Retraction, downward rotation	Rhomboids
Shoulder	Adduction and internal rotation, depression	Pectoralis major, latissimus dorsi, teres major, subscapularis
Elbow	Flexion	Biceps, brachialis, brachioradialis
Forearm	Pronation	Pronator teres, Pronator quadratus
Wrist	Flexion, adduction	Flexor carpi radialis
Hand	Finger flexion, clenched fist thumb, adducted in palm	Flexor digitorum profundus/sublimis, adductor pollicis brevis, flexor pollicis brevis

Table 5.3 Typical Patterns of Spasticity in Upper Motor Neuron Syndrome—cont'd

Lower Limbs	Actions	Muscles Affected
Pelvis	Retraction (hip hiking)	Quadratus lumborum
Hip	Adduction (scissoring) Internal rotation Extension	Adductor longus/brevis Adductor magnus, gracilis Gluteus maximus
Knee	Extension	Quadriceps
Foot and ankle	Plantarflexion Inversion Equinovarus Toes claw (tarsometatarsal extension, metatarsophalangeal flexion) Toes curl (tarso- and metatarsophalangeal flexion)	Gastrocnemius/soleus Tibialis posterior Long toe flexors Extensor hallucis longus Peroneus longus
Hip and knee (prolonged sitting posture)	Flexion Sacral sitting	Iliopsoas Rectus femoris, pectineus Hamstrings
Trunk	Lateral flexion with concavity Rotation	Rotators Internal/external obliques
Posture forward (prolonged sitting posture)	Excessive forward flexion Forward head	Rectus abdominis, external obliques Psoas minor

The form and intensity of spasticity may vary greatly, depending on the CNS lesion site and extent of damage. The degree of spasticity can fluctuate within each individual (i.e., due to body position, level of excitation, sensory stimulation, and voluntary effort). Spasticity predominates in antigravity muscles (i.e., the flexors of the upper extremity and the extensors of the lower extremity). If left untreated, spasticity can result in movement deficiencies, subsequent contractures, degenerative joint changes, and deformity.
MP: meta

Adapted from Mayer, NH, Esquenazi, A, and Childers, MK: Common patterns of clinical motor dysfunction. Muscle and Nerve 6:S21, 1997.

unresponsive. Some older adults may find it difficult to relax; their stiffness should not be mistaken for hypertonicity. Varying the speed of movement is an important determinant of spasticity. In a spastic limb, resistance may be near normal when the limb is moved at a slow velocity. Faster movements intensify the resistance to passive motion. It is also important to remember that muscle stiffness with spasticity will offer the greatest resistance during the first stretch and that with each successive stretch resistance can be reduced by as much as 20% to 60%.[15] In the patient with rigidity, resistance is constant and not responsive to increasing the velocity of passive motion.

Clonus, a phasic stretch response, is examined using a quick stretch stimulus that is then maintained. For example, ankle clonus is tested by sudden dorsiflexion of the foot and maintaining the foot in dorsiflexion. The presence of a clasp-knife response should also be noted. All limbs and body segments are examined, with particular attention given to those identified as problematic in the initial observation. Comparisons should be made between upper and lower limbs and right and left extremities. Asymmetrical tonal abnormalities are always indicative of neurological dysfunction.

A subjective determination of the degree of tone can be made. Therapists need to be familiar with the wide range of normal and abnormal tonal responses to develop an appropriate frame of reference to grade tone. For documentation in the medical record, tone is typically graded on a 0 to 4+ scale:

0 No response (flaccidity)
1+ Decreased response (hypotonia)
2+ Normal response
3+ Exaggerated response (mild to moderate hypertonia)
4+ Sustained response (severe hypertonia)

Modified Ashworth Scale

The *Modified Ashworth Scale (MAS)* is a clinical scale used to assess muscle spasticity that is in commonly used in many rehabilitation facilities and spasticity clinics (Table 5.4). The original Ashworth Scale (AS), a 4-point ordinal scale, was developed as a simple clinical tool to test the efficacy of an antispastic drug in patients with MS.[19] Bohannon and Smith[20] modified the instrument scale by adding an additional 1+ grade to increase the sensitivity of the instrument, making it a 5-point scale. In both versions, the examiner uses passive motion to evaluate resistance to passive motion due to spasticity. The MAS has been shown to have moderate to good intrarater reliability but only poor to moderate interrater reliability.[21-26] Limitations with use of the scale include (1) inability to detect small changes, (2) inability to distinguish between soft tissue viscoelastic and neural changes, and (3) problems with psychometric properties (unequal distances of scores). Agreement on the MAS middle scores (1, 1+, and 2) is the most problematic. Training should be considered to improve interrater reliability between examiners. See Box 5.1 Evidence Summary on the reliability of the Modified Ashworth Scale as a clinical tool for assessing spasticity.

Special Tests

In the lower limbs, spasticity can be examined using the *pendulum test*. The patient is positioned in supine with knees flexed over the end of a table. The examiner passively extends the knee fully against gravity and then allows the leg to drop and swing like a pendulum. A normal and hypotonic limb will swing freely for several oscillations. In patients with quadriceps or hamstring spasticity, the leg is resistant to full extension and when dropped swings for only a few repetitions. It quickly returns to the initial dependent starting position. The pendulum test can be quantified using an isokinetic dynamometer, an electrogoniometer, or computerized video equipment with high test–retest reliability.[27,28]

Tonic stretch reflexes can be accurately measured using electromyography (EMG). Response to stretch can be documented for various velocities of stretch and spastic co-contraction can be quantified (see EMG section later in this chapter). A *myotonometer* is a handheld computerized electronic device developed by Leonard and co-workers that can be used to measure muscle tone. It provides quantitative measurements of force and displacement of muscle tissue and is able to detect small changes in both extremity and postural tone.[29,30]

Table 5.4 Modified Ashworth Scale for Grading Spasticity

Grade	Description
0	No increase in muscle tone.
1	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the ROM when the affected part(s) is moved in flexion or extension.
1+	Slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the ROM.
2	More marked increase in muscle tone through most of the ROM, but affected part(s) easily moved.
3	Considerable increase in muscle tone, passive movement difficult.
4	Affected part(s) rigid in flexion or extension.

From Bohannon and Smith,[20, p. 207] with permission.

Documentation

Documentation of tone abnormalities should include a determination of the specific body segments demonstrating abnormal tone, the type of abnormality present (e.g., spasticity, rigidity), whether the changes are symmetrical or asymmetrical, resting postures and associated signs (e.g., UMN syndrome), and factors that modify (increase or diminish) tone. It is important to remember that measurement of tone in one position does not mean that tone will be the same in other positions or during functional activities. A change in position such as sitting up or standing up can substantially alter the requirements for postural tone. Of great importance is a description of the effects of tone on active movements, posture, and function.

Reflex Integrity

Deep Tendon Reflexes

A **reflex** is an involuntary, predictable, and specific response to a stimulus dependent on an intact reflex arc (sensory receptor, afferent neurons, efferent neurons, and responding muscles or gland). The *deep tendon reflex (DTR)* results from stimulation of the stretch-sensitive IA afferents of the neuromuscular spindle producing muscle contraction via a monosynaptic pathway. DTRs are tested by tapping sharply over the muscle tendon with a standard reflex hammer or with the tips of the therapist's fingers. To ensure adequate response, the muscle is positioned in midrange and the patient is instructed to relax. Stimulation can result in observable movement of the joint (brisk or strong responses). Weak responses may be evident only with palpation (slight or sluggish responses with little or no joint movement). The quality and magnitude of responses should be carefully documented. In the medical record, reflexes are graded on a 0 to 4+ scale:

0 Absent, no response
1+ Slight reflex, present but depressed, low normal
2+ Normal, typical reflex
3+ Brisk reflex, possibly but not necessarily abnormal
4+ Very brisk reflex, abnormal, clonus

Box 5.1 Evidence Summary Reliability of Measurements Obtained With the Modified Ashworth Scale (MAS)

Reference	Subjects	Design/Interventions	Results	Comments
Ghotbi et al (2011)[21]	Tested 23 subjects with LE spasticity and stroke or MS (14 w; 9 m)	Test-retest study of intrarater reliability; MAS scores obtained by one senior PT using standardized test positions; testing 2 days apart; three LE muscles assessed	Kappa (k) value for overall agreement was very good (weighted k = 0.87); mod. for hip adductors, good for knee extension, and very good for PF).	Intrarater reliability with patients with LE spasticity was very good. Reliability for ankle PF was significantly higher than that for hip adductors.
Craven and Morris (2010)[22]	Tested 20 subjects with chronic SCI (C5–T10, ASIA A–D, > 12 mo)	Test-retest study of intrarater and interrater reliability; MAS scores obtained by two blinded raters; ratings taken at same time of day, weekly for 5 weeks, using standardized positions; six LE muscles assessed	Intrarater reliability was substantial to high (0.6 < k < 1.0) for rater A; poor to fair for rater B (k < 0.4); interrater reliability was poor-to-moderate for all muscle groups (k < 0.6).	Intrarater reliability with patients with LE spasticity was very good; showed poor to mod. interrater and modest intersession reliability. Differences existed in abilities of raters. An alternative measure for quantifying spasticity was recommended.
Ansari et al (2008)[23]	Tested 30 subjects with UE and LE muscle spasticity	Test-retest study of intrarater and interrater reliability; MAS scores obtained by two experienced PTs; examined 1 week apart; random order of muscles tested using both UE and LE muscles.	Interrater reliability was mod. (k = 0.514); intrarater reliability also mod. (k = 0.590). Agreement between UE and LE was similar. Agreement on UE distal wrist flexor was significantly higher between rater than proximal shoulder adduction.	Interrater and intrarater reliability was mod. Limbs had no effect on reliability. Researchers question validity of measurements.
Mehrholz et al (2005)[24]	Tested 30 subjects with severe TBI and impaired consciousness	Test-retest study of intrarater and interrater reliability; MAS scores obtained by four experienced PTs; examined over 2 consecutive days; random order of muscles tested using both UE and LE muscles.	Intrarater reliability was mod. to good (k = 0.47–0.62); interrater reliability was poor to mod. (k = 0.16–0.42)	Interrater reliability is limited. Both intrarater and interrater reliability were significantly higher with the Modified Tardieu Scale compared to the MAS. Researchers question the use of MAS as the gold standard for assessing spasticity.
Blackburn et al (2002)[25]	Tested 20 subjects 2 weeks post-stroke; 20 subjects 12 weeks post-stroke	Test-retest study of intrarater and interrater reliability; MAS scores obtained by experienced PTs; testing performed 1 hour apart; testing	Interrater reliability for 2 raters was poor, correlation was .062 (P = .461); intrarater reliability was .567 (P < .001)	Intrarater reliability was mod. for a single examiner; interrater reliability between examiners was poor.

Box 5.1 Evidence Summary Reliability of Measurements Obtained With the Modified Ashworth Scale (MAS)—cont'd

Reference	Subjects	Design/Interventions	Results	Comments
		repeated 1 week later; three LE muscles tested.		Most agreement at grade of 0; poor agreement on grades of 1, 1+, and 2. Researchers question the use of the MAS
Pandyan et al (1999)[26]	Seven reliability studies identified; four using MAS, two using AS, one using both	Systematic review of the literature of studies on MAS	Intrarater reliability was superior to interrater reliability.	Confusion exists on the characteristics and limitations of MAS and AS. AS scale is an ordinal measure of resistance to PM. MAS is a nominal measure of resistance to PM; ambiguity exists between 1 and 1+ grades. Training should be considered to improve reliability between examiners.
Bohannon and Smith (1987)[20]	Tested 30 subjects (1 MS; 5 TBI; 24 CVA)	Test-retest study of interrater reliability; MAS scores obtained by two senior PTs using standardized test positions; testing several minutes apart; elbow flexor muscles assessed	Interrater agreement was 86.7%, Kendall's tau correlation of .847 ($P < .001$)	Interrater reliability of a manual test of elbow flexor spasticity was good.

ASIA = American Spinal Injury Association Impairment Scale; AS = Ashworth Scale; k = kappa; LE = lower extremity; m = men; mod. = moderate; MAS = Modified Ashworth Scale; MS = multiple sclerosis; PF = plantarflexors; PM = passive movement; PT = physical therapist; SCI = spinal cord injury; TBI = traumatic brain injury; UE = upper extremity; w = women.

Table 5.5 presents an overview of the examination of DTRs.

If DTRs are difficult to elicit, responses can be enhanced by specific reinforcement maneuvers. In the *Jendrassik maneuver,* the patient hooks together the fingers of the hands and strongly pulls them apart. While this pressure is maintained, LE reflexes are tested. Maneuvers that can be used to reinforce responses in the upper extremities (UEs) include squeezing the knees together, clenching the teeth, or making a fist with the contralateral extremity. The use of any reinforcing maneuvers to elicit responses in patients with hyporeflexia should be carefully documented.

DTRs are increased in UMN syndrome (e.g., stroke) and decreased in LMN syndrome (e.g., peripheral neuropathy, nerve root compression), cerebellar syndrome, and muscle disease. *Reflex spread* (the extension of the response beyond the muscle normally expected to contract) is indicative of UMN syndrome. Because each DTR arises from specific spinal segments, an absent reflex can be used to identify the level of a spinal lesion (e.g., radiculopathy).

Superficial Cutaneous Reflexes

Superficial cutaneous reflexes are elicited with a light stroke applied to the skin. The expected response is brief contraction of muscles innervated by the same spinal segments receiving the afferent inputs from the cutaneous receptors. A stimulus that is strong may produce irradiation of cutaneous signals with activation of protective withdrawal reflexes. Cutaneous reflexes include the plantar reflex, confirming toe signs (Chaddock), and abdominal reflexes. The *plantar reflex* (S1, S2) is tested by applying a stroking stimulus on the sole of the foot along the lateral border and up across the ball of the foot.

Table 5.5 Examination of Deep Tendon Reflexes

Myostatic Reflexes (Stretch)	Stimulus	Response
Jaw (CN V)	Patient is sitting, with jaw relaxed and slightly open. Place finger on top of chin; tap downward on top of finger in a direction that causes the jaw to open.	Jaw rebounds and closes
Biceps Musculocutaneous nerve (C5, C6)	Patient is sitting with arm flexed and supported. Place thumb over the biceps tendon in the cubital fossa, stretching it slightly. Tap thumb or directly on tendon.	Slight contraction of elbow flexors
Brachioradialis (supinator) Radial nerve (C5, C6)	Patient is sitting with arm flexed onto the abdomen. Place finger on the radial tuberosity and tap finger with hammer.	Slight contraction of elbow flexors, slight wrist extension or radial deviation
Triceps Radial nerve (C6, C7)	Patient is sitting with arm supported in abduction, elbow flexed. Palpate triceps tendon just above olecranon. Tap directly on tendon.	Slight contraction of elbow extensors
Finger flexors Median nerve (C6–T1)	Hold hand in neutral position. Place finger across palmar surface of distal phalanges of four fingers and tap.	Slight contraction of finger flexors
Hamstrings Tibial branch, sciatic nerve (L5, S1, S2)	Patient is prone with knee semiflexed and supported. Palpate tendon at the knee. Tap on finger or directly on tendon.	Slight contraction of knee flexors
Quadriceps (patellar, knee jerk) Femoral nerve (L2, L3, L4)	Patient is sitting with knee flexed, foot unsupported. Tap tendon of quadriceps muscle between the patella and tibial tuberosity.	Slight contraction of knee extensors
Achilles (ankle jerk) Tibial (S1–S2)	Patient is prone with foot over the end of the plinth or sitting with knee flexed and foot held in slight dorsiflexion. Tap tendon just above its insertion on the calcaneus. Maintaining slight tension on the gastrocnemius-soleus group improves the response.	Slight contraction of plantarflexors

A normal response consists of flexion of the big toe; sometimes the other toes will demonstrate a downgoing (flexion) response, or no response at all. An abnormal response (positive Babinski sign) consists of extension dorsiflexion (upgoing) of the big toe, with fanning of the lateral four toes. It is indicative of a corticospinal (UMN) lesion. The *Chaddock's reflex (or sign)* is elicited by stroking around the lateral ankle and up the lateral dorsal aspect of the foot. It also produces extension dorsiflexion of the big toe and is considered a confirmatory toe sign. The *abdominal reflex* is elicited with brisk, light strokes over the skin of the abdominal muscles. A localized contraction under the stimulus is produced, with a resultant deviation of the umbilicus toward the area stimulated. Each quadrant should be tested in a diagonal direction. Umbilical deviation in a superior/lateral direction indicates integrity of spinal segments T8 to T9. Umbilical deviation in an inferior/lateral direction indicates integrity of spinal segments T10 to T12. Loss of response is abnormal and indicative of pathology (e.g., thoracic spinal cord injury). Asymmetry from side to side is highly significant with respect to neurological disease. Abdominal reflexes may be absent with in patients with obesity or abdominal surgeries. Table 5.6 presents an overview of the examination of superficial cutaneous reflexes.

Primitive and Tonic Reflexes

Primitive and *tonic reflexes* are present during infancy as a stage in normal development and become integrated by the CNS at an early age. Once integrated, these reflexes are not generally recognizable in adults in their pure form. They may continue, however, as adaptive fragments of behavior, underlying normal motor control. Persistent reflexes (sometimes termed *obligatory reflexes*) beyond the expected age of development or appearing in adult patients following brain injury are always indicative of neurological involvement. Patients who exhibit these reflexes typically present with extensive brain damage (e.g., stroke, TBI) and other UMN signs.

Reflexes important to examine in the patient suspected of abnormal reflex activity include flexor withdrawal, traction, grasp, tonic neck, tonic labyrinthine, positive support, and associated reactions. *Flexor withdrawal reflex*

Table 5.6 Examination of Superficial Cutaneous Reflexes

Superficial Reflexes (Cutaneous)	Stimulus	Response
Plantar (S1, S2)	With blunt object (key or wooden end of applicator stick), stroke the lateral aspect of the sole, moving from the heel to the ball of the foot, curving medially across the ball of the foot.	Normal response is flexion (plantarflexion) of the great toe, and sometimes the other toes (negative Babinski sign). Abnormal response, termed a **positive Babinski sign**, is extension (dorsiflexion) of the great toe with fanning of the four other toes (indicates UMN lesions).
	Alternate stimuli for plantar (for sensitive feet): • Chaddock: stroke lateral ankle and lateral aspect of foot. • Oppenheim: stroke down tibial crest	Same as for plantar.
Abdominal reflexes	Position patient in supine, relaxed. Make brisk, light stroke over each quadrant of the abdominals from the periphery to the umbilicus.	Localized contraction under the stimulus, causing the umbilicus to move toward the stimulus.
Above umbilicus = T8–T10		Masked by obesity.
Below umbilicus = T10–T12		Can be absent in both UMN and LMN disorders.

is generally the simplest to observe and is judged by appearance of an overt movement response. *Tonic neck reflexes,* on the other hand, bias the musculature and may not be visible through overt movement responses. In fact, movement is rarely produced but rather posture is typically influenced through tonal adjustments. Thus, the term *tuning reflexes* is an appropriate description of their function. Abnormal postures should be examined for their reflex dependence (e.g., the patient with brain injury exhibits excessive extensor tone in supine but not in side lying). To obtain an accurate examination, the therapist must be concerned with several factors. The patient must be positioned appropriately to allow for the expected response. An adequate test stimulus is essential, including both an adequate magnitude and duration of stimulation. Keen observation skills are needed to detect what may be subtle movement changes and abnormal responses. Palpation skills can assist in identifying tonal changes not readily apparent to the eye. Primitive and tonic reflexes are graded using a 0 to 4+ scale:[31,32]

0+ Absent
1+ Tone change: slight, transient with no movement of the extremities
2+ Visible movement of extremities
3+ Exaggerated, full movement of extremities
4+ Obligatory and sustained movement, lasting for more than 30 seconds

Table 5.7 presents an overview of the examination of primitive and tonic reflexes.

Documentation of Reflex Integrity

Documentation of reflex abnormalities should include a determination of (1) specific reflexes tested, (2) the degree of abnormality observed, (3) associated signs (e.g., UMN syndrome), and (4) factors that modify reflexes. Of great importance is a description of the effects of abnormal reflex behavior on active movements, posture, and function.

Cranial Nerve Integrity

There are 12 pairs of cranial nerves (CNs), all distributed to the head and neck with the exception of CN X (vagus), which is distributed to the thorax and abdomen. CNs I, II, and VIII are purely sensory and carry the special senses of smell, vision, hearing, and equilibrium. Cranial nerves III, IV, and VI are purely motor and control pupillary constriction and eye movements. Cranial nerves XI and XII are also purely motor, innervating the sternocleidomastoid, trapezius, and tongue muscles. Cranial nerves V, VII, IX, and X are mixed, containing both motor and sensory fibers. Motor functions include chewing (V), facial expression (VII), swallowing (IX, X), and vocal sounds (X). Sensations are carried from the face and head (V, VII, IX), alimentary tract, heart, vessels, and lungs (IX, X), and tongue, mouth, and palate (VII, IX, X). Parasympathetic secretomotor fibers (ANS) are carried by CN III for control of smooth muscles in the eyeball, VII for control of salivary and lacrimal glands, IX to the parotid salivary

Table 5.7 Examination of Primitive and Tonic Reflexes

Primitive/Spinal Reflexes	Stimulus	Response
Flexor withdrawal	Noxious stimulus (pinprick) to sole of foot. Tested in supine or sitting position.	Toes extend, foot dorsiflexes, entire LE flexes uncontrollably. Onset: 28 weeks of gestation. Integrated: 1–2 months.
Crossed extension	Noxious stimulus to ball of foot of LE fixed in extension; tested in supine position.	Opposite LE flexes, then adducts and extends. Onset: 28 weeks of gestation. Integrated: 1–2 months.
Traction	Grasp forearm and pull up from supine into sitting position.	Grasp and total flexion of the UE. Onset: 28 weeks of gestation. Integrated: 2–5 months.
Moro	Sudden change in position of head in relation to trunk; drop patient backward from sitting position.	Extension, abduction of UEs, hand opening, and crying followed by flexion, adduction of arms across chest. Onset: 28 weeks of gestation. Integrated: 5–6 months.
Startle	Sudden loud or harsh noise.	Sudden extension or abduction of UEs, crying. Onset: birth. Integrated: persists.
Grasp	Maintained pressure to palm of hand (palmar grasp) or to ball of foot under toes (plantar grasp).	Maintained flexion of fingers or toes. Onset: palmar, birth; plantar, 28 weeks of gestation. Integrated: palmer, 4–6 months; plantar, 9 months.
Tonic/Brainstem Reflexes	**Stimulus**	**Response**
Asymmetrical tonic neck (ATNR)	Rotation of the head to one side.	Flexion of skull limbs, extension of the jaw limbs, "bow and arrow" or "fencing" posture. Onset: birth. Integrated: 4–6 months.
Symmetrical tonic neck (STNR)	Flexion or extension of the head.	With head flexion: flexion of UEs, extension of LEs; with head extension: extension of UEs, flexion of LEs. Onset: 4–6 months. Integrated: 8–12 months.
Symmetrical tonic labyrinthine (TLR or STLR)	Prone or supine position.	With prone position: increased flexor tone/flexion of all limbs; with supine: increased extensor tone/extension of all limbs. Onset: birth. Integrated: 6 months.
Positive supporting	Contact to the ball of the foot in upright standing position.	Rigid extension (co-contraction) of the LEs. Onset: birth. Integrated: 6 months.
Associated reactions	Resisted voluntary movement in any part of the body.	Involuntary movement in a resting extremity. Onset: birth–3 months. Integrated: 8–9 years.

LE = lower extremity; UE = upper extremity.

gland, and X to the heart, lungs, and most of the digestive system.

An examination of CN function should be performed with suspected lesions of the brain, brainstem, and cervical spine. Deficits in olfactory function (CN I) should be suspected with lesions of the nasal cavity and anterior/inferior cerebrum. Lesions of the optic pathways (optic nerve [CN II], optic chiasma, optic tract, lateral geniculate body, superior colliculus) and visual cortex may produce visual deficits. Midbrain (mesencephalic) lesions may result in deficits of CNs III and IV (oculomotor, trochlear). Pontine lesions may involve several CNs, including V (ophthalmic, maxillary, and mandibular branches) and VI (abducens). Nuclei of CNs VII (facial) and VIII (vestibular and cochlear branches) are located at the junction of the pons and medulla. Lesions affecting the medulla may involve CNs IX (glossopharyngeal), X (vagus), XI (spinal accessory), and XII (hypoglossal). The spinal root of XI is found in the upper five cervical segments. The CNs, their function, clinical tests, and possible abnormal findings are presented in Table 5.8.

Documentation of Cranial Nerve Integrity

Documentation of an examination of CN integrity should include a determination of (1) specific cranial nerves tested, (2) the degree of abnormality observed (specific deficits), and (3) the effects of abnormal cranial nerve integrity on function. The patient's perceptions of loss of function should also be identified.

Muscle Performance

Muscle Atrophy

Atrophy, the loss of muscle bulk (wasting), occurs as a result of the loss of functional mobility (disuse atrophy), LMN disease (neurogenic atrophy), or protein-calorie malnutrition. *Disuse atrophy* is evident after periods of inactivity, developing in weeks or months. It is generally widespread and affects antigravity muscles to a greater extent. Strength can be negatively influenced by disuse atrophy. The lack of resistive load on muscle reduces the overall number of sarcomeres and results in diminished capacity of muscle for developing torque (contractile strength). It also results in reduced passive tension of

Table 5.8 Examination of Cranial Nerve Integrity

Cranial Nerve	Function	Test	Possible Abnormal Findings
I Olfactory	Smell	Test sense of smell on each side (close off other nostril): use common, nonirritating odors.	Anosmia (inability to detect smells), seen with frontal lobe lesions
II Optic	Vision	Test visual acuity. Central: Snellen eye chart; test each eye separately (covering other eye); test at distance of 20 ft. Test peripheral vision (visual fields) by confrontation.	Blindness, myopia (impaired far vision), presbyopia (impaired near vision) Field defects: homonymous hemianopsia
II, III Optic and oculomotor	Pupillary reflexes	Test pupillary reactions (constriction) by shining light in eye light; if abnormal, test near reaction. Examine pupillary size/shape.	Absence of pupillary constriction Anisocoria (unequal pupils) Horner's syndrome, CN III paralysis
III, IV, VI Oculomotor, trochlear, and abducens	Extraocular movements	Test saccadic (patient is asked to look in each direction) and pursuit eye movements (patient follows moving finger).	Strabismus (eye deviates from normal conjugate position) Impaired eye movements Double vision
III	Medial, superior, and inferior rectus: inferior oblique; turns eye up, down, in. Elevates eyelid.	Observe position of eye. Test eye movements.	Strabismus: eye pulled outward by CN VI Eye cannot look upward, downward, inward movements. May see ptosis, pupillary dilation.
IV	Superior oblique: turns eye down when adducted.	Test eye movements.	Eye cannot look down when eye is adducted.
VI	Lateral rectus: turns eye out.	Observe position of eye. Test eye movements.	Esotropia (eye pulled inward) Eye cannot look out.

Table 5.8 Examination of Cranial Nerve Integrity—cont'd

Cranial Nerve	Function	Test	Possible Abnormal Findings
V Trigeminal Ophthalmic, maxillary, mandibular divisions	Sensory: face	Test pain, light touch sensations: forehead, cheeks, jaw (eyes closed). Test corneal reflex: touch lightly with wisp of cotton.	Loss of facial sensations, numbness with CN V lesion Trigger area with trigeminal neuralgia Loss of corneal reflex ipsilaterally (blinking in response to corneal touch)
	Sensory: cornea		
	Motor: muscles of mastication	Palpate temporal and masseter muscles. Observe spontaneous movements. Have patient clench teeth, hold against resistance.	Weakness, wasting of muscles When opened, deviation of jaw to ipsilateral side
VII Facial	Facial expression	Test motor function facial muscles. Raise eyebrows, frown. Show teeth, smile. Close eyes tightly. Puff out both cheeks.	Paralysis: Inability to close eye, Drooping corner of mouth, Difficulty with speech articulation Unilateral LMN: Bell's palsy (PNI) Bilateral LMN: Guillain-Barré Unilateral UMN: stroke
	Taste to anterior two thirds of tongue	Apply saline solution and sugar solution using a cotton swab.	Incorrectly identifies solution.
VIII Vestibulocochlear (acoustic)	Vestibular function	Test balance: vestibulospinal function (VSR). Test eye–head coordination: vestibular ocular reflex (VOR).	Vertigo, dysequilibrium Gaze instability with head rotations, nystagmus (constant, involuntary cyclical movement of the eyeball)
	Cochlear function	Test auditory acuity. Test for lateralization (Weber test): place vibrating tuning fork on top of head, mid-position; check if sound heard in one ear, or equally in both. Compare air and bone conduction (Rinne test): place vibrating tuning fork on mastoid bone, then close to ear canal; sound heard longer through air than bone.	Deafness, impaired hearing, tinnitus Unilateral conductive loss: sound lateralized to impaired ear Sensorineural loss: sound heard in good ear Conductive loss: sound heard through bone is equal to or longer than air Sensorineural loss: sound heard longer through air
IX Glossopharyngeal	Sensory to posterior one third of tongue, pharynx, middle ear	Apply saline solution and sugar solution. Not typically tested	Incorrectly identifies solution.
IX, X Glossopharyngeal and vagus	Phonation Swallowing	Listen to voice quality. Examine for difficulty in swallowing glass of water.	Dysphonia: hoarseness denotes vocal cord weakness; nasal quality denotes palatal weakness. Dysphagia
	Palatal, pharynx control	Have patient say "ah"; observe motion of soft palate (elevates) and position of uvula (remains midline).	Paralysis: palate fails to elevate (lesion of CN X); asymmetrical elevation with unilateral paralysis
	Gag reflex	Stimulate back of throat lightly on each side.	Absent reflex: lesion of CN IX; possibly CN X

Continued

Table 5.8 Examination of Cranial Nerve Integrity—cont'd

Cranial Nerve	Function	Test	Possible Abnormal Findings
XI Spinal accessory	Motor function: Trapezius muscle	Examine bulk, strength. Shrug both shoulders upward against resistance.	LMN: atrophy, fasciculations, ipsilateral weakness Inability to shrug ipsilateral shoulder; shoulder droops
	Sternocleidomastoid	Turn head to each side against resistance.	Inability to turn head to opposite side UMN: weakness of ipsilateral sternocleidomastoid and contralateral trapezius
XII Hypoglossal	Tongue movements	Listen to patient's articulation.	Dysarthria (seen with lesions of CN X or CN XII, also V, VII)
		Examine resting position of tongue.	Atrophy or fasciculations of tongue (LMN, ALS)
		Examine tongue movements: ask patient to protrude tongue, move side-to-side.	Impaired movements, deviation to weak side UMN lesion: tongue deviates away from side of cortical lesion

From O'Sullivan and Siegelman,[18, p. 119] with permission.

muscle with loss of joint stability and increased risk for postural abnormality.[33] *Neurogenic atrophy* accompanies LMN injury (e.g., peripheral nerve injury, spinal root injury) and occurs rapidly, generally within 2 to 3 weeks. Atrophy is also accompanied by other signs of LMN injury (e.g., decreased or absent tone or decreased or absent DTRs, fasciculations, weak or absent voluntary movements). Distribution is limited to a segmental or focal pattern (nerve root).

Examination of Muscle Bulk

During the examination, the therapist should visually inspect the muscle symmetry and shapes, comparing and contrasting their size and contour. Muscles that look flat or concave are indicative of atrophy. Comparisons should be made between and within limbs. Is the atrophy unilateral or bilateral? Are multiple limbs involved? Is the atrophy more proximal, or distal, or both? Limb girth measurements can be used to compare a limb undergoing neurogenic atrophy with the corresponding normal limb. Palpation at rest and during muscle contraction is used to determine muscle tension. Girth measurements or volumetric displacement measures (e.g., hands or feet) can be used to confirm visual inspection findings.

Strength and Power

Muscle performance is "the capacity of a muscle or a group of muscles to generate forces."[4, p. 688] **Muscle strength** is "the muscle force exerted by a muscle or a group of muscles to overcome a resistance under a specific set of circumstances."[4, p. 688] Isotonic contractions involve active shortening of muscles, and eccentric contractions involve active lengthening of muscles. Isometric contractions produce high levels of tension for holding contractions without overt movement. **Muscle power** is "work produced per unit of time or the product of strength and speed."[4, p. 688] Muscle performance depends on a number of interrelated factors, including length–tension characteristics, viscoelasticity, velocity, and metabolic adequacy (fuel storage and delivery). Of equal importance are the integrated actions of the CNS (neuromuscular control factors) acting on motor units, including (1) the number of motor units recruited, (2) the type of motor units recruited, and (3) the discharge rate and continuing modulation of motor units. The CNS controls the recruitment order and timing of muscles. Synergistic movements and postural adjustments are also dependent on the integrity of the peripheral nerves, as well as the muscle fibers.

Patients with impairments in motor control and neurological injury pose unique challenges for the examination of muscle performance. *Weakness* is the inability to generate sufficient levels of force and can vary from *paresis* (partial weakness) to *plegia* (absence of muscle strength). Weakness is seen in patients with UMN syndrome, along with spasticity and hyperactive reflexes. Patients may present with *hemiplegia* (one-sided paralysis), *paraplegia* (LE paralysis), or *tetraplegia* (quadriplegia). Weakness also appears in patients with LMN lesions.

Patients with stroke demonstrate significant changes in muscle performance, including altered recruitment patterns, abnormal times to achieve force, and decreased motor unit firing rates.[34-36] They also demonstrate up to a 50% decrease in motor units of affected extremities within 2 months after insult with greater losses of Type II (fast twitch) fibers.[37,38] Impairments in grip

strength impairments are observed, including an exaggeration of grip force, altered times to achieve grip, and difficulty maintaining grip.[39] Muscle performance in patients with stroke is influenced by the presence of other UMN impairments including spasticity, disordered synergistic activity/mass patterns of movements, abnormal muscle co-contraction, and/or profound sensory deficit.[40-42] Strength losses are typically greater in the distal extremity than proximal. Strength losses have also been found on the "supposedly normal" extremities.[43-45] The bilateral effects of an ipsilateral cortical lesion is evidence of the small percentage (estimated 10%) of corticospinal tract fibers that remain uncrossed. Possible other unidentified factors may also exist. This information has prompted use of terms such as "less involved" or "less affected" in place of more traditional terms such as "unaffected," "uninvolved," "sound," "normal," or "good" side. This also casts doubt as to the validity of using the contralateral uninvolved side as a reference for normal muscle strength in patients with hemiplegia.

In patients with peripheral sensorimotor neuropathy (e.g., chronic diabetic neuropathy) or acute motor neuropathy (e.g., Guillain-Barré), strength losses are typically greater in distal segments (i.e., foot and ankle) than proximal with involvement of more proximal segments as the disease progresses. In neuropathy, the progression is slow (months or years) whereas in Guillain-Barré the progression is rapid (days or weeks) and more complete, involving not just the proximal LEs but also the trunk, UEs, and in some cases the lower CN nerves. Patients with primary muscle disease (e.g., myopathies) typically experience proximal weakness whereas patients with myasthenia gravis experience decremental strength losses. Thus, the first contraction of a muscle may start out strong and then each succeeding contraction gets weaker and weaker.

Examination of Muscle Strength and Power

The clinical examination of muscle strength and power utilizes standardized methods and protocols (e.g., manual muscle testing [MMT], handheld dynamometers, instrumented isokinetic systems). See Chapter 4, Musculoskeletal Examination, for a thorough discussion of this topic. Analysis of muscle timing including amplitude, duration, waveform, and frequency can be obtained using EMG (see later section). Activity analysis of functional performance also yields important data about muscle performance.

Strength testing measures (MMT) were originally developed to examine motor function in patients with polio (an LMN disease). There are validity issues when used in the clinical examination of patients with UMN lesions.[46,47] Strength testing using standardized protocols may be inappropriate for some patients with UMN syndrome. Appropriate criteria are therefore critical in determining whether the standards of validity and reliability of MMT are met. First and foremost, the therapist must consider the patient's movement capabilities. Individual isolated joint movements, mandated by standardized MMT procedures and isokinetic protocols, may not be possible in the presence of UMN lesion where stereotypic abnormal movement patterns (obligatory synergies) are present. The presence of abnormal co-activation, spasticity, and abnormal posturing may preclude the patient's ability to perform isolated joint movements. These barriers to normal movement are termed *active restraint.* The prescribed test positions may also be precluded by the presence of abnormal reflex activity (e.g., supine testing influenced by presence of the tonic labyrinthine reflex). Muscle and soft tissue changes in viscoelasticity (e.g., contracture) offer a form of *passive restraint* and may also preclude the use of standardized testing. In these instances, the decision should be made *not* to use standardized MMT procedures. An estimation of strength can be made from observations of active movements during performance of functional activities. For example, shallow knee bends or sit-to-stand transfers can be used to examine the strength of hip extensors and knee extensors. Standing heel-rises or toe-rises can be used to examine the strength of foot-ankle muscles (dorsiflexors, plantarflexors). Documentation should clearly indicate that UMN involvement precluded use of standardized MMT procedures. Estimates of strength can be made based on observations during active functional movements using the following criteria:

- Muscles with visible movement that are unable to overcome gravity and move throughout the ROM receive a *poor grade.*
- Muscles that are able to move against gravity throughout the range but can take no additional resistance receive a *fair grade*.
- Muscles that can move against gravity throughout the range and against some resistance (moderate resistance) receive a *good grade*.
- Muscles that can move throughout the range and against strong resistance receive a grade of *normal*.

The reader will recognize obvious similarities to the standard MMT grading system. However, in this case muscle performance involves groups of muscles moving during specific functional tasks and not during isolated joint movements with standardized protocols.

If MMT is to be used, therapists should utilize standardized positions whenever possible. If a modified position is required (e.g., the patient lacks full ROM or adequate stabilization), it should be carefully documented. *Substitutions* (muscle actions that compensate for specific muscle weakness) should be identified, eliminated whenever possible, and carefully documented. For example, the patient with SCI typically presents with common muscle substitutions (e.g., wrist extensors are used to close the fingers using tenodesis grasp). Knowledge of common substitutions is very helpful when working with this patient group.

Handheld dynamometers are small portable devices that measure mechanical force; they have been incorporated clinically into MMT procedures. The therapist reads the exact amount of force applied to the muscle during tests for good and normal grades instead of estimating the amount of resistance. High intratester and intertester reliability scores have been reported. Limitations in their use include difficulty in stabilizing both the limb and device, controlling the rate of muscle tension development, and applying sufficient force for a break test. These may be influential factors in reports that indicate the portable dynamometer is less reliable for testing LE muscle groups.[48-51]

The use of an *isokinetic dynamometer* allows the therapist to monitor many important parameters of motor control. It allows examination of a muscle's ability to generate force throughout the range, peak torques, and ability to generate torques at changing velocities. Rate of tension development (time to peak torque) and shape of the torque curve can also be determined. Concentric, isometric, and eccentric contractions and reciprocal agonist/antagonist relationships can be analyzed. This information is especially important for an understanding of functional performance.[52]

Patients with stroke typically demonstrate a variety of deficits when tested with an isokinetic dynamometer, including (1) decreased torque overall in the more affected limb when compared to the less affected limb; (2) decreased torque with increasing movement speeds; (3) decreased limb excursion; (4) extended times to peak torque development and the duration time peak torque is held; and (5) increased time intervals between reciprocal contractions. For example, many patients with stroke are unable to develop tension above 70° to 80° per second. When this value is compared to the speed needed for normal walking (100° per second), reasons for gait difficulties become readily apparent. Normative data, when available, can provide an appropriate reference for evaluating and interpreting patient data.[53,54]

Documentation of Strength and Power

Documentation of strength and power changes should include a determination of the specific muscles and body segments tested and tests used; the type and degree of changes present (e.g., paresis, paralysis); whether the changes are symmetrical or asymmetrical, distal or proximal; presence of associated signs (e.g., UMN or LMN); presence of atrophy; and factors that modify muscle performance. A description of the effects of muscle weakness on active movements, posture, and function should also be included. When examining functional performance, it is important to remember that strength estimates taken in one position do not necessarily generalize to other positions (e.g., ability to move while supporting full body weight in upright standing).

Muscle Endurance

Muscle endurance is "the ability to sustain forces repeatedly or to generate forces over a period of time."[4, p. 688] An examination of muscle endurance is important in determining functional capacity. **Fatigue** is an overwhelming sustained sense of exhaustion and decreased capacity for physical and mental work at the usual level. Fatigue can be the result of excessive activity caused by an accumulation of metabolic waste products (e.g., lactic acid); malnutrition (i.e., deficiency of nutrients); cardiorespiratory disturbances (i.e., inadequate oxygen and nutrients to the tissues); emotional stress; and other factors. Although fatigue is protective and serves a useful function in guarding against overwork and injury, it is a serious problem for some individuals. For example, patients with postpolio syndrome or chronic fatigue syndrome may experience significant restrictions in their functional activities and work as a result of debilitating fatigue. Other groups of individuals who may also experience significant limitations as a result of fatigue include those with MS, amyotrophic lateral sclerosis (ALS), Duchenne muscular dystrophy, and Guillain-Barré syndrome.[55,56] Additional factors that can influence fatigue include health status, environmental context (e.g., stressful environment), and temperature (e.g., heat stress in the patient with MS).

Exhaustion is defined as the limit of endurance, beyond which no further performance is possible. Most patients can report with great accuracy the point at which exhaustion is reached. Of concern with some patients is **overwork weakness (injury)**, defined as "a prolonged decrease in absolute strength and endurance due to excessive activity of partially denervated muscle."[57, p. 22] For example, patients with postpolio syndrome may experience weakness following strenuous activity that is not recovered with ordinary rest. They report having to spend the entire next day or two in bed following an exhaustive exercise session. It is therefore important to document the type, length, and effectiveness of rest attempts. *Delayed onset muscle soreness (DOMS)* is prolonged in patients with overwork weakness, peaking between 1 and 5 days after activity.

Examination of Fatigue

An examination of fatigue begins with the initial interview. The patient is asked to identify those activities that are fatiguing, the frequency and severity of fatigue episodes, and the circumstances surrounding the onset of fatigue. It is important to identify the *fatigue threshold,* defined as "that level of exercise that cannot be sustained indefinitely."[58, p. 691] In most cases, the onset of fatigue is gradual, not abrupt, and dependent on the intensity and duration of the activity attempted. Precipitating activities should be identified within the context of habitual daily activity. The patient is asked to identify any solutions used to overcome debilitating fatigue and how successful they are. Self-assessment questionnaires are particularly useful for the patient with significant

fatigue. One example is the *Modified Fatigue Impact Scale (MFIS)*, an instrument initially developed to assess quality-of-life problems related to fatigue in patients with MS. It includes questions on the cognitive and social domains, as well as physical performance (see Chapter 16, Multiple Sclerosis, Appendix 16.B).[59]

The examination then proceeds with specific performance-based testing. As this is likely to be fatiguing to the patient, performance testing should be limited to those key functional activities identified in the earlier interview or questionnaire. The therapist should carefully document the patient's level of fatigue during performance testing, including level of independence, modified independence (device required), or level of assistance required (minimal, moderate, or maximal). The grading criteria for the *Functional Independence Measure (FIM)* provides a useful scoring key, and the functional activities tested (e.g., transfers, locomotion) are basic to independent living.[60] During performance testing, perceived level of fatigue can be documented using the *Borg Scale for Rating of Perceived Exertion*.[61] In order to better determine the level of muscle fatigue, the therapist should ask the patient to identify two separate scores, one for the level of muscular fatigue and one for the level of central fatigue (breathlessness). The therapist is then able to differentiate between peripheral factors and central factors contributing to fatigue.

Examination of muscle fatigue can also include both volitional and electrically elicited fatigue tests using an isokinetic dynamometer. This equipment permits quantification of torque outputs. Patients are asked to perform repetitive, submaximal isokinetic contractions. A drop-off of peak torque by 50% can be used as an index of fatigue.[62] Electrically induced fatigue tests can also be used to examine muscle performance and may provide a more reliable measure in individuals with low motivation or who have a disorder of central drive (e.g., stroke). The muscle is stimulated with groups of electrical pulses (pulse trains) and percentage of decline in force production is measured.[63,64] Timed performance on functional tasks (e.g., timed self-care tasks, time to walk a particular distance, 6-minute walk test) also provides objective and reproducible measures of muscular endurance.

Documentation

Documentation of muscle endurance should include a determination of (1) activities that result in debilitating fatigue, including onset, duration, and recovery; (2) level of assistance or assistive devices required; (3) frequency and effectiveness of rest attempts; (4) compensatory strategies adopted and effectiveness; and (5) impact on quality of life. Results of specific questionnaires and tests are documented. Social and environmental stressors should also be described along with the patient's emotional/psychological responses (e.g., degree of depression or anxiety).

Voluntary Movement Patterns

Synergies are functionally linked muscles that are constrained by the CNS to act cooperatively to produce an intended motor action. They are used to simplify control, reduce or constrain the degrees of freedom, and initiate coordinated patterns of movement. **Degrees of freedom** refers to the number of separate independent dimensions of movement that must be controlled by engaging these cooperative units of muscle action.[1] Synergistic movements are defined by precise spatial and temporal organization that requires a high degree of coordination involving control of speed, distance, direction, rhythm, and levels of muscle tension (see Chapter 6, Examination of Coordination and Balance). In individuals with normal motor control, voluntary movement patterns are functional, task specific, and highly variable, depending on the task purpose and environment. The CNS controls patterns of (1) single limb and multiple limb movements, (2) bilateral (bimanual) symmetrical and asymmetrical movements, (3) reciprocal movements, and (4) patterns of proximal stabilization and postural support. Movements are also appropriately timed with events in the environment (*coincident timing*).

Abnormal Synergistic Patterns

Synergistic organization of movement may be disturbed with pathology of the CNS. Lesions of the corticospinal tracts (e.g., stroke) can produce abnormal **obligatory synergies**, defined as movements that are primitive and highly stereotyped. Voluntary movements are limited with loss of ability to adapt movements to changing demands. Selective movement control (isolated joint movements) is severely disordered or disappears completely. Patients with stroke typically demonstrate obligatory flexion and extension synergies (see Chapter 15, Stroke, Table 15.5). Abnormal synergies are highly predictable and characteristic of middle stages of recovery from stroke.[65-67]

Examination

The examination of abnormal synergies is both qualitative and quantitative. The therapist observes whether voluntary movement can be initiated, whether it can be completed, and how the movement is carried out. If movement is stereotypic and obligatory, what muscle groups are linked together? How strong are the linkages between muscle groups? Are there linkages between upper and lower limbs or one side to another (associated reactions)? Are the movements influenced by other components of UMN syndrome, such as primitive reflexes, spasticity, paresis, or position? For example, does elbow, wrist, and finger flexion always occur when shoulder flexion is initiated? Is head turning used to initiate or reinforce UE flexion (asymmetric tonic neck reflex [ATNR])? Therapists also need to identify when these patterns occur, under what circumstances, and what variations are possible. As CNS recovery progresses, the

synergy patterns become less dominant, and reemerge only under conditions of stress or fatigue. Lessening of synergy dominance and emergence of selective movement control are evidence of sequential recovery in patients with stroke.[64-66] The *Fugl-Meyer Post-Stroke Assessment of Physical Performance* provides an objective and quantifiable measure of obligatory synergistic dominance and recovery after stroke[68] (see Chapter 15, Stroke, Appendix 15.A).

Documentation

Documentation of abnormal synergies should include a determination of (1) what abnormal synergies are present; (2) the overall strength of the synergies present; (3) the strongest components in each synergy; (4) the influence of other UMN signs on synergies; (5) what variations in movement from the typical synergies are possible, if any; and (6) the effect of obligatory synergies on function (basic activities of daily living [BADL], functional mobility skills).

Table 5.9 presents a summary of the differential diagnosis summary comparing UMN and LMN syndromes. Table 5.10 presents a summary of the differential diagnosis summary comparing the major types of CNS disorders by location of lesion/motor control disorders.

Activity-based Task Analysis

Examination at the functional level focuses on observation and classification of functional abilities and the identification of activity limitations. Performance-based instruments yield important information about function and levels of independence or dependence (supervision, assistance, assistive devices). Numerous instruments are available with quantitative scoring systems (e.g., the FIM). See Chapter 8, Examination of Function, for a thorough discussion of performance-based measures.

Activity-based task analysis is the process of breaking a specific activity down into its component parts to understand and evaluate the demands of the task and the performance demonstrated. It begins with an understanding of normal movements and normal kinesiology associated with the task. The therapist examines and evaluates the patient's performance and analyzes the differences compared to "typical" or expected performance. Critical skills in this process include accurate observation and recognition of barriers or obstacles to moving in the correct pattern. Interpretations are made about the nature of the motor performance and the possible links between documented impairments and performance difficulties. A determination of how the environment affects performance must also be made. For

Table 5.9 Differential Diagnosis: Comparison of Upper Motor Neuron (UMN) and Lower Motor Neuron (LMN) Syndromes

	UMN Lesion	LMN Lesion
Location of lesion, structures involved	Central nervous system cortex, brainstem, corticospinal tracts, spinal cord	Cranial nerve nuclei/nerves Spinal cord: anterior horn cell, spinal roots Peripheral nerve
Diagnosis/pathology	Stroke, traumatic brain injury, spinal cord injury	Polio, Guillain-Barré Peripheral nerve injury Peripheral neuropathy Radiculopathy
Tone	Increased: hypertonia Velocity dependent	Decreased or absent: hypotonia, flaccidity Not velocity dependent
Reflexes	Increased: hyperreflexia, clonus Exaggerated cutaneous and autonomic reflexes, +Babinski	Decreased or absent: hyporeflexia Cutaneous reflexes decreased or absent
Involuntary movements	Muscle spasms: flexor or extensor	With denervation: fasciculations
Strength	Weakness or paralysis: ipsilateral (stroke) or bilateral (SCI) Corticospinal: contralateral if above decussation in medulla; ipsilateral if below Distribution: never focal	Ipsilateral weakness or paralysis Limited distribution: segmental or focal pattern, root-innervated pattern
Muscle bulk	Disuse atrophy: variable, widespread distribution, especially of antigravity muscles	Neurogenic atrophy: rapid, focal distribution, severe wasting
Voluntary movements	Impaired or absent: dyssynergic patterns, obligatory mass synergies	Weak or absent if nerve interrupted

Table 5.10 Differential Diagnosis: Comparison of Major Types of Central Nervous System Disorders

Location of Lesion	Cerebral Cortex Corticospinal Tracts	Basal Ganglia	Cerebellum	Spinal Cord
Diagnosis/ pathology	Stroke	Parkinson's disease	Tumor, stroke	Trauma, tumor, vascular insult: complete, incomplete SCI
Sensation	Impaired or absent: depends on lesion location; contralateral sensory loss	Not affected	Not affected	Impaired or absent below the level of lesion
Tone	Hypertonia/spasticity velocity-dependent; clasp-knife Initial flaccidity: cerebral shock	Lead-pipe rigidity: increased, uniform resistance Cogwheel rigidity: increased, ratchet-like resistance	Normal or may be decreased	Hypertonia/spasticity below the level of the lesion Initial flaccidity: spinal shock
Reflexes	Hyperreflexia	Normal or may be decreased	Normal or may be decreased	Hyperreflexia
Strength	Contralateral weakness or paralysis: hemiplegia or hemiparesis Disuse weakness in chronic stage	Disuse weakness in chronic stage	Normal or weak: asthenia	Impaired or absent below the level of the lesion: paraplegia or paraparesis; tetraplegia or tetraparesis
Muscle bulk	Normal during acute stage; disuse atrophy in chronic stage	Normal or disuse atrophy	Normal	Disuse atrophy
Involuntary movements	Spasms	Resting tremor	None	Spasms
Voluntary movements	Dyssynergic: abnormal timing, co-activation, fatigability	Bradykinesia: slowness of movement Akinesia: absence of movement	Ataxia: intention tremor dysdiadochokinesia dysmetria dyssynergia nystagmus	Above level of lesion: intact (normal) Below level of lesion: impaired or absent
Postural control	Impaired or absent, depends on lesion location Impaired balance	Impaired: stooped (flexed) Impaired balance	Impaired: truncal ataxia Impaired balance	Impaired below level of lesion Impaired balance
Gait	Impaired: gait deficits due to abnormal weakness, synergies, spasticity, timing deficits	Impaired: shuffling, festinating gait	Impaired: ataxic gait deficits, wide-based, unsteady	Impaired or absent: depends on level of lesion

From O'Sullivan and Siegelman,[18, p. 126] with permission.
SCI = spinal cord injury.

example, the patient who is unable to transfer from bed to wheelchair may lack postural trunk support (stability), adequate LE extensor control (strength), and ability to maintain control while moving from one surface to the other. Or the patient with acute stroke sits up from supine using the less affected UE for support and propulsion. The more affected extremities lag behind, not well integrated into the movement pattern. The final sitting position is asymmetrical with most of the weight borne on the less affected side and the more affected UE held in an abnormally flexed and adducted position. In addition, the patient is highly distractible with poor attention demonstrated in the busy clinic environment. It is important to document these qualitative findings as they provide valuable information necessary for developing an effective POC to improve motor function. The term *activity demands* refers to the requirements imbedded in each step of the activity. The term

environmental demands (constraints) refers to the physical characteristics of the environment or features required for successful performance of movement (regulatory conditions). Questions posed in Box 5.2 can be used to provide a guide for qualitative task analysis.

Taxonomy of Tasks

Tasks are commonly grouped into functional categories. **Activities of daily living** (**ADL**) refer to those daily living skills necessary for an adult to manage life. **Basic ADL** (**BADL**) include grooming skills (oral hygiene, showering or bathing, dressing), toilet hygiene, feeding, and personal device care. **Instrumental ADL** (**IADL**) include money management, functional communication and socialization, functional and community mobility, and health maintenance.

Functional mobility skills (**FMS**) refer to those skills involved in:

1. Bed mobility: rolling, bridging, scooting in bed, moving from supine-to-sit and sit-to-supine
2. Sitting: scooting
3. Transfers: moving from sit-to-stand and stand-to-sit, transfers from one surface to another (e.g., bed-to-wheelchair and back, on and off a toilet, to and from a car seat), and moving from floor-to-standing
4. Standing: stepping
5. Walking and stair climbing

Control can also be examined in other postures including prone-on-elbows, quadruped (hands and knees), kneeling, and half-kneeling. It is important to note that there is considerable variability in motor

Box 5.2 Functional Task Analysis Worksheet

Task analysis begins with an appreciation of normal movements. An examination and evaluation of the patient's task performance is completed and a comparison of the differences is made. Critical skills include accurate observation, recognition and interpretation of movement deficiencies, determination of how underlying impairments relate to the movement deficiencies observed, and determination of what needs be altered and how. The following questions can be used as a guide for qualitative functional task analysis.

A. What are the normal requirements of the functional task being observed?

1. What is the overall movement sequence (motor plan)?
2. What are the initial conditions required? Starting position and initial alignment?
3. How and where is the movement initiated?
4. How is the movement executed?
5. What are the musculoskeletal components required for successful completion of the task?
6. What are the motor control strategies required for successful completion of the task?
7. What are the requirements for timing, force, and direction of movements?
8. What are the requirements for balance?
9. How is the movement terminated?
10. What are the environmental constraints that must be considered?
11. What are the motor learning factors that must be considered?

B. How successful is the patient's overall movement in terms of outcome?

1. Was the overall movement sequence completed?
2. What components of the patient's movements are normal? Almost normal?
3. What components of the patient's movements are abnormal?
4. What components of the patient's movements are missing? Delayed?
5. If abnormal, are the movements compensatory and functional? Noncompensatory and nonfunctional?
6. What are the underlying impairments that constrain or impair the movements?
7. Do the movement errors increase over time? Is fatigue a constraining factor?
8. Is this a transitional mobility activity? Are the requirements met?
9. Is this a stability level activity? Are the requirements met for static and dynamic control?
10. Is this a skill level activity? Are the requirements met?
11. Are balance requirements met? Is patient safety evident throughout the task?
12. What environmental factors constrained or impaired the movements?
13. Can the patient adapt to changing task and environmental demands?
14. What difficulties do you expect this patient will have with other functional tasks?
15. What difficulties do you expect this patient will have in other environments?
16. How successful were the motor learning strategies?

Adapted from *A Compendium for Teaching Professional Level Neurologic Content*, Neurology Section, American Physical Therapy Association, 2000.

performance of FMS across the life span.[69-73] Changes are influenced by such factors as changing body dimensions, age, health, and level of physical activity. Thus, the activities of rolling over and sitting up may vary considerably between two adults of different size, age, or health.

Tasks can also be grouped according to the actions and type and nature of motor control (neuromotor processes) required during performance of the task. These include (1) transitional mobility, (2) stability (static postural control), (3) dynamic postural control (controlled mobility), and (4) skill. Difficulty varies according to the degree of postural and movement control required. Thus, those tasks with increased degrees of freedom and attentional demands such as standing and walking are more difficult than prone or supine tasks with limited body segments to control.

Transitional mobility is the ability to move from one position to another independently and safely (e.g., rolling, supine-to-sit, sit-to-stand, transfers). Common characteristics of normal mobility include the ability to initiate movement, control movement, and terminate movement while maintaining postural control. Deficits in *mobility* range from failure to initiate or sustain movements to poorly controlled movement to failure to successfully terminate the movement. At the very lowest level, the impaired patient is only able to roll partially over to side lying and exhibits poor ability to sustain movements. At the highest end, the patient is asked to stand up and walk across the room. The impaired patient exhibits difficulty standing up (may require several attempts) but once up is able to walk with only a few abnormal gait characteristics. Key elements the therapist should observe and document include (1) the ability to initiate movements; (2) strategies utilized and overall control of movement; (3) the ability to terminate movement; (4) the level and type of assistance required (manual cues, verbal cues, guided movements); and (5) environmental constraints that influenced performance.

Stability (*static postural control*) is the ability to maintain postural stability and orientation with the center of mass (COM) over the base of support (BOS) and the body at rest. For example, the patient demonstrates stability in sitting or standing if he or she is able to maintain the posture with minimum sway, no loss of balance, and no handhold. Key elements the therapist should observe and document include (1) the BOS; (2) the position and stability of the COM within the BOS; (3) the degree of postural sway; (4) the degree of stabilization from UEs or LEs (e.g., handhold, hooked legs); (5) the number of episodes and direction of loss of balance (LOB) and fall safety risk; (6) the level and type of assistance required (manual cues, verbal cues, guided movements); and (7) environmental constraints that influenced performance.

Dynamic postural control (*dynamic balance,* or *controlled mobility*) is the ability to maintain postural stability (a stable, nonmoving BOS, COM within the BOS) while parts of the body are in motion. Thus, an individual is able to weight shift or rock back and forth or side to side in a posture (e.g., in sitting or standing) without losing control. The adjustment of postural control while performing a secondary task with a limb freed from weight-bearing is also evidence of dynamic postural control (sometimes called *static-dynamic control*). The initial weight shift and redistributed weight-bearing places increased demands for stability on the support segments while the dynamic limb challenges control. For example, a patient with TBI is positioned in quadruped and demonstrates difficulty when asked to lift either an upper or lower limb, or lift the opposite upper and lower limbs together. In sitting, the patient with stroke is unable to reach forward and toward the affected side with the less affected limb without losing balance and falling over. In standing, the patient with cerebellar ataxia is unable to step forward, backward, or out to the side without losing balance. Key elements the therapist should observe and document include (1) the degree of postural stability maintained by the weight-bearing segments; (2) the range and degree of control of the dynamically moving segments; (3) the level and type of assistance required (e.g., verbal cues, manual cues, guided movements); and (4) environmental constraints that influenced performance.

Skill is the ability to consistently perform coordinated movement sequences for the purposes of attaining an action goal. Skilled behaviors allow for purposeful investigation and interaction with the physical and social environment (e.g., manipulation or transport). Skills are learned, and are the direct result of practice and experience with actions organized in advance of movement using a motor plan. Skilled movements are variable and not constrained by one set movement pattern but rather are organized by the action goal and the environment. Thus, a skilled individual is able to adapt movements easily to changes in task demands and the environments in which they occur. For example, control of walking is evident in the clinic as well as in home and community environments. Skills can be performed using consistent or variable movements. Regulatory conditions can vary from a stationary environment to motion in the environment.[74]

Motor skills can be further categorized. Kicking a ball is an example of a *discrete skill*, with a recognizable beginning and end. Walking is a *continuous skill* (no recognizable beginning and end), and playing a piano represents a *serial skill* (a series of discrete actions put together). A movement skill performed in a stable , nonchanging environment is called a **closed motor skill**, and a movement skill performed in a variable, changing environment is called an **open motor skill**.[1] A skilled individual is also able to perform a simultaneous secondary task while moving (**dual task control**). For example, the patient with stroke is able to stand or walk while holding or manipulating an object (e.g., bouncing a ball), talking, or performing a cognitive task (counting backwards

by 3's from 100). Table 5.11 provides a summary of categories of motor skills.

During functional task analysis, key elements the therapist should observe and document include (1) the ability to organize and control movements; (2) economy of effort; (3) the success of attaining an action-goal (outcome); (4) ability to easily and successfully adapt a task; (5) ability to easily and successfully adapt to changing environments; and (6) verbal cues and assistance, if any, required. Box 5.2 provides a Functional Task Analysis Worksheet.

Videography

The qualitative analysis of motor skills can be enhanced by the use of videography. Patient responses are recorded, providing a permanent record of motor performance that allows the therapist the opportunity to compare responses over time. Recordings made at 3 or 6 weeks of recovery can be compared easily without reliance on the therapist's memory or written notes. Accuracy of observations can be improved. A therapist who is closely involved in assisting or guarding during performance may not be attentive enough to observe all movement parameters (e.g., when assisting the patient with TBI with severe ataxia). Depending on equipment capabilities, videotapes can be viewed repeatedly at different speeds to determine control during different tasks and at different body segments. For example, a patient's performance in a task such as sitting up from supine can be observed first at regular speeds, then at slow motion speeds. Stop-action or freezing a frame can be used to isolate a problematic point in the movement sequence. This may be helpful, particularly for the inexperienced therapist, in improving both the quality and reliability of observations. Repeat trials on a functional performance test may needlessly tire the patient while yielding a decrease in performance. Sequential recordings over the course of rehabilitation provide visual documentation of patient progress and can be an important motivational and educational tool in therapy for use with the patient and family. Reliability of recordings for intersession comparisons can be improved by the following measures. Placement of equipment should be planned in advance to achieve the best location and should be consistently placed over subsequent sessions. Use of a tripod can improve the stability of the recording. Verbal descriptions of the performance during each trial can be edited directly onto a videotape or documented in a written summary.[75]

MOTOR LEARNING

Motor learning is a complex process that requires spatial, temporal, and hierarchical organization within the CNS

Table 5.11 Categories of Motor Skills

Categories	Characteristics	Examples	Impairments
Transitional mobility	Ability to move from one posture to another; BOS and/or COM is changing	Rolling; supine-to-sit; sit-to-stand; transfers	Failure to initiate or sustain movements through the range; poorly controlled movements
Static postural control (stability, static equilibrium, or static balance)	Ability to maintain postural stability and orientation with the COM over the BOS with the body not in motion; BOS is fixed	Holding in antigravity postures: prone-on-elbows, quadruped, sitting, kneeling, half-kneeling, modified plantigrade, or standing	Failure to maintain a steady posture; excessive postural sway; wide BOS; high guard arm position or handhold; loss of balance (COM exceeds BOS)
Dynamic postural control (controlled mobility, dynamic equilibrium, or dynamic balance)	Ability to maintain postural stability and orientation with the COM over the BOS while parts of the body are in motion; BOS is fixed	Weight shifting; UE reaching in any of the above antigravity postures; LE stepping in modified plantigrade or standing	Failure to maintain or control posture during dynamic trunk or extremity movements; loss of balance
Skill	Ability to consistently perform coordinated UE and LE movement sequences for the purposes of investigation and interaction with the physical and social environment; during locomotion, COM is in motion and BOS is changing	UE skills: Grasp and manipulation LE skills: Bipedal locomotion	Poorly coordinated movements; lack of precision, control, consistency, and economy of effort

BOS = base of support; COM = center of mass; LE = lower extremity; UE = upper extremity.

that allows for acquisition and modification of movement. As mentioned earlier, changes in the CNS are not directly observable, but rather are inferred from improvement in performance as a result of practice or experience. Individual differences in learning are expected and influence both the rate and degree of learning possible. Motor learning abilities among individuals vary across three main foundational categories of abilities: cognitive abilities, perceptual speed ability, and psychomotor ability.[76] Differences occur as a result of both genetics and experience. The therapist should be sensitive to such factors as alertness, anxiety, memory, speed of processing information, speed and accuracy of movements, and uniqueness of the setting. In addition, recovering patients may vary in their learning potential according to the pathology present, the number and type of impairments, recovery potential and general health status, and comorbidities. Although most skills can be learned through practice or experience, the therapist should be sensitive to the patient's underlying capabilities (abilities) that support certain skills. For example, some patients with SCI may not be able to learn to manage curbs using "wheelies" because of the difficulty of the task, their residual abilities, and their general health status.

Stages of Motor Learning

Fitts and Posner[77] described three main stages in learning a motor skill. Their model provides a useful framework for examining and developing strategies to improve motor learning and is used in this chapter as well as in Chapter 10, Strategies to Improve Motor Function. A three-stage process is supported by the work of Anderson,[78,79] whereas Gentile proposed a two-stage process.[80]

In the early **cognitive stage** the learner develops an understanding of task. During practice *cognitive mapping* allows the learner to assess abilities and task demands, identify relevant and important stimuli, and develop an initial movement strategy (motor program) based on explicit memory of prior movement experiences. The learner performs initial practice of the task, retaining some strategies while discarding others in order to develop an initial movement strategy. During successive practice trials, the learner modifies and refines the movements. During this stage there is considerable cognitive activity and each movement requires a high degree of conscious attention and thought. The learner is highly dependent on use of visual feedback. Performance is initially inconsistent with large gains occurring as the patient progresses to the next stage. The basic "What to do" decision is answered.

The second and middle stage is the **associated stage** of motor learning. During this stage, the learner practices and refines the motor patterns, making subtle adjustments. Spatial and temporal organization increases while errors and extraneous movements decrease. Performance becomes more consistent and cognitive activity decreases. The learner is less dependent on visual feedback while use of proprioceptive feedback increases. Thus, the learner begins to learn the "feel" of the movement. This stage can persist for a long time, depending on the learner and the level of practice. The "How to do" decision is answered.

The third and final stage is the **autonomous phase** of motor learning. The learner continues to practice and refine motor patterns. The spatial and temporal components of movement become highly organized. Performance is at a very high level (e.g., skilled athletes). At this stage of learning, movements are largely error free and automatic with only a minimal level of cognitive monitoring and attention. The "How to succeed" decision has been answered.

Patients with brain injury admitted to active rehabilitation often have to relearn basic motor skills using entirely different motor control mechanisms and strategies. Activities and movements that were easily done before now become unfamiliar and challenging. These patients can persist in the cognitive learning stage for some time before they develop the idea of a movement skill. Impairments in motor control can influence performance and learning during the middle or associated stage, which can also be prolonged. Many times patients are discharged from rehabilitation before the skills become refined and learning completed. Many patients fail to reach the third stage of learning evidenced by highly skilled performance.

Measures of Motor Learning

Performance Observations

Traditionally, improvements in performance during practice have been used to assess motor learning. Performance criteria are established and used for comparison to determine the success of learning outcomes. Table 5.12 presents some possible measures of motor performance. For example, an individual recovering from stroke is able to demonstrate functional independence in transfers after a series of training sessions. Improvement in functional scores (e.g., FIM scores) documents changes in the level of assistance needed. Qualitative changes in performance compared to the criterion skill can also be used to document motor learning. Thus, the movement is performed with improved coordination, indicative of changes in spatial and temporal organization. Error scores can be used to document accuracy of movement. Thus, therapists can report the number and type of errors (constant, variable) that occur within a given practice session and across practice sessions. A decrease in the frequency of error provides indirect evidence of improvements in learning. One common measurement problem in skill learning is the *speed–accuracy trade-off.* Typically, initial practice sessions are characterized by slowed performance in order to improve movement accuracy. As learning progresses, performance speed is increased once accuracy demands are satisfied. The therapist needs to document the time it takes to complete the activity along with number of errors. Reduced effort and concentration are indicative of improved performance and should be documented. A high degree

Table 5.12 Measures of Motor Performance

Category	Examples of Measures	Performance Examples
Outcome Measures	**Movement Time (MT):** The time interval between the initiation of a movement and completion of a movement, in seconds or minutes	10-Meter Walk Test (10-MWT) Time to complete a functional task (e.g., transfer wheelchair to mat) Minnesota Rate of Manipulation Test
	Reaction Time (RT): The time interval between the presentation of a stimulus and the initiation of a response, in seconds or minutes	Time to initiate a functional task after cueing is provided (e.g., supine-to-sit or sit-to-stand transfers)
	Distance: The total distance completed, in meters or feet	6- or 12-Minute Walk Test
	Observational Performance Changes: Observation of deviations of performance with respect to target behaviors	Observational gait analysis: Systematic examination of movement patterns of body segments at each point in the gait cycle
	Changes in Performance Scores using a standardized outcome measure	Changes in scores on the Functional Independence Measure, Barthel Index, Berg Balance Scale, or Purdue Pegboard Test
	Errors in Performance using a criterion task	*Error in program selection*: Patient with stroke incorrectly transfers to the less affected side when asked to transfer to the more affected side *Error in program execution*: Patient with TBI becomes distracted and is unable to complete a transfer
	Constant Error (CE): The average error of a set of scores from a target value; a measure of average bias	Patient exhibits an average distance on a Functional Reach Test of 6 inches on 3 trials; mean for age ([72 years, women] ≥13.8 inches)
	Variable Error (VE): The SD of a set of scores about the subject's own average score; a measure of movement consistency	Patient exhibits an average SD on a Functional Reach Test of 3 inches on 3 trials
	Number of Successful Attempts: During practice of an activity compared to total number of attempts	Patient performs an independent sit-to-stand transfer 4 out of 10 attempts
	Percentage of Successful Attempts	Patient performs an independent sit-to-stand transfer 40% of attempts
	Time on Target, compared to total time of the activity, in sec or min	Patient is able to maintain independent stability in sitting (or standing) for 2 min during a 5 min trial
	Time in Balance	Number of seconds patient is able to maintain BOS within COM while standing on foam
	Trials to Completion: Number of trials required until correct response obtained	10 practice trials required for patient to be independent in wheelchair to mat transfers
Instrumental Response Measures	**Limb displacement, trajectory**	Distance limb(s) traveled to produce response during instrumental motion analysis, kinematic gait analysis
	Velocity	Speed limb(s) moved while performing response during instrumental motion analysis or isokinetic dynamometry
	Acceleration/deceleration	Acceleration/deceleration pattern while moving during instrumental motion analysis or isokinetic dynamometry
	Joint angle	Angle of each joint during movement during instrumental motion analysis, or using electrogoniometry
	Muscle activity/electromyography (EMG) testing: The electrical activity of muscle based on motor unit activity	Patterns and timing of muscle activity at rest and during contraction compared to normative muscle activity values (e.g., amplitude, duration, shape, sound, and frequency); correlated with clinical findings of muscle weakness and performance

Table 5.12 Measures of Motor Performance—cont'd

Category	Examples of Measures	Performance Examples
	Nerve conduction velocity (NCV) testing: The conduction time (speed) with which a peripheral motor or sensory nerve conducts an impulse.	Direct stimulation to a nerve with recording of the evoked potential at a different point, compared to normative NCV values (e.g., evoked potentials, elapsed time); correlated with clinical findings of muscle weakness and sensory changes

BOS = base of support; COM = center of mass; min = minutes; SD = standard deviation; sec = seconds; TBI = traumatic brain injury.

of cognitive monitoring is necessary in early learning (cognitive stage). In contrast, performance across the associative and autonomous stages of motor learning is characterized by a reducing level of cognitive monitoring and increasing automaticity.[76] As learning progresses, performance is increasingly characterized by persistence and consistency. Thus, the acquired skills are observed for variability within and across practice sessions, which can be expected to decrease.

Performance observations can be misleading in that while they indicate initial learning, they are not considered an accurate reflection of long-term learning or retention. It is possible to practice enough to temporarily improve performance but not retain the learning. Conversely, factors such as fatigue, anxiety, poor motivation, boredom, or drugs can cause performance to deteriorate while learning may still be occurring. For example, the patient with MS who is fatigued or stressed performs very poorly during scheduled treatment but returns after the weekend rested and calm, and is able to perform the task with ease. *Performance plateaus,* defined as a leveling off of performance after a period of steady improvement, characterize normal practice and can be expected to occur. During plateaus, learning may still be going on whereas performance is not changing. Problems can also occur with the measurement instruments selected. Failure to demonstrate improved performance can be the result of *ceiling effects,* defined as a high level of performance in which further improvement cannot be detected owing to limitations in the performance measure. Conversely, *floor effects* are a low level of performance in which further decreases cannot be detected by limitations in the performance measure. They can affect a determination of negative learning.[1]

Retention Tests

More reliable inferences about learning can be made through the use of retention tests and transfer tests. **Retention** refers to the ability of the learner to demonstrate the skill over time and after a period of no practice (**retention interval**). A **retention test** is defined as "a performance test administered after a retention interval for the purposes of assessing learning."[1, p. 499] It provides an important measure of learning. Retention intervals can be of varying lengths. For example, a patient who is seen only once a week in an outpatient clinic is asked to demonstrate a skill practiced the previous week. Performance after the retention interval is compared to performance on the initial practice session. A *difference score* can be determined and documented, that is, the difference in performance scores from the end of the original acquisition phase and the beginning of the retention phase. Performance may show a slight initial decrease but should return to original performance levels within relatively few practice trials after the retention interval if learning has occurred (termed *warm-up decrement*). It is important not to provide any verbal cueing or knowledge of results (KR) during the retention trial. This same patient may have been given a home exercise program (HEP) that includes daily practice of the desired skill. If, on return to the clinic some weeks later, performance of the desired skill has not been maintained or has deteriorated, the therapist might reasonably conclude that the patient has not been diligent with the HEP and learning has not been retained.

Transfer Tests

Transfer of learning refers to the gain (or loss) in the capability of task performance in one task as a result of practice or experience on some other task. Learning obtained from the criterion task enhances (*positive transfer*) or detracts from (*negative transfer*) learning on other tasks. For example, the patient with stroke practices feeding skills using the less affected UE. Performance on the feeding task using the more affected UE is then evaluated. The therapist should observe and document the effectiveness of the prior practice (e.g., number and frequency of practice trials, time, effort) on performance using the more affected extremity. Transfer of learning is greatest when tasks are similar, that is, have similar stimuli and similar responses.

Adaptability

Adaptation is the ability to modify and adapt how movements are performed in response to changing task and environmental demands. Thus, the individual is able to apply a learned skill to the learning of other similar tasks. Individuals who learn to transfer from wheelchair-to-platform mat can apply that learning to other variations of transfers (e.g., wheelchair-to-car, wheelchair-to-bathtub). The number of practice trials, time, and effort required to perform these new types of transfers should be observed and documented. These parameters are typically reduced from that required to learn the initial skill.

Resistance to Contextual Change

Resistance to contextual change is also an important measure of learning. This is the adaptability required to perform a motor task in altered environmental situations. Thus, an individual who has learned a skill (e.g., walking with a cane) should be able to apply that learning to new and variable environments (e.g., walking at home, walking outdoors, walking downtown on a busy street). The therapist observes and documents how successful the individual is in performing the skill in the new and varying environments. The patient who is able to perform the skill in only one type of environment, for example, the patient with TBI who is only able to function within a tightly controlled, clinic environment (*closed environment*), demonstrates limited and largely nonfunctional skills in other environments. This patient is not likely to return home independent in the community environment (*open environment*), and will likely require placement in an assisted living (structured) setting.

Active Problem Solving

The patient who is able to engage in active introspection and self-evaluation of performance and reach decisions independently about how to improve performance demonstrates an important element of learning. Some physical therapists overemphasize guided movements and errorless practice. Although this may be important for safety reasons, lack of exposure to performance errors may preclude the patient from developing capabilities for self-evaluation. In an era of fiscal responsibility and limitations on the amount of physical therapy sessions allowed, many patients are able to learn only the very basic skills while in active rehabilitation. Much of the necessary learning of functional skills occurs after discharge and during outpatient episodes of care. The therapist cannot possibly structure practice sessions to meet all of the functional challenges the patient may face. The acquisition of independent problem solving/decision making skills ensures that the final goal of rehabilitation—independent function—can be achieved. The therapist needs to promote, observe, and document this very important function.

Learning Styles

Individuals vary in their *learning style,* defined as their characteristic mode of acquiring, processing, and storing knowledge. Learning styles differ according to a number of factors, including personality characteristics, reasoning styles (inductive or deductive), and initiative (active or passive). Some individuals utilize an *analytical/objective* learning style. They process information in a step-by-step order and learn best with factual information and structure. Other individuals are more *intuitive/global* learners. They tend to process information all at once, and learn best when information is personalized and presented within the context of practical, real-life examples. They may have difficulty in ordering steps and comprehending details. Some individuals rely heavily on visual processing and demonstration to learn a task. Others depend more on auditory processing, talking themselves through a task. Individual characteristics and preferences are best determined by talking with the patient and family, using careful listening and observation skills. The medical record may also provide information concerning relevant premorbid history (e.g., educational level, occupation, interests). A thorough understanding of each of these factors allows the therapist to appropriately structure the learning environment and therapist–patient interactions.

ELECTROPHYSIOLOGICAL INTEGRITY OF MUSCLE AND NERVE

In the evaluation of muscle performance and motor control, we are concerned with the integrity of both central and peripheral mechanisms. The assessment of electrophysiological properties of nerve and muscle provides essential information to understand diagnosis of neuromuscular disease or trauma, the location of a lesion within the PNS, and prognosis or rate of healing or decay. Such disorders typically result in weakness or lack of motor coordination in movement, resulting in disruption to feedback and motor control mechanisms. Such disorders may be related to neuropathic or myopathic processes, or diseases affecting the neuromuscular junction.[81] Clinical **electromyography (EMG)** is used to evaluate the scope of a neuromuscular disorder through assessment of muscle activity. **Nerve conduction velocity (NCV)** tests determine the speed with which a peripheral motor or sensory nerve conducts an impulse. Together, data from EMG and NCV tests assist with establishing anticipated goals and expected outcomes for patients with musculoskeletal and neuromuscular disorders. EMG findings are not diagnostic in isolation, however, and must be considered in relation to clinical findings, as well as findings from other physical therapy, medical, and physiological tests and measurements.

Concepts of Electromyography

EMG is the recording of the electrical activity of muscle based on motor unit activity. Motor units are composed of one anterior horn cell, one axon, its neuromuscular junctions, and all the muscle fibers innervated by that axon (Fig. 5.1). The single axon conducts an impulse to all its muscle fibers, causing them to depolarize at relatively the same time. This depolarization produces electrical activity that is manifested as a **motor unit action potential (MUAP)** and recorded and displayed graphically as the EMG signal. The characteristics of the MUAP will change when there is damage to either the nerve or muscle.

Recording the EMG Signal

EMG signals are captured using a needle electrode, which is inserted into the muscle through the skin. The

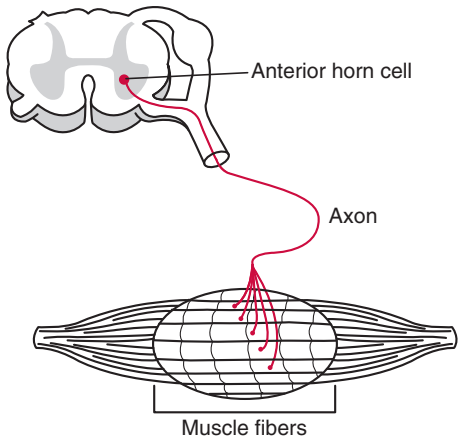

Figure 5.1 The motor unit is composed of one anterior horn cell, one axon, its neuromuscular junction, and all the muscle fibers innervated by that axon.

most common types of needle electrodes are bipolar and monopolar. A *bipolar electrode* is a hypodermic needle, through which a single wire of platinum or silver is threaded. The cannula shaft and wire are insulated from each other, and only their tips are exposed. The wire and the needle cannula act as recording and reference electrodes, and the difference in potential between them is recorded in volts.

A *monopolar needle electrode* is composed of a single fine needle, insulated except at the tip. A second surface electrode placed on the skin near the site of insertion serves as the reference electrode. These electrodes are less painful than concentric electrodes because they are smaller in diameter.

It is important to understand the process by which an MUAP is transmitted to an amplifier in order to understand how such potentials can be interpreted. Because of the dispersion of the fibers in a single motor unit, the muscle fibers from several motor units will be interspersed with one another (Fig. 5.2). Therefore, when one motor unit contracts, the depolarizing fibers are not necessarily close together. Consequently, a needle electrode cannot be situated precisely within one motor unit.

All the fibers of a single motor unit contract almost synchronously, and the electrical potentials arising from them travel through body fluids in all directions, not just in the direction of the inserted needle. Fibrous tissue, fat, and blood vessels act as insulators in this process. Therefore, the actual pattern of the flow of electrical activity is not predictable. The signals that do reach the electrode are transmitted to an amplifier. The activity produced by all the individual fibers contracting at any one time is summated, reaching the electrode almost simultaneously. Electrodes only record potentials they pick up, without differentiating their origin. Therefore, if two motor units contract at the same time, from the same or adjacent muscles, the activity from fibers of both units will be summated and recorded as one large potential.

The size and shape of the MUAP can be affected by several variables. The proximity of the electrodes to the

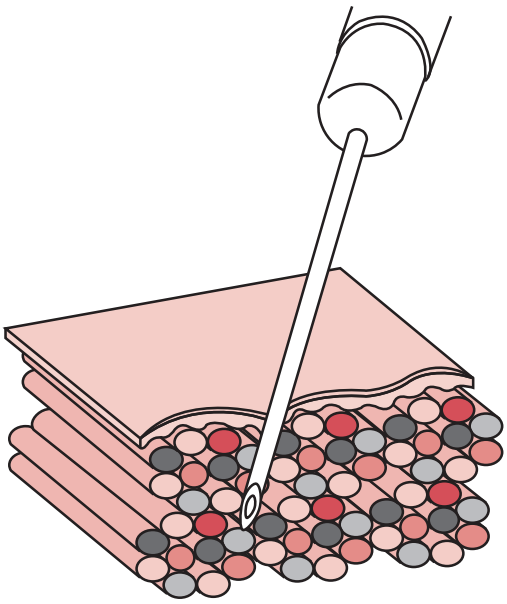

Figure 5.2 Cross-sectional view of muscle belly with needle electrode inserted. Differently shaded fibers represent different motor units.

fibers that are firing will affect the amplitude and duration of the recorded potential. Fibers that are further away will contribute less to the recorded potential. The tissue between the electrode and active muscle fibers also acts as a low-pass filter, attenuating the higher-frequency components of the signal. The number and size of the fibers in the motor unit will influence the potential's size. A larger motor unit will produce more activity. Finally, the distance between the fibers will affect the output, because if the fibers are very spread out, less of their total activity is likely to reach the electrodes.

In addition to these variables, many excess signals, or *artifacts,* can be recorded and processed simultaneously with the EMG signal. An artifact is any unwanted electrical activity that arises outside of the tissues being examined. These artifacts can be of sufficient voltage to distort the output signal markedly, such as those coming from other electrical equipment or fluorescent lights. Electromyographers will usually observe the output signal on an oscilloscope or computer screen to monitor artifacts.

An MUAP is actually the summation of electrical potentials from all the fibers of that unit close enough to the electrodes to be recorded. The amplitude (voltage) is affected by the number of fibers involved or by the motor unit territory. The duration and shape are functions of the distance of the fibers from the recording electrodes, the more distant fibers contributing to terminal phases of the potential. Because of these variables, each motor unit will have a distinctive shape (see Fig. 5.3).

The EMG Examination

EMG testing is only part of a complete examination, which will include a thorough understanding of the patient's history and clinical findings. For example,

the therapist might also examine muscle strength, pain, reflexes, fatigue, sensory function, and the presence of atrophy, as well as functional abilities. This clinical examination will suggest which muscles and/or nerves should be tested.

Initially, the patient is asked to relax the muscle to be examined during insertion of the needle electrode. Insertion into a contracting muscle is uncomfortable, but bearable. At this time, the electromyographer will observe a spontaneous burst of potentials, called *insertional activity,* which is possibly caused by the needle breaking through muscle fiber membranes. This normally lasts less than 300 milliseconds (msec).[82] Insertional activity can be described as normal, reduced, absent, increased, or prolonged.

Following cessation of insertional activity, a normal relaxed muscle will exhibit *electrical silence*, which is the absence of electrical potentials. Observation of silence in the relaxed state is an important part of the EMG examination. Potentials arising spontaneously during this period are significant abnormal findings.

After observing the muscle at rest, the patient is asked to contract the muscle minimally. This weak voluntary effort should cause individual motor units to fire. These motor unit potentials are examined with respect to amplitude, duration, shape, sound, and frequency (Fig. 5.3). These five parameters are the essential characteristics that distinguish each normal and abnormal potential.

Finally, the patient is asked to increase levels of contraction progressively to a strong effort, allowing determination of recruitment patterns. Gradually increasing the force of contraction will allow the electromyographer to observe the pattern of recruitment in the muscle. With greater effort, increasing numbers of motor units fire at higher frequencies, until the individual potentials are summated and can no longer be recognized, and an *interference pattern* is seen (Fig. 5.4). This is the normal finding with a strong contraction.

The needle electrode will be moved to different areas and depths of each muscle to sample different muscle fibers and motor units. This is necessary because of the small area from which a needle electrode will pick up electrical activity, and because the effects of pathology may vary within a single muscle. Up to 25 different points within a muscle may be examined by moving and reinserting the needle electrode.

In normal muscle, the peak-to-peak amplitude of a single MUAP, recorded with a concentric needle, may range from 100 microvolts (μV) to 5 millivolts (mV). The amplitude is determined primarily by a limited number of fibers located close to the electrode tip. Therefore, motor units must be sampled from different sites in a muscle to determine the amplitude of motor units in that muscle accurately. The normal motor unit has an identifying sound as a clear, distinct thump. The duration of the potential is a measure of time from onset to cessation of the electrical potential, typically from 2 to 14 msec.[84]

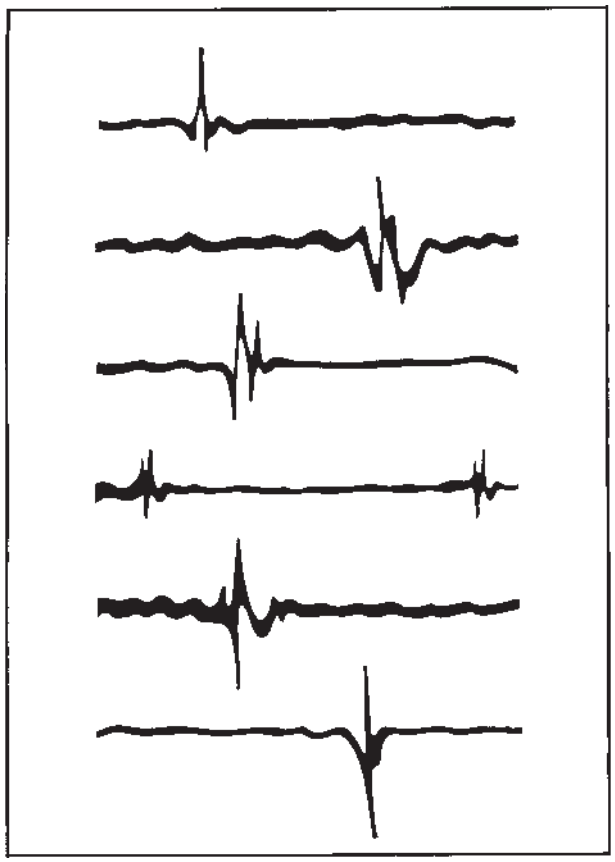

Figure 5.3 Single motor unit potentials as seen on an oscilloscope or computer. Each unit has a distinct shape.

The number of phases in a normal motor unit can be from one to four phases. The typical shape of an MUAP is diphasic or triphasic, with a *phase* representing a section of a potential above or below the baseline. It is not abnormal to observe small numbers of *polyphasic potentials,* having five or more phases, in normal muscle. However, when polyphasic potentials represent more than 10% of a muscle's output, it may be an abnormal finding.

Spontaneous Abnormal Potentials

Because a normal muscle at rest exhibits electrical silence, any activity seen during the relaxed state can be considered abnormal. Such activity is termed *spontaneous* because it is not produced by voluntary muscle contraction. Several types of spontaneous potentials have been identified. **Fibrillation potentials** are believed to arise from spontaneous depolarization of a single muscle fiber. They are not visible through the skin. Fibrillation potentials are biphasic spikes, classically indicative of LMN disorders, such as peripheral nerve lesions, anterior horn cell disease, radiculopathies, and polyneuropathies with axonal degeneration (Fig. 5.5). They are also found to a lesser extent in myopathic diseases such as muscular

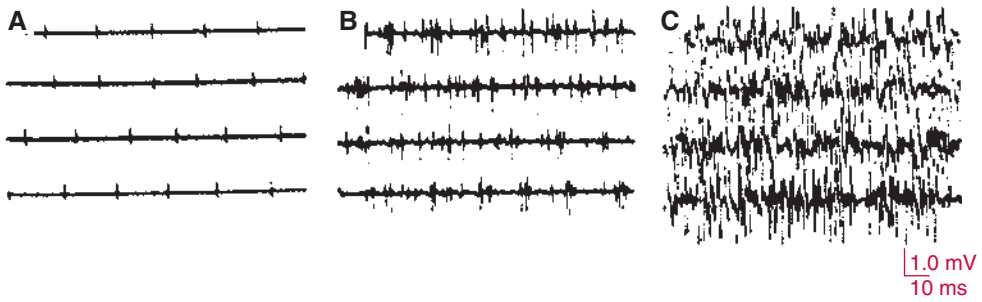

Figure 5.4 Normal recruitment of the triceps brachii in a 44-year-old healthy man. Activity was recorded during minimal contraction **(A)** when single motor unit potentials are visible, during moderate contraction **(B)** when motor units are recruited, and during maximal contraction **(C)** when an interference pattern is visible. *(From Kimura,[83, p. 24] with permission.)*

dystrophy, dermatomyositis, polymyositis, and myasthenia gravis. Their sound is a high-pitched click, which has been likened to rain falling on a roof or wrinkling tissue paper.

Positive sharp waves have been observed in denervated muscle at rest, usually accompanied by fibrillation potentials; however, they are also reported in primary muscle disease, especially muscular dystrophy and polymyositis. The waves are typically biphasic, with a sharp initial positive deflection (below baseline) followed by a slow negative phase (see Fig. 5.5). The negative phase is of much lower amplitude than the positive phase, and of much longer duration, sometimes up to 100 msec. The peak-to-peak amplitude may be variable, with voltages from 50 μV up to 2 mV. The sound has been described as a dull thud.

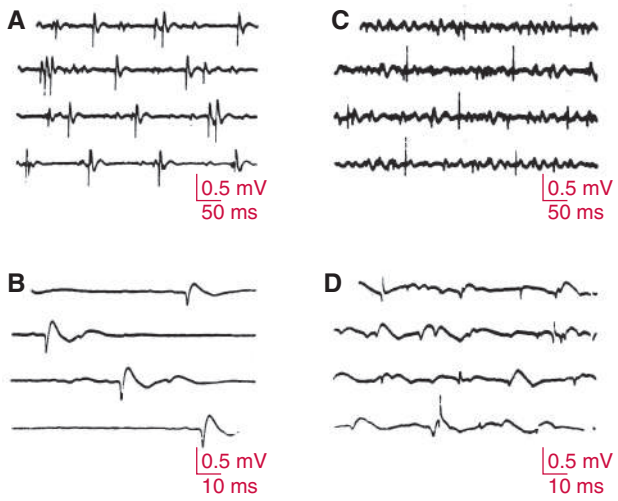

Figure 5.5 Spontaneous activity of the anterior tibialis in a 68-year-old woman with amyotrophic lateral sclerosis. Positive sharp waves **(A, B)** have a consistent configuration with a sharp positive deflection followed by a long-duration, low-amplitude negative deflection **(B)**. Fibrillation potentials **(C, D)** are low-amplitude biphasic spikes. *(From Kimura,[83, p. 256] with permission.)*

Investigators have demonstrated spontaneous potentials in normal muscles of healthy subjects, primarily in muscles of the feet.[85] They have suggested that pathological changes involving axonal loss, segmental demyelination, and collateral sprouting may be associated with aging or mechanical trauma to the feet.

Fasciculations are spontaneous potentials seen with irritation or degeneration of the anterior horn cell, chronic peripheral nerve lesions, nerve root compression, and muscle spasms or cramps. They are believed to represent the involuntary asynchronous. Their sound has been described as a low-pitched thump. Fasciculations are often visible through the skin, seen as a small twitch. They are not by themselves a definitive abnormal finding, however, because they are also seen in normal individuals, particularly in calf muscle, eyes, hands, and feet.[86]

Complex repetitive discharges may be seen with lesions of the anterior horn cell and peripheral nerves, and with myopathies. The discharge is characterized by an extended train of potentials with the same or nearly the same waveform. The feature that distinguishes these discharges from other spontaneous potentials is their regular and repetitive waveform. The frequency usually ranges from 5 to 100 impulses per second. *Myotonic repetitive discharges* that increase and decrease in amplitude in a waxing and waning fashion are found in myotonic disorders such as myotonic dystrophy, as well as other myopathies (Fig. 5.6). The sound is highly characteristic and sounds like a "dive-bomber." High-frequency discharges are probably triggered by movement of the needle electrode within unstable muscle fibers, or by volitional activity.

Polyphasic Potentials

Polyphasic potentials are generally considered abnormal, and are elicited on voluntary contraction, not at rest. By definition, polyphasic potentials are motor unit

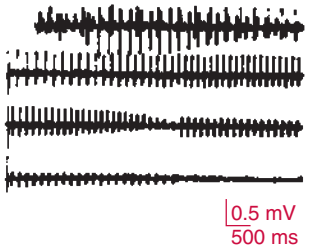

Figure 5.6 Repetitive discharge from the right anterior tibialis of a 39-year-old man with myotonic dystrophy. The waxing and waning quality of these discharges will result in a "dive-bomber" sound. *(From Kimura,[83, p. 254] with permission.)*

potentials with five or more phases (Fig. 5.7). They are typical of myopathies, peripheral nerve involvement, and nerve root compression. In primary muscle disease (myopathies), these potentials are generally of smaller amplitude than normal motor units, are of shorter duration, and have been described by some as myopathic potentials. These multiphasic changes occur because of a decrease in the number of active muscle fibers within the individual motor units due to pathology. Although the entire unit will fire during voluntary contraction, fewer fibers are available in each unit to contribute to the total voltage and the duration of the potential.

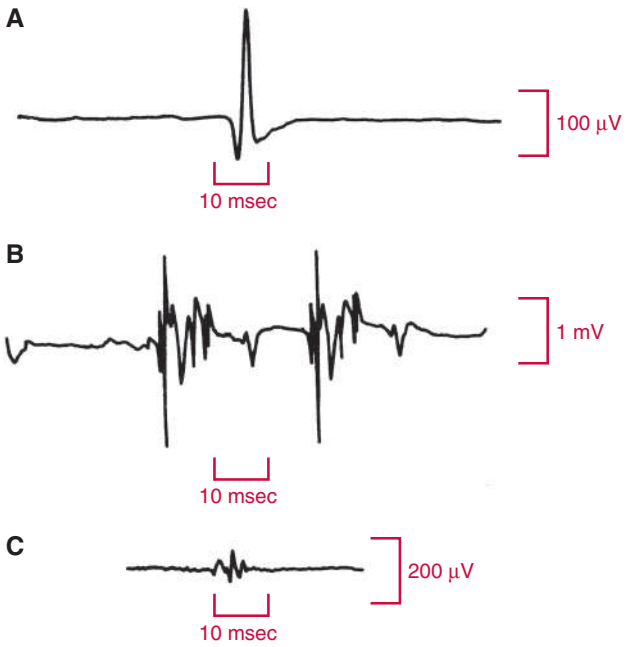

Figure 5.7 Motor unit action potentials. **(A)** Normal potential. **(B)** Long-duration polyphasic potential (shown twice). **(C)** Short-duration, low-amplitude, polyphasic potential. *(From Aminoff, MJ: Electromyography in Clinical Practice, ed 3. Churchill Livingstone (Elsevier), New York, 1997, p. 74, with permission.)*

The polyphasic configuration may be a result of slight firing asynchrony of muscle fibers within a motor unit. This phenomenon is probably due to the difference in the length of the terminal branches of the axon extending to each individual fiber. The effects of this are normally not seen because the time differences are so slight. When some fibers are no longer contracting, or a delay in conduction is found in the terminal branches, these differences become more apparent, resulting in a fragmentation of the motor unit potential.

Polyphasic potentials may also be seen during degeneration and after regeneration of a peripheral nerve. As some muscle fibers become reinnervated, they will generate action potentials with voluntary contraction. However, there are significantly fewer fibers acting than were present in the original unit, and these fibers will clearly reflect asynchronous depolarization. These polyphasic potentials are also much smaller in amplitude and duration than normal units, and they have been termed *nascent motor units*. Although polyphasic potentials are generally considered an abnormal finding, they are a positive finding in patients with regenerating peripheral nerve lesions because they indicate reinnervation.

Some forms of neuropathic involvement, such as chronic peripheral nerve lesions, peripheral neuropathies, and anterior horn cell disease, will result in a change in motor unit territory of an intact motor unit by collateral sprouting of axons to fibers of denervated motor units, forming *"giant" motor units,* which are larger than normal motor unit potentials. In the early stages of this process these sprouts are of small diameter and have slow conduction velocities, resulting in a dispersion in the recorded potential, which increases the amplitude and duration and results in a polyphasic shape. These potentials may be seen in postpolio syndrome.[87-89] If this situation is sufficiently prevalent, the interference pattern may be incomplete. The amplitude of these potentials is greater than 5 mV in small muscles such as the intrinsic muscles of the hands and feet. In other muscles, amplitudes of 3 mV or more could be considered as larger than normal. Duration of these motor units is 4 to 5 msec up to 25 to 30 msec. Other characteristics are similar to normal motor units.

Nerve Conduction Tests

Nerve conduction velocity (NCV) tests involve direct stimulation to initiate an impulse in motor or sensory nerves. The *conduction time* is measured by recording the *evoked potential* either from the muscle innervated by the motor nerve or from the sensory nerve itself. NCV can be tested on any peripheral nerve that is superficial enough to be stimulated through the skin at two different points. The most commonly tested motor nerves are the ulnar, median, fibular (peroneal), tibial, radial, femoral, and sciatic nerves. Commonly tested sensory nerves include the median, ulnar, radial, sural, and superficial fibular nerves. Complete guidelines for

performing NCV tests are available in comprehensive references.[82,84,90]

Motor Nerve Conduction Velocity Testing

Because a peripheral nerve trunk houses both sensory and motor fibers, recording potentials directly from a peripheral nerve makes monitoring of purely sensory or motor nerves impossible. Therefore, to isolate the potentials conducted by motor axons of a mixed nerve, the evoked potential is recorded from a distal muscle innervated by the nerve under study. Although the stimulation of the nerve will evoke sensory and motor impulses, only the motor fibers contribute to the contraction of the muscle. For example, to test the ulnar nerve, the test muscle is typically the abductor digiti minimi. Other examples are the following: for the median nerve, the abductor pollicis brevis; for the fibular nerve, the extensor digitorum brevis; and for the tibial nerve, the abductor hallicus or abductor digiti minimi.

Small surface electrodes are usually used to record the evoked potential from the test muscle. The *recording electrode* is placed over the belly of the test muscle and a reference electrode is taped over the tendon of the muscle.

For the purposes of illustration, the test procedure for the motor NCV of the median nerve will be described (Fig. 5.8). The technique is basically the same for all nerves, except for the sites of stimulation and placement of the electrodes. For this example, the recording electrode is taped over the abductor pollicis brevis. The stimulating electrode is placed over the median nerve at the wrist, just proximal to the distal crease on the volar surface.

At the moment the stimulus is produced, the *stimulus artifact* is seen at the left of the oscilloscope screen (Fig. 5.9). A trigger mechanism controls this and it will, therefore, always appear in the same spot on the screen, facilitating consistent measurements. This spike is purely mechanical and does not represent any muscle activity.

The stimulus intensity starts out low and is slowly increased until the evoked potential is clearly observed. When the stimulating electrode is properly placed over the nerve, all muscles innervated distal to that point will contract and the patient will see and feel the hand "jump." The intensity is then increased until the evoked response no longer increases in size. At that time, the intensity is increased further to be sure that the stimulus is *supramaximal*. Because the intensity must be sufficient to reach the threshold of all motor fibers in the nerve, a supramaximal stimulus is required. It is also essential that the stimulator be properly placed over the nerve trunk so that the stimulus reaches all the motor axons.

As in the EMG signal, the potentials seen on the screen represent the electrical activity detected by the recording electrode. The signal will represent the

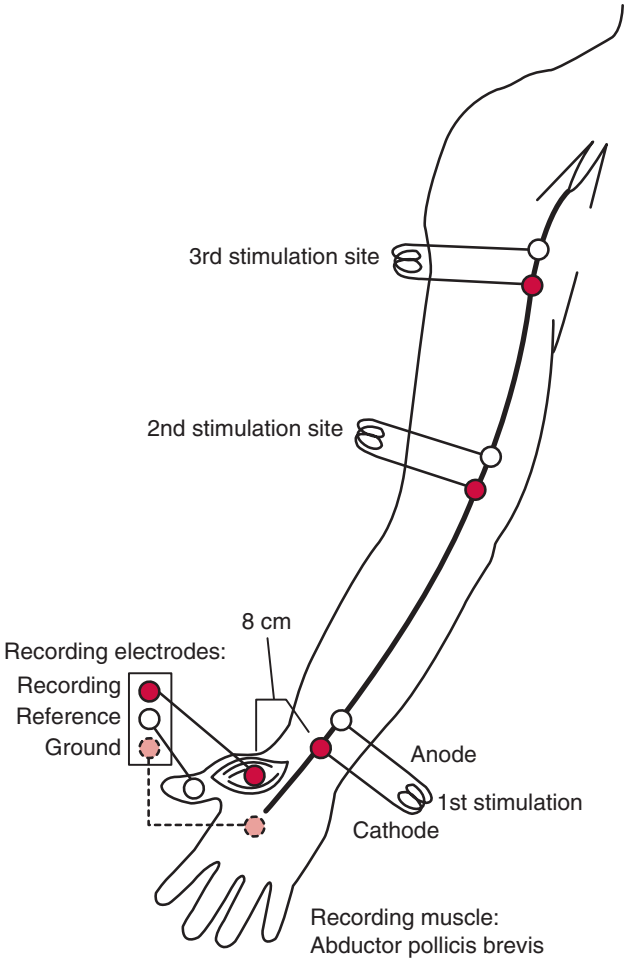

Figure 5.8 Sites of stimulation for motor nerve conduction study of the median nerve. *(From Echternach,[84, p. 34] with permission.)*

difference in electrical potential between the recording and reference electrodes. When the supramaximal stimulus is applied to the median nerve at the wrist, all the axons in the nerve will depolarize and begin conducting an impulse, transmitting the signal across the

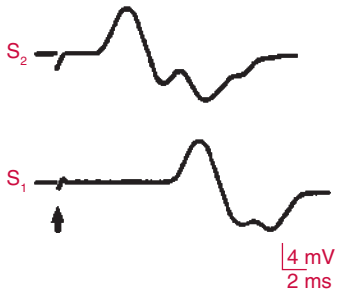

Figure 5.9 Recording of the M wave from a nerve conduction velocity test of the median nerve. The upper trace is from the distal stimulation site, and the lower trace is from the proximal stimulation site. The stimulus artifact appears at the left of both traces. The latencies are measured from the stimulus artifact to the start of the M wave.

motor end plate, initiating depolarization of the muscle fibers. During these events, the recording electrodes do not record a difference in potential because no activity is taking place beneath the electrodes. When the muscle fibers begin to depolarize, the electrical potentials are transmitted to the electrodes, and a deflection is seen on the oscilloscope. This is the evoked potential, which is called the *M wave* (see Fig. 5.9). The M wave is also referred to as the motor action potential (MAP) or compound motor action potential (CMAP). The M wave represents the summated activity of all motor units in the muscle that responded to stimulation of the nerve trunk. The amplitude of this potential is, therefore, a function of the total voltage produced by the contracting motor units. The initial deflection of the M wave is the negative portion of the wave, above the baseline.

Calculation of Motor Nerve Conduction Velocity

The point at which the M wave leaves the baseline indicates the time elapsed from the initial propagation of the nerve impulse to the depolarization of the muscle fibers beneath the electrodes. This is called the response *latency*. The latency is measured in milliseconds from the stimulus artifact to the onset of the M wave. This time alone is not a valid measurement of nerve conduction because it incorporates other events besides pure nerve conduction—namely, transmission across the myoneural junction and generation of the muscle action potential. Therefore, these extraneous factors must be eliminated from the calculation of the motor NCV, so that the measurement reflects only the speed of conduction within the nerve trunk.

To account for these distal variables, the nerve is stimulated at a second, more proximal point. This will produce a response similar to that seen with distal stimulation. The stimulus artifact will appear in the same spot on the screen, but the M wave will originate in a different place because the time for the impulses to reach the muscle would, obviously, be longer. Subtraction of the *distal latency* from the *proximal latency* will determine the conduction time for the nerve trunk segment between the two points of stimulation. *Conduction velocity (CV)* is determined by dividing the distance between the two points of stimulation (measured along the surface) by the difference between the two latencies (velocity = distance/time).

$$\text{CV} = \text{Conduction distance}/(\text{Proximal latency} - \text{Distal latency})$$

Conduction velocity is always expressed in meters per second (m/sec), although distance is usually measured in centimeters and latencies in milliseconds. These units must be converted during calculation.

To complete the example of the median nerve, two other sites would be stimulated, where the median nerve crosses the elbow and in the axilla (see Fig. 5.8). Although motor NCV tests can be performed on these more proximal segments of the nerve trunk, these areas are tested less frequently than the distal-most site.

To compute the motor NCV, the proximal and distal latencies are determined by measuring the time from the stimulus artifact to the initial M wave deflection. The conduction time is calculated by taking the difference between these latencies. *Conduction distance* is then determined by measuring the length of the nerve between the two points of stimulation. For example:

Proximal latency: 7 msec
Distal latency: 2 msec
Conduction distance: 300 mm or 30 cm
CV = 30 cm / (7 msec – 2 msec) = 30 cm/5 msec = 60 m/sec

Interpretation of the motor NCV is made in relation to normal values, which are usually expressed as mean values, standard deviations, and ranges. Many investigators in different laboratories have determined normal values. Even so, average values seem to be fairly consistent. The motor NCV for the UE has a fairly wide range, with values reported from 50 to 70 m/sec. The average normal value is about 60 m/sec. For the LE, the average value is about 50 m/sec. Distal latencies and average normal amplitudes of M waves are also available in such tables, but these must be viewed with caution, because technique, electrode setup, instrumentation, and patient size can affect these values. Age and temperature can also influence NCV measurements, decreasing after age 35 and with lower temperature.[81] The reader is referred to more comprehensive discussions for complete details about techniques for studying various nerves and for tables of normal values.[84,90]

It is important to note that the value calculated as the conduction velocity is actually a reflection of the speed of the fastest axons in the nerve. Although all axons are stimulated at the same point in time, and supposedly fire at the same time, their conduction rates vary with their size. Not all motor units will contract at the same time; some receive their nerve impulse later than others. Therefore, the initial M wave deflection represents the contraction of the motor unit, or units, with the fastest conduction velocity. The curved shape of the M wave is reflective of the progressively slower axons reaching their motor units at a later time.

The M wave can also provide useful information about the integrity of the nerve or muscle. Three parameters should be examined: amplitude, shape, and duration. Any change occurring in these characteristics is called *temporal dispersion*. These parameters reflect the summated voltage over time produced by all the contracting motor units within the test muscle. Therefore, if the muscle is partially denervated, fewer motor units will contract after nerve stimulation. This will cause the M wave amplitude to decrease. Duration may change

depending on the conduction velocity of the intact units. Similar changes may also be evident in myopathic conditions, in which all motor units are intact, but fewer fibers are available in each motor unit.

The shape of the M wave can also be variable. Deviation from a smooth curve need not be abnormal, and it is often useful to compare the proximal and distal M waves with each other as well as with the contralateral side if indicated. They should be similar. In abnormal conditions, changes in shape may be the result of a significant slowing of conduction in some axons, repetitive firing, or asynchronous firing of axons after a single stimulus.

Sensory Nerve Conduction Velocity Testing

Sensory neurons demonstrate the same physiological properties as motor neurons, and NCV can be measured in a similar way. However, some differences in technique are necessary to differentiate between sensory and motor axons. Although sensory fibers can be tested using *orthodromic conduction* (physiological direction) or *antidromic conduction* (opposite to normal conduction), antidromic measurements appear to be more common. For the same reason that motor axons are examined by recording over muscle, sensory axons are either stimulated or recorded from digital sensory nerves. This eliminates the activity of the motor axons from the recorded potentials.

The stimulating electrode used for sensory NCV tests is typically provided by ring electrodes placed around the base of the middle of the digit innervated by the nerve. The recording electrodes can be surface or needle electrodes. Surface electrodes are placed over the nerve trunk, where it is superficial to the skin.

Sensory potentials for the median and ulnar nerves can be recorded antidromically by stimulating at the wrist, elbow, and upper arm. Typically the sensory study of these nerves is limited to stimulation at the wrist. Other sensory nerves can be studied in the UEs, which include the superficial radial nerve, the medial and lateral antibrachial cutaneous nerves, and the dorsal branch of the ulnar nerve. In the LEs, the sensory nerves most commonly studied are the sural nerve and the superficial fibular (peroneal) nerves. Other nerves that have been studied include the lateral femoral cutaneous nerve and the saphenous nerve. Normal sensory NCV ranges between 40 and 75 m/sec. Amplitude, measured with surface electrodes, may be 10 to 120 μV, and duration should be short, less than 2 msec. Sensory evoked potentials are usually sharp, not rounded like the M wave. Sensory NCVs are slightly faster than motor NCVs because of the larger diameter of sensory nerves.

H Reflex

The *H reflex* is a useful diagnostic measure for radiculopathy and peripheral neuropathy. Its most common application is in testing the integrity of the sensory and motor monosynaptic pathways of S1 nerve roots, and to a lesser extent at C6 and C7.[91] A submaximal stimulus is applied to the tibial nerve at the popliteal fossa, and a motor response is recorded from the medial portion of the soleus muscle. The action potentials travel along the IA afferent neurons toward the spinal cord, synapsing onto alpha motor neurons within the anterior horn. The consequent activation of the motor neuron leads to an impulse traveling peripherally to the soleus muscle, resulting in a muscle contraction. Because the stimulus causes impulses to travel both distally and proximally within a mixed motor and sensory neuron, the latency of this response is a measure of the integrity of both sensory and motor fibers.

A normal response falls within ± 5.5 msec of this calculated latency. An average response is 29.8 msec (± 2.74 msec).[92] A slowed latency is indicative of abnormal dorsal root function, often from a herniated disc or impingement syndrome. Because of this central involvement, the peripheral motor and sensory NCV would not be affected. This latency may also identify nerve root compression before obvious EMG changes occur.

The F Wave

F waves are a form of NCV test that allows for study of proximal nerve segments that would otherwise be inaccessible to routine nerve conduction studies. F wave abnormalities can be a sensitive indicator of peripheral nerve pathology. The F wave ratio compares the conduction in the proximal half of the total pathway with the distal and may be used to determine the site of conduction slowing—for example, to distinguish a root lesion from a distal generalized neuropathy.[93]

The F wave is elicited by the supramaximal stimulus of a peripheral nerve at a distal site, leading to propagation of impulses in both directions. While the orthodromic impulse travels to the distal muscle, the antidromic response travels to the anterior horn cell, depolarizing the axon hillock, leading to depolarization of dendrites, which in turn depolarizes the axon hillock once again, generating an orthodromic volley back to the muscle. No synapse is involved, so the F wave is not considered a reflex, but only a measure of motor neuron conduction.

The F wave is a useful supplement to nerve conduction and EMG measures, and is most helpful in the diagnosis of conditions where the most proximal portion of the axon is involved, such as Guillain-Barré syndrome, thoracic outlet syndrome, brachial plexus injuries, and radiculopathies with more than one nerve root involved.[84] The latency of the F wave is normally approximately 30 seconds in the upper limb and less than 60 seconds in the lower limb. Only a small percent of motor neurons actually participate in the F response.[94] Because it is an inconsistent response, it must be calculated on the basis of at least 10 successive trials.

Disorders of Peripheral Nerve

Electrophysiological findings usually correlate with clinical signs in patients with neuropathic or myopathic involvement. Lesions of peripheral nerve fall into three categories. **Neurapraxia** is a temporary impairment in nerve conduction typically caused by some form of local compression or blockage, such as in carpal tunnel syndrome. NCV tests can detect evidence of degeneration and slowing of fibers across the site of compression, but may be normal above and below that site. Normal values must be interpreted relative to other disorders such as diabetes or active workers.[95] **Axonotmesis** results from a nerve injury that damages the axon but leaves the neural tube is intact. *Wallerian degeneration*, the dying back of the axons of nerves after insult, occurs distal to the lesion. This may be progressive due to long-standing neurapraxia, or it may occur from a traumatic lesion. NCV will be affected depending on the number of axons involved. Fibrillations and positive sharp waves are typically present 2 to 3 weeks after denervation. **Neurotmesis** is a nerve injury with complete loss of axonal function and disruption of the neural tube. Conduction ceases below the lesion and NCV tests cannot be performed. Spontaneous potentials will appear on EMG at rest. Regeneration may be evident through serial testing, showing appearance of small polyphasic potentials.

Neuropathy is any disease of nerves. *Polyneuropathy* affects multiple nerves and typically results in sensory changes, distal weakness, and hyporeflexia. It can be related to medical conditions, such as diabetes, alcoholism, or renal disease, as well as secondary complications related to cancer and its treatments.[96] These conditions are typically manifested as axonal damage or demyelinization or both. With axonal lesions, EMG recruitment patterns are decreased and spontaneous potentials are typically seen (Fig. 5.10). With demyelinization, NCV measurements are most useful to identify slowing in motor or sensory fibers.

Motor Neuron Disorders

Motor neuron disorders typically involve degeneration of the anterior horn cell, such as in poliomyelitis, or diseases that involve both UMNs and LMNs, such as amyotrophic lateral sclerosis. Spontaneous potentials are classically seen with these disorders, as well as reduced recruitment, allowing single motor unit potentials to be visible even with an interference pattern. Motor NCV can be slowed, depending on the distribution of degeneration. Large polyphasic potentials are often seen later in the course of the disease, due to collateral sprouting and reinnervation.

Myopathies

Myopathy is a primary muscle disease that may be acquired or congenital (e.g., muscular dystrophy, limb girdle myopathy). The motor unit remains intact, but degeneration of muscle fibers is evident. Therefore, motor NCV may be normal, although the M wave amplitude will be reduced. Sensory potentials will also be normal. In early stages, EMG will show prolonged insertion activity, fibrillations and positive sharp waves at rest, and short-duration, low-amplitude polyphasic potentials with voluntary activity, reflecting loss of muscle fibers (Fig. 5.11). Interference patterns will be evident with less than maximal contractions. In advanced stages, no electrical activity may be seen due to fibrosis of muscle tissue.

EVALUATION

Evaluation refers to the clinical judgments therapists make based on the data gathered from the examination.[4] Numerous factors influence the judgments therapists make when working with patients with impairments of motor function, including complexity and understanding of the nervous system, clinical findings, psychosocial considerations, and overall physical function and health. Therapists evaluate data in terms of severity of problems (impairments, activity limitations, participation

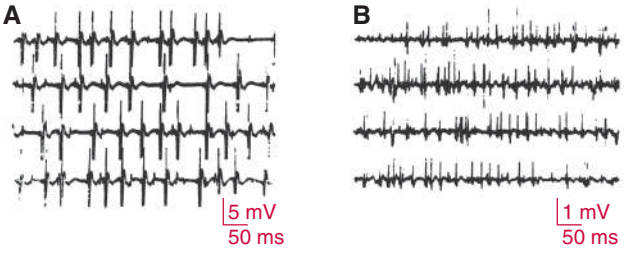

Figure 5.10 Large-amplitude, long-duration motor unit potentials from the first dorsal interosseus **(A)** compared with relatively normal motor unit potentials from orbicularis oculi **(B)** in a patient with polyneuropathy. Note discrete single-unit interference pattern during maximal voluntary contraction. *(From Kimura,[83, p. 267] with permission.)*

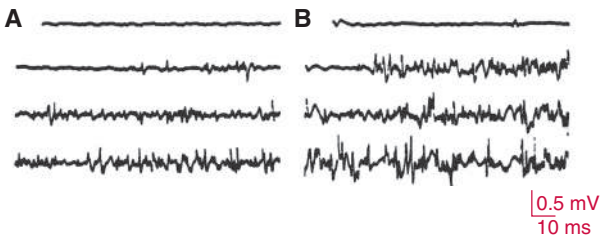

Figure 5.11 Low-amplitude, short-duration motor unit potentials recorded during minimal voluntary contraction from the biceps brachii **(A)** and tibialis anterior **(B)** in a 7-year-old boy with Duchenne's dystrophy. A high number of discharging motor units during minimal contraction reflects early recruitment because of decreased fiber activity. *(From Kimura,[83, p. 268] with permission.)*

restrictions) and level of chronicity. Therapists must also consider the consequences of failure to intervene appropriately when the patient is at risk for additional impairments or prolonged activity limitation. Potential discharge placement and resources also influence evaluation of the data and development of the POC. There is a clear need for the therapist to focus on those problems that directly affect function and can be successfully remediated.

DIAGNOSIS

The *physical therapy diagnosis* is determined from evaluation of examination findings and is based on a cluster of signs, symptoms, or categories. The *Guide to Physical Therapist Practice,*[4] a consensus document developed by expert physical therapy clinicians, identifies diagnostic categories and preferred practice patterns that delineate appropriate interventions (see Chapter 1, Clinical Decision Making, Appendix 1.A). For example, Impaired Motor Function and Sensory Integrity Associated with Acquired Nonprogressive Disorders of the Central Nervous System includes patients with TBI, cerebrovascular accident, or tumor.[4, p. 365] The reader is referred to this document for comparison to and refinement of his or her own practice. Novice therapists can gain understanding and insights into the complex practice issues facing therapists who work with patients with impairments in motor function.

SUMMARY

Examination of motor function is a challenging, multifaceted process, critically related to the therapist's ability to accurately determine and categorize findings. An understanding of normal motor control and motor learning mechanisms is essential to this process. Determining the causative factors responsible for abnormal movement patterns and behaviors must be based on comparison of expected or normal responses (norm-referenced behaviors) with the patient's abnormal ones. This can best be achieved by a systematic and thorough approach to examination. Emphasis should be on the use of valid, reliable, and responsive measurement tools.

Examination of systems yields valuable information about the integrity of individual components (e.g., neuromuscular, musculoskeletal, cognitive). However, it is important to recall that normal motor control and motor learning is achieved through the integrated action of the CNS. The therapist must therefore also focus on integrated function evidenced through an examination at the functional level. Success in rehabilitation is also dependent on our ability to understand the learning abilities of the patient and potential training strategies important for cognitive engagement and practice. Our theoretical understanding of the CNS, motor control, and motor learning processes is both incomplete and imperfect. Therapists must, therefore, be constantly aware of the changing knowledge base in neuroscience and in neurological rehabilitation to incorporate new ideas into their examination and intervention plan.

Questions for Review

1. Differentiate between recovery of function and compensation.
2. Describe the examination of consciousness and arousal. How can the levels of consciousness and arousal influence the motor function examination?
3. Differentiate between selective attention and alternating attention. How should each be examined?
4. Differentiate between spasticity and rigidity. How should each be examined?
5. Describe the examination of a hyperactive patellar deep tendon reflex. What scores are used to document an increased DTR?
6. A patient with stroke exhibits abnormal control of eye muscles and is unable to move the eyes smoothly in all directions. Cranial nerve testing should include what nerves and tests?
7. What are the issues of validity for using manual muscle testing as part of the examination of a patient with UMN syndrome (stroke) who exhibits strong spasticity and strong obligatory synergies?
8. A patient with multiple sclerosis reports fatigue as the number one symptom that impairs functional independence in the home environment. How should this patient's fatigue be examined and documented?
9. Define stability. How should it be examined?
10. Differentiate between the use of performance observations and retention tests in providing evidence of motor learning.

11. What is a fibrillation potential on EMG? What is it indicative of?

12. How is nerve conduction velocity calculated?

CASE STUDY

The patient is a 17-year-old female who is 6 months post–motor vehicle accident (MVA). At the time of admission to the hospital, she was comatose and decerebrate. CT scan revealed intracranial bleeding into the right occipital horn. She received a tracheostomy and a gastrostomy. Two months post-MVA, she was transferred to a *long-term care facility* specializing in TBI.

On initial admission she was able to open her eyes to verbal and tactile stimuli but was unable to visually track. She withdrew her upper and lower extremities in response to stimulation but was not able to move them on command. She was alert but confused, and was unable to carry on a conversation. ROM was within normal limits (WNL) except for right elbow flexion (20° to 100°) and right knee flexion (10° to 110°). She demonstrated increased tone (Modified Ashworth Scale 3) in her left upper extremity (LUE), 4 in her right upper extremity (RUE), and 4 in both lower extremities (BLEs). She exhibited 4+ bilateral ankle clonus. She was unable to sit unsupported. During supported sitting in the wheelchair, her head and trunk control was poor, with persistent posturing to the left side.

She is now 6 months post-MVA and is currently being examined for transfer to active rehabilitation status.

PHYSICAL THERAPY EXAMINATION FINDINGS

Consciousness/Arousal

Fully awake; responds appropriately to varying stimuli.
Oriented to person; some confusion with orientation to place and time.
Can become agitated with minimal stimulation, especially when tired.

Cognition/Behavior

Demonstrates difficulty with concentration and attention.
Able to follow simple instructions (one- or two-level commands) but occasionally forgets what is asked of her.
Reaction time is slowed as the number of choices is increased.
Easily forgets what she is doing.

Sensory Integrity

Aware of sensory input (pinprick, vibration, light touch) to all extremities.
Unable to discern common objects placed in either hand for stereognosis discrimination.

Joint Integrity and Mobility

RLE: plantarflexion contracture (40° to 50°); flexion contractures at the hip (10° to 120°) and knee (10° to 120°).
RUE: flexor contracture at the elbow (10° to 110°).
Full passive ROM in the LUE and LLE.

Tone

Increased bilaterally (R > L).
On Modified Ashworth Scale: RUE and RLE 3; LUE and LLE 2.

Reflex Integrity

Hyperactive, 3+ DTRs RUE, RLE.
3+ bilateral ankle clonus.

Cranial Nerve Integrity

Dysphagia and dysphonia are present.

Muscle Performance

Strength is decreased in the RUE, RLE, and trunk (unable to test with MMT).
She is unable to sustain R knee extension during standing.

Voluntary Movement Patterns

RUE moves in partial range, obligatory mass flexor synergy pattern only.
RLE moves in flexor and extensor synergy patterns with no variation.
LUE and LLE demonstrate full voluntary control with isolated joint movements. Coordination is decreased. Unable to reach directly to an object that is held out to her and demonstrates foot placement problems with the LLE in sitting or in standing.
Demonstrates problems with coordinating limb and trunk movements.

Postural Control and Balance

Demonstrates good head control in all positions.

Sitting: can sit independently for up to 5 minutes. Demonstrates difficulty in maintaining weight equally on both buttocks. Tends to list to the right side while placing weight primarily on her left buttock. Able to reach to the left and forward; demonstrates loss of balance (LOB) with minimal reaching to right.

Standing: able to stand in parallel bars with minimal assistance 1 for up to 2 minutes. Has to be reminded to place weight on RLE. Tends to lose her balance easily if she moves quickly; associated with brief episodes of dizziness and vertigo.

Functional Mobility Skills

Rolling: requires supervision and occasional minimal assistance with rolling to the right; she requires maximal assist when rolling to the left.

Supine-to-sit: able to come to sitting by rolling to the L side and pushing up with her LUE; requires minimal assistance.

Transfers: able to perform stand pivot transfers with minimal assistance of 1.

Gait: does not initiate ambulation on her own. Can ambulate the length of the parallel bars (2 m or 6 ft) with maximal assistance of two persons. Requires posterior splint to stabilize R knee.

Propels wheelchair by using the LUE and both feet for pushing; requires supervision for safety.

Motor Learning

Demonstrates profound deficits in short-term memory; unable to remember new information presented during therapy. Her memory for events and learning that occurred before the MVA is good.

GUIDING QUESTIONS

Based on your evaluation of the data presented in the case history and the physical therapy examination, answer the following questions:

1. How has this patient's level of consciousness/arousal changed from admission to the long-term care facility to the current evaluation? How might this influence the examination of motor function?
2. Develop a physical therapy problem list. Categorize the patient's problems in terms of (a) direct impairments, (b) indirect impairments, and (c) functional limitations.
3. Prioritize the problems in terms of this patient's needs for the POC.
4. Determine the physical therapy diagnosis using the preferred practice patterns identified by the *Guide to Physical Therapist Practice* (Chapter 1, Appendix 1.A).

Chapter 6

Examination of Coordination and Balance

Thomas J. Schmitz, PT, PhD
Susan B. O'Sullivan, PT, EdD

LEARNING OBJECTIVES

1. Understand the purposes of performing an examination of coordination and balance.
2. List the types of data generated from the examination.
3. Describe the common coordination and balance impairments associated with lesions of the central nervous system.
4. Explain the primary age-associated changes that affect coordination and balance.
5. Discuss the purpose of screenings within the context of motor function.
6. Provide a rationale for the preliminary patient observation before performing an examination.
7. Identify the motor task requirements and movement capabilities addressed during an examination of coordination and balance.
8. Differentiate between tests used to examine coordination and balance.
9. Using the case study example, apply clinical decision making skills to application of coordination and balance examination data.

- Movement Strategies for Balance *231*

STANDARDIZED INSTRUMENTS: POSTURAL CONTROL AND BALANCE *234*
SUMMARY *240*

EXAMINATION OF COORDINATION

Motor control is "the ability of the central nervous system to control or direct the neuromotor system in purposeful movement and postural adjustment by selective allocation of muscle tension across appropriate joint segments."[1, p. 688] Motor control has also been defined "as the ability to regulate or direct the mechanisms essential to movement."[2, p. 3] Components of motor control include normal muscle tone and postural response mechanisms, selective movements, and coordination.[3]

Coordination is the ability to execute smooth, accurate, controlled movement. "Coordinated movement involves multiple joints and muscles that are activated at the appropriate time and with the correct amount of force so that smooth, efficient, and accurate movement occurs. Thus, the essence of coordination is the sequencing, timing, and grading of the activation of multiple muscles groups."[2, p. 121]

The ability to produce these responses is dependent on somatosensory, visual, and vestibular input, as well as a fully intact neuromuscular system from the motor cortex to the spinal cord.[4] Coordinated movements are characterized by appropriate speed, distance, direction, timing, and muscular tension. In addition, they involve appropriate synergistic influences (muscle recruitment), easy reversal between opposing muscle groups

(appropriate sequencing of contraction and relaxation), and proximal fixation to allow distal motion or maintenance of a posture.[5] Schmidt and Lee define coordination as the "behavior of two or more degrees of freedom in relation to each other to produce skilled activity."[6, p. 494] Awkward, extraneous, uneven, or inaccurate movements characterize *coordination impairments*.

Two terms often associated with coordination are *dexterity* and *agility*.[1] *Dexterity* refers to skillful use of the fingers during fine motor tasks.[7] *Agility* refers to the ability to rapidly and smoothly initiate, stop, or modify movements while maintaining postural control.

There are several general types of coordination. *Intralimb* coordination refers to movements occurring within a single limb[8-13] (e.g., alternately flexing or extending the elbow; use of one upper extremity to brush the hair; or motor performance of a single lower extremity during a gait cycle). *Interlimb* (bimanual) coordination refers to the integrated performance of two or more limbs working together[14-18] (e.g., alternately flexing one elbow while extending the other; bilateral upper extremity tasks as required during sliding transfers or dressing activities; or between limb movements of the lower extremities and/or upper extremities during walking). *Visual motor* coordination[19-23] refers to the ability to integrate both visual and motor abilities with the environmental context to accomplish a goal (e.g., tracing over a zigzag line, writing a letter, riding a bicycle, or driving an automobile). A subcategory of visual motor coordination with important implications for activities of daily living (ADL) is *eye–hand* coordination[24-30] such as required for using eating utensils, personal hygiene, or reaching for a visual target (e.g., a book from a shelf). Eye–hand coordination is perhaps more aptly termed *eye–hand–head* coordination because movement of the head is typically required for the eyes to fixate on a target or object.

Physical therapists are frequently involved in management of patients with coordination impairments. Data from the examination of coordination inform the therapist about existing impairments. These impairments are often associated with activity limitations that are related to, and indicative of, the type, extent, and location of central nervous system (CNS) pathology. Some CNS lesions present very classic and stereotypical impairments, but others are much less predictable. Examples of medical diagnoses that typically demonstrate coordination impairments include traumatic brain injury, Parkinson's disease, multiple sclerosis, Huntington's disease, cerebral palsy, Sydenham's chorea, cerebellar tumors, vestibular pathology, and some learning disabilities.

The *Guide to Physical Therapist Practice*[1] includes coordination (together with dexterity and agility) as a subcategory of Motor Function (Motor Control and Motor Learning) among the list of 24 categories of tests and measures that may be used by physical therapists during patient examination. In addition, the *Guide to Physical Therapist Practice*[1] includes coordination among the tests and measurements identified for all Musculoskeletal Practice Patterns, Neuromuscular Practice Patterns A–H, and Cardiovascular/Pulmonary Practice Pattern D.

The purposes of performing a coordination examination of motor function are to determine the following:

1. Muscle activity characteristics during voluntary movement
2. Ability of muscles or groups of muscles to work together to perform a task or functional activity
3. Level of skill and efficiency of movement
4. Ability to initiate, control, and terminate movement
5. Timing, sequencing, and accuracy of movement patterns
6. Effects of therapeutic and pharmacological intervention on motor function over time

In addition, data from the coordination examination assist the therapist with establishing the diagnosis of underlying impairments, activity limitations, and participation restrictions (disability); assist with establishing anticipated goals to remediate impairments and formulating expected outcomes that encompass remediation of activity limitations and participation restrictions; and support decision making in establishing a prognosis and determining specific, direct interventions.

OVERVIEW OF THE MOTOR SYSTEM

The motor system can be grossly divided into *peripheral* and *central* elements. The peripheral somatic motor system includes muscles, joints, and their sensory and motor innervation.[31] The central elements can be divided into three hierarchical levels to assist understanding their organization as well as delineating the contribution of each neuroanatomical structure. However, this does not imply a strictly top-down control of coordinated movement as each level of the nervous system can influence other levels (above and below) depending on task demands (i.e., flexible hierarchical theory). Bear et al provide a practical description of the three hierarchical levels relative to their functional contributions to motor control as follows: "The highest level, represented by the association areas of the neocortex and basal ganglia of the forebrain, is concerned with *strategy:* the goal of the movement and the movement strategy that best achieve[s] the goal. The middle level, represented by the motor cortex and cerebellum, is concerned with *tactics:* the sequences of muscle contractions, arranged in space and time, required to smoothly and accurately achieve the strategic goal. The lowest level, represented by the brain stem and spinal cord, is concerned with *execution:* activation of the motor neuron and interneuron pools that generate

the goal-directed movement and make any necessary adjustments of posture."[31, p. 452]

The motor system can also be viewed as having a *parallel arrangement*. For example, information is conveyed not only from the motor cortex to the spinal cord but also directly from premotor areas as well. Although the cerebellum and basal ganglion are involved in movement, they have no direct output to the spinal cord. Instead, their effect on movement is provided via connections to the motor cortex.[32]

The critical role of sensory input on the motor system cannot be overemphasized. The integration of sensory input provides an internal representation of the environment that informs and guides motor responses.[5] These sensory representations provide the foundation on which motor programs for purposeful movements are planned, coordinated, and implemented.[4] Sensory input to the motor system guides selection and adaptation of motor responses and shapes motor programs for corrective action. For example, the somatosensory system provides the needed information to adjust walking when moving from a smooth surface to an uneven terrain; to maintain standing balance on a moving bus; or to make the required adjustments when throwing a ball from a stable sitting surface (chair) versus an unstable one (therapy ball). To rule out sensory impairments as a contributing factor to coordination impairments, examination of sensory function (see Chapter 3) typically *precedes* the coordination examination.

The Motor Cortex

The principal brain area involved in motor function is the motor cortex, which comprises cortical (Brodmann's) areas 4 and 6 located in a demarcated area of the frontal lobe called the precentral gyrus (Fig. 6.1). However, planning coordinated movement to accomplish a task involves many areas of the neocortex as it requires knowledge of the body's position in space, the location of the intended target, selection of an optimum movement strategy (i.e., which joints, muscles, or body segments will be used), memory storage until time of execution, and specific instructions to implement the movement strategy selected (where to move or what to do).[31,33]

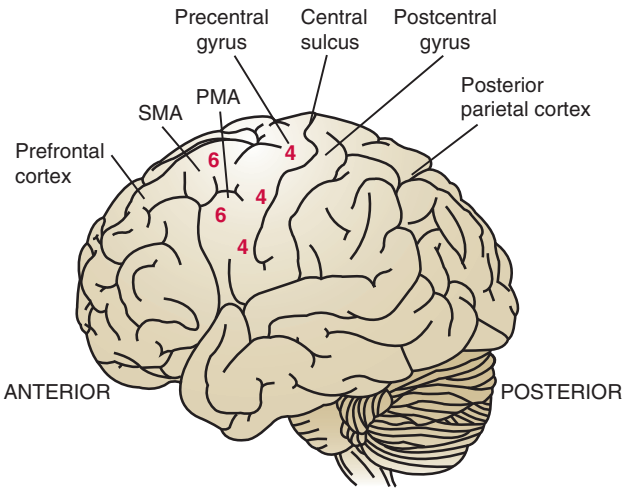

Figure 6.1 Primary areas of the cortex involved in coordinated movement.

Brodmann's area 4 is designated the *primary motor cortex (PMC)* as it is the most specific cortical motor area containing the largest concentration of corticospinal neurons.[34] This area is electrically excitable and stimuli of low intensity evoke a motor response. It lies anterior to the central sulcus on the precentral gyrus and controls contralateral voluntary movements. Brodmann's area 6 is also electrically excitable but requires stimuli of higher intensities to cause a motor response.[35] It lies just anterior to area 4 and is subdivided into the superiorly placed *supplementary motor area (SMA)* and the inferiorly positioned *premotor area (PMA)*.[35]

The SMA gives rise to axons that directly innervate motor units involved in initiation of movement, simultaneous bilateral grasping movements, sequential tasks, and orientation of the eyes and head. The PMA provides input to the reticulospinal neurons innervating motor units that control trunk and proximal limb movements and contributes to anticipatory postural changes.[31,36] Stimulation of area 4 typically results in uncomplicated movements of a single joint whereas stimulation to the premotor areas (area 6) evokes more intricate coordinated movements involving multiple joints.[33]

The somatotopic organization of the motor cortex is very similar to the sensory cortex. The motor homunculus schematically illustrates the amount of cortical area devoted to motor control of a given body part or region (Fig. 6.2). Beginning on the lateral aspect of the homunculus, the mouth and face areas are represented; moving upward are areas devoted to the hands, trunk, lower extremities, and feet. Note that areas requiring finer gradations of control such as the fingers, hand, and face (including muscles of speech) occupy a disproportionately larger representation (approximately half) in the motor cortex. The SMA and PMA are similarly somatotopically organized.

The motor cortex receives information from three primary sources: the *somatosensory cortex* (peripheral receptive fields), the *cerebellum,* and the *basal ganglia*. Somatosensory input is relayed directly to the primary motor cortex from the thalamus (e.g., cutaneous tactile sensations, joint and muscle receptors). The thalamus also relays information to the motor areas from the cerebellum and the basal ganglia. These connections allow for integration of motor control functions of the motor cortex, cerebellum, and basal ganglia (i.e., to carry out the appropriate course of motor action).[37]

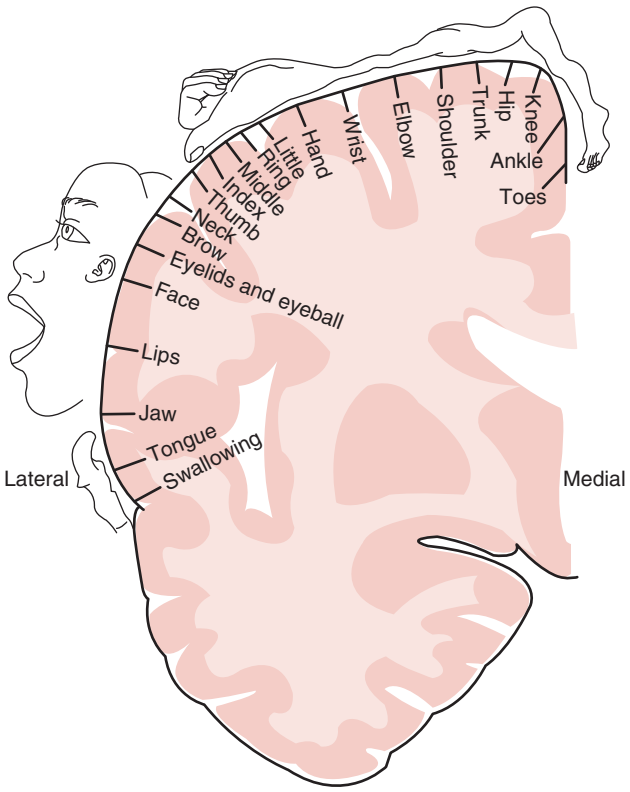

Figure 6.2 The motor homunculus indicates the **somatotopic** organization of the motor cortex. The relative size of body parts reflects the proportion of the motor cortex devoted to controlling that area.

Descending Motor Pathways

The most important descending pathway of the motor system is the corticospinal (pyramidal) tract that transmits signals from the motor cortex directly to the spinal cord. It is among the longest and largest CNS tracts. It originates primarily in areas 4 and 6 and passes through the internal capsule and the brainstem. A majority of fibers then cross to the opposite side in the medulla and descend through the lateral corticospinal tracts of the spinal cord. The fibers that do not cross at the medulla form the ventral corticospinal tracts, but a majority of these eventually cross to the opposite side in the cervical or upper thoracic regions. All fibers of the corticospinal tract terminate on the interneurons of the cord gray matter. The corticospinal tract is concerned with skilled, fine motor control, especially of the distal limbs.[37] The other major descending motor pathways that control neurons innervating muscle include the following:

- Corticobulbar tract: Some fibers project directly to motor cranial nerve (CN) nuclei (e.g., trigeminal, facial, hypoglossal), and others to the reticular formation before reaching cranial nerve nuclei.
- Tectospinal tract: This relatively small tract projects to motor neurons in the cervical cord; fibers influence neurons innervating neck muscles, as well as the spinal accessory nucleus (CN XI); important in guiding head movements during visual motor tasks.
- Reticulospinal tract (medial and lateral): Projects to the anterior horn of the spinal cord; important influence on muscle tone and reflex activity via influence on muscle spindle activity (increasing or decreasing sensitivity); the pontine (medial) reticulospinal tract facilitates extension of the lower extremities (excitation of extensor motor neurons) augmenting antigravity reflexes of the spinal cord; important influence on posture and gait. The medullary (lateral) reticulospinal tract has the reverse effect (excitation of flexor motor neurons).
- Vestibulospinal tracts (medial and lateral): The lateral vestibulospinal tract descends to all levels of the spinal cord; important contributions to postural control and movements of the head (facilitates axial extensors; inhibits axial flexors). The medial vestibulospinal tract projects primarily to the ipsilateral cervical spinal cord; also involved in coordinated head and eye movements.
- Rubrospinal tract: This tract merges with the corticospinal tract in the cervical region. Its role in human motor control is considered insignificant. It is believed that during primate evolution the role of this tract was completely taken over by the corticospinal tract.

Cerebellum

The primary function of the cerebellum is regulation of movement, postural control, and muscle tone. Although all of the mechanisms of cerebellar function are not clearly understood, lesions have been noted to produce typical patterns of impaired motor function and balance and decreased muscle tone (see Cerebellar Pathology later in this chapter).

Several theories of function of the cerebellum in motor activity have been established. Among the more widely held is that the cerebellum functions as a *comparator* and *error-correcting mechanism.*[33,38] The cerebellum compares the commands for the *intended* movement transmitted from the motor cortex with the *actual* motor performance of the body segment. This occurs by a comparison of information received from the cortex with that obtained from peripheral feedback mechanisms (termed *feedforward control*). The motor cortex and brainstem motor structures provide the commands for the intended motor response (internal feedback).[38] Peripheral feedback during the motor response is provided by muscle spindles, Golgi tendon organs, joint and cutaneous receptors, the vestibular apparatus, and the eyes and ears (external feedback). This feedback provides continual input regarding posture and balance, as well as position, rate, rhythm, and force of slow movements of peripheral body segments. If the input from the feedback systems does not compare appropriately (i.e., movements deviate from the intended command), the cerebellum

supplies a corrective influence. This effect is achieved by corrective signals sent to the cortex, which, via motor pathways, modifies or corrects the ongoing movement (e.g., increasing or decreasing the level of activity of specific muscles). The cerebellum also functions to modify cortical commands for subsequent movements.[38,39]

This CNS analysis of movement information, determination of level of accuracy, and provision for error correction is referred to as a **closed-loop system**. Schmidt and Lee define this model as "a control system employing feedback, a reference for correctness, a computation of error, and subsequent correction in order to maintain a desired state."[6, p. 493] It should be noted that not all movements are controlled by this system. Stereotypical movements (e.g., gait activities) and rapid, short-duration movements, which do not allow sufficient time for feedback to occur, are believed to be controlled by an **open-loop system**, defined as "a control system with preprogrammed instructions to a set of effectors; it does not use feedback information and error-detection processes."[6, p. 497] In this system, control originates centrally from a **motor program**, which is a memory or preprogrammed pattern of information for coordinated movement. The motor system then follows the established pattern largely independent of feedback or error-detection mechanisms. Motor programs can be called up in their entirety, modified, or reassembled in a new order. They provide the important function of freeing higher executive levels from attending to all aspects of a motor response.

Basal Ganglia

The basal ganglia are a group of nuclei located at the base of the cerebral cortex. The three main nuclei of the basal ganglia are the *caudate nucleus,* the *putamen,* and the *globus pallidus.* These nuclei have close anatomical and functional connections with two other subcortical nuclei that are also frequently considered as part of the basal ganglia: the *subthalamic nucleus* and the *substantia nigra.*[32,40]

Although the influences of the basal ganglia on movement are not understood as clearly as those of the cerebellum, there is evidence that the basal ganglia play an important role in several complex aspects of movement and postural control. These include the initiation and regulation of gross intentional movements, planning and execution of complex motor responses, facilitation of desired motor responses while selectively inhibiting others, and the ability to accomplish automatic movements and postural adjustments.[37,41,42] In addition, the basal ganglia play an important role in maintaining normal background muscle tone. This is accomplished by the inhibitory effect of the basal ganglia on both the motor cortex and lower brainstem. The basal ganglia also are believed to influence some aspects of both perceptual and cognitive functions.[41]

The motor portion of the basal ganglia assumes a somatotopic organization. The anatomical positioning of the basal ganglia provides insight into its contribution to motor performance. The areas of the brain associated with movement (primary motor cortex, supplementary motor area, premotor area, and the somatosensory cortex) form dense projections to the motor portion of the putamen. Output of this pathway forms the *motor circuit* of the basal ganglia, which is directed back to the supplementary motor area and the premotor area. These two areas and the primary motor cortex are all interconnected, and each has descending projections to the brainstem motor centers and spinal cord. This anatomical arrangement indicates that the influence of the basal ganglia on motor function is indirect and mediated by descending projections from the cortical motor areas.[41-43] Figure 6.3 schematically illustrates the motor circuit of the basal ganglion.

Dorsal Column–Medial Lemniscal Pathway

Regulation of movement is dependent on sensory afferent information. Peripheral somatosensory receptors and pathways provide information about the

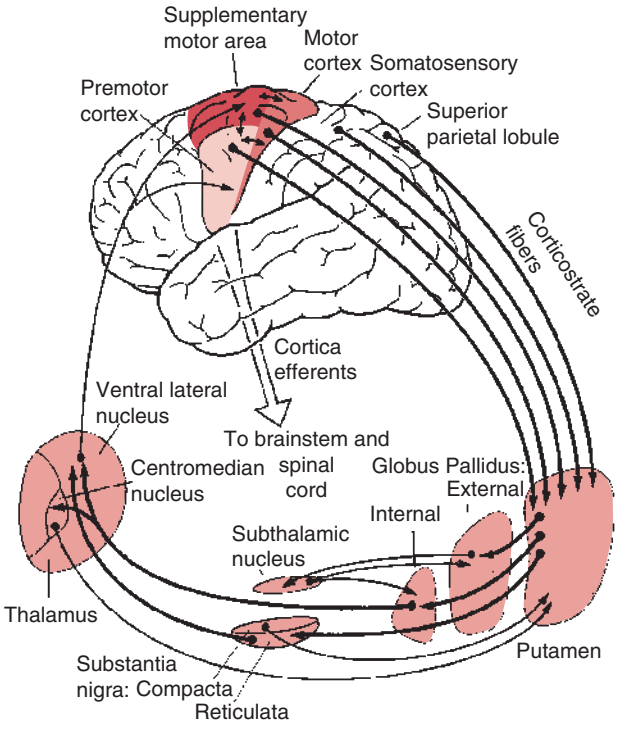

Figure 6.3 The motor circuit of the basal ganglia provides a subcortical feedback loop from the motor and somatosensory areas of the cortex, through portions of the basal ganglia and thalamus, and back to the cortical motor areas (premotor cortex, supplementary motor area, and motor cortex). *(From Ghez and Gordon,[43, p. 548] with permission.)*

status of the environment, the status of the body, and the status of the body in relation to the environment.[6] This information is encoded and conveyed to various parts of the CNS. The data are processed based on peripheral feedback and memory, which leads to selection (or modification) of a movement strategy appropriate to the task demands and environmental conditions.

The dorsal column–medial lemniscal pathway is particularly important to coordinated movement, as it is responsible for the afferent transmission of discriminative sensations. Sensory modalities that require fine gradations of intensity and precise localization on the body surface are mediated by this system. Sensations transmitted by the dorsal column–medial lemniscal pathway include discriminative touch, stereognosis, tactile pressure, barognosis, graphesthesia, recognition of texture, kinesthesia, two-point discrimination, proprioception, and vibration.

This system is composed of large, myelinated, rapidly conducting fibers. After entering the dorsal column the fibers ascend to the medulla and synapse with the dorsal column nuclei (nuclei gracilis and cuneatus). From here they cross to the opposite side and pass up to the thalamus through bilateral pathways called the *medial lemnisci*. Each medial lemniscus terminates in the ventral posterolateral thalamus. From the thalamus, third-order neurons project to the somatic sensory cortex.

FEATURES OF COORDINATION IMPAIRMENTS

As the cerebellum, basal ganglia, and dorsal column–medial lemniscal pathway provide input to, and act together with, the cortex in the production of coordinated movement, lesions in any of these areas affect higher-level processing and execution of coordinated motor responses. Although it is incorrect to assign all problems of incoordination to one of these sites, lesions in these areas are responsible for many characteristic motor deficits seen in adult populations. The following sections present an overview of common clinical features associated with lesions in each of these areas.

Cerebellar Pathology

A number of specific motor impairments that affect coordinated movement are associated with cerebellar pathology.[43-47] Many of these impairments either directly or indirectly influence the patient's ability to execute accurate, smooth, controlled movements. The motor deficits identified emphasize the crucial influence of the cerebellum on equilibrium, posture, muscle tone, and initiation and force of movement. **Ataxia** is perhaps the most common term used to describe motor impairments of cerebellar origin. Cerebellar ataxia is a general, comprehensive term used to describe loss of muscle coordination as a result of cerebellar pathology. Ataxia may affect gait, posture, and patterns of movement and is linked to difficulty initiating movement, as well as errors in the rate, rhythm, and timing of responses.

Perlman[48] provides an adept summary of the motor impairments associated with each of the major anatomic regions of the cerebellum as follows: "The cerebellum has three anatomic divisions that account for the three types of dysfunction commonly seen: (1) the midline (vermis, paleocerebellum), which underlies titubation, truncal ataxia, orthostatic tremor, and gait imbalance; (2) the hemispheres (neocerebellum—right controlling the right side of the body and left controlling the left side), which contribute to limb ataxia (e.g., dysdiadochokinesia, dysmetria, and kinetic tremor), dysarthria, and hypotonia; and (3) the posterior (flocculonodular lobe, archicerebellum), which also influences posture and gait as well as causing eye movement disorders (e.g., nystagmus, vestibulo-ocular reflex disruption)."[48, p. 216]

The following motor impairments are manifestations of cerebellar pathology:

- **Asthenia** is generalized muscle weakness associated with cerebellar lesions.
- **Dysarthria** is a disorder of the motor component of speech articulation. The characteristics of cerebellar dysarthria are referred to as **scanning speech** (often described as having a *one-word-at-a-time* quality). This speech pattern is typically slow, and may be slurred, hesitant, with prolonged syllables and inappropriate pauses. Word use, selection, and grammar remain intact, but the melodic quality of speech is altered.[38,39]
- **Dysdiadochokinesia** is an impaired ability to perform rapid alternating movements. This deficit is observed in movements such as rapid alternation between pronation and supination of the forearm. Movements are irregular, with a rapid loss of range and rhythm especially as speed is increased.[39]
- **Dysmetria** is an inability to judge the distance or range of a movement. It may be manifested by an overestimation (**hypermetria**) or an underestimation (**hypometria**) of the required range needed to reach an object or goal.
- **Dyssynergia** (**movement decomposition**) describes a movement performed in a sequence of component parts rather than as a single, smooth activity. For example, when asked to touch the index finger to the nose, the patient might first flex the elbow, and then adjust the position of the wrist and fingers, further flex the elbow, and finally flex the shoulder. **Asynergia** is the loss of ability to associate muscles together for complex movements.
- **Gait ataxia** involves ambulatory patterns that typically demonstrate a broad base of support. Upright stance stability is often poor and the arms may be held away from the body to improve balance (high guard position). Stepping patterns are irregular in direction and distance. Initiation of forward progression of a lower extremity may start slowly, and then the extremity may unexpectedly be flung rapidly and

forcefully forward and audibly hit the floor.[49] Gait patterns tend to be generally unsteady (postural instability), irregular, and staggering, with deviations from an intended forward line of progression (veering to one side; swaying or pitching in different directions).

- **Hypotonia** is a decrease in muscle tone. It is believed to be related to the disruption of afferent input from stretch receptors and/or lack of the cerebellum's facilitatory efferent influence on the fusimotor system. A diminished resistance to passive movement will be noted, and muscles may feel abnormally soft and flaccid. Diminished deep tendon reflexes also may be noted.[38] *Note:* After testing the patellar tendon jerk with a reflex hammer in a normal subject, the knee typically returns immediately to the resting state. With cerebellar pathology, the knee may oscillate six to eight times before returning to rest.[38]
- **Nystagmus** is a rhythmic, quick, oscillatory, back-and-forth movement of the eyes. It is typically apparent as the eyes move away from midline to fix on an object in either the medial or lateral field (i.e., extremes of temporal or nasal vision).[50] The patient has difficulty holding the gaze on the object in the peripheral field. An involuntary drift back to midline with immediate return to the object may be observed.[51] Nystagmus causes difficulty with accurate fixation and vision and is believed linked to the cerebellum's influence on synergy and tone of the extraocular muscles.
- **Rebound phenomenon**, originally described by Holmes, is the loss of the check reflex,[49] or check factor, which functions to halt forceful active movements when resistance is eliminated. Normally, when application of resistance to an isometric contraction is suddenly removed, the limb will remain in approximately the same position by action of the opposing muscle(s). For example, in applying resistance to an isometric contraction in the middle range of elbow flexion and then releasing it without warning, the intact subject will "check" or stop the motion quickly through activation of the opposing triceps, as well as feedback regarding joint position and force required to prevent further motion. With cerebellar involvement, the patient is unable to stop the motion, and the limb will move suddenly when resistance is released. The patient may strike himself or herself or other objects when the resistance is removed.
- **Tremor** is an involuntary oscillatory movement resulting from alternate contractions of opposing muscle groups. Different types of tremors are associated with cerebellar lesions. An **intention tremor**, or **kinetic tremor**, occurs during voluntary motion of a limb and tends to increase as the limb nears its intended goal or speed is increased.[38] Intention tremors are diminished or absent at rest. **Postural (static) tremor** may be evident by back-and-forth oscillatory movements of the body while the patient maintains a standing posture. Postural tremors also may be observed as up-and-down oscillatory movements of a limb when it is held against gravity. *Titubation* typically refers to rhythmic oscillations of the head (side-to-side or forward-and-backward movements, or the movements may have a rotary component); however, the term is also less frequently used to refer to axial involvement of the trunk.

In addition to these characteristic clinical features of cerebellar involvement, a greater length of time may also be required to initiate voluntary movements (delayed **reaction time**). Difficulty may also be observed in stopping or changing the force, speed, or direction of movement, prolonging **movement time**.[32] Motor learning will also be affected. Recall that the cerebellum compares the intended movement (internal feedback) with the actual movement (external feedback). For subsequent movements, the cerebellum generates corrective signals to reduce the errors (feedforward control). Lack of this feedforward control is responsible for deficits in motor learning and coordination.

Basal Ganglia Pathology

Patients with lesions of the basal ganglia typically demonstrate several characteristic motor deficits. These include (1) poverty and slowness of movement; (2) involuntary, extraneous movement; and (3) alterations in posture and muscle tone.[36,42] Thus, patients with basal ganglia involvement present on a continuum of motor behavior from severely diminished as seen in advanced Parkinson's disease to excessive extraneous movements apparent with Huntington's disease.[42]

The following motor impairments are manifestations of basal ganglia pathology:[52-59]

- **Akinesia** is an inability to initiate movement and is seen in the late stages of Parkinson's disease. This deficit is associated with assumption and maintenance of fixed postures (freezing episodes). A tremendous amount of mental concentration and effort is required to perform even the simplest motor activity.
- **Athetosis** is characterized by slow, involuntary, writhing, twisting, "wormlike" movements. Frequently, greater involvement in the distal upper extremities is noted;[60] this may include fluctuations between hyperextension of the wrist and fingers and a return to a flexed position, combined with rotary movements of the extremities. Many other areas of the body may be involved, including the neck, face, tongue, and trunk. The phenomena are also referred to as *athetoid movements*. Pure athetosis is relatively uncommon and most often presents in combination with spasticity, tonic spasms, or chorea. Athetosis can be a clinical feature of some forms of cerebral palsy.
- **Bradykinesia** is a decreased amplitude and velocity of voluntary movement. It may be demonstrated in a variety of ways, such as a decreased arm swing; slow, shuffling gait; difficulty initiating or changing

direction of movement; lack of facial expression; or difficulty stopping a movement once begun. Bradykinesia is characteristic of Parkinson's disease.

- **Chorea** is characterized by involuntary, rapid, irregular, and jerky movements involving multiple joints. Choreiform movements demonstrate irregular timing, are most apparent in the upper extremities, and cannot be voluntarily inhibited; associated with Huntington's disease.[61]
- **Choreoathetosis** is a term used to describe a movement disorder with features of both chorea and athetosis.
- **Dystonia** (dystonic movements) involves sustained involuntary contractions of agonist and antagonist muscles[42] causing abnormal posturing (*dystonic* posture) or twisting movements. Most common in trunk and extremity musculature but also may affect the neck, face, and vocal cords. Torsion spasms also are considered a form of dystonia, with spasmodic torticollis being the most common.[49]
- **Hemiballismus** involves large-amplitude sudden, violent, flailing motions of the arm and leg of one side of the body. Primary involvement is in the axial and proximal musculature of the limb. Hemiballismus results from a lesion of the contralateral subthalamic nucleus.[32,35]
- **Hyperkinesis** is abnormally increased muscle activity or movement; **hypokinesis** is a decreased motor response especially to a specific stimulus.
- **Rigidity** is an increase in muscle tone causing greater resistance to passive movement. It tends to be more pronounced in the flexor muscles of the trunk and extremities causing activity limitations in such areas as dressing, transfers, speech, eating, and postural control.[2] Two types of rigidity may be seen: *lead-pipe* and *cogwheel.* **Lead-pipe rigidity** is a uniform, constant resistance felt by the examiner as the extremity is moved through a range of motion (ROM). **Cogwheel rigidity** is considered a combination of the lead-pipe type with tremor. It is characterized by a series of brief relaxations or "catches" as the extremity is passively moved.
- **Tremor** is an involuntary, rhythmic, oscillatory movement observed at rest (**resting tremor**). Resting tremors typically disappear or decrease with purposeful movement, but may increase with emotional stress. Tremors associated with basal ganglia lesions (e.g., Parkinson's disease) are frequently noted in the distal upper extremities in the form of a "pill-rolling" movement, where it looks as if a pill is being rolled between the first two fingers and the thumb. Motion of the wrist, and pronation and supination of the forearm, may be evident. Tremors also may be apparent at other body parts as well, such as the jaw; characteristic of Parkinson's disease. Table 6.1 provides a summary of common coordination impairments associated with pathology of the cerebellum and basal ganglia.

Dorsal Column–Medial Lemniscal Pathology

Coordination impairments associated with dorsal column–medial lemniscal (DCML) lesions are somewhat less characteristic than those produced by either cerebellar

Table 6.1 Common Coordination Impairments Associated with Pathology of the Cerebellum and Basal Ganglia

	Cerebellar Pathology
Asthenia	Generalized muscle weakness
Asynergia	Loss of ability to associate muscles together for complex movements
Delayed reaction time	Increased time required to initiate voluntary movement
Dysarthria	Disorder of the motor component of speech articulation
Dysdiadochokinesia	Impaired ability to perform rapid alternating movements
Dysmetria	Inability to judge the distance or range of a movement
Dyssynergia	Movement performed in a sequence of component parts rather than as a single, smooth activity; decomposition
Gait disorders	Ataxic pattern; broad base of support; postural instability; high-guard position of UEs
Hypotonia	Decrease in muscle tone
Hypermetria	Overestimation of distance or range needed to accomplish a movement
Hypometria	Underestimation of distance or range needed to accomplish a movement
Nystagmus	Rhythmic, quick, oscillatory, back-and-forth movement of the eyes
Rebound phenomenon	Inability to halt forceful movements after resistive stimulus removed; patient unable to stop sudden limb motion

Continued

Table 6.1 Common Coordination Impairments Associated with Pathology of the Cerebellum and Basal Ganglia—cont'd

Cerebellar Pathology	
Tremor	Involuntary oscillatory movement resulting from alternate contractions of opposing muscle groups
• Intention (kinetic)	Oscillatory movement during voluntary motion; increases as the limb nears target; diminished or absent at rest
• Postural (static)	Exaggerated oscillatory movement of the body in standing posture or of a limb held against gravity
Titubation	Rhythmic oscillations of the head; axial involvement of the trunk
Basal Ganglia Pathology	
Akinesia	Inability to initiate movement; associated with fixed postures
Athetosis	Slow, involuntary, writhing, twisting, "wormlike" movements; frequently greater involvement in distal UEs
Bradykinesia	Decreased amplitude and velocity of voluntary movement
Chorea	Involuntary, rapid, irregular, jerky movements involving multiple joints; most apparent in UEs
Choreoathetosis	Movement disorder with features of both chorea and athetosis
Dystonia (dystonic movements)	Sustained involuntary contractions of agonist and antagonist muscles
Hemiballismus	Large-amplitude sudden, violent, flailing motions of the arm and leg of one side of the body
Hyperkinesis	Abnormally increased muscle activity or movement
Hypokinesis	Decreased motor response especially to a specific stimulus
Rigidity	Increase in muscle tone causing greater resistance to passive movement; greater in flexor muscles
• Lead-pipe	Uniform, constant resistance as limb is moved
• Cogwheel	Series of brief relaxations or "catches" as limb is passively moved
Tremor (resting)	Involuntary, rhythmic, oscillatory movement observed at rest

UEs = upper extremities.

or basal ganglia pathology. Lesions of the DCML typically result in coordination and equilibrium impairments related to the patient's lack of joint position sense and awareness of movement, and impaired localized touch sensation. Recall that this ascending pathway carries the peripheral (external) feedback required for feedforward control. It mediates sensations critical to coordinated movement such as proprioception, kinesthesia, and discriminative touch.

Disturbances of gait are a common finding with DCML pathology. The gait pattern is usually wide-based and swaying, with uneven step lengths and excessive lateral displacement. The advancing leg may be lifted too high and then dropped abruptly with an audible impact. Watching the feet during ambulation is typical and is indicative of a proprioceptive loss. Another common deficit seen with DCML pathology is dysmetria. As mentioned, this is an impaired ability to judge the required distance or range of movement and may be noted in both the upper and lower extremities. It is manifested by the inability to place an extremity accurately or to reach a target object. For example, in attempting to lock a wheelchair brake, the patient may inaccurately judge (overestimate or underestimate) the required movement needed to reach the brake handle. Fine motor skills may also be impaired owing to alterations in discriminative tactile and object recognition abilities.

Because vision can assist in guiding movements and maintaining balance, as well as improve accuracy of discriminative tasks, visual feedback can be an effective mechanism to compensate partially for DCML pathology. Thus, coordination and/or balance problems will be exaggerated when vision is occluded or when the patient's eyes are closed. The inability to maintain standing balance with the feet together when the eyes are closed is termed a positive **Romberg sign** and is usually indicative of proprioceptive loss. Visual guidance will also reduce the manifestations of dysmetria and diminished tactile perception. However, some noticeable slowing of movements may be observed as

visually guided motions are generally more accurate when speed of movement is reduced.

AGE-RELATED CHANGES AFFECTING COORDINATED MOVEMENT

Alterations in the ability to execute smooth, accurate, controlled motor responses occur with aging. The importance of understanding the basis of these changes is reflected in the large and ever expanding body of literature devoted to examining various aspects of motor performance in older adults.[62-78] This section presents an overview of the most salient age-associated changes affecting coordinated movement. For a more comprehensive perspective on the physiological, neurological, and musculoskeletal changes associated with aging, the reader is referred to the work of Guccione, Wong, and Avers[79] and Lewis and Bottomley.[80]

Decreased strength. Diminished strength is a well-documented finding in older adults.[76,78,81,82] *Sarcopenia* refers an age-associated loss of skeletal muscle mass (decreased cross-sectional area) as well as changes in the ability of muscle tissue to regenerate. This loss has a direct impact on strength, endurance, mobility, and the ability to perform smooth controlled motor responses. A combination of factors are believed to contribute to this loss of muscle mass, including nutritional deficiencies, decreased ability to synthesize protein, altered endocrine function, lack of exercise, and the presence of a chronic disease (co-morbidity).[83-85] Other contributing factors to decreased strength include a loss of alpha motor neurons (decreased number of functional motor units), loss or atrophy of fast-twitch fibers (most notably type IIb), reduced number and diameter of muscle fibers,[82] diminished oxidative capacity of exercising muscle, and a subsequent reduction in ability to produce torque.[86] In general, there appears to be a greater loss of strength in antigravity muscles of the back and lower extremities (e.g., latissimus dorsi, hip extensors, quadriceps) as compared to the upper extremity and greater loss in proximal than distal muscles.[80]

Slowed reaction time. Older adults typically move more slowly. This is particularly evident for tasks that require both speed and accuracy; speed will decrease to ensure greater accuracy (speed–accuracy trade-off).[87] In general, the time interval between application of a stimulus and initiation of movement is increased.[6] This finding is also linked to degenerative changes in the motor unit. In addition, *premotor reaction time* (time interval between onset of a stimulus and initiation of a response) and *movement time* (time interval between the initiation of movement and the completion of movement) are lengthened with normal aging. Evidence also suggests that greater cognitive resources are required to accomplish a task, especially those involving fine motor skills and dual-task performance.[88]

Decreased range of motion. Early investigations examining subjects from various age groups have found a reduced ROM in older adults.[89-91] Decreases in ROM with advancing age have been found for wrist flexion and extension and hip and shoulder rotation;[89] small decreases (5° or less) were found in mean active hip and knee motions;[90] and James and Parker[91] found consistent declines in both active and passive ROM for 10 lower extremity joints in a population of 80 healthy adults older than 70 years of age. Increased joint tightness tends to be most evident toward the end of ROM and may affect the overall skill in performing coordinated movements. Decreased ROM has been linked to biological aging of joint surfaces,[91] degenerative changes in collagen fibers, dietary deficiencies, and sedentary lifestyle.[80] Walker et al[92] examined active ROM of 28 joints in two groups of elders (60 to 69 and 75 to 84 years). No significant differences in ROM were found between the two age groups.

Postural changes. A straight line projecting through the ear, acromion, greater trochanter, posterior patella, and lateral malleolus represents the lateral view of normal postural alignment. Common postural changes seen with aging include forward head, rounded shoulders (kyphosis), altered lordotic curve (either flattened or exaggerated), and a slight increase in hip and knee flexion.[80] The base of support may also be widened. Diminished strength and ROM, as well as inactivity and prolonged sitting, may contribute to poor postural alignment. Of particular importance is the potential loss of ability to fully accomplish preparatory postural adjustments before execution of a movement.

Impaired balance (postural control). Decreased balance and increased postural sway (oscillating movements of body over feet during relaxed standing) both occur with advancing age.[93-96] A reduction in postural limits of stability (LOS) and functional reach magnitude has also been documented.[97-99] However, Robinovitch and Cronin[100] found that elderly subjects with impaired LOS lacked awareness of their limitations and as a result tended to plan movements that resulted in a loss of balance.

Changes in skilled motor performance are a predictable aspect of normal aging. However, this information should not negate or undermine the importance of treatment strategies to improve functional performance and quality of life. An important consideration in treatment planning is that the aging neuromuscular system maintains its physiological adaptive response to training stimuli.[101] Physical therapy intervention is highly effective in promoting and sustaining a more successful approach to aging.[102-109] This is an important consideration as the population ages. The 2010 Census indicates that the population age 65 and over is approximately 40.3 million, representing 13% of the total population.[110] It is estimated that by 2030, there will be 71 million older adults accounting for about 20% of the population.[111]

Clinical Note: The identified changes affecting coordinated movement in the older adult may be accentuated further by degenerative joint changes, reduced flexibility, alterations in sensation (see Chapter 3, Examination of Sensory Function), perceptual impairments (see Chapter 27, Cognitive and Perceptual Dysfunction), and diminished vision and hearing acuity. Knowledge of these anticipated age-related changes improves the therapist's ability to establish effective communication to optimize patient performance, as well as assist with interpretation of test results. The potential presence of these changes has important implications for how the therapist communicates with, and provides directions to, the patient during the coordination examination. Sensitive and accurate communication that enhances the therapeutic interaction is central to the role of the physical therapist. This involves conveying information in a language or context that is meaningful and intelligible to the patient and communicates trust, respect, and compassion.

SCREENING

Screenings are a series of brief tests that provide the therapist an "overview" of the area of interest (e.g., sensation, ROM, strength). Recall that screenings are used to (1) determine the need for further or more detailed examination; (2) rule out or differentiate specific system involvement; (3) determine if referral to another health care practitioner is warranted; (4) focus the search for the origin of symptoms to a specific location or body part; and (5) identify system-related impairments that contribute to activity limitations or disability.[1,112] In combination with the information from the history and review of systems, screenings assist the therapist in proficiently identifying the needed tests and measures and assist in setting priorities within the examination process.

An important starting point for identification of areas to be screened is consideration of all potential (possible) contributing factors to an observed activity limitation. For example, observation of a coordination impairment imposing activity limitations on dressing abilities would direct the therapist's attention to consider its origin. However, before a detailed systematic examination of all systems, screenings can quickly and efficiently direct the therapist's attention to the following:

- Areas grossly intact that can subsequently be "ruled out" as contributing to the activity limitation; additional examination of these areas is likely not warranted.
- Areas suspected of contributing to the clinical problem (screening findings are abnormal); further examination is indicated.
- Identification of the need for referral to another practitioner (e.g., occupational therapist for management of a perceptual deficit).

For example, ROM, strength, and level of function of the sensory system have direct implications for successful execution of coordinated movements. It may be likely that formal examination of these areas has already been accomplished before a coordination examination. If not, however, screening of these areas is indicated.

Clinical Note: An initial screening of ROM, strength, and sensation before the coordination examination is necessary because impairments in any of these areas may influence the ability to produce smooth, accurate, controlled motor responses. However, it is also important to note that coordination impairments may occur in the presence of normal ROM, strength, and intact sensation.

Examples of Screenings

By virtue of their purpose (i.e., providing quickly and efficiently obtained information), screenings are generally performed with the patient seated on a firm surface. However, to fully screen some areas (e.g., the hip) or if several different screenings are planned in sequence, the supine position may be preferable. If abnormal findings are identified during screening, it is a clear indication that more detailed testing is warranted.

Range of Motion

Generally, ROM screenings involve active movements. The patient is asked to selectively move different joints and body segments actively through their available range. For example, the patient might be asked to flex, abduct, and then extend the shoulder; flex and extend the elbow; flex, extend, or circumduct (flexion–abduction–extension–adduction) the wrist; flex and extend the knee; and plantarflex, dorsiflex, and circumduct the ankle. To minimize time required in providing verbal directions, the therapist may opt to sit directly in front and perform the movements while directing the patient to "mirror" the movements. Alternatively, functional movements can be used that combine motions of several joints. For example, the patient might be asked to individually place each hand on the back or top of the head, to reach as high as possible toward the ceiling with each (or both) upper extremity, to place each hand on the small of the back, or to reach down and touch the ankle.

Using careful observation and knowledge of normative ROM values, the therapist makes a gross determination of whether the ROM is *within normal limits* (WNL); if functional movements are used, the designation is *within functional limits* (WFL). If complete, active, painless ROM is available, additional testing

is likely not necessary. If active ROM is incomplete or painful, a more detailed examination is needed to determine the cause and extent of the screening findings.[113]

Strength

Typically the ROM screening will precede the strength screening, so some information about strength will already be gathered. If the patient performed active ROM movements against the resistance of gravity, a logical assumption is that gross strength is at least a fair (3/5) grade (ability to move through the ROM against the resistance of gravity). The screening will then be directed toward further refining this estimate using application of manual resistance. Although standard manual muscle testing positions[114,115] are not used for screening, adherence to foundational principles is indicated. Segments proximal to those being screened should be stabilized; resistance (break test) is applied at the distal end of the segment being tested and at a 90° angle (perpendicular) to the primary axis of movement.

From the sitting position, the patient might be asked to raise the knee toward the ceiling to test hip flexion with application of resistance on the distal femur; to extend the knee to test knee extension strength with resistance on the distal leg; and to bring the hand toward the shoulder to test elbow flexion strength with resistance applied on the distal forearm.

Sensation

To perform a sensory screening, several easily tested (i.e., requiring little or no specialized equipment) modalities of sensation are selected. Modalities from each of the general categories of sensations should be selected. For example, the therapist might select pain and light touch (superficial), kinesthesia and vibration (deep), and two-point discrimination or stereognosis (combined). For modalities such as pain and light touch, the sensory screening is performed by using the selected modalities to screen randomly over somewhat large surface areas. For example, several applications of each stimulus might be distributed over the upper and lower extremities and trunk. For sensations such as kinesthesia or proprioception, screening should include selected joints and movements of both the upper and lower extremities. Abnormal findings indicate the need for a more detailed examination of sensory function.

FEATURES OF COORDINATION TESTS

Coordination tests generally can be divided into two main categories: *gross motor movements* and *fine motor movements.* **Gross motor tests** include body posture, balance, and extremity movements involving large muscle groups. Examples of gross motor activities include crawling, kneeling, standing, walking, and running. **Fine motor tests** address movements concerned with utilization of small muscle groups that involve skillful, controlled manipulation of objects. Examples of fine motor activities include finger dexterity tasks such as buttoning a shirt, typing, or handwriting.

Two subdivisions of coordination tests (***nonequilibrium*** and ***equilibrium***) have traditionally been used for providing structure and organization to administration of the tests. *Nonequilibrium* tests address components of limb movements. *Equilibrium* or *balance* tests consider the ability to maintain the body in equilibrium with gravity both statically (i.e., when stationary) and dynamically (i.e., while moving).[1] However, it should be noted that the "nonequilibrium" division is somewhat of a misnomer in that elements of posture and balance are required during these tests (i.e., maintaining an upright sitting posture).

Coordination tests also address patient capabilities in four basic areas of functional task requirements: transitional mobility, stability (static postural control), dynamic postural control (controlled mobility), and skill. See discussion in Chapter 5, Examination of Motor Function: Motor Control and Motor Learning, and Table 5.11, Categories of Motor Skills.

Movement Capabilities

The nonequilibrium coordination examination focuses on movement capabilities in several main areas:

- *Alternate* or *reciprocal motion,* which is the ability to reverse movement between opposing muscle groups
- *Movement composition,* or synergy, which involves movement control achieved by muscle groups acting together
- *Movement accuracy,* which is the ability to gauge or judge distance and speed of voluntary movement
- *Fixation or limb holding,* which addresses the ability to hold the position of an individual limb or limb segment

The progression of difficulty of coordination tests (increases in challenge to the patient) typically utilizes the following sequence: (1) unilateral tasks; (2) bilateral symmetrical tasks; (3) bilateral asymmetrical tasks; and (4) multilimb tasks (these constitute the highest level of difficulty). Difficulty is also increased by progressively adding increased challenges to balance (i.e., movements performed in sitting progressing to standing).

ADMINISTERING THE COORDINATION EXAMINATION

Before initiating the coordination examination, the testing environment should be identified and prepared, needed equipment gathered, and consideration given to patient preparation (i.e., what information and instruction will be provided).

Preparation

Testing Environment

The coordination examination should be administered in a quiet, well-lighted treatment area sufficiently large to accommodate walking activities included in the equilibrium portion of the tests. Ideally, the room should be equipped with two standard chairs and a mat or treatment table. A watch or clock with a second hand should be available for timed components of the examination, as well as a method of occluding vision (an inexpensive blindfold used for sleeping works well).

Patient Preparation

The coordination examination should be administered when the patient is well rested. A full explanation of the purpose of the testing should be provided. Each coordination test is described and demonstrated individually by the therapist before actual testing. Such demonstrations should be attended to carefully, as lack of clarity will negatively affect motor responses. Because testing procedures require mental concentration and some physical activity, fatigue, apprehension, or fear may adversely influence test results.

Preliminary Observation

Observation is an essential skill in clinical decision making. Accurate and careful patient observation provides a rich source of preliminary information before performing a coordination examination. Inasmuch as treatment intervention will be directed, at least in part, toward improving functional performance and activity levels, initial observations should logically focus here. Depending on the practice setting environment, the patient might be observed performing any number of functional activities such as bed mobility, self-care routines (e.g., dressing, combing hair, brushing teeth), transfers, eating, writing, changing position from lying or sitting to standing, maintaining a standing position, and walking. Use of appropriate patient guarding techniques is indicated. While observing the patient, general information can be obtained that will assist in localizing specific areas of impairment. This information will include the following:

- General level of skill in each activity and amount of assistance or assistive devices required
- The occurrence of extraneous limb movements, oscillations; specific extremities involved
- Postural sway or unsteadiness
- Distribution: proximal and/or distal musculature, unilateral or bilateral
- Situations or occurrences that alter (increase or decrease) impairments
- Amount of time required to perform an activity
- Level of safety, fall risk

From this initial observation, the therapist will be guided in selecting the appropriate tests for the general areas of impairment noted. Table 6.2 presents sample tests appropriate for examining nonequilibrium coordination. It should be noted that a single test is often appropriate to examine several different movement capabilities simultaneously to conserve time. The tests presented are intended as samples and are not all-inclusive. Other activities may be developed that are equally effective in examining a particular impairment and may be more appropriate for an individual patient. As noted, performance in any variety of functional skills (e.g., self-care routines, wheelchair skills, transfers, dressing) is also an effective means of examining many aspects of movement capabilities (e.g., alternate or reciprocal motion, movement composition, movement accuracy).

Table 6.3 includes selected impairments and suggested tests appropriate for the clinical problem.

Examination

Guided by information from the preliminary observation of functional activities, tests should be selected (see Table 6.3) to address the required movement capabilities of interest for the individual patient. Generally, nonequilibrium tests are completed first, followed by the equilibrium tests. Attention should be directed to carefully guarding the patient during testing; use of a safety belt may be warranted. During testing, the following questions can be used to help

Table 6.2 Nonequilibrium Coordination Tests*

1. Finger-to-nose	The shoulder is abducted to 90° with the elbow extended. The patient is asked to bring the tip of the index finger to the tip of his or her nose. Alterations may be made in the initial starting position to observe performance from different planes of motion.
2. Finger–to–therapist's finger	The patient and therapist sit opposite each other. The therapist's index finger is held in front of the patient. The patient is asked to touch the tip of his or her index finger to the therapist's index finger. The position of the therapist's finger may be altered during testing to observe ability to change distance, direction, and force of movement.
3. Finger-to-finger	Both shoulders are abducted to 90° with the elbows extended. The patient is asked to bring both hands toward the midline and approximate the index fingers from opposing hands.

Table 6.2 Nonequilibrium Coordination Tests—cont'd

4. Alternate nose-to-finger	The patient alternately touches the tip of his or her nose and the tip of the therapist's finger with the index finger. The position of the therapist's finger may be altered during testing to observe ability to change distance, direction, and force of movement.
5. Finger opposition	The patient touches the tip of the thumb to the tip of each finger in sequence. Speed may be gradually increased.
6. Mass grasp	An alternation is made between opening and closing fist (from finger flexion to full extension). Speed may be gradually increased.
7. Pronation/supination	With elbows flexed to 90° and held close to body, the patient alternately turns the palms up and down. This test also may be performed with shoulders flexed to 90° and elbows extended. Speed may be gradually increased. The ability to reverse movements between opposing muscle groups can be examined at many joints. Examples include active alternation between flexion and extension of the knee, ankle, elbow, or fingers.
8. Rebound test	The patient is positioned with the elbow flexed. The therapist applies sufficient manual resistance to produce an isometric contraction of biceps. Resistance is suddenly released. Normally, the opposing muscle group (triceps) will contract and "check" movement of the limb. Many other muscle groups can be tested for this phenomenon, such as the shoulder abductors or flexors and the elbow extensors.
9. Tapping (hand)	With the elbow flexed and the forearm pronated, the patient is asked to "tap" the hand on the knee.
10. Tapping (foot)	The patient is asked to "tap" the ball of one foot on the floor without raising the knee; heel maintains contact with floor.
11. Pointing and past pointing	The patient and therapist are opposite each other, either sitting or standing. Both patient and therapist bring shoulders to a horizontal position of 90° of flexion with elbows extended. Index fingers are touching or the patient's finger may rest lightly on the therapist's. The patient is asked to fully flex the shoulder (fingers will be pointing toward ceiling) and then return to the horizontal position such that index fingers will again approximate. Both arms should be tested, either separately or simultaneously. A normal response consists of an accurate return to the starting position. In an abnormal response, there is typically a "past pointing," or movement beyond the target. Several variations to this test include movements in other directions such as toward 90° of shoulder abduction or toward 0° of shoulder flexion (finger will point toward floor). After each movement, the patient is asked to return to the initial horizontal starting position.
12. Alternate heel-to-knee; heel-to-toe	From a supine position, the patient is asked to touch the knee and big toe alternately with the heel of the opposite extremity.
13. Toe to examiner's finger	From a supine position, the patient is instructed to touch the great toe to the examiner's finger. The position of finger may be altered during testing to observe ability to change distance, direction, and force of movement.
14. Heel on shin	From a supine position, the heel of one foot is slid up and down the shin of the opposite LE.
15. Drawing a circle	The patient draws an imaginary circle in the air with either UE or LE (a table or the floor also may be used). This also may be done using a figure-eight pattern. This test may be performed in the supine position for the LE.
16. Fixation or position holding	UE: The patient holds arms horizontally in front (sitting or standing). LE: The patient is asked to hold the knee in an extended position (sitting).

*Tests should be performed first with eyes open and then with eyes closed. Abnormal responses include a gradual deviation from the "holding" position and/or a diminished quality of response with vision occluded. Unless otherwise indicated, tests are performed with the patient in a sitting position.

LE = Lower extremity; UE = upper extremity.

Table 6.3 Sample Tests for Selected Coordination Impairments

Impairment	Sample Test
Dysdiadochokinesia	Finger-to-nose Alternate nose-to-finger Pronation/supination Knee flexion/extension Walking, alter speed or direction
Dysmetria	Pointing and past pointing Drawing a circle or figure eight Heel on shin Placing feet on floor markers; sitting, standing
Dyssynergia	Finger-to-nose Finger–to–therapist's finger Alternate heel-to-knee Toe–to–examiner's finger
Hypotonia	Passive movement Deep tendon reflexes
Tremor (intention)	Observation during functional activities (tremor will typically increase as target is approached or movement speed increased) Alternate nose-to-finger Finger-to-finger Finger–to–therapist's finger Toe–to–examiner's finger
Tremor (resting)	Observation of patient at rest; limb or jaw movements Observation during functional activities (tremor will diminish significantly or disappear with movement)
Tremor (postural)	Observation of steadiness of normal posture; sitting, standing
Asthenia	Fixation or position holding (upper and lower extremity) Application of manual resistance to determine ability to hold
Rigidity	Passive movement Observation during functional activities Observation of resting posture(s)
Bradykinesia	Walking, observation of arm swing and trunk motions Walking, alter speed and direction Request that a movement or gait activity be stopped abruptly Observation of functional activities: timed tests
Disturbances of posture	Fixation or position holding (upper and lower extremity) Displace balance unexpectedly in sitting or standing (perturbation) Standing, alter base of support (e.g., one foot directly in front of the other; standing on one foot)
Disturbances of gait	Walk along a straight line Walk sideways, backward March in place Alter speed and direction of ambulatory activities Walk in a circle

direct the therapist's observations. The findings should be included in the comment section of the coordination examination form.

- Are movements direct, precise, and easily reversed?
- Do movements occur within a reasonable or normal amount of time?
- Does increased speed of performance affect quality of motor activity?
- Can continuous and appropriate motor adjustments be made if speed and direction are changed?
- Can a position or posture of the body or specific extremity be maintained without swaying, oscillations, or extraneous movements?
- Are placing movements of both upper and lower extremities accurate?
- Does occluding vision alter the quality of motor activity?
- Is there greater involvement proximally or distally?
- Is there greater involvement on one side of body versus the other?
- Does the patient fatigue rapidly?
- Is there a consistency of motor response over time?

Recording Test Results

A generally accepted format for recording results from coordination tests has not been established and approaches to documentation vary considerably among institutions and individual therapists. Owing to the nature of the tests and the wide variation in types and severity of deficits, observational coordination forms are not highly standardized. However, exceptions to this are the upper extremity standardized tests addressing specific components of manual dexterity through the use of functional or work-related tasks. Some of these tests originally were developed to assist with determining if an individual had the needed manual skills required for specific employment tasks. Several examples of these tests are presented later in this chapter under Standardized Instruments: Upper Extremity Coordination.

Several options are available for recording results from a comprehensive examination of coordination. A

coordination examination form is useful to provide a composite picture of the areas of impairment noted. These forms are often developed within clinical settings. They may be general (a sample is presented in Table 6.4), or they may be specific to a given group of patients, such as those with brain injuries. In general, these forms lack reliability testing. However, they do provide a systematic method of data collection and documentation. In addition, use of the same form for periodic reexamination facilitates ease of comparison of changes over time. These forms frequently include some type of rating scale in which level of performance is weighted using a scale with descriptors attached. An example of such a scale can be found in Table 6.4.

During testing, postural instability may be evident, particularly in unsupported sitting, and contact guarding may be required. This should be noted in the comments section.

A score from the rating scale would then be assigned to each component of the coordination examination. An advantage of using rating scales is that they provide a mechanism for quantifying patient performance based

Table 6.4 Coordination and Balance Examination Form

Patient Name: _____ Examiner: _____ Date: _____

Part I: Nonequilibrium Coordination Tests

Key to Grading

4 *Normal Performance*
3 *Minimal Impairment:* Able to accomplish activity; slightly less than normal control, speed, and steadiness
2 *Moderate Impairment:* Able to accomplish activity; movements are slow, awkward, and unsteady
1 *Severe Impairment:* Able only to initiate activity without completion; movements are slow with significant unsteadiness, oscillations, and/or extraneous movements
0 *Activity Impossible*

Notations should be made under comments section if:

- Lack of visual input renders activity impossible or alters quality of performance
- Verbal cuing is required to accomplish activity
- Alterations in speed affect quality of performance
- Excessive amount of time required to complete activity
- Changes in arm position alters sitting balance
- Postural instability is evident: unsteadiness, oscillations, extraneous movements
- Fatigue alters consistency of response
- Performance affects patient safety; requires contact guarding

Part II: Postural Control And Balance Tests

Key to Grading

4 *Normal:* Able to maintain steady balance without handhold support (static)
Accepts maximal challenge and can shift weight easily within full range in all directions (dynamic)
3 *Good:* Able to maintain balance without handhold support, limited postural sway (static)
Accepts moderate challenge; able to maintain balance while picking object off floor (dynamic)
2 *Fair:* Able to maintain balance with handhold support; may require occasional minimal assistance (static)
Accepts minimal challenge; able to maintain balance while turning head/trunk (dynamic)
1 *Poor:* Requires handhold support and moderate to maximal assistance to maintain position (static)
Unable to accept challenge or move without loss of balance (dynamic)
0 *Absent:* Unable to maintain balance

Notations should be made under comments section if:

- Lack of visual input renders activity impossible or alters quality of performance
- Verbal cuing is required to accomplish activity
- Alterations in speed affect quality of performance
- Excessive amount of time required to complete activity
- Changes in limb position alters standing balance/postural stability
- Postural instability is evident: extraneous movements, unsteadiness, or oscillations
- Fatigue alters consistency of response
- Performance impacts patient safety, fall risk

GRADE	BALANCE TEST	COMMENTS
	Sitting in a normal comfortable position	
	Sitting, weight shifting in all directions	
	Sitting, multidirectional functional reach	
	Sitting, picking an object up off floor	
	Standing in a normal comfortable posture	
	Standing, feet together (narrow base of support)	
	Standing on one foot	
	Standing, with one foot directly in front of the other (tandem position)	
	Standing: eyes open (EO) to eyes closed (EC) (*Romberg Test*)	
	Standing in tandem position: EO to EC (*Sharpened Romberg Test*)	
	Standing, multidirectional functional reach	
	Walking, placing feet on floor markers	
	Walk: sideways	
	Walk: backwards	
	Walk: cross-stepping	
	Walk: in a circle, alternate directions	
	Walk: on heels	
	Walk: on toes	
	March in place	
	Walk with horizontal and vertical head turns	
	Step over or around obstacles	
	Stairclimbing with handrail	
	Stairclimbing without handrail	
	Stairclimbing: one step at a time	
	Stairclimbing: step-over-step	

on subjective ratings. Inherent limitations of using scales include the following: (1) the descriptions may not be reflective of individual patient performance; (2) descriptors may not be defined adequately or detailed appropriately; and (3) without training, individual interpretation decreases reliability of intraexaminer and interexaminer testing. Frequently, coordination forms include a comments section. This component of the form allows for additional narrative descriptions of patient performance. Using a combination of a rating scale and narrative comments or summary will ensure that all coordination impairments are adequately documented.

Measuring the length of time required to complete a motor or functional task provides an important quantitative measure of movement capability. Because accomplishing an activity in a reasonable amount of time is an important criterion of performance, the length of time required to accomplish certain activities is recorded by use of a stopwatch. Using time as a measure of performance has important implications for both function and safety. For example, assume a patient with multiple sclerosis who uses a wheelchair plans to return to school but requires 2.5 hours to complete dressing activities. The time element here would not be considered functional, especially if attempting to make an early morning class. Consider also an ambulatory patient with an ataxic gait unable to cross a street in the allotted time provided by the traffic signal. This time requirement presents a considerable patient safety issue and, as such, would also not be considered functional. Some standardized measurement tools have been developed based on timed activities (e.g., timed Up and Go test [116, 117,]). However, timed performance measures may be incorporated into any variety of motor or functional tasks.

Periodic videotaping of patient performance can be used effectively to document coordination impairments and monitor progress over time. For some patients, such recordings can provide the basis for suggestions about altering movement strategies to improve function and direct attention to safety precautions. Viewed in sequence over time, the visual record can also improve patient motivation to attain further gains. Videotapes have also been used to determine the impact of medications on coordinated movement via preintervention and postintervention administration (e.g., patients with Parkinson's disease).

QUANTITATIVE COORDINATION TESTING AND SPECIALIZED TESTING INSTRUMENTS

CATSYS System

The *CATSYS* (Danish Product Development, Ltd., Denmark) is a Windows®-based testing system that allows quantification of several types of coordination impairments.[118-120] The system interfaces with a computer via a small data logger box (serial cable). The data logger records information from four sensors:

- Tremor Pen™ for documenting tremor intensity and frequency
- Reaction time handheld switch activated by the thumb
- Touch recording plate for measuring pronation/supination and finger tapping
- Force platform for measuring postural sway

Normative data are available and the system allows comparison of interpatient and intrapatient data over time. This system has been used to document movement dysfunction associated with neurodegenerative pathology, as well as pathologies associated with neurotoxic exposure to mercury[121] and magnesium.[122] In response to subthalamic nucleus deep brain stimulation (DBS) for Parkinson's disease, it has been used to quantify features of tremor and finger tapping[123] and to examine the response to DBS in a case study report of essential tremor.[124]

Choice Reaction Time Analyzer

The *Choice Reaction Time Analyzer* (Neuro-Test Inc., Pasadena, CA 91117) is a computerized instrument that allows monitoring of both simple reaction time (SRT) and choice reaction time (CRT). SRT involves only one stimulus and one response (no decisions about the stimuli are required) whereas CRT involves multiple stimuli and requires choosing a response that corresponds to the stimulus. Reaction times are measured from the time a stimulus appears on the screen to the time a response is recorded by pressing one of two small key pads labeled "A" and "S" (pressing a keypad stops the timed measure). For example, in measuring SRT, the patient may be asked to press keypad "A" as quickly as possible each time the color blue appears (note that the color blue here is an arbitrary example, because any number of letters, colors, or objects can serve as the target stimulus; items can also be presented at various angle orientations [sideways, upside-down, and so forth]). For CRT, the subject responds differentially by pressing either the "A" or the "S" key in response to two separate target stimuli. For example, the patient may be instructed to press keypad "A" as quickly as possible each time an inverted number "2" appears and keypad "B" each time the number "2" appears in its normal orientation.

STANDARDIZED INSTRUMENTS: UPPER EXTREMITY COORDINATION

Several standardized tests are available to examine arm–hand and eye–hand coordination, as well as fine motor dexterity of the fingers, through use of function-based skills or activities. Many of these tests

were originally designed to predict employment success for jobs requiring manipulation of small parts such as might be required for assembly-line work. The vast majority of these tests are scored based both on time required for completion and on quality (accuracy) of results.

Most of these standardized tests include an examiner's manual containing normative data to assist with interpretation of test results. Adherence to the prescribed method of administration is particularly important when using standardized tests. Any deviations from the established protocol will affect the validity and reliability of the measures and consequently make comparisons with published norms invalid. The skill of the examiner is another important consideration. An individual knowledgeable about testing guidelines and interpretation of results should administer the tests. The same individual should perform subsequent retests. These standardized tests are useful in providing objective measures of patient progress over time. The following is a description of several of these tests.

The *Jebsen-Taylor Hand Function Test* (Sammons Preston Rolyan, Bolingbrook, IL 60440) examines hand and finger coordination using seven subtests of functional skills: writing; card turning; picking up small objects; simulated feeding; stacking; picking up large, lightweight objects; and picking up large, heavy objects (Fig. 6.4). The test is easy to construct, administer, and score (commercially available test kits contain all materials together with instructions in a tote bag). Normative data are included relating to age, gender, maximum time, and hand dominance. The test allows examination of hand function in seven common activities of daily living.[125-129]

The *Minnesota Manual Dexterity Test* (Lafayette Instrument Co., Lafayette, IN 47903) was designed to select personnel for semiskilled operations requiring coordinated arm/hand/finger movements, as well as eye–hand coordination such as required for handling small tools or assembly materials that do not require differentiating size or shape (Fig. 6.5). The test includes placing and turning tasks and requires use of a board with wells and round disks. Normative data are available. An expanded variation of this test is the Minnesota Rate of Manipulation Test, which includes five operations: placing, turning, displacing, one-hand turning and placing, and two-hand turning and placing.[129-132]

The *Purdue Pegboard* (Lafayette Instrument Co., Lafayette, IN 47903) Test addresses both gross coordination of the arm/hand/fingers and fine coordination (dexterity) of the fingers by placement of pins, collars, and/or washes on a pegboard (Fig. 6.6). There are several subtests, including right-hand prehension, left-hand prehension, prehension test with both hands, and assembly. The test has been used to select personnel for industrial jobs that require manipulative skills. Normative values are available, and both unilateral and bilateral coordinated movement can be examined.[133,134] This test requires use of a testing board, pins, collars, and washers. The Purdue Pegboard was found to have high test–retest reliability in persons with multiple sclerosis.[135]

The *Crawford Small Parts Dexterity Test* (Harcourt Assessment, San Antonio, TX 78270) uses the manipulation of small tools to examine motor performance. The test uses pins, collars, and screws, as well as a board into which these small objects fit. Use of tweezers is required

Figure 6.4 The Jebsen-Taylor Hand Function Test includes a subset of seven functional tasks allowing examination of a broad range of skills requiring coordinated movement of the hand and fingers. Common items are used such as spoons, paper clips, cans, and pencils. *(Courtesy of Sammons Preston Rolyan, Bolingbrook, IL 60440-3593.)*

Figure 6.5 Minnesota Manual Dexterity Test consists of two operations: *placing* and *turning*. After a practice trial, scores are based on the time required to complete each of four trials for each operation.

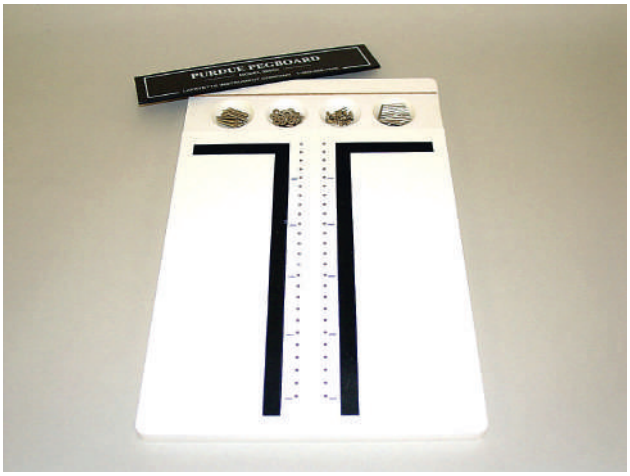

Figure 6.6 The Purdue Pegboard Test includes a pegboard equipped with pins, collars, and washers. Scores are based on the number of assemblies completed within either a 30- or 60-second period.

both to place the pins in holes and to place a collar over the pin. The screws must be placed with the fingers and screwed in with a screwdriver. This test has been used in prevocational testing. Normative data are available. This test is scored by time.[129,136]

The *O'Connor Tweezer Test* (Fig. 6.7, *left*) and the *Finger Dexterity Test* (Fig. 6.7, *right*) examine the ability to rapidly manipulate small objects (Lafayette Instrument Co., Lafayette, IN 47903). The Tweezer Test emphasizes eye–hand and fine motor dexterity by requiring the subject to use a tweezers to place a single pin in each 1/16th-inch–diameter hole. The Finger Dexterity Test also addresses fine motor dexterity through manual placement of three pins per hole. Both of these tests were originally developed to predict successful employment for assembly-line work requiring rapid manipulation of small parts (e.g., assembling miniature components of watches).

The *Hand Tool Dexterity Test* (Fig. 6.8) utilizes ordinary tools to examine coordinated movement of arm/hand/fingers during a functional task. The test frame consists of a flat board to which two side uprights are attached. The test requires disassembly of the nuts and bolts on one upright using the appropriate tools and reassembling them on the opposite upright. The test is timed and normative data are available.

The *Roeder Manipulative Aptitude Test* (Fig. 6.9) measures arm/hand/finger coordination (including thrusting and twisting) as well as eye–hand coordination. The test materials consist of a high-density plastic board with four wells for washers, rods, caps, and nuts; a T-bar for placement of washer–nut assemblies; and rows of sockets for installing nuts. The test protocol includes four timed operations: dominant hand rod–cap assembly and T-bar washer–nut assembly using both hands, right hand, and left hand. Normative data are available.

Other standardized and commercially distributed tests are available. Selection of standardized instruments should be based on (1) the intended movement capabilities to be examined, such as reciprocal motion, movement composition, reaction time, or accuracy;

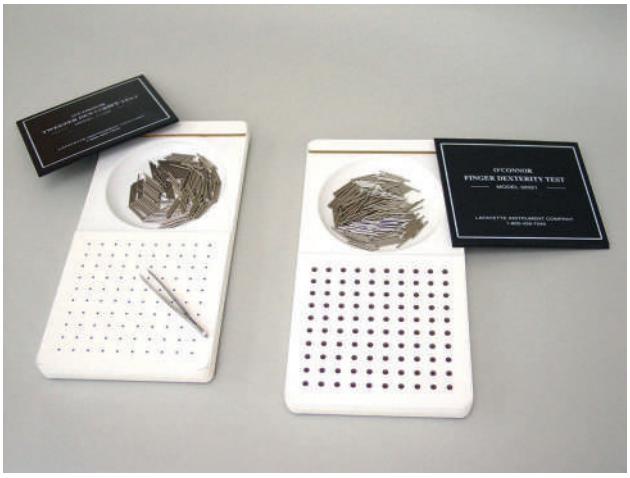

Figure 6.7 The O'Connor Tweezer (*left*) and Finger Dexterity (*right*) Tests examine fine motor coordination. Each board is 11 × 5.5 inches (28 cm × 14 cm) with 100 holes and shallow wells to hold the pins. The black covers slide through grooved channels to keep pins in place during storage.

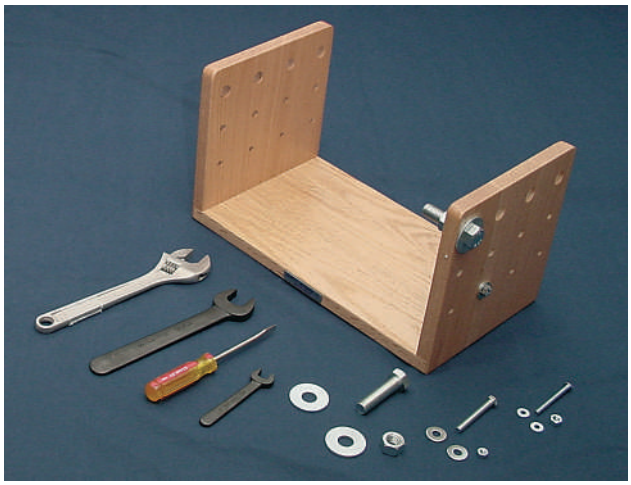

Figure 6.8 The Hand Dexterity Tool Test utilizes ordinary tools for removing and remounting the nuts and bolts. The test is timed from initiation of task (picking up first tool) until the last bolt is secured. *(Courtesy of Lafayette Instrument Co., Lafayette, IN 47903.)*

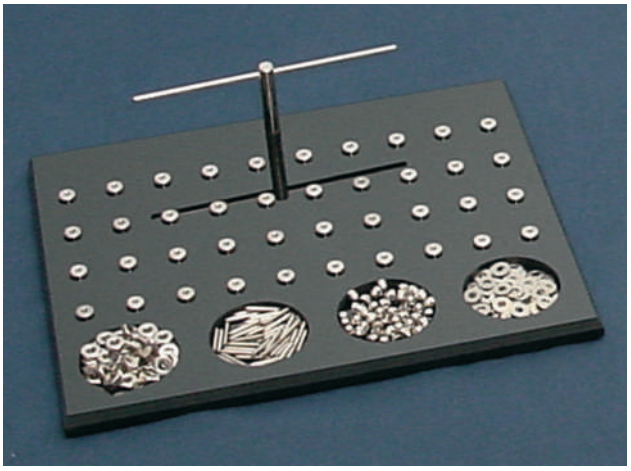

Figure 6.9 The Roeder Manipulative Aptitude Test is scored by counting the number of nuts and washers assembled within the allotted time. *(Courtesy of Lafayette Instrument Co., Lafayette, IN 47903.)*

and (2) the required tasks needed to fully explore coordinated movement for an individual patient (i.e., unilateral tasks, bilateral symmetrical tasks, or bilateral asymmetrical tasks). In addition, careful consideration should be made of criteria used for standardization of the testing instrument and the availability of normative data to assist interpretation of findings.

EXAMINATION OF POSTURAL CONTROL AND BALANCE

Postural orientation involves control of the relative positions of body parts by skeletal muscles with respect to each other and gravity. **Balance** is the condition in which all the forces acting on the body are balanced such that the *center of mass (COM)* is within the stability limits, the boundaries of the *base of support (BOS).* The overall goals of the postural control system, stability and function, are achieved through integrated CNS systems of control. *Reactive postural control* occurs in response to external forces acting on the body (e.g., perturbations) displacing the COM or moving the BOS (e.g., moveable platform, therapy ball). Feedback systems provide the sensory inputs required to initiate corrective responses. *Proactive (anticipatory) postural control* occurs in anticipation of internally generated, destabilizing forces imposed on the body's own movements (e.g., catching a weighted ball). An individual's prior experiences allow the various elements of the postural control system to be pretuned or readied for upcoming movements using feedforward mechanisms. Postural requirements vary depending on the characteristics of the task and the environment. *Adaptive postural control* allows the individual to modify sensory and motor systems in response to changing task and environmental demands.[2] Balance emerges from a complex interaction of (1) sensory/perceptual systems responsible for the detection of body position and motion, (2) motor systems responsible for organization and execution of motor synergies, and (3) higher-level CNS processes responsible for integration and action plans. An examination of balance must therefore focus on each of these three areas.

Postural Alignment and Weight Distribution

Normal postural alignment in standing can be examined by observing skeletal alignment using a plumb or weighted line. More sophisticated analysis can be achieved using motion analysis systems with light-emitting signals, photography, and electromyography. In standing, the COM occurs at a point about two thirds of the body height above the BOS. Static posture in standing is examined by positioning the patient with the feet apart, normal stance width. When viewed from the side (sagittal plane alignment) the plumb line is positioned just in front of the lateral malleolus. The vertical *line of gravity (LOG)* is expected to fall close to most joint axes: slightly anterior to the ankle and knee joints, at or slightly posterior to the hip joint, through midline of the trunk, just anterior to the shoulder joint, and through the external auditory meatus (Fig. 6.10).

Natural spinal curves are present but flattened in upright stance depending on the level of postural tone, lumbar and cervical lordosis, and thoracic or dorsal kyphosis. The pelvis is held in neutral position, with no anterior or posterior tilt. When viewed from the front or back (frontal plane analysis), the feet are positioned equidistant from the plumb line. The examiner looks for equal weight distribution between feet and symmetry of the trunk and extremities. Normal alignment minimizes the need for active muscle contraction during standing. Muscles that are tonically active at low levels during quiet stance include tibialis anterior and gastrocnemius-soleus; tensor fascia latae, gluteus medius, and iliopsoas; and abdominals and erector spinae.[137]

In sitting when viewed from the side, head and trunk are vertical. Natural spinal curves are present and the pelvis is maintained in a neutral position (Fig. 6.11). When viewed from the front or back, the trunk and head are held in a midline orientation with symmetrical weight-bearing on both lower extremities (buttocks, thighs, and feet).[137]

Limits of stability is defined as the maximum distance an individual is able or willing to lean in any direction without loss of balance or changing the BOS. Thus, in standing an individual can shift forward and backward or side-to-side without losing

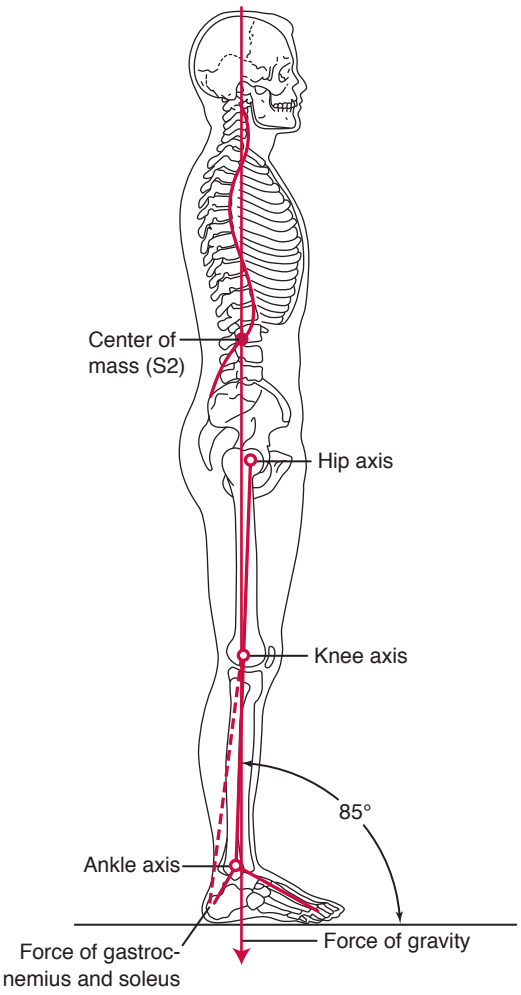

Figure 6.10 Normal postural alignment in standing-sagittal plane. In optimal alignment, the LOG passes through the identified anatomical structures.

balance or taking a step. Limits of stability is influenced by a number of factors, including individual characteristics such as height and foot length for anterior/posterior (AP) LOS and distance between the feet and height for medial/lateral (ML) LOS.[138] Both COM position and movement (velocity and displacement) influence LOS.[139] The midpoint of LOS is termed the *COM alignment. Steadiness* refers to the ability to maintain a given posture with minimum movement (sway).[140] During standing, an individual normally exhibits small range postural shifts (*postural sway*), cycling intermittently from side-to-side and from heel-to-toe. *Sway envelope* refers to the path of the body's movement during standing. During walking, there are minimal COM movements up and down and side-to-side, resulting in a smooth sinusoidal curve. In sitting, the BOS is larger and COM lower (just above the support base), resulting in greater LOS.

Examination and Documentation

Postural alignment and sway can be examined using visual inspection with the patient standing against a postural grid.[141] More sophisticated instrumentation, posturography, utilizes force plates to measure and quantify ground reaction forces, either center of force (COF) measures or center of pressure (COP) measures. COF is calculated using only vertical forces, and COP is calculated using both vertical and horizontal shear forces. The weight of each foot is determined, forces calculated, and converted into a visual image (Fig. 6.12). Software analysis of data provides an indication of the initial stance position (center of alignment), mean sway path, total sway excursion (LOS), and the zone of stability. These findings are valid and reliable measures of postural control.[142,143]

Using this information, the therapist can objectively determine the patient's postural symmetry, which is a reflection of the amount of weight placed on each foot. Patients with asymmetry may present with the COP positioned away from midline. For example, the patient with stroke typically stands with most of the weight on the less affected limb. Steadiness can be determined by using postural sway measures. A large sway path is evidence of postural unsteadiness. Another example is the patient with ataxia who typically demonstrates hypermetric responses, with excessive sway, uncoordinated movements, and limited postural steadiness. The patient with Parkinson's disease presents with the opposite problem, hypometric responses with diminished sway and excessive stabilization.[144,145] Limits of stability are determined by asking the patient to actively shift weight in any direction as far as possible without losing balance or taking a step. Patients with deficits in motor control typically have reduced LOS (reduced COP excursion). For example, the patient with stroke demonstrates reduced stability limits to the more affected side. The patient with Parkinson's disease typically demonstrates reduced LOS overall with significant anterior stability limits if a stooped posture is evident. LOS and COM alignment are also typically altered in other pathological states (e.g., muscle weakness, skeletal deformity, and tonal abnormalities). Reexamination after training using force platform biofeedback has been used to document recovery of postural control following stroke.[146,147] It has also been used to demonstrate the effectiveness of training using biofeedback force platform training devices.[140,145,148]

Sensorimotor Integration in Postural Control

The sensory systems (vision, somatosensory, and vestibular) provide the CNS with important information about postural control and balance, including information about the results of our own actions and the surrounding environment. The CNS integrates

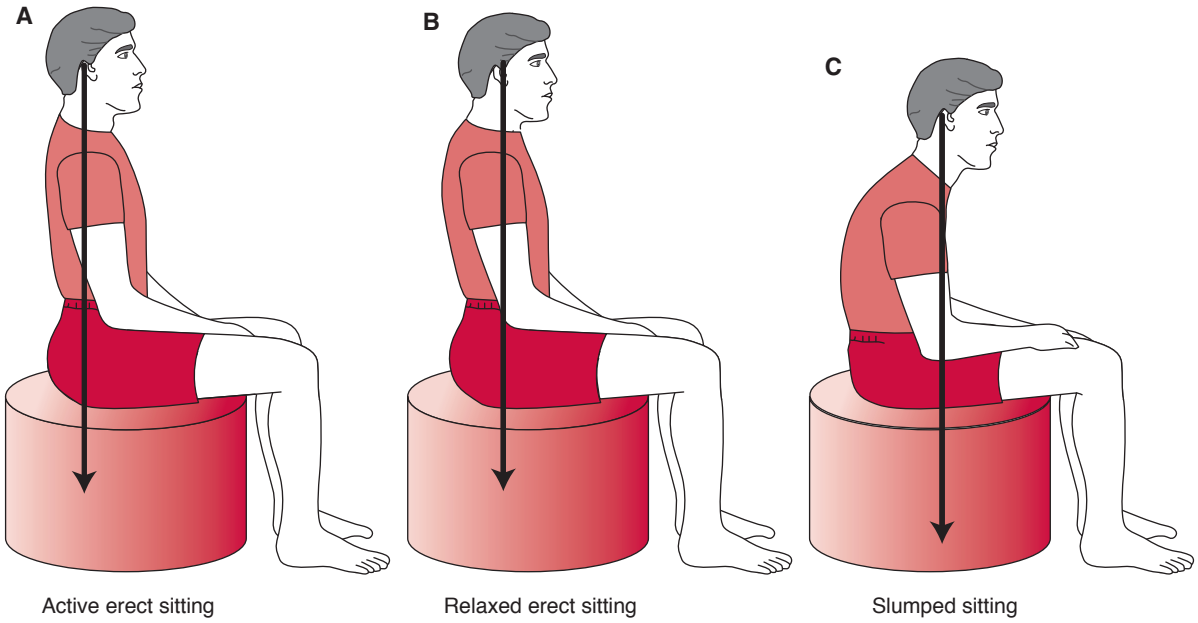

Figure 6.11 Normal sagittal plane postural alignment in sitting: (A) In optimal alignment, the line of gravity passes close to the axes of rotation of the head and neck, and trunk. (B) During relaxed sitting, the line of gravity changes very little, remaining close to those axes. (C) During slumped sitting, the line of gravity is well forward of the spine and hips. *(From O'Sullivan, SB and Schmitz, TJ.* Improving Functional Outcomes in Physical Rehabilitation. *Philadelphia: FA Davis; 2010.)*

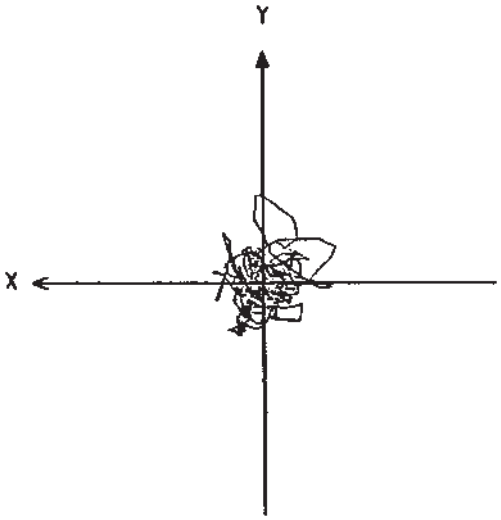

Figure 6.12 Postural sway. Recording of the movement of the center of pressure for 60 seconds in a subject standing on a balance platform. Values: mean amplitude of sway path in inches = .13 × .15; length of path = 32.2; and velocity = .45 in/sec. *(From Smith, L, et al: Brunnstrom's Clinical Kinesiology, ed 5. Philadelphia, FA Davis, 1996, p 406, with permission.)*

these inputs and initiates both goal-directed conscious actions and automatic, unconscious adjustments in posture and movements. Each individual sensory system provides unique and important information and no one system provides all the information needed.

The visual system serves as an important source of information for the ability to perceive movements and detect the relative orientation of body segments and orientation of the body in space. This ability has been termed **visual proprioception**.[149] Two separate functional visual systems have been identified. Various different names have been used: (1) *focal vision* (cognitive or explicit vision) and (2) *ambient vision* (sensorimotor or implicit vision). Focal vision plays a major role in localizing features in the environment and in our conscious reaction to visual events. In contrast, ambient vision utilizes the entire visual field to provide information on the localizing features about the environment and to guide movements using largely nonconscious awareness.[6] Thus, each visual system has a unique functional significance. For example, the patient with brain injury who has a condition called *optic ataxia* can recognize an object using focal vision but cannot use visual information to accurately guide the hand to the object (impaired ambient vision). The opposite occurs in a patient with stroke experiencing *visual agnosia*. The patient cannot recognize common objects, but can use the ambient visual system to reach and grasp an object or navigate an environment. Vision also contributes to righting reactions of the head, trunk, and limbs (optical righting reactions).

Visual acuity (focal vision) can be examined using a Snellen eye chart. A distance acuity poorer than 20/50 will have a significant effect on postural stability.[150]

Whereas focal vision is detected by the central retina only, ambient vision is detected by the entire visual field (central and peripheral vision). Patients with loss of peripheral vision (e.g., a patient with stroke and hemianopsia or a patient with glaucoma) may demonstrate deficits in visual proprioception and functional performance. Peripheral vision can be examined using the *confrontation method*. The patient sits in front of the therapist and is instructed to focus gaze on the therapist's nose. The therapist then slowly brings a target (moving finger or pencil) slowly into the patient's field of view from the right or left side. The patient is instructed to indicate (point or declare) when and where the target is detected. Ambient vision can be examined by instructing the patient to navigate across the busy physical therapy gym. The abilities to navigate safely, to localize features in the environment, and to anticipate changes necessary to avoid obstacles and successfully reach the target area are determined. Patients with stroke who exhibit *topographical disorientation* will have difficulty navigating their environment and understanding the relationship of one place to another.

Somatosensory inputs include the cutaneous and pressure sensations from the body segments in contact with the support surface (e.g., the feet in standing, the buttocks, thighs, and feet in sitting) and muscle and joint proprioception throughout the body. Light touch contact from the hands on a stable surface is also used as a balance aid.[151] This provides information about the relative orientation and movement of the body in relation to the support surface. Cutaneous sensation (touch and pressure) of the feet/ankles and proprioception of the feet/ankles and hips are particularly important in maintaining upright standing balance. Sensory examination of the extremities and trunk is therefore essential (See Chapter 3, Examination of Sensory Function).

The vestibular system is an important source of information for postural control and balance. The semicircular canals (SCCs) detect angular acceleration and deceleration forces acting on the head whereas the otolith organs detect linear acceleration and orientation of the head with reference to gravity. The SCCs are sensitive to fast (phasic) movements of the head, and the otoliths respond to slow head movements and positional change referenced to gravity. The vestibular system functions to stabilize gaze during head movements via the *vestibulo-ocular reflex (VOR),* and to assist in the regulation of postural tone and postural muscle activation via the vestibulo-spinal reflex (VSR). Tests for vestibular function include positional and movement testing. The patient is observed for symptoms of vestibular dysfunction (e.g., dizziness, vertigo, nystagmus).[152] See Chapter 21, Vestibular Disorders, for a complete discussion of this topic.

During stance, all sensory inputs contribute to the maintenance of posture. Sensory weighting theory specifies that the CNS weights the various sensory inputs depending on the specific sensory environment and task.[153-156] *Quiet stance* is defined as standing with a stable support surface and surroundings. *Perturbed stance* is defined as standing during a brief displacement of the support surface (moving surface) or displacement of the COM over BOS (perturbation). In intact adults during quiet stance, the CNS places greater weight on somatosensory inputs. During an unexpected perturbation, somatosensory inputs are activated quicker and provide much of the early restabilizing control whereas vision and vestibular inputs with slower processing speeds contribute to later components of the postural re-stabilizing response.[157] If somatosensory inputs are impaired (e.g., peripheral neuropathy) or if somatosensory conflict is introduced (e.g., standing on dense foam), vision assumes a greater role. If both somatosensory and visual inputs are impaired or absent, vestibular inputs are critical to maintaining posture and resolving sensory conflict. Central nervous system use of sensory inputs is flexible. Balance responses are task and context dependent and are triggered by CNS weighting based on availability, timing, and accuracy of specific sensory inputs.

Because sensory inputs are redundant, stable balance can be maintained with significant impairment, on unstable surfaces, or in sensory conflict situations. However, if more than one sensory system is deficient, substantial deficiencies in balance control will be evident.[158] For example, the patient with chronic diabetes who has significant diabetic neuropathy (loss of somatosensory inputs from the feet and ankles) and significant diabetic retinopathy (impaired vision) will demonstrate significant postural instability and fall risk. In addition, the cognitive system plays an important role in attending to and interpreting the information for CNS planning of effective postural responses. Attentional demands vary depending on the task (new learning versus familiar response) and the environment (open versus closed or dual-tasking). Patients with impairments in cognition or attention demonstrate increased fall risk, especially for those activities with high stability demands.

Romberg Test

The **Romberg Test** is historically one of the oldest sensory tests for postural control.[159] During the test, the patient is instructed to stand with feet together, eyes open (EO) unaided for 20 to 30 seconds. (If the patient demonstrates significant sway or instability with EO, the test is over.) The patient is then asked to stand with eyes closed (EC). If the test is negative, there is no change or only minimal worsening with EC. If the test is positive, the patient is able to stand with EO but demonstrates a

significant increase in sway and/or instability with EC. The *Romberg Quotient* refers to the ratio of body sway during EO and EC conditions and can be used as a measure of stability.[2] During testing, it is important to tell the patient you are prepared to catch him or her in the event of a fall. A positive Romberg test is indicative of a loss of proprioception (*sensory ataxia*) that occurs with posterior column lesions in the spinal cord (e.g., cervical spondylosis, tumor, degenerative spinal cord disease, tabes dorsalis) and peripheral neuropathy. If unsteadiness occurs in standing with EO, it is likely the patient is demonstrating other CNS dysfunction (e.g., cerebellar ataxia or vestibular dysfunction). In the sharpened Romberg test, the feet are placed in tandem (heel–toe position) and the EO to EC conditions imposed.

Sensory Organization Test

The *Sensory Organization Test (SOT)* is based on the work of Nashner[153,154] and determines the effectiveness of the CNS to utilize and integrate different sensory inputs. It examines body sway during quiet standing under six different sensory test conditions (Fig. 6.13). Dynamic posturography equipment is used to provide a moving platform that introduces mechanical perturbations (sliding or tilting movements). A moving visual surround screen is sway referenced and introduces visual conflict. Both the surround and force plate are referenced to the patient by means of hydraulic mechanisms. Test condition 1 provides accurate somatosensory, visual, and vestibular information and is the baseline reference. Each of the other five conditions systematically varies sensory inputs, increasing the level of sensory conflict and postural difficulty (Table 6.5).

Conditions 1 to 3 are all performed with the patient standing on a stable support surface, providing accurate somatosensory inputs. Visual inputs are varied: condition 1 uses EO, and condition 2 uses EC. Condition 3 uses a moving visual surround (screen) referenced to body sway, thus providing inaccurate visual information. Conditions 4 through 6 repeat the visual conditions but with an altered support surface (moving platform) that provides inaccurate somatosensory information. In conditions 5 and 6 maintenance of posture depends on availability and accuracy of vestibular inputs with the reduction of both vision and somatosensory inputs. Thus, patients with vestibular dysfunction will demonstrate maximum instability in conditions 5 and 6. Patients who are visually dependent for postural control will demonstrate instability in conditions 2, 3, 5, and 6. Patients who are surface dependent will demonstrate instability in conditions 4, 5, and 6. Patients who demonstrate sensory selection problems present with abnormal findings in conditions 3 through 6.[2] Each condition is maintained for 30 seconds. If the patient is able to stand for the required 30 seconds, the test is progressed

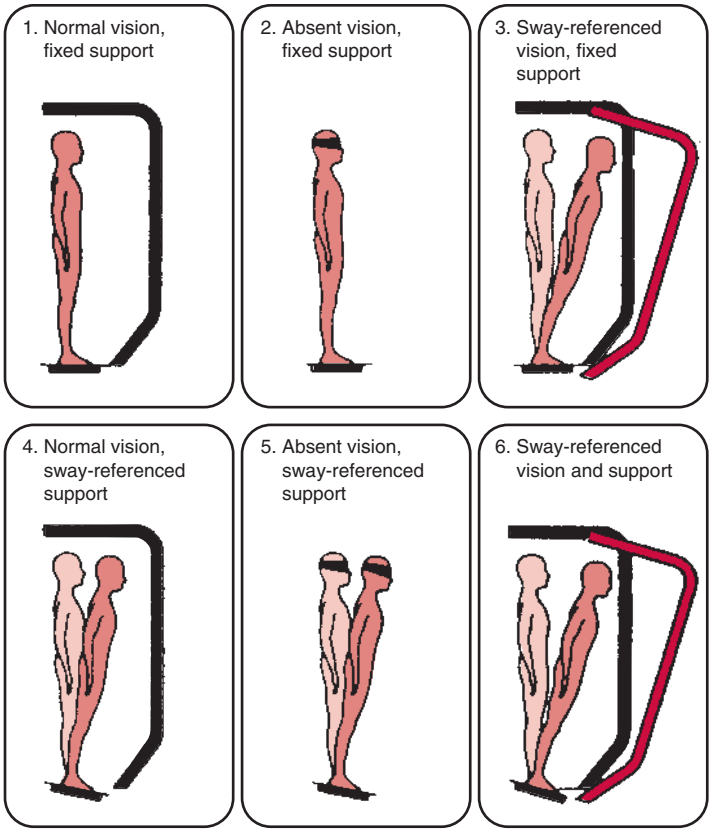

Figure 6.13 The Sensory Organization Test.

Table 6.5 Sensory Organization Test Conditions

Condition	Sensory Input
Condition 1 Eyes Open, Stable Surface (EOSS)	All sensory systems unaltered
Condition 2 Eyes Closed, Stable Surface (ECSS)	Vision absent Somatosensory unaltered Vestibular intact
Condition 3 Visual Conflict with Moving Surround, Stable Surface (VCSS)	Vision altered Somatosensory unaltered Vestibular intact
Condition 4 Eyes Open, Moving Surface (EOMS)	Vision unaltered Somatosensory altered Vestibular intact
Condition 5 Eyes Closed, Moving Surface (ECMS)	Vision absent Somatosensory altered Vestibular intact
Condition 6 Visual Conflict with Moving Surround, Moving Platform (VCMS)	Vision altered Somatosensory altered Vestibular intact

to the next sensory condition. If the patient is unsuccessful on the first attempt, a second trial can be given. The SOT is scored by observing changes in the amount and direction of postural sway. A numerical scoring system can be used.

1 Minimal sway
2 Mild sway
3 Moderate sway
4 Loss of balance

Posturography equipment provides a printed bar graph indicating how well the patient performed during each of the six conditions in terms of postural sway. Ratios comparing one condition to another can provide information regarding reliance on one sensory system over another. Additional analyses of motor coordination using electromyography (EMG) can provide information about the relative level of individual muscle activity, as well as overall muscle recruitment patterns.

As in all testing of postural control and balance, patient safety is an important consideration. During posturography the patient typically wears a safety harness to prevent falls. Upper extremity support is not allowed during the test. However, the equipment includes hand rails that can be used as an additional safety net.

Clinical Test for Sensory Interaction in Balance

In the absence of sophisticated and expensive posturography equipment, a modified version can be performed in clinical or home settings. The *Clinical Test for Sensory Interaction in Balance (CTSIB)* is a low-tech version of the SOT developed by Shumway-Cook and Horak.[160] It utilizes medium-density foam to substitute for a moving platform and a modified visual dome (Japanese lantern affixed to the subject's head) to substitute for a moving visual surrounding. Six sensory conditions are tested, similar to the SOT.[161] A simpler to perform modified version of the CTSIB (m-CTSIB) also exists. It utilizes 4 different sensory test conditions (EO and EC on flat surface and on foam). Conditions 3 and 6 are omitted (visual dome conditions). The same posture is adopted in both versions (i.e., feet shoulder-width apart). Three 30-second trials are used. Times in balance and increased sway or loss of balance are recorded. Subjective patient complaints (e.g., nausea, dizziness) and postural strategies used (e.g., ankle or hip strategies, arms widen and elevate) are also documented. The test is stopped if the patient alters the posture (widens or moves feet, opens eyes) or loses balance, requiring manual assistance.[162]

Movement Strategies for Balance

In observational studies of infants and young children and lesioned animals (decerebration experiments), righting and equilibrium reactions comprise the *postural reflex mechanism.* Automatic *righting reactions (RR)* orient the head in space (optical RR, labyrinthine RR, body-on-head RR) and the body in relation to the head and support surface (neck-on-body RR, body-on-body RR). *Equilibrium reactions* include tilting reactions and parachute or protective reactions. In normal adults, however, postural adjustments are far more complex and demonstrate a high degree of adaptability in response to both task and environmental context demands. Postural adjustments vary from the simple stretch reflex responses to the activation of specific movement strategies (synergistic patterns). Muscles closest to the BOS are particularly important to the maintenance of balance. As the LOS is reached with a COM disturbance, the magnitude of the postural response is increased.

Fixed Support Strategies

The term *fixed-support strategies* refers to those movement strategies used to control the COM over a fixed BOS (in-place strategies). In standing, the *ankle strategy* involves shifting the COM forward and back by moving the body (legs and trunk) as a relatively fixed pendulum about the ankle joints (Fig. 6.14). Muscles are activated in a distal-to-proximal sequence. With forward sway, gastrocnemius is activated first, followed by hamstrings, then paraspinal muscles. With backward

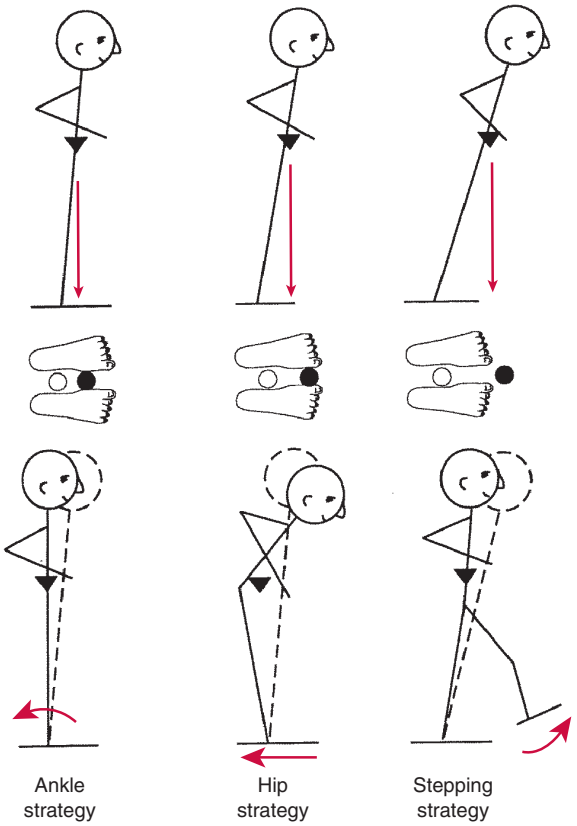

Figure 6.14 Strategies for correcting balance perturbations.

sway, the anterior tibialis is activated first, followed by quadriceps, then abdominals. The ankle strategy is a commonly used strategy when sway frequencies are low and disturbances of the COM are small and well within the LOS.

The *hip strategy* involves shifts in the COM by flexing or extending at the hips (see Fig. 6.14). It has a proximal pattern of muscle activation before distal activation. With forward sway abdominals are activated first, followed by quadriceps. With backward sway, paraspinal muscles are activated first, followed by hamstrings. Hip strategies provide primary control for mediolateral stability. Hip muscles (abductors and adductors) are activated to control lateral sway. The hip strategy is typically recruited with faster sway frequencies (greater than 1 Hz) and larger disturbances of the COM or when the support surface is small (less than the size of the feet) or compliant (e.g., standing on foam).[163,164]

Change-in-Support Strategies

Change-in-support strategies are defined as movements of the lower or upper limbs to make a new contact with the support surface.[97] The *stepping strategy* realigns the BOS under the COM by using rapid steps or hops in the direction of the displacing force, for example, forward or backward steps. In instances of lateral destabilization, the individual takes a side step or a cross step to bring the BOS back under the COM. The stepping strategies are typically recruited in response to fast, large postural perturbations when ankle and hip strategies are not adequate to recover balance (e.g., when the COM exceeds the BOS) (see Fig. 6.14). Change-in-support movements of the upper limbs (reach or grasp) can also assist in stabilizing the COM over the BOS, and serve a protective function in absorbing impact and protecting the head in a fall event. *Reaching movements* assist in extending the BOS and stabilizing posture. These reactions were found to be prevalent in destabilization situations, occurring in 85% of trials. Stepping strategies were also frequent, leading researchers to suggest that change-in-support strategies should not be viewed just as strategies of last resort. They are often initiated well before the COM nears or exceeds the LOS, contrary to the traditional view.[164-166]

Although these movement strategies have been investigated individually as distinct movement patterns, research has also shown that during normal balance combinations of strategies are used.[163] Control of movement strategies should be viewed on a continuum. The CNS quickly moves between patterns depending on the control demands of the activity and environment. Thus, a destabilizing force may yield an initial ankle strategy that progresses quickly to a hip strategy as increased control is warranted to recover balance. When the displacement is large and ankle and hip strategies prove inadequate, a stepping strategy may be necessary to prevent a fall.[167] The CNS uses continuous sensory feedback monitoring to achieve flexibility and adaptability of movement strategies for multidirectional postural control.

In sitting, the BOS is comprised of the thighs and buttocks and the feet if in contact with the support surface. Postural strategies to maintain balance include movement of the trunk about the hips. Backward sway elicits primary responses in hip flexors along with activity of the abdominals and neck flexors. In forward sway, extensor muscles of the hips are activated along with the extensors of the neck and trunk. If the feet are in contact with the floor, tibialis anterior is recruited during forward reaching movements of the arm and the gastrocnemius is recruited to brake forward movements and return the body to erect sitting.[168] Somatosensory inputs from backward rotation of the pelvis may have an important role in triggering the postural strategies in sitting.[169] In frontal plane movements, activity of the hip abductors and adductors along with the quadratus lumborum is important for providing mediolateral stability.

Examination and Documentation of Movement Strategies

Standing Control

An examination of movement strategies should first begin with the musculoskeletal elements (ROM, postural tone, and strength). Weakness and limited ROM in the ankles will influence successful use of an ankle strategy, whereas weakness and limited ROM about the

hips will influence the hip strategy. Limitations of neck ROM can be expected in patients with primary vestibular disorders. Available movement strategies in response to AP and ML destabilizations should be determined.

Dynamic posturography provides the ideal way to study motor strategies during standing. The *Movement Coordination Test (MCT)* developed by Nashner and co-workers[164] provides information about postural responses to control the COM when the platform moves, including symmetry of weight-bearing and forces generated, latency of postural responses, amplitude of response in relation to the stimulus size, and strategy utilized (ankle or hip). EMG monitoring can reveal specific muscle activation patterns and latencies. The main disadvantage of this equipment is limited use in the clinic due to expense and lack of portability (e.g., it is typically found in specialized Balance or Vestibular Dysfunction Clinics). Correlation with performance during functional tasks (e.g., walking) is also lacking.

During perturbed stance, the direction of perturbations can be varied (AP and ML). The movement strategies utilized and success of restabilization efforts should be examined and documented. Specific directional instability may be evident. Patients may demonstrate an absence or decreased use of one strategy with increased dependence on another. For example, older adults with somatosensory loss in the feet and ankles typically forgo the ankle strategy and utilize an early hip strategy. The sequencing of movement synergies should be examined and a determination of the pattern of activation made. For example, the ascending pattern of activation (distal-proximal) may be absent in patients with strong spasticity. The therapist is likely to see a proximal-to-distal activation pattern with strong co-activation of spastic muscles in the hips and knees.

Seated Control

Seated postural control and balance should be examined. During quiet sitting, the degree and direction of sway should be determined. During perturbed unsupported sitting, the available movement strategies to prevent destabilization should be examined and documented. Grasp strategies (holding on to the edge of the seat) or lower extremity hooking strategies (the foot and leg hook around the platform mat leg) are common strategies in the presence of significant instability. Seated instability is common in many patients with neurological dysfunction. For example, patients with stroke may demonstrate increased sway, problems activating trunk muscles (e.g., voluntary trunk flexion and extension), limited extent and direction of reaching, and altered postural alignment with greater weight placed on the less affected side.

Documentation

For both standing and seated control, the therapist determines and documents if the movement strategies are (1) present and normal, (2) present but limited or delayed, (3) present but inappropriate for the particular context or situation, (4) abnormal, or (5) absent.[91] The ability to modify postural strategies and adapt movements to changing task conditions should also be documented. For example, the patient can be asked to stand first with normal stance width, then with a narrowed BOS (feet together, in tandem, or single leg stance). Table 6.6 presents an example of a functional balance grade scale with descriptors that can be used to define both static and dynamic control in sitting and standing.

Anticipatory Postural Control

Anticipatory postural control, the ability to activate postural adjustments in advance of destabilizing voluntary movements, should be examined.[2] For example, the therapist asks the patient while standing or sitting to raise both arms overhead or catch a weighted ball. Changes in postural stability control are examined and documented during the performance of the voluntary activity. Impaired anticipatory postural control is found in many individuals with impairments in motor function, including patients with stroke,[170,171] Parkinson's disease,[172] and brain injury.[173]

Dual-Task Control

Dual-task control should be examined. This is the ability to perform a secondary task (motor or cognitive) while

Table 6.6 Functional Balance Grades

4 Normal	Patient able to maintain steady balance without handhold support (static). Patient accepts maximal challenge and can shift weight easily within full range in all directions (dynamic).
3 Good	Patient able to maintain balance without handhold support, limited postural sway (static). Patient accepts moderate challenge; able to maintain balance while picking up object off floor (dynamic).
2 Fair	Patient able to maintain balance with handhold support; may require occasional minimal assistance (static). Patient accepts minimal challenge; able to maintain balance while turning head/trunk (dynamic).
1 Poor	Patient requires handhold support and moderate to maximal assistance to maintain position (static). Patient unable to accept challenge or move without loss of balance (dynamic).
0 Absent	Patient unable to maintain balance

maintaining standing or seated control. For example, while standing the patient is asked to count backward from 100 by 7 (simultaneous verbal-cognitive task) or pour water into a glass (secondary motor task). Patients with Parkinson's disease have been shown to demonstrate significant impairment in dual-task control.[174,175] Patients with traumatic brain injury and stroke have also been shown to demonstrate problems with dual-task control.[176,177]

STANDARDIZED INSTRUMENTS: POSTURAL CONTROL AND BALANCE

This section presents selected balance tests (equilibrium coordination tests) in common use today. The reader should analyze each test to determine what aspects of postural control and balance are being examined (e.g., static or dynamic control, proactive or reactive control). The patient's unique impairments and activity limitations will help determine which tests are the most appropriate to use. The patient needs to understand that a variety of functional activities will be used during testing. Some activities will be more difficult than others and will result in instability. The patient should be assured that the therapist will at all times protect the patient from a fall. During testing, all safety precautions should be observed, including close or contact guarding and using a safety gait belt or overhead harness as indicated. Examples of balance test items can be found in Table 6.3.

Standardized instruments for the examination of balance and gait are particularly useful in (1) identifying coordination impairments associated with a skill-level motor task; (2) making decisions about the differences between the patient's performance and the parameters of normal postural control and gait; and (3) providing data to inform decisions about the underlying mechanisms responsible for producing the movement impairments. Standardized tests are available with established reliability, validity, and sensitivity. Scoring is typically based on a scale with specific criterion descriptions for successful performance. Performance observations can also be timed using a stop watch.[178,179]

The Berg Balance Scale

The Berg Balance Scale (BBS) developed by Berg et al[180-183] is an objective measure of static and dynamic balance abilities. The scale consists of 14 functional tasks commonly performed in everyday life. The items range from sitting or standing unsupported, to movement transitions (sit-to-stand, stand-to-sit), variations in standing position (EO/EC), feet together, forward reach, retrieving an object from the floor, turning, standing on one foot, to placing the foot on a stool. Scoring uses a five-point ordinal scale, with scores ranging from 0 to 4. Descriptive criteria are provided for scoring each level: a score of 4 is used to indicate that the patient *performs independently and meets time and distance criteria,* and a score of 0 is used for *unable to perform* (see Appendix 6.A). A maximum score of 56 points is possible.

The BBS was developed specifically as a measure of balance function in patients with stroke and has been shown to be a sensitive measure of functional balance in older people in general.[183] Balance scale scores have been shown to be useful in predicting falls in the elderly and evaluating changes in patients undergoing physical therapy.[183-185] Scores of 45 or below are associated with high risk of recurrent or multiple falls with significant increase below a score of 40.[186,187] Studies of community-dwelling older people and those with chronic stroke that looked at individual item analysis revealed that selected BBS items may have greater accuracy than the total BBS in classifying individuals with high fall risk. These items include picking an object up off the floor and stand on one leg,[188,189] as well as turning 360°, placing alternate foot on stool, and tandem stance.[188] Donoghue and Stokes[190] investigated the minimum detectable difference (MDD) of scores on the BBS that would be necessary to indicate significant change in elderly individuals. With baseline BBS scores of 45 to 56, the MDD is 4 points; with scores between 34 and 44, the MDD is 5 points; with scores between 25 and 34, the MDD is 7 points; and with scores of 0 to 24, the MDD is 5 points. Threshold scores have also been reported for older persons at risk for falling[191] and elderly subjects using gait aids.[192]

Performance-Oriented Mobility Assessment

The *Performance-Oriented Mobility Assessment (POMA)* developed by Tinetti et al[193,194] provides a brief and reliable measure of both static and dynamic balance.[195] Items are organized into two subtests of balance and gait. Balance test items include static sitting balance, sit-to-stand and stand-to-sit, standing balance (static, with sternal nudge, EC), and dynamic standing balance (turning 360°). Gait test items include initiation of gait, path, missed step (trip or loss of balance), turning, and timed walk. Some items are scored on a two-point scale (0 or 1) and some on a three-point (0 to 2) scale (see Appendix 6.B). The original POMA I scale has a total possible score of 28. It was developed for use with the frail elderly, especially nursing home residents with a propensity to fall.[196,197] Patients who score less than 19 are considered at high risk for falls and those who score between 19 and 24 are at moderate risk for falls. A revised form, the POMA Ia, includes five additional items and was designed for use as a predictor of falls among community-dwelling elderly (with a total possible score of 40). The POMA II was developed as an outcome measure in a frailty and injury prevention trial (the Yale Frailty and Injuries: Cooperative Studies of Intervention Techniques [FICSIT] trial) with a total possible score of 54.[198]

Reach Tests

The *Functional Reach Test (FR)* was developed by Duncan et al to provide a quick screen of balance problems in older adults.[199-201] It is the maximal distance one can reach forward beyond arm's length while maintaining a fixed BOS in the standing position. The test uses a level yardstick mounted on the wall and positioned at the height of the patient's acromion. The patient stands sideward next to the wall (without touching), feet normal stance width and weight equally distributed on both feet. The shoulder is flexed to 90° and elbow extended with the hand fisted. An initial measurement is made of the position of the 3rd metacarpal along the yardstick. For forward reach, the patient is instructed to lean as far forward as possible without losing balance or taking a step. A second measurement is taken also using the 3rd metacarpal for reference. This measurement is then subtracted from the initial measurement. See Table 6.7 for normative values of FR.

The *Multidirectional Reach Test (MDFR)* developed by Newton evolved from the earlier FR and measures how far an individual can reach in the forward, backward, and lateral directions.[202,203] For backward reach, the test position is the same as FR with the yardstick position reversed to detect posterior movements. For lateral reach, the patient faces away from the wall and reaches sideways to the right (and then to the left) as far as possible. One practice trial is allowed before the start of three test trials. The therapist records functional reach in inches for all three trials and then average the three trials. The amount of reach is influenced by several factors, including the size and height of the individual, gender, age, and health. The movement strategy used during a reach test should be documented (i.e., ankle or hip strategy, trunk rotation, scapular protraction). See Table 6.8 for normative values of MDRT for older adults. Modified reach can also be reliably measured in sitting.[204,205]

Table 6.7 Functional Reach (FR) Reference Values (NORMS) by Age

Age	Men (inches)	Women (inches)
20–40	16.7 (± 1.9)	14.6 (± 2.2)
41–69	14.9 (± 2.2)	13.8 (± 2.2)
70–87	13.2 (± 1.6)	10.5 (± 3.5)

From Duncan et al.[199]

Timed Get Up and Go Test

The *Get Up and Go (GUG) Test* developed by Mathias et al[206] is a quick measure of dynamic balance and mobility. The patient is seated comfortably in a firm chair with arms and back resting against the chair. The patient is then instructed to rise, stand momentarily, and then walk 3 m (10 ft) toward a wall at normal walking speed, turn without touching the wall, return to the chair, turn, and sit down. Tape is used to mark the walking distance and turning point. Performance on the original GUG test is scored using a five-point ordinal scale ranging from 1, Normal (no risk of falls) to 2, Very Slightly Abnormal; 3, Mildly Abnormal (increased risk of falls); 4, Moderately Abnormal; and 5, Severely Abnormal (high risk of falls). If an assistive device is required, the type is recorded. The subjective nature of the grades with very little additional descriptors yielded only limited reliability.

Efforts by Podsiadlo and Richardson[207] to improve the objectivity and reliability resulted in the *Timed Up and Go Test (TUG).* Timing with a stopwatch begins when the patient is instructed with "go" and ends when the patient returns to the start position seated in the chair. Healthy adults are able to complete the test in less than 10 seconds. Older adults (ages 60 to 80) have also been shown to average scores less than 10 (mean of 8).[207-209] Scores of 11 to 20 seconds are considered within typical for frail elderly or individuals with a disability; scores over 30 seconds are indicative of impaired functional mobility and high fall risk. The TUG has been used to examine functional mobility deficits in patients with stroke[210,211] and Parkinson's disease.[212,213] Minimal detectable changes have been reported for people with Parkinson's disease.[214]

Timed Walking Tests

A timed walking test is an important part of the examination of postural control and balance. The patient

Table 6.8 Multidirectional Reach Test (MDRT) Reference Values

REACH–MDRT	Mean (inches) Standard Deviation Mean Age, 74	Above Average (inches)	Below Average (inches)
Forward	8.9 ± 3.4	>12.2	<5.6
Backward	4.6 ± 3.1	>7.6	<1.6
Right lateral	6.2 ± 3.0	>9.4	<3.8
Left lateral	6.6 ± 2.8	>9.4	<3.8

From Newton.[203]

is asked to walk at his or her *preferred speed* over a set distance clearly marked on the floor (e.g., *10-m Walk Test* [33 ft]). The patient is then asked to walk again at *maximum speed,* as fast as possible. Time is measured using a stopwatch. The results are reported in speed (meters/second or feet/second) or less commonly in total time taken (seconds). Comparisons are made between the two trials. Gait speed has been shown to be a sensitive measure of functional performance.[215] There is a wide range of normal gait speeds reported, ranging from 1.2 to 1.5 m/sec (4 to 5 ft/sec) in healthy young adults. Gait speeds decrease in older adults (0.9 to 1.3 m/sec or 3 to 4.25 ft/sec), in individuals with a disability, and those requiring assistive devices.[216]

Distance tests (e.g., the *3-, 6-,* or *12-Minute Walk Test*) can also be used to document functional mobility.[217-220] The patient is instructed to walk at a comfortable pace. During the test the patient can stop to rest or use an assistive device as needed. The total distance achieved during the preselected timed segment of walking is recorded along with average gait velocity, number of rests, number of deviations from a 15-inch (38 cm) wide gait path, and number of episodes of loss of balance (LOB). Other parameters can also be documented, including BOS, step width, stride length, cadence, trunk and extremity movements, and exertional intolerance (heart rate, chest pain, shortness of breath, Rating of Perceived Exertion [RPE]). See Chapter 7, Examination of Gait, for a more complete description. Gait abnormalities should be carefully documented. Inconsistency and irregularity of stepping and movements, weaving, staggering, widely spaced steps, and arms held out to the sides in high or low guard position are all indicative of decreased postural control and balance.[221]

Dynamic Gait Index

The *Dynamic Gait Index (DGI)* developed by Shumway-Cook et al[187] examines a patient's ability to perform variations in walking on command. Items include changing speed (walk at normal speed and at fast speed), walk with head turns (look right or left, look up or down), walk and pivot turn, step over or around an obstacle, and climb stairs (up and down). A four-point scale (0 to 3) includes specific descriptors of normal control (3), mild impairment (2), moderate impairment (1), and severe impairment (0), with a maximum possible score of 24. The DGI appears to be sensitive in predicting likelihood for falls with older adults (a score below 19 is indicative of increased fall risk). It has also been used with individuals with vestibular dysfunction,[222-225] chronic stroke,[225,226] and multiple sclerosis.[227] Whitney et al[222] found a moderate correlation between the Dynamic Gait Index and the Berg Balance Scale when testing individuals with vestibular and balance dysfunction.

Dual-Task Tests

Stops Walking While Talking

The *Stops Walking While Talking Test (SWWT),* also known as the *Walkie-Talkie Test,* can be used to determine the effects of attentional demands by introducing a secondary task, talking, while walking. The patient walks at a self-selected comfortable speed. The therapist walks alongside the patient and initiates a conversation. Questions are posed that require more than "yes" or "no" answers. The test is positive if the patient stops walking in order to talk. This test lacks sensitivity to the wide range of changes that can occur with dual-tasking.

Sensitivity can be improved by introducing dual tasks during timed walking (Timed Up and Go, 10-m Walk Test). For example, during a 10 m-Walk Test at usual gait speed, a secondary cognitive task (e.g., serial subtraction by 3s from 100) is introduced. Times are compared between usual (single-task walking) and dual-task walking. Performance changes are examined, including hesitations or stops, reduced postural stability, and increased walking variability (steps off path). Cognitive changes (number of errors, mental slowing) are also determined. Examples of other secondary cognitive tasks that can be introduced include reciting the alphabet or alternate letters of the alphabet or walking and remembering (*digit span memory test*).[228] Patients with impaired attention and postural control (particularly automatic control of posture) can be expected to demonstrate difficulty. Dual-task performance impairments have been found in individuals with stroke,[229] traumatic brain injury,[230] multiple sclerosis,[231] Parkinson's disease,[232] and in older adults at risk for falls.[233-236] Dual-task performance impairments have also been found in patients with stroke during sitting balance activities.[237]

Secondary task interference during walking can also be introduced with performance of other motor tasks. For example, the DGI uses walking with head turns on command and obstacle avoidance. Individuals can also be asked to pick up and carry a package, a tray, or a cup of water while walking. It is important to select tasks that are within the capabilities of the individual and appropriate for the functional goals and target environments of the patient. Times are compared for usual walking (single-task performance) and dual-task performance. These forms of complex walking are also likely to result in decreased walking speeds and postural control variations.[228]

Sitting Balance Tests

The *Function in Sitting Test* (FIST) developed by Gorman et al[238] is a 14-item test that examines a person's ability to maintain sitting balance during static sitting (hands in lap) with eyes open and eyes closed, as well as during dynamic challenges to balance. Reactive challenges include nudges (anterior, posterior, and

lateral). Anticipatory challenges include moving the head side-to-side, lifting the foot, turning and picking an object up from behind, forward and lateral reach, picking up an object from the floor, and scooting (anterior, posterior, and lateral). The FIST is scored on a 5-point scale with 0 defined as complete assistance and 4 as independent. Descriptors accompany each of the scores and define the amount and type of cueing needed, the degree of upper extremity assistance, or additional physical assistance required. The FIST was developed by a panel of experts and tested on adults with acute stroke (within 3 months of insult). It demonstrates good validity (content, construct, and concurrent) and reliability and provides an objective and easy to administer measure of early sitting in persons with limited functional ability.

Perceived Balance Confidence

During the initial interview, the therapist should ask what activities the patient feels most insecure performing and likely to cause a fall. The therapist should also determine a history of fall events that may have occurred in recent days or months, as well as any injuries received. If possible, the patient can also be asked to self-assess balance abilities using a self-report measure of balance confidence (see scales below). Because each is a measure of perceived confidence, it should not be administered after a performance test that might jeopardize perceptions if difficulties become apparent. Individuals with low self-confidence (self-efficacy) and a history of falls typically demonstrate reduced physical activities and increased fall risk.[239,240]

Activities-Specific Balance Confidence (ABC) Scale

The Activities-Specific Balance Confidence (ABC) Scale developed by Powell and Meyers[241] is a 16-item scale that asks individuals to rate their overall level of self-confidence in performing both household and community activities. Household activities include walking around the house, walking up and down stairs, picking up a slipper off the floor, and several reaching activities (reach at eye level, reach on tiptoes, stand on chair to reach). Community activities include walking to a car, getting in and out of a car, walking on various surfaces (parking lot, ramp) and environments (crowded mall, icy sidewalk), and riding an escalator. The individual is asked to rate his or her confidence on a scale from 100% (complete confidence) to 0% (no confidence).

The Balance Efficacy Scale

The *Balance Efficacy Scale (BES)* developed by Tinetti et al[242] is a self-report measure that examines how confident an individual feels while performing 10 items of ADL and functional mobility. The ADL items on the test include both basic ADL (getting dressed and undressed, taking a bath or shower) and instrumental ADL (cleaning house, preparing simple meals, simple shopping). The functional mobility items include getting in and out of a car, going up and down stairs, walking around the neighborhood, reaching, and hurrying to answer the phone. Individuals are asked to consider how confident they feel in doing each of the activities listed without falling. The individual is asked to rate his or her confidence level on a 0 (not at all) to 10 (completely confident) scale. The highest score is 100 (completely confident on all 10 items) and represents high self-efficacy whereas the bottom score of 0 represents low self-efficacy.

An examination of balance using the International Classification of Functioning, Disability, and Health (ICF) Model is included in Table 6.9. Box 6.1 Evidence Summary provides a review of validity and reliability test results of selected functional balance tests discussed in this chapter.

Table 6.9 Examination of Balance Using the International Classification of Functioning, Disability, and Health (ICF) Model

Components of ICF Model	Examination of Balance
Health Condition	• Medical chart review: disorder or disease, medications • Interview, history (fall history)
Body Functions Body Structure Impairments	• Cardiovascular/vitals; orthostatic hypotension • Joint flexibility and range of motion • Muscle strength and endurance • Postural alignment • Posturography: Center of pressure (COP), sway • Coordination, movement strategies (fixed support, change of support) • Sensory integrity: Somatosensory, visual, vestibular • Romberg Test • Sensory Organization Test (SOT) • Clinical Test for Sensory Interaction in Balance (CTSIB) • Cognitive integrity: Memory, attention • Motor function: Adaptive control (changing tasks, changing environment)

Box 6.1 Evidence Summary Functional Balance Tests

Instrument	Content	Validity	Reliability	Comments
The Balance Scale (Berg Balance Scale) Berg et al[180] (1989)	Multitask test of 14 balance tasks common in everyday living: 6 static balance items; 8 dynamic balance items Focuses on: • Maintenance of position • Postural adjustment to voluntary movement	Content validity: expert consensus (health professionals and geriatric patients). Concurrent validity: correlation with Tinetti Balance Sub test = .91	Reliability (ICC) Interrater = .98 Intrarater = .99 Individual items ranged from .71 to .99 Internal consistency (Cronbach's alpha) = .96	High degree of agreement of raters Strong internal consistency Simple, easy to administer (15–20 min); comprehensive Requirements: able to stand independently
Equipment needed: chairs with and without arms, stopwatch, ruler, 6-inch step	Items 1–5 = tests of basic balance ability Scoring: 5-point ordinal scale (graded 0–4) with specific task criteria for levels ranging from I > D; some items timed Max score = 56	Barthel Mobility = .67 TUG = .76 Predictive: of falls in the elderly (hospitals, long-term care, community)		Does not include items on gait or reaction to external stimulus/ uneven surface Provides baseline, and outcome data; scores of 45 or below are predictive of falls in the elderly
Tinetti Performance-Oriented Mobility Assessment (POMA) Tinetti et al[193] (1986)	Multitask test: Balance subtest: 9 items (4 static; 5 dynamic) Gait subtest: 8 items Focuses on: • Maintenance of position • Postural response to voluntary movement	Content validity: expert consensus Concurrent validity: correlation with Berg = .91 Barthel index = .76 Predictive of falls in the elderly (long-term care)	Reliability (ICC) Interrater = .85 Lacks intrarater reliability testing	High degree of agreement of raters Simple, easy to administer (15 min) Requirements: able to stand and walk independently

Box 6.1 Evidence Summary Functional Balance Tests—cont'd

Instrument	Content	Validity	Reliability	Comments
Equipment needed: chair, walkway; patient can use usual walking aid	• Postural response to perturbation • Gait mobility Scoring: some items graded can/cannot perform; some 3-point scale with specific task criteria Max score = 28			Some scoring criteria vague; difficult to detect small changes Provides baseline data; predictive of falls in elderly: > 24 low risk 19–24 mod risk 18 > high risk
Timed Up and Go (TUG) Podsiadlo and Richardson[207] (1991) Equipment needed: stopwatch, armchair, measured walkway patient can use AD	Single task test: stand-up, walk 3 m (10 ft), turn around, and return to chair Focuses on: functional mobility Scoring: timed test Uses 1 practice/3 trials for average score	Content validity: expert consensus Concurrent validity: Berg = .81 Barthel = .78	Reliability (ICC) Interrater = .99 Intrarater = .98	High degree of agreement of raters Simple, easy to administer, quick screen (< 3 min) Requirements: able to stand and walk independently Provides baseline and outcome data; Predictive of falls in elderly: < 10 sec = independent 20 – 29 sec = normal for frail elderly or disabled patients > 30 sec = dependent in mobility skills and most ADL
Functional Reach (FR) Duncan et al[199] (1990) Equipment needed: level yardstick mounted on wall at shoulder height	Single task test: Examines forward UE reach with shoulder at 90° flexion, feet still Focuses on: • Postural responses related to voluntary UE movement • Examines Limits of Stability (LOS) Scoring: distance in inches Uses 1 practice/3 trials for average score	Content validity: expert consensus Concurrent validity: Duke mobility = .65 Gait speed = .71	Reliability (ICC) Interrater = .98 Intrarater = .92	High degree of agreement of raters Simple, easy to administer, quick screen (5 min) Requirements: • Able to stand independently • Requires adequate shoulder ROM FR affected by age and height Provides baseline and outcome data Predictive of falls in the elderly
Multidirectional Reach Test (MDRT) Newton[203] (2001)	Single-task test: Examines UE reach with shoulder at 90° flexion, feet still—forward, sideward, and backward			Same as for FR

Continued

Box 6.1 Evidence Summary Functional Balance Tests—cont'd

Instrument	Content	Validity	Reliability	Comments
	Focuses on: • Postural responses related to voluntary UE movements • Examines Limits of Stability (LOS) Scoring: distance in inches			
Equipment needed: yardstick, wall	Uses 1 practice/3 trials for average score			
Timed Walking Test Murray et al[216] (1966)	Single, continuous test item Compares self-paced, preferred gait speed and fast speed Focuses on • Overall gait speed (distance over time) • Ability to adapt gait speed • Can calculate stride length			Simple, easy to administer, quick screen (3 min) Requirements: independent ambulation, for moderate- to high-functioning adults
Equipment needed: measured walkway and stopwatch	Uses 1 practice/3 trials for average score			Provides screening, baseline and outcome data; results reported as time taken (seconds) or speed (distance/sec) Use of AD is associated with slower gait speeds Age-related norms: • Healthy young adults = 1.2–1.5 m/sec • Older adults = 0.9–1.3 m/sec

AD = Assistive devices; D = dependent; I = independent.

SUMMARY

An examination of coordination and balance provides the physical therapist with important information related to motor performance. Findings provide information about the underlying origin of impairments (although some clinical findings may not be attributable to a single area of CNS involvement). Data from the examination of coordination and balance also assist with establishing anticipated goals and expected outcomes, determining a plan of care, and identifying the effectiveness of treatment interventions.

A variety of coordination and balance tests have been identified. Although the tests have been presented individually for clarity, the therapist selects and chooses individual items to determine a battery of tests appropriate for the specific patient. Because some observational tests are not highly standardized, there is a potential for error and misinterpretation of results. Standardized tests with proven sensitivity and reliability should be selected whenever possible. Sources of potential error can be reduced by the use of well-defined

rating scales, administration of tests by skilled examiners, and subsequent retesting performed by the same therapist. Documentation should include the type, severity, and location of the impairments, as well as factors that alter the quality of performance. Emphasis has been placed on the variety of influences that affect movement capabilities. As such, test results must be considered with respect to findings from other examinations such as sensation, ROM, muscle strength, muscle tone, and functional status.

Questions for Review

1. What are the purposes of performing a coordination examination of motor function?
2. What are the believed contributions (function) of the cerebellum to coordinated movement?
3. How is peripheral feedback provided during a motor response?
4. Differentiate between motor impairments associated with cerebellar pathology and basal ganglion pathology. Provide at least five characteristic impairments for each area.
5. What predictable aspects of normal aging may affect coordinated movement?
6. Accurate and careful patient observation is an important source of preliminary information before performing a coordination examination. What type of activities would you select for the observation? What information will the observation provide?
7. Assume you are about to initiate a coordination examination. What screenings would be appropriate?
8. Identify three upper extremity and three lower extremity nonequilibrium coordination tests that could be used to examine a patient with severe ataxia as a result of traumatic brain injury.
9. Differentiate between coordination tests for intention tremor and postural tremor.
10. Differentiate between the Berg Balance Scale and the Performance-Oriented Mobility Test (Tinetti) in terms of aspects of balance tested.

CASE STUDY

The patient is a 62-year-old man with a 5-year history of Parkinson's disease. Since the time of the diagnosis, he reports a progressive decline in functional activity level. With encouragement from his wife and children, he took an early retirement 3 years ago from his career as a commercial airline pilot. He lives with his wife of 38 years in a one-level suburban home. His four adult children all live in neighboring communities.

Initial examination reveals the following:

- Movements are decreased and slowed.
- A uniform, constant resistance is felt as the extremities are moved passively; patient reports an overall feeling of stiffness that is worse during medication "off" times.
- Involuntary, rhythmic, oscillatory movements of the distal upper extremities are observed at rest (pill rolling).
- Patient has difficulty with distal upper extremity (UE) movements required for buttoning shirts, using eating utensils, and writing.
- Patient has difficulty initiating movement transitions, and is unable to stand up from a chair or roll from prone to supine without difficulty.
- Patient stands with a flexed, stooped posture, positioned at the forward limits of the BOS.
- Standing balance is easily displaced with tendency to fall stiffly.
- Patient has difficulty changing direction of movement or stopping while walking.
- Reports regular falls (two to three times per week).

The patient takes Sinemet (a combination of L-dopa/carbidopa). The physical therapy referral is for examination to document baseline function before beginning outpatient rehabilitation.

GUIDING QUESTIONS

1. Describe this patient's motor impairments and activity limitations.
2. Explain the clinical manifestations of bradykinesia.
3. Select the coordination tests you would use to examine the patient's movement capabilities in performing alternating distal UE movements.

4. What are the requirements for documentation?
5. Select the tests appropriate to examine the patient's altered postural control and balance.
6. What functional balance test might yield the best results in terms of this patient's limitations?

appendix 6.A

Berg Balance Scale

1. Sitting to standing

Instructions: *Please stand up, try not to use your hands for support.*

( ) 4 able to stand without using hands and stabilizes independently
( ) 3 able to stand independently using hands
( ) 2 able to stand using hands after several tries
( ) 1 needs minimal aid to stand or stabilize
( ) 0 needs moderate or maximal assist to stand

2. Standing unsupported

Instructions: *Please stand for 2 minutes without holding.*

( ) 4 able to stand safely 2 minutes
( ) 3 able to stand 2 minutes with supervision
( ) 2 able to stand 30 seconds unsupported
( ) 1 needs several tries to stand unsupported 30 seconds
( ) 0 unable to stand 30 seconds without support

3. Sitting with back unsupported but feet supported on floor or on a stool

Instructions: *Please sit with arms folded for 2 minutes.*

( ) 4 able to sit safely and securely 2 minutes
( ) 3 able to sit 2 minutes with supervision
( ) 2 able to sit 30 seconds
( ) 1 able to sit 10 seconds
( ) 0 unable to sit without support 10 seconds

4. Standing to sit

Instructions: *Please sit down.*

( ) 4 sits safely with minimal use of hands
( ) 3 controls descent by using hands
( ) 2 uses back of legs against chair to control descent
( ) 1 sits independently, but has uncontrolled descent
( ) 0 needs assistance to sit

5. Transfers

Instructions: *Arrange chairs for a pivot transfer. Ask the patient to transfer one way toward a seat without armrests and one way toward a seat with arms. You may use two chairs or a bed/mat and a chair.*

( ) 4 able to transfer safely with minor use of hands
( ) 3 able to transfer safely with definite need of hands
( ) 2 able to transfer with verbal cuing and/or supervision
( ) 1 needs one person to assist
( ) 0 needs two people to assist or supervise to be safe

6. Standing unsupported with eyes closed

Instructions: *Please close your eyes and stand still for 10 seconds.*

( ) 4 able to stand 10 seconds safely
( ) 3 able to stand 10 seconds with supervision
( ) 2 able to stand 3 seconds
( ) 1 unable to keep eyes closed for 3 seconds but stands safely
( ) 0 needs help to keep from falling

7. Standing unsupported with feet together

Instructions: *Place your feet together and stand without holding.*

( ) 4 able to place feet together independently and stand safely 1 minute
( ) 3 able to place feet together independently and stand with supervision for 1 minute
( ) 2 able to place feet together independently but unable to hold for 30 seconds
( ) 1 needs help to assume the position but can stand for 15 seconds, feet together
( ) 0 needs help to assume the position and unable to stand for 15 seconds

8. Reaching forward with outstretched arm while standing

Instructions: *Lift arm to 90°. Stretch out your fingers and reach forward as far as you can. (Clinician places a ruler at the tips of the outstretched fingers—subject should not touch the ruler when reaching.) Distance recorded is from the fingertips with the subject in the most forward position. The subject should use both hands when possible to avoid trunk rotation.*

( ) 4 can reach forward confidently 20–30 cm (10 inches)
( ) 3 can reach forward safely 12 cm (5 inches)
( ) 2 can reach forward safely 5 cm (2 inches)
( ) 1 reaches forward but needs supervision
( ) 0 loses balance when trying, requires external support

9. Pick up object from the floor from a standing position

Instructions: *Pick up the shoe slipper which is placed in front of your feet.*

( ) 4 able to pick up the slipper safely and easily
( ) 3 able to pick up the slipper but needs supervision
( ) 2 unable to pick up the slipper, but reaches 2–5 cm (1–2 inches) from the slipper and keeps balance independently
( ) 1 unable to pick up and needs supervision while trying
( ) 0 unable to try/needs assistance to keep from losing balance/falling

10. Turning to look behind over your left and right shoulders while standing

Instructions: *Turn and look directly behind you over toward the left shoulder. Repeat to the right. Examiner may pick an object to look at directly behind the subject to encourage a better twist.*

( ) 4 looks behind from both sides and weight shifts well
( ) 3 looks behind one side only, other side shows less weight shift
( ) 2 turns sideways only but maintains balance
( ) 1 needs close supervision or verbal cuing
( ) 0 needs assistance while turning

11. Turn 360°

Instructions: *Turn completely around in a full circle, pause, then turn a full circle in the other direction.*

( ) 4 able to turn 360° safely in 4 seconds or less
( ) 3 able to turn 360° safely, one side only, 4 seconds or less
( ) 2 able to turn 360° safely, but slowly
( ) 1 needs close supervision or verbal cuing
( ) 0 needs assistance while turning

12. Place alternate foot on step or stool while standing unsupported

Instructions: *Place each foot alternately on the step stool. Continue until each foot has touched the step stool 4 times.*

( ) 4 able to stand independently and safely and complete 8 steps in 20 seconds
( ) 3 able to stand independently and complete 8 steps >20 seconds
( ) 2 able to complete 4 steps without aid with supervision
( ) 1 able to complete >2 steps needs minimal assistance
( ) 0 needs assistance to keep from falling/unable to try

13. Standing unsupported one foot in front

Instructions: *Demonstrate to subject. Place one foot directly in front of the other. If you feel that you cannot place your foot directly in front, try and step far enough ahead that the heel of your forward foot is ahead of the toes of your other foot. To score three points, the length of the step should exceed the length of the other foot and the width of the stance should approximate the subject's normal stance width.*

( ) 4 able to place foot tandem independently and hold 30 seconds
( ) 3 able to place foot ahead of the other independently and hold 30 seconds
( ) 2 able to take a small step independently and hold 30 seconds
( ) 1 needs help to step but can hold 15 seconds
( ) 0 loses balance while stepping or standing

14. Standing on one leg

Instructions: *Stand on one leg as long as you can without holding*

( ) 4 able to lift leg independently and hold >10 seconds
( ) 3 able to lift leg independently and hold 5–10 seconds
( ) 2 able to lift leg independently and hold >2 seconds
( ) 1 tries to lift leg unable to hold 3 seconds but remains standing independently
( ) 0 unable to try or needs assistance to prevent fall

_____ **TOTAL SCORE (Maximum 56)**

Performance-Oriented Assessment of Mobility I—POMA I (Tinetti) BALANCE

appendix **6.B**

Instructions: *Subject is seated in hard armless chair. The following maneuvers are tested.*

1. Sitting balance

0 = leans or slides in chair
1 = leans in chair slightly or slight increased distance from buttocks to back of chair
2 = steady, safe, upright

2. Arising

0 = unable without help or loses balance
1 = *able* but uses arm to help *or* requires more than two attempts or excessive forward flexion
2 = *able* without use of arms in one attempt

3. Immediate standing balance (first 5 seconds)

0 = unsteady marked staggering, moves feet, marked trunk sway or grabs object for support
1 = steady but uses walker or cane *or* mild staggering but catches self without grabbing object
2 = steady without walker or cane or other support

4. Side-by-side standing balance

0 = unsteady
1 = unsteady, but wide stance (medial heels more than 4 inches apart) or uses cane, walker or other support
2 = narrow stance without support

5. Pull test (subject at maximum position as above, examiner stands behind and exerts mild pull back at wrist)

0 = begins to fall
1 = staggers, grabs, but catches self
2 = steady

6. Turn 360°

0 = unsteady (grabs, staggers)
1 = steady but steps discontinuous
2 = steady and steps continuous

7. Able to stand on one leg for 5 seconds (pick one leg)

0 = unable or holds onto any object
1 = some staggering, swaying or moves foot slightly
2 = able

8. Tandem stand

0 = unable to stand with one foot in front of other or begins to fall
1 = some staggering, swaying, moves arms, or moves foot slightly
2 = able to tandem stand 5 seconds

9. Reaching up—Examiner holds 5-pound weight at height of subject's fully extended reach

0 = unable or holds onto any object
1 = some staggering, swaying or moves foot slightly
2 = able

10. Bending over (place 5-pound weight on floor and ask subject to pick it up)

0 = unable or is unsteady
1 = able and is steady

10a. Time required_____seconds

11. Sit down

0 = unsafe (misjudged distance; falls into chair)
1 = uses arms or not a smooth motion
2 = safe, smooth motion

11a. Timed rising

Time required to rise from chair three times _____ seconds

Total Balance Subtest: 21 points
Timed items: 10, 11

GAIT

Instructions: *Subject stands with examiner. Walks down 15 foot walkway (measured). Ask subject to walk down walkway, turn and walk back. Subject should use customary walking aid.*

1. Initiation of gait (immediately after told to "go")

0 = any hesitancy or multiple attempts to start
1 = no hesitancy

2. Path (estimated in relation to line on floor or rug). Observe excursion of one foot over middle 10 feet of course.

0 = marked deviation
1 = mild/moderate deviation or uses walking aid
2 = straight without walking aid

3. Missed step (trip or loss of balance)

0 = yes and inappropriate attempt to recover balance
1 = yes, but appropriate attempt to recover
2 = no

4. Turning (while walking)

0 = staggers, unsteady
1 = discontinuous, but no staggering, or uses walker or cane
2 = steady, continuous without walking aid

5. Timed walk performed after 1–7 complete (measure out 15 foot walkway)

a) Ask subject to walk at normal pace _____ seconds
b) Ask subject to walk as "fast as feels safe" _____ seconds

6. Step over obstacle (to be assessed in a separate walk with a block placed on course)

0 = begins to fall or unable
1 = able but uses walking aid or some staggering but catches self
2 = able and steady

Total Gait Subtest: 9 points
Timed items: 5

_____ TOTAL SCORE (**Maximum = 30 points**)

Examination of Gait

Judith M. Burnfield, PT, PhD
Cynthia C. Norkin, PT, EdD

Chapter 7

LEARNING OBJECTIVES

1. Define the terms used to describe normal gait.
2. Explain reliability, validity, sensitivity, and specificity in relation to gait analysis.
3. Describe the variables that are examined in each of the following types of gait analyses: kinematic qualitative analysis, kinematic quantitative analysis, and kinetic analysis.
4. Describe and provide examples of some of the most commonly used types of gait profiles.
5. Compare and contrast the advantages and disadvantages of kinematic qualitative and kinematic quantitative gait analyses.
6. Using the case study example, apply clinical decision making skills in evaluating gait analysis data.

CHAPTER OUTLINE

PURPOSES OF GAIT ANALYSIS *251*
SELECTION OF APPROACH TO GAIT ANALYSIS *252*

- Kinematic Quantitative Gait Analysis *274*
- Kinetic Gait Analysis *285*
- Summary of Kinematic and Kinetic Gait Analysis *290*
- Gait Pattern Classification *292*
- Energy Cost Analysis During Gait *292*

SUMMARY *294*

One of the major purposes of rehabilitation is to help patients achieve the highest level of function given their specific impairments so they can participate optimally in activities of interest. Human ambulation, or gait, is one of the basic components of independent function commonly affected by either disease processes or injury. Consequently, the desired outcome of many physical therapy interventions is to either restore or improve a patient's ambulatory status. *Gait*, defined as the manner in which a person walks (e.g., cadence, step length, stride length, speed, and rhythm) differs from *locomotion*, which refers to an individual's capacity to move from one place to another.[1] Although there are many specific reasons for performing a gait analysis, all of them require some information about the walking capacity of either an individual or a group of people with a particular disability. Because there are multiple approaches to gait analysis, ranging from very simple to extremely complex, the therapist must carefully consider how information obtained from a gait analysis is to be used. General as well as specific clinical indications for conducting a gait analysis may be found in the *Guide to Physical Therapist Practice,* some of which are included below.[1]

PURPOSES OF GAIT ANALYSIS

1. To assist with understanding the gait characteristics of a particular disorder. This includes the following:
- Obtaining accurate descriptions of gait patterns and gait variables typical of different conditions
- Identifying and describing gait deviations present, or typically present in specific disorders
- Determining balance, endurance, energy expenditure, and safety
- Determining the functional ambulation capabilities of the patient in relation to functional ambulation demands of the home, community, and work environments
- Classifying the severity of disability
- Predicting a patient's future status

2. To assist with movement diagnosis by:
- Identifying and describing gait deviations and describing the differences between a patient's performance and the parameters of normal gait
- Analyzing gait deviations and identifying the mechanisms responsible for producing them
- Examining balance, endurance, energy expenditure, and safety and determining their impact on gait

3. To inform selection of intervention(s) by guiding the therapist in:
   - Proposing appropriate treatment of impairments that may improve gait performance
   - Determining the need for adaptive, assistive, orthotic, prosthetic, protective, or supportive devices or equipment
4. To evaluate the effectiveness of treatment and guide the therapist in:
   - Determining how interventions such as therapeutic exercise, endurance activities, developmental activities, strengthening or stretching, electrical stimulation, balance training, surgical procedures, and medication will affect gait
   - Determining the effectiveness and fit of devices or equipment selected in providing joint protection and support, correcting deviations and dysfunctions, reducing energy expenditure, and promoting safe locomotive function.

Many examples illustrating these purposes are found in the literature: descriptions of the differences between a patient's performance and the parameters of normal gait,[2-11] identification of the mechanisms causing dysfunction,[12,13] determination of either the need for or the effectiveness of a prosthetic device,[12,14] comparison of the effects of different types of assistive devices,[15,16] determination of either the need for or the effectiveness of an orthotic device,[17-21] determination of the effects of treatment interventions,[22,23] determination of energy expenditure,[14,15,24] and prediction of future status.[25-27]

SELECTION OF APPROACH TO GAIT ANALYSIS

The type of gait analysis that is selected depends not only on the purpose of the analysis, but also on the type of equipment available and the experience, knowledge, and skills of the therapist. The equipment necessary for performing a specific type of gait analysis, in turn, depends on the purpose of the analysis, equipment availability, and the amount of time the therapist can expend. Equipment used in a gait analysis may be either as simple as a pencil, paper, and stopwatch,[28] or as complex as an electronic imaging system with force plates embedded in the floor and electromyography electrodes placed on the client.[29-32] To select the appropriate method, the therapist must be aware of the types of analyses available and be able to determine which methods are reliable and valid. Much of the information about gait characteristics of particular disorders, as well as the mechanisms responsible for producing them, has been achieved in clinical research settings using complex instrumentation often not available for general patient use. However, given a firm understanding of the biomechanics of normal gait, including characteristic joint motions and muscle demands, a therapist can use less complex methods to identify variations in movement patterns from normal and problem solve likely causes. Efficacious treatment approaches can then be employed to address underlying causes.

Regardless of the method, a gait analysis of individual patients should provide accurate, reliable, and valid data that can be used as a basis for describing present status (performance limitations and strengths), planning and implementing interventions, evaluating effectiveness and progress over time, evaluating outcomes, and, in some instances, predicting future status.

Reliability

Reliability, as applied to gait analysis, refers to the level of consistency of either a measuring instrument (e.g., footswitches, force plates, motion analysis systems, electrogoniometers) or a method of analysis (e.g., observational gait analysis checklists, ambulation profiles, and formulas for measuring stride length). To determine if a measuring instrument is reliable, the measurements obtained from successive and repeated use of the instrument must be consistent. For example, if an electrogoniometric measurement of a known angle of 60° consistently measures 60° on every Monday morning for 2 months, the instrument is said to be reliable. However, if the measurement obtained were 60° on the first Monday morning, 30° on the second, and 40° on the third, the instrument would have very low reliability. Two types of reliability may be referred to: relative (association) or absolute (concordance). Relative reliability uses statistical techniques that are correlational;[33] they detect the existence of a relationship between sets of data. The statistical techniques used by absolute reliability can detect the magnitude of differences between measures.

Unlike more tightly controlled scientific conditions, the measures used in gait for determining reliability reflect all of the variability present in the measurement process. This includes trial-to-trial or day-to-day performance variation of the subject, as well as differences in the way the tester carries out the test. To make the best possible determination of the reliability of an instrument, one must rule out factors other than the instrument that could influence the measurement (e.g., that a subject has not injured a knee between successive measurements or that the placement of the instrument has not changed).

To determine whether an analysis method has both relative and absolute reliability, two different forms of reliability need to be determined: *intratester* and *intertester* reliability. The intratester reliability of an analysis method can be determined by examining the consistency of the results obtained when one individual uses a particular method repeatedly. For example, a therapist uses a particular method to examine a student physical therapist's gait. The therapist repeats the examination at 2-week intervals for 8 weeks and obtains the same results each time. In this instance, the method would be considered as having high intratester reliability because the results obtained by the same person are consistent over time. However, this example is strictly hypothetical, as factors

other than the therapist's skill, such as fatigue, time of day, and other variables, may affect performance and must be controlled in any analysis.

Intertester reliability is determined by examining the consistency of the data obtained from repeated analyses performed by a number of different persons. If the results obtained by numerous examiners are in agreement both relatively and absolutely, and no significant differences in the results exist among testers, the method has high intertester reliability.

Sensitivity and Specificity

Sensitivity and specificity are important considerations when selecting a method of analysis. **Sensitivity**, as it relates to gait analysis, refers to the proportion of times that a method of analysis correctly identifies a gait abnormality or condition when that abnormality or condition is actually present. **Specificity** refers to the proportion of times that a method of analysis correctly identifies the abnormality as being absent when it truly is absent.[34] Additional information about these parameters will be available as more sophisticated statistical treatment of gait findings becomes common practice.

Validity

Validity refers to the degree that a measurement reflects what it is supposed to measure. There are several types of validity:

- *Construct validity*—determined through logical argumentation based on theoretical research evidence (the ability of an instrument to measure an abstract concept or construct).
- *Content validity*—determined by providing evidence that the measuring instrument contains all relevant elements of a construct and no extraneous elements. In this instance, the test developer might justify the test by demonstrating that all items in the test were correlated with each other.
- *Criterion-based validity*—established by comparisons of either one instrument with another or with data obtained from other forms of testing.
- *Concurrent validity*—the inference is justified by comparisons between the results of a specific test (gait analysis) and another test (functional examination) taken at approximately the same time.
- *Predictive validity*—validity is determined by the capability of the instrument to predict future events, such as falls.

It is difficult to imagine a method of measuring or analyzing gait that is not inherently valid for gait itself. However, gait is not a single construct, but a complex process that mirrors the complexity of human performance. Using a fairly simple approach, one can ask if a particular measure is valid for the specific purpose identified. Examining the tools described below, one may reflect on the purposes of gait analysis identified earlier, and ask if the tool being considered would be valid for that purpose.

By examining the literature, the therapist may determine if the reliability and validity of an instrument or method of analysis has been established. If the instrument or method has not been tested, therapists may wish to incorporate methods such as repeated testing within the context of a research study to confirm reliability.

GAIT TERMINOLOGY

The Gait Cycle

The fundamental unit of walking is the *gait cycle,* which has both spatial (distance) and temporal (time) parameters. In normal walking, a gait cycle begins when the heel of the reference extremity contacts the supporting surface and ends when the heel of the same extremity contacts the ground again. In some abnormal gaits, the heel may not be the first part of the foot to contact the ground, so the gait cycle may be considered to begin when some other portion of the reference limb contacts the ground. The cycle ends with the next ipsilateral contact of that portion of the foot with the ground.

The gait cycle is divided into two periods, *stance* and *swing* (Fig. 7.1). In normal gait at a comfortable walking speed, *stance* constitutes approximately 60% of the gait cycle, and is defined as the interval in which the reference foot is in contact with the ground. *Swing* comprises approximately 40% of the gait cycle, and occurs when the reference limb is not in contact with the ground. A single gait cycle includes periods of stance and swing for both the right and left limbs. During gait, body weight is smoothly transferred from one limb to the next during two intervals of double limb stance in the gait cycle when both limbs are in contact with the ground at the same time. *Initial double limb stance* occurs at the beginning of the gait cycle as weight transfers onto the outstretched reference limb from the trailing limb. *Terminal double limb stance* occurs at the end of stance as body weight transfers from the trailing reference limb to the lead limb. Initial double limb stance on the reference limb corresponds with the contralateral limb's terminal double limb stance. *Single limb support,* arising between the two double limb stance periods, is the portion of the gait cycle when only one limb supports body weight. The duration of each of these variables may be measured, for example, *cycle time, stance time* (right and left), *swing time* (right and left), initial *double limb stance time, terminal double limb stance time,* and *single limb support time.*

Two steps, a right step and a left step, form a *stride,* and a stride is equal to a gait cycle. Step and stride may be defined in two dimensions: distance and time. *Step length* is the distance from the point of heel strike of one extremity to the point of heel strike of the opposite extremity, whereas *stride length* is the distance from the point of heel strike of one extremity to the point of heel strike of the same extremity. An alternative portion of the foot that consistently contacts the ground can be used as a reference point if the heel is not the first point of contact, as with some abnormal gait patterns. *Stride*

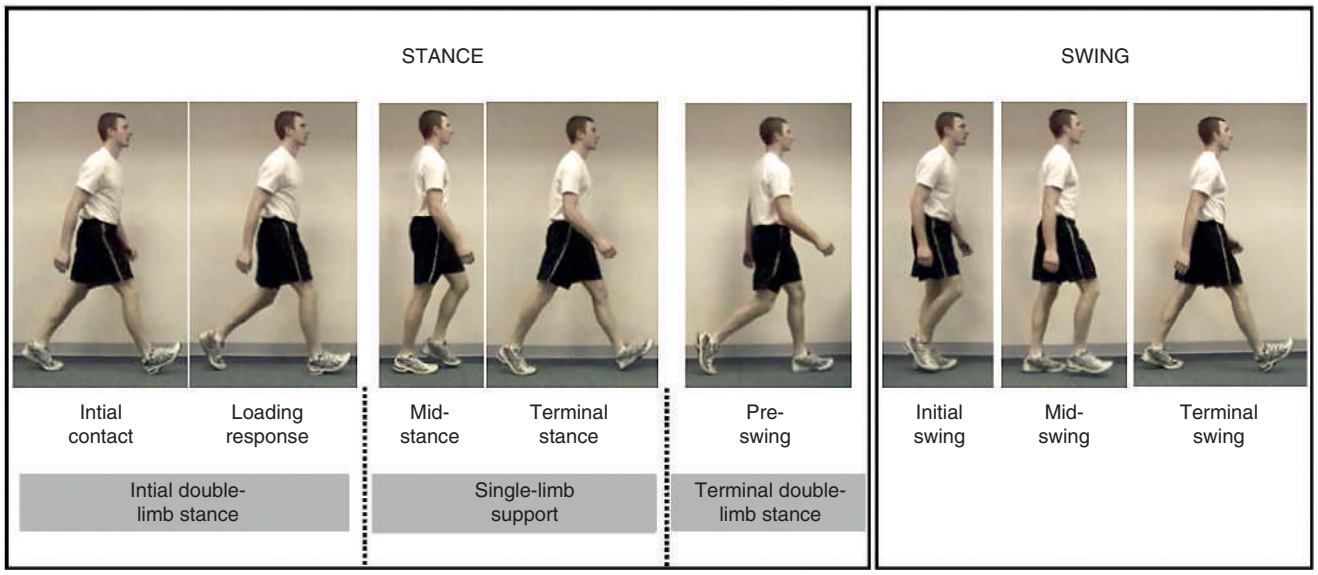

Figure 7.1 The eight phases of the gait cycle. Stance, the period when the reference limb is in contact with the ground, is comprised of the following five phases: initial contact, loading response, mid stance, terminal stance, and pre-swing. Swing, the period when the limb is off the ground, is comprised of the following three phases: initial swing, mid swing, and terminal swing. In addition, there are two periods in gait when both limbs are in contact with the ground: initial double limb stance (initial contact and loading response) and terminal double limb stance (pre-swing). Also, there is one period, single limb support, in which only one limb is in contact with the ground. Single limb support includes the phases of mid stance and terminal stance. Note that the contralateral limb is in swing during the reference limb's single limb support. *(Courtesy of Movement and Neurosciences Center, Institute for Rehabilitation Science and Engineering, Madonna Rehabilitation Hospital, Lincoln, NE 68506.)*

time and *step time* refer to the length of time required to complete a step and a stride, respectively (Fig. 7.2).

Phases of Gait

Early terminology describing the phases of gait included descriptors for both stance (i.e., heel strike, footflat, mid-stance, heel-off, and toe off) and swing (i.e., acceleration, mid swing, and deceleration). Though useful for describing normal gait, the terminology is sometimes confusing in the presence of pathology. For example, many individuals with pretibial weakness or severe plantarflexion contractures lack a heel first contact at "heel strike." Some individuals with plantarflexor spasticity maintain their heel off the ground throughout stance, not just during heel-off. Others with profound plantarflexor weakness may fail to achieve a period of heel-off and instead lift the full foot from the ground at the end of stance.

To avoid the confusions associated with earlier terminology, Perry and colleagues from Rancho Los Amigos National Rehabilitation Center developed a generic terminology to describe the eight functional phases of gait.[32,35] The first five phases constitute stance: *initial contact, loading response, mid stance, terminal stance*, and *pre-swing*. The latter three comprise swing: *initial swing, mid swing,* and *terminal swing*. The similarities and differences between the two terminologies are presented in Table 7.1.

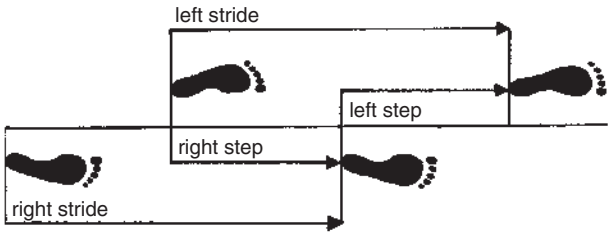

Figure 7.2 A right stride and a left stride. Right stride length is the distance between the point of contact of the right heel (at the lower left corner of the diagram) and the next contact of the right heel. Left stride length is the distance between the point of contact of the left heel (at the top left of the diagram) to the point of contact at the next left heel. Each stride contains two steps, but only both steps in the left stride are labeled. The left stride contains a right step and a left step. The right step length (shown in the middle of the diagram) is the distance between the left heel contact to the point of the right heel contact. Left step length is the distance between the right heel contact and the next left heel contact. Step and stride times refer to the amount of time required to complete a step and to complete stride, respectively.

Table 7.1 Comparison of Gait Terminology

	Rancho Los Amigos[3,32]	Traditional
Stance	*Initial Contact:* Beginning of stance when heel or some other portion of foot contacts ground. Component of initial double limb stance.	*Heel Strike:* Beginning of stance when heel first contacts ground.
	Loading Response: Body weight rapidly loads onto lead limb from trailing limb. Hip remains stable, knee flexes to absorb shock, and forefoot lowers to ground. Immediately follows initial contact and is final component of initial double limb stance. Ends when opposite limb lifts from ground for swing.	*Foot Flat:* Immediately follows heel strike when sole of foot contacts floor.
	Mid Stance: Trunk progresses from behind to in front of ankle over single stable limb. First half of single limb support. Starts when contralateral foot lifts from ground for swing.	*Midstance:* Point at which body passes directly over reference extremity.
	Terminal Stance: Trunk continues forward progression relative to foot. Heel rises from ground and limb achieves trailing limb posture. Second half of single limb support. Ends with contralateral initial contact.	*Heel Off:* Point following mid stance when reference limb's heel leaves ground.
Swing	*Pre-swing:* Body weight rapidly unloads from reference limb and reference limb prepares for swing during this terminal double limb stance period. Starts with contralateral initial contact and ends at ipsilateral limb toe off.	*Toe Off:* Point following heel- off when only the reference limb's toe is contacting ground.
	Initial Swing: Starts when reference foot lifts from ground. Hip, knee, and ankle rapidly flex for clearance and advancement during this initial 1/3 of swing.	*Acceleration:* Beginning portion of swing from reference limb toe off to point when reference limb is directly under the body.
	Mid Swing: Thigh continues advancing, knee begins to extend, and ankle achieves neutral posture during this middle 1/3 of swing.	*Mid swing:* Portion of swing when reference limb passes directly below body. Extends from the end of acceleration to beginning of deceleration.
	Terminal Swing: During this final 1/3 of swing, knee achieves maximal extension and ankle remains at neutral in preparation for heel first initial contact. Ends when foot contacts ground.	*Deceleration:* Portion of swing when reference limb is decelerating in preparation for heel strike.

The first stance phase, *initial contact*, represents the moment in time when the outstretched limb first hits the ground. During the next phase, *loading response*, body weight is rapidly accepted onto the outstretched limb. A small wave of knee flexion helps dissipate the impact forces associated with body weight loading onto the limb. Initial contact and loading response are the two phases that constitute *initial double limb stance,* which is sometimes referred to as *weight acceptance.*[32] Initial double limb stance ends when the foot opposite the reference limb lifts from the ground for swing.

During the next two phases, *mid stance* and *terminal stance*, body weight progresses forward over a single stable limb. By terminal stance, the heel rises from the ground, the leg achieves a "trailing limb" posture, and the trunk advances well in front of the reference foot. Another term for the combined phases of mid stance and terminal stance is *single limb support*, reflective of only one limb being in contact with the ground.[32]

Pre-swing, the last phase of stance, is sometimes referred to as *terminal double limb stance* or *push-off.* During pre-swing, body weight transfers from the trailing limb to the contralateral lead limb, which is experiencing initial contact and loading response. As the proportion of body weight supported by the trailing limb diminishes, residual energy stored in the Achilles tendon during mid and terminal stance rapidly plantarflexes the ankle despite a lack of significant plantarflexor muscle activity.[32,36-38] The knee flexes to 40°, over half of the 60° required for foot clearance during the subsequent phase.

Lifting of the foot from the ground reflects the onset of the first phase of swing, *initial swing*. Rapid flexion of the knee and hip ensue. During *mid swing,* the thigh continues to advance into flexion, achieving a peak of approximately 25° relative to vertical. The knee begins to extend and the tibia achieves a characteristic vertical position by the end of mid swing. The ankle reaches neutral (0° dorsiflexion). During *terminal swing,* further thigh flexion is curtailed; however, the knee continues to extend until it observationally appears neutral. The ankle remains at neutral in preparation for a heel first initial contact.

Characteristic features of normal gait are presented in Tables 7.2 to 7.4. The gait phases, as well as normative values for joint motions, internal moments of force, and

Table 7.2 Ankle and Foot: Normative Sagittal Plane Data and Impact of Weakness[32,35]

Phase	Characteristic Joint Position	Internal Joint Moment	Normative Muscle Activity	Effect(s) of Weakness	Possible Compensation(s)
Initial Contact	Neutral (0° dorsiflexion)	Dorsiflexor moment achieves peak during loading response	Pretibial muscles (tibialis anterior, extensor digitorum longus, extensor hallucis longus) decelerate forefoot lowering and draw tibia forward following initial contact.	Borderline weakness (3+/5) may be accompanied by a foot slap following a heel first initial contact. Profound weakness (2+/5 or less) may result in foot flat or forefoot initial contact if pretibial strength is insufficient for achieving neutral ankle.	With borderline weakness, may slow gait to decrease demands on pretibial muscles during loading response. Alternatively, may contact ground with excess plantarflexion to decrease demands on pretibial muscles.
Loading Response	5° plantarflexion				
Mid Stance	5° dorsiflexion	Plantarflexor moment reaches peak during terminal stance	Plantarflexors (gastrocnemius, soleus, flexor digitorum longus, flexor hallucis longus, tibialis posterior, peroneus longus, and peroneus brevis) progressively increase activity throughout two phases to allow controlled forward progression of tibia. Elastic energy stored in Achilles tendon.	Excess dorsiflexion, uncontrolled tibial advancement, delayed or absent heel-off. However, if vastii are weak (vastus intermedius, vastus lateralis, vastus medialis longus, and oblique), may avoid excess dorsiflexion as it would contribute to excess knee flexion and high demand on weakened vastii.	Shortened step length and slower velocity to reduce demands on calf muscles.
Terminal Stance	10° dorsiflexion				
Pre-Swing	15° plantarflexion		Calf muscles cease in early pre-swing. Stored elastic energy in Achilles tendon contributes to rapid plantarflexion as limb unloads.	Low or no heel-off and lack of rapid plantarflexion.	Use of more proximal muscles to prepare limb for advancement and clearance.
Initial Swing	5° plantarflexion	Low dorsiflexor moment	Pretibial muscles elevate foot to neutral by mid swing and then maintain in that posture.	Excess plantarflexion and foot drag, particularly in mid swing. Poor posture for subsequent initial contact.	Hip hike, excess hip flexion or abduction to assist with limb clearance, or contralateral vault (excessive plantarflexion) to facilitate reference limb clearance.
Mid Swing	Neutral				
Terminal Swing	Neutral				

Table 7.3 Knee: Normative Sagittal Plane Data and Impact of Weakness[32,35]

Phase	Characteristic Joint Position	Internal Joint Moment	Normative Muscle Activity	Effect(s) of Weakness	Possible Compensation(s)
Initial Contact	Appears fully extended	Brief flexor moment	Low-amplitude hamstring activity (semimembranosus, semitendinosus, biceps femoris [long head]) resists knee hyperextension.	Reliance on posterior capsule to stabilize joint and to prevent hyperextension.	*Shading represents column heading information not applicable to the identified phase of gait.*
Loading Response	20° flexion	Extensor moment	Eccentric vastii activity (vastus intermedius, vastus lateralis, vastus medialis longus, and oblique) allows knee flexion for shock absorption but prevents collapse.	Unable to stabilize knee during flexion leading to limb collapse.	Avoid knee flexion (as flexion increases vastii demand) by use of (1) excess plantarflexion; or (2) forward trunk lean to lessen knee extensor moment.
Mid Stance	Appears fully extended	Extensor moment transitions to flexor moment	Vastii activity ceases by middle of mid stance.		
Terminal Stance	Appears fully extended	Flexor moment			
Pre-Swing	40° flexion	Extensor moment	Rectus femoris modulates rate of knee flexion.		
Initial Swing	60° flexion		Biceps femoris [short head], gracilis, and sartorius contribute to knee flexion.	Limited knee flexion for foot clearance.	Compensatory hip hike, excess hip flexion, or abduction to assist clearance.
Mid Swing	25° flexion	Flexor moment	Hamstrings modulate rate of knee extension (and thigh advancement).		
Terminal Swing	Appears fully extended		Hamstrings continue activity and vastii become active in preparation for demands of initial double limb stance.	With profound vastii weakness (less than 2+/5) may see inadequate knee extension in terminal swing.	Past retract of thigh or extension thrust of knee to ensure full knee extension.

Table 7.4 Hip: Normative Sagittal Plane Data and Impact of Weakness[32,35]

Phase	Characteristic Joint Position (thigh relative to vertical)	Internal Joint Moment	Normative Muscle Activity	Effect(s) of Weakness	Possible Compensation(s)
Initial Contact	20° flexion	Extensor moment	Single joint hip extensors and abductors contract vigorously to stabilize pelvis and trunk over femur. Hamstring activity diminishing.	Difficulty stabilizing pelvis and hip joint leading to anterior tilt and increased hip flexion in sagittal plane. If abductors weak, contralateral pelvic drop may occur.	Decrease terminal swing hip flexion to limit demands on weak hip extensors during initial contact and loading response. Posterior trunk lean to reduce extensor moment. For weak abductors, may lean trunk laterally toward stance limb to reduce abductor demands.
Loading Response	20° flexion				
Mid Stance	Neutral	Extensor moment transitions to flexor moment	Residual hamstring activity assists with hip extension at beginning of phase. Low-level abductor activity stabilizes pelvis.	Contralateral pelvic drop.	May lean trunk laterally toward stance limb to reduce abductor demands.
Terminal Stance	20° apparent hyperextension (anatomical hip joint does not allow 20° extension, but hip appears to be extended 20° due to the combined impact of hip extension, backward pelvic rotation, and anterior pelvic tilt on thigh angulation relative to vertical).	Increasing flexor moment	Low amplitude tensor fascia lata activity.	Contralateral pelvic drop.	May lean trunk laterally toward stance limb to reduce abductor demands.
Pre-Swing	10° apparent hyperextension	Flexor moment	Rectus femoris assists with early thigh advancement.		
Initial Swing	15° flexion	Flexor moment	Iliacus, adductor longus, gracilis, and sartorius actively advance thigh.	With profound hip flexor weakness (less than 2/5), may exhibit limited hip flexion, thigh advancement, and foot clearance.	To facilitate limb clearance, may compensate with ipsilateral hip hiking, excess hip abduction, or contralateral limb vaulting (excessive plantarflexion).
Mid Swing	25° flexion	Extensor moment	Increasing hamstring activity at end of phase restrains further thigh advancement.		

Table 7.4 Hip: Normative Sagittal Plane Data and Impact of Weakness[32,35]—cont'd

Phase	Characteristic Joint Position (thigh relative to vertical)	Internal Joint Moment	Normative Muscle Activity	Effect(s) of Weakness	Possible Compensation(s)
Terminal Swing	20° flexion	Extensor moment	Hamstrings continue to control thigh posture, while single joint hip extensors and abductors rapidly increase activity in preparation for demands of next phase of gait.	Failure to achieve optimum limb position before initial contact.	Alter speed.

muscle activity, are presented in the first four columns. Familiarity with the normal motion patterns provides the therapist with a basis of comparison to identify deviations from standard. The internal moments (or torques) at each joint reflect the forces generated by muscles' contractile and noncontractile components, as well as ligaments and joint capsules. Internal moments counterbalance the external moments that are created by forces such as gravity and inertia acting on the body segments. In the current chapter, we have elected to describe internal joint moments as this appears to be the more common reference point used in published literature. However, knowledge of the external moments (and thus the internal moments) is helpful for interpreting the characteristic patterns of muscle activation that contribute to stability, forward progression, shock absorption, and limb clearance throughout the gait cycle. For example, during the single limb support period of normal gait, a progressively increasing external dorsiflexion moment occurs as body weight progresses anterior to the ankle joint. Without a counteracting force from the plantarflexors, the ankle would collapse into dorsiflexion. The force generated by the plantarflexors contributes to an internal plantarflexor moment that allows controlled forward progression but prevents tibial collapse. Thus, the internal plantarflexor moment generated by the plantarflexors resists the external dorsiflexion moment created in large part by the force of gravity on the body.

Abnormalities in timing (e.g., activity that is premature or delayed) and amplitude (either too much or too little) can disrupt normal gait patterns. Familiarity with the muscle activity and function associated with normal gait allows therapists to identify potential causes of deviations. In Tables 7.2 to 7.4, the possible effects of muscle weakness and potential compensations are presented in the last two columns. The purpose of the tables is to identify components of normal gait that must be considered when observing gait and to provide an example of how to proceed with an analysis of the causes of an atypical gait pattern or particular deviation.

TYPES OF GAIT ANALYSES

The types of analyses in use today can be classified under two broad categories: **kinematic** and **kinetic**. Kinematic gait analysis is used to describe movement patterns without regard for the forces involved in producing the movement. A kinematic gait analysis consists of a description of movement of the body as a whole and/or body segments in relation to each other during gait. Kinematic gait analysis can be either *qualitative* or *quantitative.* Kinetic gait analysis is used to determine the forces involved in gait. In some instances, both kinematic and kinetic gait variables may be examined in one analysis. In addition to examining kinematic and kinetic variables, physiological variables such as heart rate, oxygen consumption, energy cost, and muscular activation patterns (electromyography) may be considered.

Kinematic Qualitative Gait Analysis

The most common method used in clinical settings is a *qualitative gait analysis.* This method usually requires only a small amount of equipment and a minimal amount of time. The primary variable examined in a qualitative kinematic analysis is *displacement,* which includes a description of patterns of movement, deviations from normal body postures, and joint angles at specific points in the gait cycle.

Observational Gait Analysis

Few clinical settings have the resources (space, money, or time) required to complete an instrumented gait analysis on every patient. As a result, observational gait analysis (OGA) often serves as an essential component of many physical therapy examinations. The results of an OGA are used to identify structural and activity limitations, as well as to plan an intervention and assess the outcomes. While physical therapists seek an easy to

administer tool to identify gait abnormalities, guide treatment approaches (e.g., need for orthotic devices), and assess progress,[39] the validity and reliability of existing scales remains less than optimal. This section highlights tools/approaches that clinicians may consider using.

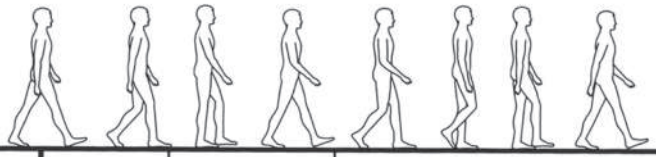
The *Rancho Los Amigos Observational Gait Analysis* system is probably the most common OGA system used by physical therapists.[32,35] The Rancho Los Amigos OGA method involves a systematic examination of the movement patterns of key body segments (foot, ankle, knee, hip, pelvis, and trunk) during each phase of the gait cycle. The system uses a recording form comprising 45 descriptors of common gait deviations such as toe drag, excess plantarflexion and dorsiflexion, excess knee varus or valgus, pelvic hiking, and forward or backward trunk leans (Fig. 7.3). The observing therapist must determine whether or not a deviation is present and note the occurrence and timing of the deviation on the special form.[35]

Considerable training and practice are necessary to develop the observational skills needed for performing any OGA. Therapists who wish to learn the Rancho method can study the *Rancho Los Amigos Observational Gait Analysis Handbook*.[35] Practice gait videos, useful for developing and improving one's observational skills and for learning how to use the recording forms, may be obtained by visiting the Los Amigos Research and Education Institute (LAREI) website (www.larei.org) or by writing to LAREI, Rancho Los Amigos National Rehabilitation Center, 7601 East Imperial Highway, Downey, CA 90242.

Podiatrists have developed their own unique OGA system.[40] A biomechanical gait analysis form for podiatrists, described by Southerland,[40] is presented in Figure 7.4. This form is used in conjunction with a static quantitative analysis that includes measurements of range of motion (ROM) of all joints from the hip to the toes, as well as measurements of limb length. Detailed information is also collected on both the dorsal and plantar surfaces of the feet such as callus formation and corns. The examiner is expected to document abnormalities such as hallux valgus and hammer toes. The dynamic qualitative component of the analysis uses a shorthand system for recording the details of the OGA. The acronym GHORT (*G*ait, *H*omunculus, *O*bserved, *R*elational, and *T*abulator) is used to assist in recording information gathered from the observational analysis (Fig. 7.5). An example of the recording method is shown in Figure 7.6. Following completion of the dynamic portion, the rater's qualitative impressions of the patient's gait are compared with the results of the static analysis to verify the accuracy of the findings and determine the causes of abnormal function. The author states that after the first five analyses, a new rater's results are the same as or similar to those of other raters; however, the author did not reference any reliability and/or validity studies.[40] In general, these observational protocols provide the therapist with a systematic approach to OGA by directing the observer's attention to a specific joint or body segment during a given point in the gait cycle.

The advantages of OGAs are that they require little or no instrumentation, are inexpensive to use, and can yield general descriptions of gait variables. The disadvantages are that the observational method, being dependent on both the therapist's training and observational skills, is subjective and has only low to moderate reliability, and validity has not been demonstrated.[41] Difficulties involved in observing and making accurate judgments about motions occurring simultaneously at numerous body segments, and inadequate training in OGA methods are thought to contribute to the low reliability. Also, therapists differ in their observational skills. A drawback to using the Rancho Los Amigos OGA technique is that reliability and validity of the method have not been published.

Digital Video Recording



If therapists decide to use an OGA method, they should consider using a digital video recorder (DVR) that has the capability of slowing or stopping motion. A visual record is especially important when using the Rancho Los Amigos format because of the time involved in examining a large number of variables at six body parts. Most patients cannot walk continuously for the length of time required to complete a detailed, full-body observational analysis. Furthermore, the observers cannot rate or score a large number of variables while a subject is walking. Digital records of a patient's initial performance that can be replayed in slow motion allow therapists the time needed to make judgments about gait events. Activating the DVR pause feature, a goniometer, aligned with body segments displayed on the video monitor, can be used to assess (validate) joint angles during critical phases. This may also help refine the therapist's observational skills.

Although the use of digital video recordings may provide an opportunity for observers to determine the reliability of their scoring, reliability will probably remain low to moderate unless therapists are knowledgeable about normal gait parameters and variables and are adequately trained to use the measuring instrument. Russell et al[42] found that when observers were trained in the scoring of a Gross Motor Function Measure (GMFM), a significant improvement occurred following training compared with the observers' pretraining scoring of the videotape. Brunnekreef and colleagues[43] identified higher interrater reliability among expert raters of orthopedic gait disorders (intraclass correlation coefficient [ICC] = 0.54) when using a form developed by the experts than the values documented for experienced (ICC = 0.42) and inexperienced (ICC = 0.40) raters using the same form. On the other hand, Eastlack et al[44] found only low to moderate interrater reliability among 54 practicing physical therapists who rated 10 gait variables while observing the

videotaped gait of three patients. These therapists had reported that they were comfortable performing observational gait analyses. The lack of agreement among raters found in this study, as well as the raters' lack of knowledge of normal gait parameters and terminology, has serious implications for patient treatments based on the results of observational gait analyses.[44] Krebs[45] argues that OGA is impossible to perform in a clinical setting. However, in a study using OGA, physical therapists were able to make accurate and reliable judgments of scored push-off power in the videotaped gait of subjects following stroke. This study suggests that focused analysis on specific gait parameters may be more reliable than general analyses.[46]

Specialized video analysis software may improve interrater reliability of gait measures compared to traditional video viewing methods. Borel et al[47] reported increased measurement agreement between two raters when using Dartfish®, a program that allows users to measure joint angles, distance, and time variables directly from digital videos. (*Note:* For this chapter, all manufacturer contact information is presented in Appendix 7.C.) Raters used Windows Media Player® and Dartfish® to perform the measurements required to determine Observational Gait Scale scores for 20 videos of children with cerebral palsy (CP). Interrater agreement values increased for select variables (knee position mid stance, foot contact mid stance, timing of heel rise, hindfoot mid stance, and the composite total score) when using the digital goniometer, line drawing, and temporal tools of Dartfish®. One potential negative was that it took longer to complete the analysis using Dartfish® than Windows Media Player (18 versus 10 minutes per video, respectively). Additionally, this study did not determine whether the more consistent values also were valid. If OGA is employed, it should be used in conjunction with quantitative measures. Digital video recordings or videotape can provide a permanent record of the patient's gait. Videography may also be used to examine joint ROM at the hip, knee, and ankle, by taking goniometric measurements directly from the paused screen. Stuberg et al[48] found no significant differences between goniometric measurements calculated from videotaped gait and measurements generated using a digitizer in 10 children with CP and 9 typically developing children. Six blue markers, placed over key anatomical locations of the lower extremity (LE) and shoulder, guided measurements. The use of markers to guide measurements emphasizes the importance of ensuring that joints (or apparent axes of rotation) are clearly visible to facilitate measurements with the eye or a goniometer.

Observational Gait Analysis Process

The purpose of this section is to introduce the process involved in an OGA. The first step in the process involves the identification and accurate description of the patient's gait pattern and any existing deviations. The second step involves a determination of the causes of the deviations. To properly identify and describe a patient's gait, the therapist must have good knowledge of gait terminology and an accurate mental picture of normal gait postures and normal displacements of the body segments during each gait phase, and in each plane of analysis (sagittal, coronal, and transverse). To determine the causes of a patient's gait pattern and specific deviations, the therapist must understand the normal roles and functions of muscles during gait and the normal forces involved.[32,35,49,50] Deviations occur because of an inability to perform the tasks of walking in a normal fashion. For example, a patient with paralysis of the dorsiflexors (which causes a foot drop) cannot attain the normal neutral position of the ankle necessary to complete the task of clearing the floor during swing. Therefore, the patient must find some other method of

clearing the floor. The patient could compensate for inadequate dorsiflexion by increasing the amount of hip and knee flexion, by circumduction of the entire limb, or by hiking the hip. The type of compensation that a particular individual selects depends on the specific disability. Increased hip and knee flexion may be used if the patient has an isolated problem in the ankle and adequate muscle strength and ROM in the extremity. Circumduction or hip hiking may be used if the patient has either a stiff knee or extensor thrust, which prevents use of increased knee flexion to raise the plantarflexed foot above the floor.[6] The therapist must be aware that patients may use a variety of methods to compensate for joint or muscle deficits.

Overview of Common Deviations and Underlying Causes

Tables 7.5 to 7.8 present common gait deviations and possible causes for the deviations. Given that muscle demands vary across phases of gait, the causes of a specific deviation also frequently vary based on the phase. For example, a common cause of excess plantarflexion during swing is weak pretibial muscles. However, this is not a common cause of excess plantarflexion during mid stance and terminal stance, as the pretibial muscles are not normally active during this period. Instead, excess plantarflexion during mid and terminal stance would more likely arise from the influence of plantarflexor spasticity or contractures on joint motion during. Thus, detective work is required to link the observed gait deviations with the specific demands of a phase in order to determine the most likely cause(s). Accurate determination of the impairments leading to the gait deviation is essential for guiding treatment interventions.

Appendix 7.A, Recording Form for Observational Gait Analysis, provides a sample gait analysis recording form. Check marks (√) are used to indicate observation of a specific deviation in the Recording Form for Observational Gait Analysis included in Appendix 7.A. The two columns on the far right are used to record possible causes and findings from the clinical analyses. To guide the OGA process, note that the form presented in Appendix 7.A has been formatted similarly to Tables 7.5 through 7.8. If the reader decides to use the gait analysis recording forms presented in this text, reliability tests should be conducted because these forms are presented only as guides and have not been evaluated.

Guidelines for Performing an OGA

Guidelines for performing an OGA are presented below.

1. Select the area in which the patient will walk and measure the distance that you want the patient to traverse.
2. Position yourself to allow an unobstructed view of the subject. If digitally recording, the cameras should be positioned to view the patient's entire body (LEs as well as the head and trunk) from both the sagittal and coronal perspectives. To avoid errors in estimating the amplitude of joint angles due to angle parallax,[32,48] it is important to perform measurements on paused digital images only when the patient's LEs or body is in the same plane as the image view. Out-of-plane views can lead to distorted angle measurements.
3. Select the joint or body segment to be observed first (e.g., ankle and foot), and mentally review the normative joint positions and muscle activity for the phase of the gait period being observed (e.g., initial contact).

(Text continues on page 268)

Table 7.5 Common Ankle and Foot Deviations[32,35]

Deviation	Phase(s)	Description	Possible Causes	Analysis
Toes or forefoot contact	Initial contact	Toes or forefoot are first point of contact with ground instead of heel	Leg length discrepancy; plantarflexion contracture or spasticity; profound dorsiflexor weakness; painful heel; excessive knee flexion when combined with any impairment that limits ability to achieve neutral ankle.	Examine range of motion (ROM) and leg lengths and for hip and/or knee flexion contractures and/or ankle plantarflexion contractures. Examine muscle tone and timing of activity in plantarflexors. Examine pretibial strength and for heel pain.
Foot flat contact	Initial contact	Entire foot simultaneously touches ground at initial contact	Plantarflexion contracture; weak dorsiflexors; knee flexion contracture that prevents optimal tibial alignment before initial contact.	Examine ROM at ankle and knee and strength of pretibial muscles.

Table 7.5 Common Ankle and Foot Deviations[32,35]—cont'd

Deviation	Phase(s)	Description	Possible Causes	Analysis
Foot slap	Loading response	Forefoot "slaps" the ground following a heel first initial contact	Weak dorsiflexors or reciprocal inhibition of dorsiflexors.	Examine strength. Evaluate muscle activation timing of pretibial muscles.
Excess plantarflexion	Mid stance and/or terminal stance	Ankle fails to achieve 5° dorsiflexion at mid stance and/or 10° dorsiflexion at terminal stance	Plantarflexion contracture; overactivity or spasticity of the plantarflexors; could be intentional to avoid ankle and knee collapse if plantarflexors and vastii are weak.	Examine ROM and tone for plantarflexion contracture and plantarflexor tone (spasticity); examine strength of calf muscles and vastii. Evaluate if deviation may be intentional due to dual areas of weakness.
Excess dorsiflexion	Mid stance and/or terminal stance	Ankle collapses into more than 5° dorsiflexion at mid stance and/or more than 10° dorsiflexion at terminal stance	Inability of plantarflexors to control tibial advance. Knee flexion or hip flexion contractures.	Examine ROM and plantarflexor strength and for hip and knee flexion contractures.
Early heel rise	Mid stance	Heel comes off ground in mid stance	Spasticity or contracture of plantarflexors.	Examine ROM and tone for plantarflexor spasticity and contractures.
No heel off	Terminal stance and/or pre-swing	Heel fails to elevate from ground appropriately during terminal stance	Weak plantarflexors; weak invertors, which fail to lock midfoot in terminal stance; inadequate toe extension ROM; painful forefoot or toes.	Examine strength of plantarflexors and tibialis posterior; toe extension ROM, particularly the 1st metatarsal phalangeal joint; and for forefoot pain.
Toe clawing	Stance	Toes flex and "grab" floor	Spasticity of toe flexors; excessive activation of toe flexors to compensate for weakness of the gastrocnemius and soleus; plantar grasp reflex that is only partially integrated; positive supporting reflex.	Examine tone of toe flexors, strength of plantarflexors, and presence of primitive reflexes.
Excess inversion or eversion	Stance or swing	Subtalar joint is excessively inverted or everted in contrast to expected position	Excessive inversion: overactivity or contracture of invertors; reduced activity of evertors; primitive extensor pattern. Excessive eversion: overactivity or contracture of evertors; reduced activity or strength of invertors; primitive flexor pattern.	Examine strength and timing of lower extremity movements and tone; and for contractures.
Drag	Swing	Some portion of reference foot contacts ground during swing	Pretibial muscle weakness; plantarflexor spasticity or contractures; inadequate knee or hip flexion.	Examine ROM of ankle, knee, and hip; strength of muscles critical for limb clearance.

Table 7.6 Common Knee Deviations[32,35]

Deviation	Phase	Description	Possible Causes	Analysis
Excess knee flexion	All phases	Knee is in greater flexion than expected for the given phase	Knee flexor spasticity or contracture that exceeds position required for given phase; painful or effused knee; proprioceptive loss at knee; shorter LE on contralateral side. In addition, consider weak calf or hip flexion contracture if it occurs during single limb support.	Examine tone, spasticity, and ROM (contractures); and for pain, effusion, and proprioceptive loss at knee; leg length discrepancy.
Limited knee flexion	Loading response	Knee achieves less than expected 20° flexion	May be intentional to decrease demands on weak quadriceps; secondary to plantarflexor or quadriceps tone, spasticity or contracture; or proprioceptive impairment at knee.	Examine strength, tone, spasticity, of plantarflexors and quadriceps; plantarflexion and knee extension ROM; knee proprioception.
	Pre-swing and initial swing	Knee achieves less than expected flexion for given phase (i.e., 40° and 60° flexion, respectively)	May be secondary to plantarflexor tone, spasticity, or contracture that limits forward tibial progression in terminal stance; quadriceps tone, spasticity; proprioceptive impairment at knee; knee pain or effusion; calf weakness or hip flexion contracture that limits ability to achieve the trailing limb posture in terminal stance (a critical precursor to rapid knee flexion during pre-swing and initial swing). During initial swing, weakness of knee flexors also may contribute.	Examine tone and spasticity of plantarflexors, vastii, and rectus femoris; ROM and knee proprioception. Examine for pain and effusion. Examine plantarflexor strength and for hip flexion contracture. Evaluate if these factors may be inhibiting achievement of optimum limb posture.
Knee hyperextension	Stance	Extension of knee beyond anatomical neutral	Structural abnormality; may develop over time in presence of flaccid/weak quadriceps which is compensated for by excess plantarflexion and/or posterior pull on thigh by gluteus maximus; quadriceps spasticity, accommodation to a fixed plantarflexion deformity, or impaired proprioception can contribute to hyperextension if knee is exposed to deforming forces for extended duration.	Examine strength of vastii; tone, spasticity of plantarflexors and quadriceps; ROM and knee proprioception.
Wobble	Stance	Alternating flexion and extension at knee joint	Consider proprioceptive impairments or alternating spasticity of knee flexors and extensors.	Examine knee for proprioceptive impairments and spasticity.

Table 7.7 Common Hip Deviations[32,35]

Deviation	Phase(s)	Description	Possible Causes	Analysis
Excess flexion	Initial contact and loading response	Hip positioned in greater flexion (thigh relative to vertical) than expected for given phase	Single joint hip extensor weakness (gluteus maximus, adductor magnus) with compensation by hamstrings; severe hip and/or knee flexion contractures; hypertonicity of hip or knee flexors.	Examine single joint hip extensor and hamstring strength; hip and knee flexion range of motion (ROM), tone, and spasticity.
	Mid stance through pre-swing		Hip flexion or knee flexion contractures or spasticity; weak plantarflexors failing to control excess tibial advancement; painful or effused hip.	Examine tone and spasticity of hip and knee flexors; ROM of hip and knee; strength of plantarflexors and hip for joint pain.
	Swing		Compensatory to assist with limb clearance if limb is functionally too long; flexion synergy during swing resulting in too much flexion.	Examine for compensation, determine if ankle and knee of reference limb are achieving correct joint positions. Examine contralateral limb to determine if deviations are occurring on opposite side (e.g., excess stance dorsiflexion) could contribute to clearance problems on reference side.
Limited flexion	Initial contact, loading response, initial swing, mid swing, terminal swing	Hip positioned in less flexion (thigh relative to vertical) than expected for given phase	May be intentional to limit demand on weak hip extensors during loading response; weak hip flexors, or single joint hip extensor; hamstring spasticity or contracture limiting terminal swing advancement before initial contact.	Examine strength of hip flexors and extensors; ROM of hip and for spasticity of hip extensors and hamstrings.
Circumduction	Swing	Lateral circular movement of limb consisting initially of abduction, external rotation, followed by adduction and internal rotation in latter portion of swing	Compensation for weak hip flexors or for inability to shorten leg for limb clearance.	Examine strength of hip flexors, knee flexors, and ankle dorsiflexors; ROM in hip and knee flexion, and ankle dorsiflexion and for abnormal extensor pattern.
Internal rotation	All phases	Internal rotation of femur	Spasticity or contractures of internal rotators; weakness of external rotators; excessive forward rotation of contralateral pelvis.	Examine tone, internal rotation ROM, and strength of external rotators.
External rotation	All phases	External rotation of femur	Spasticity or contractures of external rotators; weakness of internal rotators.	Examine tone, external rotation ROM, and strength of internal rotators.
Abduction	All phases	Abducted position of femur relative to vertical	Contracture of the gluteus medius or iliotibial band; during swing, could be used to assist with foot clearance.	Examine hip abductor range of motion and for any factors that would necessitate compensatory assistance with clearance.
Adduction	All phases	Adducted position of femur relative to vertical	Hip adductor spasticity/ contracture. Excess contralateral pelvic drop.	Examine tone of hip flexors and adductors; muscle strength of hip abductors.

Table 7.8 Common Pelvis and Trunk Deviations[32,35]

Deviation	Phase(s)	Description	Possible Causes	Analysis
Backward trunk lean	Stance or swing	Posterior lean of the trunk relative to vertical	Purposeful to reduce demands on weakened stance limb gluteus maximus or to assist with limb advancement when hip flexion capability is limited.	Examine hip extensor and flexor strength.
Forward trunk lean	Primarily stance	Anterior lean of trunk relative to vertical	Compensation for quadriceps weakness. Forward lean reduces knee extensor moment and thus demand on vastii. May also be used to accommodate hip or knee flexion contractures.	Examine quadriceps strength and hip and knee for contractures.
Ipsilateral trunk lean	Most commonly occurs during reference limb stance	Lateral trunk lean toward reference extremity	Most commonly occurs during reference limb stance. Compensation for ipsilateral hip abductor weakness, hip joint pain, iliotibial band tightness, or scoliosis.	Examine ipsilateral gluteus medius strength; hip pain and ipsilateral iliotibial band tightness and for trunk ROM.
Contralateral trunk lean	Most commonly occurs during reference limb swing	Lateral trunk lean toward opposite extremity	May be used to assist with pelvic elevation to ensure foot clearance if reference limb is functionally too long (owing to deviations or leg length discrepancy). Compensation for contralateral hip abductor weakness, hip joint pain, iliotibial band tightness, or scoliosis.	Examine contralateral gluteus medius strength, hip pain and for iliotibial band tightness and for trunk ROM. Examine for factors contributing to swing limb being too long (e.g., limited knee flexion or excess plantarflexion during initial swing or a leg length discrepancy).
Contralateral pelvic drop	Stance	Drop of contralateral iliac crest below ipsilateral iliac crest	Ipsilateral hip abductor weakness, hip adductor spasticity, or hip adduction contracture.	Examine strength, flexibility, and tone of ipsilateral hip abductors and adductors.
Ipsilateral pelvic drop	Swing	Drop of ipsilateral iliac crest below contralateral iliac crest	Contralateral hip abductor weakness, hip adductor spasticity, or hip adduction contracture.	Examine strength, flexibility, and tone of contralateral hip abductors and adductors.
Pelvic hike	Swing	Elevation of ipsilateral iliac crest above contralateral iliac crest	Action of quadratus lumborum to assist with limb clearance when hip flexion, knee flexion, and/or ankle dorsiflexion are inadequate for limb clearance.	Examine strength and ROM at knee, hip, and ankle; examine muscle tone at knee and ankle.

4. Select the plane of observation that will be used first, either the sagittal plane (view from the side) or the coronal plane (view from the front and/or back) and which side of the patient's body (either right or left) will be observed first.
5. Observe the selected body segment at a specific phase (e.g., initial contact) and make a decision about the segment's joint position. Note any deviations from normal.
6. Observe either the same body segment during the next phase or another segment at the same phase (e.g., initial contact) of the gait period. As described in number 5 above, again make a decision about the segment's joint position. Note any deviations from normal.
7. Repeat the process described in number 6 above until you have completed an observation of all segments across all phases of the gait cycle in both the

sagittal and coronal planes. Remember to concentrate on one body segment or joint at a time during one phase of the gait cycle. Do not jump from one segment to another or from one phase to another.

8. Always perform observations on both sides (right and left). Although only one side may be involved pathologically, the other side of the body may be affected.
9. Hypothesize likely causes of gait deviations (e.g., impairments in strength, impairments in ROM, or spasticity).
10. Confirm likely causes of gait deviations based on physical therapy clinical evaluation.
11. Develop and implement a treatment plan to address key underlying causes of gait dysfunction.
12. Periodically use OGA to reassess the patient's gait and determine response to treatment.

OGA in Neuromuscular Disorders

The gait patterns of individuals with neuromuscular deficits are influenced primarily by weakness, abnormalities in muscle tone and synergistic organization, influences of nonintegrated early reflexes, diminished influence of righting and balance reactions, dissociation among body parts, and incoordination. If proximal stability (e.g., co-contraction of the postural muscles of the trunk) is threatened by atypically low, high, or fluctuating muscle tone, controlled mobility is lost. In gait, a loss of control over the sequential timing of muscular activity may result in asymmetrical step and stride lengths. In addition, deviations may occur such as forward or backward trunk leaning, excessive or decreased hip or knee flexion, or altered dorsiflexion or plantarflexion.

In the presence of multiple muscle involvement or neurological deficits that affect balance, coordination, and muscle tone, the deviations observed and the analysis of these deviations will be more complex than indicated in the tables. Examples of gait patterns associated with spasticity and with hypotonus follow.

An individual with spasticity (e.g., an individual with diplegic CP) may have a posteriorly tilted pelvis, forward flexion of the upper trunk, protracted scapulae, and somewhat excessive neck extension. Excessive hip flexion with adduction and internal rotation (scissoring) may be observed during stance and may be accompanied by either excessive knee flexion or hyperextension. During late stance, plantarflexor weakness may allow the ankle to collapse into excess dorsiflexion and the knee into excess flexion. Alternatively, the ankle may be positioned in excess dorsiflexion in late stance as a means of accommodating a knee flexion contracture or hamstring tightness/spasticity.

In other individuals with hypertonia, hyperextension at the knee occurs in stance and may be accompanied by plantarflexion and inversion at the ankle and foot. Electromyographic (EMG) recordings may show prolonged activity in the quadriceps and in the gastrocnemius-soleus muscle group. The hamstring, gluteal, and dorsiflexor muscle groups may be reciprocally inhibited.

In individuals with low muscle tone (hypotonia) in the trunk, core stability (tonic extension and co-contraction of axial muscles) is diminished. The pelvis may be anteriorly tilted so that the upper trunk is slightly extended. The scapulae may be retracted and the head may be forward. During stance, the hip may be flexed and the knee may be hyperextended, accompanied by ankle plantarflexion. The foot may be pronated with the majority of body weight borne on the medial border. Frequently, these individuals show diminished longitudinal trunk rotation and sluggish trunk balance reactions. They tend to rely on protective extension reactions of the limbs to maintain balance. The staggering or stepping reactions of the LEs may be pronounced, stride length and step length may be uneven, and gait may be wide based and unsteady.

Although neurological gait patterns may be complex and an analysis of the causes may be difficult, a detailed OGA can provide valuable data. Generally, to analyze gait patterns in persons who have sustained neurological damage, the following preliminary questions must be asked:

1. What is the influence of abnormal tone (hypertonicity, hypotonicity, fluctuating tone) on joint position and movement?
2. How does the position of the head influence muscle tone, position, and movement?
3. How does weight-bearing influence muscle tone, position, and movement?
4. What is the influence of abnormal (obligatory) synergistic activity on position and movement?
5. What is the impact of weakness (paresis) on position and movement?
6. How do coordination impairments affect position and movement?
7. What is the influence of impaired balance reactions on position and movement?
8. How do contractures alter position and movement?
9. What is the impact of sensory loss (e.g., proprioceptive, visual, vestibular) on position and movement?

Ambulation Profiles and Scales

Profiles and rating scales constitute types of gait analyses that often include both qualitative (observational) and quantitative (spatial and temporal) measures. Profiles and scales are used for a variety of reasons, for example, examination of ambulation skills,[51,52] determination of the patient's need for assistance, identification of a change in a patient's status,[52] screening for identification of the patient's need for physical therapy,[53] and identification of individuals (e.g., older adults) who are at risk for falling.[25,26] Gait analyses of one type or another may be either the sole focus of a profile, or the

gait analysis may constitute only a small portion of a broad examination profile that includes balance skills and other functional activities. One particular advantage of some of these profiles is that subordinate gait skills such as standing balance may be examined in individuals who may be unable to walk independently. Since many of these profiles were developed for use with specific populations, comparative data may be available to the therapist.

The following profiles have been selected for review in this chapter because they are in current use and have been examined for reliability and/or validity: the Functional Ambulation Profile;[51] the Emory Functional Ambulation Profile[54] and the Modified Emory Functional Ambulation Profile;[55] the Iowa Level of Assistance Score;[56] the Functional Independence Measure;[57] the Functional Independence Measure plus the Functional Assessment Measure;[58,59] the Community Balance and Mobility Scale;[52,60,61] the Gait Abnormality Rating Scale (GARS)[62] and the Modified GARS;[25] the Dynamic Gait Index;[63-65] the Functional Gait Assessment;[66-70] the High-Level Mobility Assessment Tool;[71-76] the Fast Evaluation of Mobility, Balance, and Fear;[77] and the Figure-of-8 Walk Test.[78]

Functional Ambulation Profile and Modifications

The *Functional Ambulation Profile* (FAP), developed by Arthur J. Nelson, PT, PhD, FAPTA, is designed to examine gait skills on a continuum from standing balance in the parallel bars to independent ambulation.[51] A stopwatch is used to measure the amount of time required either to maintain a position or perform a task. The test consists of three phases. In the first phase, the patient is asked to perform three tasks in the parallel bars: bilateral stance, uninvolved leg stance, and involved leg stance. In the second phase, the patient is asked to transfer weight from one LE to the other as rapidly as possible. In the third phase, the patient is asked to walk 20 ft (6 m) in the parallel bars, with an assistive device, and, if possible, independently. Wolf et al[54] evaluated the tool's reliability and validity in a study of 56 adults (28 with stroke and 28 without). The authors reported high interrater reliability ((0.997) between two examiners who rated subjects' test performance. Construct validity was supported based on the test's ability to distinguish between those with and without a stroke. Concurrent validity was demonstrated by strong correlations with participants' outcomes on the Timed 10-meter Walk Test and the Berg Balance Scale. A more recent version of the FAP developed at Emory University is called the *Emory Functional Ambulation Profile* (EFAP).[54] This profile differs from the original FAP in that five environmental challenges have been added. The individual may negotiate the environmental challenges with or without the use of orthotics or assistive devices.

The *Modified Emory Functional Ambulation Profile*[55] (mEFAP) incorporates manual assistance into the EFAP. Subtasks include 16.4-ft (5-m) walks on a hard floor and on a carpeted floor, rising from a chair and completing a 9.8-ft (3-m) walk and sitting back down, negotiating through a standardized obstacle course and ascending and descending five stairs. Liaw et al[79] evaluated the psychometric properties of the mEFAP in 40 individuals during the early phase of stroke recovery and 20 individuals with chronic strokes. The authors concluded that the mEFAP had good reliability, validity, and responsiveness for assessing walking function in patients with stroke undergoing rehabilitation.

Iowa Level of Assistance Scale

The *Iowa Level of Assistance Scale* (ILAS)[56] examines four functional tasks: getting out of bed, standing from bed, ambulating 15 ft (4.57 m), and walking up and down three steps. The patient's performance on the tasks is rated according to the following seven levels: (1) not tested for safety reasons; (2) activity attempted but not completed; (3) maximum assistance (therapist applies three or more points of contact); (4) moderate assistance (therapist applies two points of contact); (5) minimal assistance (therapist provides one point of contact); (6) standby assistance (no therapist contact but therapist not comfortable leaving patient); and (7) independence (therapist comfortable leaving room). Shields et al[56] examined the reliability, validity, and responsiveness of the ILAS in 86 inpatients recovering from total hip or knee replacements and reported good intratester ($k = 0.79$ to 0.90) and moderate intertester ($k = 0.48$ to 0.78) reliability. Scores on the tool correlated highly with Harris Hip Rating Scale scores ($r = -.86$).

Functional Independence Measure

The *Functional Independence Measure* (FIM) was created as part of a project funded by the National Institute of Handicapped Research (NIHR), designed to develop the Guide for a Uniform Data Set for Medical Rehabilitation.[80] The FIM is an 18-item measure that examines elements of a patient's physical, psychosocial, and social function. The FIM is now proprietary, and is the trademark (FIM™) of the Uniform Data System for Medical Rehabilitation, a division of the University of Buffalo Foundation Activities, Inc. (see Chapter 8, Examination of Function, for further discussion of the FIM). The FIM Locomotion: Walk/Wheelchair Guide is the portion of the document titled *Guide for the Uniform Data Set (Including the FIM™ instrument)* related to gait and includes a seven-point level of assistance rating scale ranging from complete independence to total assistance (Table 7.9). A study designed to evaluate the accuracy of clinical judgments of patient functioning found that bias and poor judgment of a

Table 7.9 The Functional Independence Measure (FIM™) Instrument Seven-Point Scoring System for Locomotion—Version 5.1

LOCOMOTION: WALK/WHEELCHAIR: Includes walking, once in a standing position, or if using a wheelchair, once in a seated position, on a level surface. Performs safely. Indicate the most frequent mode of locomotion (Walk or Wheelchair). If both are used about equally, code: "Both."

NO HELPER

7 Complete Independence—Subject walks a minimum of 150 ft (50 m) without assistive devices. Does not use a wheelchair. Performs safely.

6 Modified Independence—Subject *walks* a minimum of *150* ft (50 m) but uses a brace (orthosis) or prosthesis on leg, special adaptive shoes, cane, crutches, or walkerette; takes more than reasonable time or there are safety considerations.

If not walking, subject operates manual or motorized wheelchair independently for a minimum of *150* ft (50 m); turns around; maneuvers the chair to a table, bed, toilet; negotiates at least a 3% grade; maneuvers on rugs and over door sills.

5 Exception (Household Ambulation)—Subject walks only short distances (a minimum of *50* ft or 17 m) *independently* with or without a device. Takes more than reasonable time, or there are safety considerations, or operates a manual or motorized wheelchair independently only short distances (a minimum of *50* ft or 17 m).

HELPER

5 Supervision

If walking, subject requires standby supervision, cueing, or coaxing to go a minimum of *150* ft (50 m).

If not walking, requires standby supervision, cueing, or coaxing to go a minimum of *150* ft (50 m) in wheelchair.

4 Minimal Contact Assistance—Subject performs 75% or more of locomotion effort to go a minimum of *150* ft (50 m).

3 Moderate Assistance—Subject performs 50% to 74% of locomotion effort to go a minimum of *150* ft (50 m).

2 Maximal Assistance—Subject performs 25% to 49% of locomotion effort to go a minimum of *50* ft (17 m). Requires assistance of one person only.

1 Total Assistance—Subject performs less than 25% of effort, or requires assistance of two people, or does not walk or wheel a minimum of *50* ft (17 m).

Comment: If the subject requires an assistive device for locomotion (wheelchair, prosthesis, walker, cane, AFO, adapted shoe, and so forth), the Walk/Wheelchair score can never be higher than level 6. The mode of locomotion (Walk or Wheelchair) must be the same on admission and discharge. If the subject changes mode of locomotion from admission to discharge (usually wheelchair to walking), record the admission mode and scores based on the *more frequent mode of locomotion at discharge.*

From The Uniform Data System for Medical Rehabilitation, a division of UB Foundation Activities, Inc. (UDS_{MR}^{SM}). Guide for the Uniform Data Set for Medical Rehabilitation (Including the FIM™ Instrument), Version 5.1, Buffalo: UDSMR, 1997, with permission.

patient's functional level played a significant role in 50 rehabilitation professionals' ratings of patient functioning. The authors of the study suggested that blind ratings of the FIM and training in eliminating bias would improve accuracy.[81]

Functional Assessment Measure

The 12-item *Functional Assessment Measure* (FAM) was developed by a multidisciplinary group of clinicians at Santa Clara Valley Medical Center, San Jose, California,[58] to provide a measure of disability that reflected the communication, psychosocial adjustment, and cognitive functions of the populations of individuals who sustained traumatic brain injury (TBI) and stroke. The FAM uses a seven-point rating scale modeled after the FIM to examine the individual's level or degree of independence, amount of assistance required, use of adaptive or assistive devices, and percentage of tasks completed successfully (Table 7.10).[82]

The 12 items of the FAM have been combined with the 18-item FIM to produce the FIM + FAM with the intent of providing more detailed data for TBI[59] and stroke populations. The FIM and FIM + FAM total scales are psychometrically similar measures of global disability whereas the Barthel Index, FIM, and FIM + FAM motor scales are similar measures of physical disability.[83] However, in a study of 376 patients with stroke in Canadian inpatient rehabilitation units who were concurrently given

Table 7.10 The Functional Assessment Measure (FAM) Items

1. Swallowing	7. Emotional Status
2. Car Transfer	8. Adjustment to Limitations
3. Community Access	9. Employability
4. Reading	10. Orientation
5. Writing	11. Attention
6. Speech Intelligibility	12. Safety Judgment

The 12 items of the FAM are not designed to stand alone but to be added to the 18 items of the FIM to produce the FIM + FAM.

Courtesy of Santa Clara Valley Medical Center (1998). The Functional Assessment Measure. The Center for Outcome Measurement in Brain Injury. Retrieved June 14, 2011, from http://tbims.org/combi/FAM.

the FIM and the FAM, the results of a Rasch analysis showed that in the motor domain, only the FAM community access item was more difficult for subjects to accomplish than the FIM items. In the cognitive domain, the only FAM item that extended the range of the FIM was the one assessing employability. In light of the results, Linn et al[84] concluded that adding the FAM items to the FIM reduced test efficiency and provided only minimal protection against ceiling effects of the FIM.

Community Balance and Mobility Scale

The *Community Balance and Mobility Scale*[52] was developed to evaluate balance and mobility skills in individuals who have experienced mild to moderate TBI. The scale consists of 13 items that include opportunities to assess multitasking (e.g., walking and looking at a target placed to the right or left), sequencing of movements (crouching to pick up an object from the floor and then continuing to walk), and complex motor skills (laterally and rapidly moving sideways by crossing one foot over the other and having to respond to unexpected commands to change direction). Six items are performed on both the right and left side, each of which is rated on a 6-point scale from 0 (poorest performance) through 5 (best performance).[52,60] Although the tool was developed specifically for assessment of individuals who have sustained mild to moderate TBI, it also has been used to measure balance and mobility in community-dwelling individuals following a stroke and in those with varying severity of chronic obstructive pulmonary disease (COPD).[52,60,61]

Gait Abnormality Rating Scale and Modifications

The *Gait Abnormality Rating Scale* (GARS)[62] was designed to distinguish nursing home residents with a recent history of two or more falls from a control group of residents without a recent fall history. The test developers selected 16 features of the gait cycle and a scoring system, in which the features are scored on a 0 to 3 rating scale (0 = normal, 1 = mildly impaired, 2 = moderately impaired, and 3 = severely impaired). Among the 16 features rated, arm-swing amplitude, upper extremity (UE) and LE synchrony, and guardedness best distinguished fallers from other subjects. The distinguishing features could be used to identify residents at risk for falling. Time, space, and resources are often very limited in nursing homes, and the only expenses involved in administering the GARS include purchase of a digital video recorder, recording media, and the therapist's time to film, review, and rate the digital recordings. However, the GARS does not provide information regarding the type of falls (trips, slips, losing balance) sustained by this population.[62] Therefore, it is not helpful in determining the cause of falls.

The *Modified GARS* (GARS-M), which is a seven-item version of the GARS, contains the following variables: (1) variability, (2) guardedness, (3) staggering, (4) foot contact, (5) hip ROM, (6) shoulder extension, and (7) arm–heel strike synchrony. These variables were selected for inclusion because they were found to be the most reliable in the original GARS. Scoring is the sum of the seven items; the total score represents a rank ordering for risk of falling based on the number of gait abnormalities recognized and the severity of any abnormality identified. A higher score is associated with a more abnormal gait. Similar to the GARS, the GARS-M scores distinguished between older adults with a history of falling and those individuals who had no fall history. The GARS-M has been deemed a good predictor for persons at risk for falls.[25]

Dynamic Gait Index

The *Dynamic Gait Index* (DGI) was designed to examine the ability to adapt gait to changes in task demands. The tool was initially developed for use in community-dwelling older adults with balance and vestibular disorders,[85] but has since been used across a variety of ages and patient populations.[86] The DGI uses a 0 (severe impairment) to 3 (normal) scale to rate performance on eight items, including gait on even surfaces, gait while changing speeds, gait and head turns in a vertical or horizontal direction, stepping over obstacles, and gait with pivot turns and steps. Whitney et al[85] evaluated DGI scores and fall history in adults with vestibular disorders and reported that the odds of falling within the past 6 months were 2.58-fold higher with DGI scores of 19 or lower.[85] The tool has since been used to evaluate dynamic gait and balance in a variety of patient populations, including individuals with Parkinson disease,[87] stroke,[64] and multiple sclerosis.[88]

The *Four-Item Dynamic Gait Index* consists of only half of the original eight DGI items (i.e., gait on level surfaces, changes in gait speed, and horizontal and vertical head turn activities).[65] It is faster to administer and displays adequate capacity to differentiate between individuals with and without balance and vestibular disease.

Functional Gait Assessment

The *Functional Gait Assessment* (FGA) is another modification of the original eight-item DGI. It was developed to address some of the ceiling effect attributes of the DGI when used with individuals with vestibular disorders and to clarify instructions and operational definitions associated with administering the tool.[69] Seven of the eight original DGI tasks were preserved, and three new items were added: gait with a narrow base of support, ambulating backwards, and gait with eyes closed. In a study assessing age-referenced norms for FGA performance in independently living adults between the ages of 40 and 89 years, the tool was found to have excellent interrater reliability (ICC = 0.93).[68] In addition, intrarater reliability and interrater reliability were deemed adequate given seven physical therapists' and three physical therapist students'

repeated ratings of six patients with vestibular disorders (total FGA score reliability: intrarater = 0.83; interrater = 0.84).[69] Use of a threshold FGA score of 20/30 or less correctly predicted the unexplained falls experienced by six participants during a 6-month follow-up period in a study of community-dwelling 60- to 90-year-olds.[67] However, the authors recommend use of a threshold score of 22/30 or less as a more conservative criterion for those at risk for falls. The FGA has been used in studies of specific patient populations, including Parkinson disease[66] and stroke.[70]

High-Level Mobility Assessment Tool

The *High-Level Mobility Assessment Tool* (HiMAT) was designed to measure high-level mobility skills required for employment and social roles, as well as leisure and sporting activities for younger adults recovering from a TBI.[73] The tool consists of 13 items, and requires only a stopwatch, a 14-step staircase, inked moleskin markers, a brick-size object, and a tape measure to complete.[71,72] Tasks assessed include walking (forward, backward, on toes, over an obstacle, in a figure 8), running, a run stop, skipping, hopping forward, bounding (affected and nonaffected), and going up and down stairs with and without a railing. All items are marked on a five-point scale (0 = unable to perform to 4 = performing item normally) except for two stair items that are rated on a six-point scale (0 to 5). The maximum achievable score is 54. The tool is only appropriate for patients able to ambulate independently for at least 20 meters without an assistive device. Thus, it is most appropriate for higher-functioning patients, such as those in the latter stages of an inpatient rehabilitation program or already living in the community. Interrater reliability and test-retest reliability are high (both ICCs = 0.99).[74] Between-day testing scores demonstrated a small improvement over the 24 hours (1 point), suggestive of improved performance with test familiarity. This highlights the importance of allowing patients an opportunity to practice the test at least once before scoring.

The original 13-item HiMAT has been revised to a shorter, faster to administer version that includes only eight items: walk (forward, backward, toes, obstacle), run, skip, hop, and bound on the nonaffected LE.[76] One key difference between the two versions is that stair items were eliminated. This addresses a challenge clinicians experience when trying to administer the 13-item HiMAT test in environments lacking a 14-step staircase. Because it was the easiest item on the original scale, elimination of stairs is not expected to influence assessment of high-level mobility skills. However, it is possible that the tool may be more susceptible to a floor effect because it is less able to distinguish between abilities of more severely disabled individuals.

Fast Evaluation of Mobility, Balance, and Fear

The *Fast Evaluation of Mobility, Balance, and Fear* (FEMBAF) is another instrument designed to identify risk factors, functional performance, and factors that hinder mobility.[77] It consists of a 22-item risk factor questionnaire and an 18-item performance component, which includes, among other measures, stair ascent and descent, stepping over an obstacle, and one-legged standing. Di Fabio and Seay[77] reported that the FEMBAF served as a valid and reliable measurement of risk factors, functional performance, and factors that hinder mobility in their study of 35 community-dwelling older adults.

Figure-of-8 Walk Test

Many measures of overground walking focus primarily on gait performed along a straight path (e.g., the 5-meter walk test). In contrast, the *Figure-of-8 Walk Test* (F8W)[78] was developed to assess both curved and straight path walking in older adults with walking difficulties. The number of steps, total time, and smoothness of movement are examined as an individual completes a single figure-of-8 walk around two cones spaced 5 ft apart (Fig. 7.7). In a study of performance on the F8W in 51 older community-dwelling adults with walking difficulty, Hess et al[78] reported significant correlations between the time to complete the F8W and overground gait speed, the GARS-M score, select physical function and efficacy measures, step length and width variability, and measures of executive function (i.e., the Trail Making Test B, Trails B). The number of steps required to complete the F8W correlated significantly with gait speed, select physical function and efficacy measures, step width variability, and performance on the Trails B. Movement smoothness correlated significantly only with step width variability.

Figure 7.7 Individual performing the Figure-of-8 Walk Test, a tool developed to quantify walking ability in older adults with mobility disorders. Time to complete, number of steps, and smoothness of movement are used to score an individual's walking performance of a single figure-of-8 path around two cones spaced 5 feet apart.

Kinematic Quantitative Gait Analysis

Kinematic quantitative gait analysis is used to obtain information on spatial and temporal gait variables, as well as motion patterns. The data obtained through these analyses are quantifiable and therefore provide the therapist with baseline data that can be used to plan treatment programs and evaluate progress toward goals or goal attainment. The fact that the data are quantifiable is important because third-party payers are demanding that therapists use measurable parameters when examining patient function, establishing treatment strategies, and documenting outcomes. However, data derived from qualitative observations may be necessary to determine degrees of motor impairment and to determine the validity of the quantitative variables measured.

Spatial and temporal measures may be critical factors in determining a patient's independence in ambulation. For example, a patient may need to attain a certain gait speed to cross a local street within the time allotted by a crossing light, or a patient may need to walk a certain distance to shop in the local supermarket. In a study of walking capability of individuals greater than 3-months post-stroke, Perry et al[89] established that walking speed was a valid predictor of community walking status. Speeds of less than 79 ft/min (24 m/min) predicted household walking, and speeds between 79 and 157 ft/min (24 and 48 m/min) predicted limited community walking status. The ability to walk faster than 157 ft/min (48 m/min) predicted unlimited community walking. It is interesting to note that the mean velocity of the community ambulators was only 60% of the 262 ft/min (80 m/min) average velocity of typical, nondisabled adults.[32] This slower velocity is sufficient for many typical activities that individuals recovering from a stroke may need to perform, yet is less than the normal capacity required to cross a wide commercial street within the traffic signal time.[90] In a study by Graham et al[91] of 174 ambulatory adults 65 years of age and older who were admitted to a medical-surgical unit, an even slower walking velocity (69 ft/min [21 m/min]) was identified as a meaningful threshold to differentiate those capable of independent ambulation in a hospital setting from those requiring assistance.

Therapists need to survey the community to determine the distances and time requirements for accessing stores and public buildings before making a judgment about a patient's functional ambulation status. Robinett and Vondran[92] found that target goals on a sample of gait analysis forms were low compared to distance and velocity requirements for crossing the street found in a community survey. Walsh et al[93] reported that individuals 1 year after total knee arthroplasty (TKA) achieved more than 80% of the normal walking speeds of their age- and gender-matched counterparts. However, for 62% of the females and 25% of the males, the normal walking speed attained would not be sufficient to cross a street intersection safely.

Spatial and Temporal Variables

The variables measured in a quantitative gait analysis are listed and described in Table 7.11. Because spatial and temporal variables are affected by a number of factors such as age,[94-98] gender,[99,100] height and weight,[101,102] level of physical activity,[103,104] and level of maturation,[105] attempts have been made to take some of these factors into account. Ratios, such as stride-length divided by functional leg length, may be used to normalize for differences in patients' leg lengths. Step length divided by the subject's height is a method sometimes used to normalize differences among patients' heights. In an attempt to control for both height and weight, body weight is divided by standing height to yield the **body mass index (BMI)**. Other ratios are used to assess symmetry, for example, right swing time divided by left swing time and swing time divided by stance time. Sutherland et al[105] listed the ratio of pelvic span to ankle spread as one of the determinants of development of mature gait in children.

Measurement of Spatial and Temporal Variables

The techniques and equipment required for measurement of spatial and temporal variables range from simple to complex. The time requirements also vary, and the therapist must be familiar with different methods of examining these variables in order to select the method most appropriate to each situation. Before selecting a measurement method, the therapist must understand the variable in question and how that variable is related to the patient's gait.

Simple Methods of Measuring Spatial and Temporal Variables

Measurement of spatial variables such as degree of foot angle, width of base of support (BOS), step length, and stride length can be determined simply and inexpensively by recording the patient's footprints during gait. Simple methods of recording footprints include either the application of paints, ink, or chalk to the bottom of the patient's foot or shoe. For example, ink-soaked patches[106] and felt-tipped markers[107] have been attached to the bottom or back of patient's shoes to measure variables such as step length, stride length, step width, and foot angle.

Another way of obtaining step length and stride length data is by placing a grid pattern on the floor.[108] Masking tape is placed on the floor to create a straight-line grid pattern about 1 ft (30 cm) wide and 32 ft (10 m) long. The tape is marked off in 1-in (3-cm) increments for its entire length, and the segments are numbered consecutively so that the patient's heel strikes can be identified. The therapist then calls out the heel strike locations from the numbers on the grid pattern into a tape recorder.

Many variables, such as velocity, stride length, step length, and cadence, may be calculated by using a stop watch to measure the elapsed time required for a

Table 7.11 Gait Variables: Quantitative Gait Analysis

Variable	Description
Speed	A scalar quantity that has magnitude but not direction.
Free speed	A person's normal walking speed.
Slow speed	A speed slower than a person's normal speed.
Fast speed	A rate faster than normal.
Cadence	The number of steps taken per unit of time (e.g., steps/minute).
	Cadence = Number of steps ÷ Time A simple method of measuring cadence is by counting the number of steps taken in a given amount of time. The only equipment necessary is a stopwatch, paper, and pencil. The average cadence of adult women (117 steps/min) is slightly higher than of adult men (111 steps/min).[3]
Velocity **Linear velocity** **Angular velocity** **Walking velocity**	A measure of a body's motion in a given direction. The rate at which a body moves in a straight line. The rate of rotation of a body segment around an axis. The rate of linear forward motion of the body. This is measured in either centimeters per second or meters per minute. To obtain a person's walking velocity, divide the distance traversed by the time required to complete the distance. Walking velocity = Distance ÷ Time Walking velocity may be affected by age, level of maturation, height, gender, type of footwear, and weight. Also, velocity may affect cadence, step, stride length, and foot angle as well as other gait variables. The average self-selected walking velocity of 20 to 85 year old males (86 m/min) is slightly faster than similar aged females (77 m/min).[32]
Acceleration	The rate of change of velocity with respect to time. Acceleration is usually measured in meters per second per second (m/s^2).
Angular acceleration	The rate of change of the angular velocity of a body with respect to time. Angular acceleration is usually measured in radians per second per second ($radians/s^2$).
Stride time	The amount of time that elapses during one stride; that is, from one foot contact (heel strike if possible) until the next contact of the same foot (heel strike). Both stride times should be measured. Measurement is usually in seconds.
Step time	The amount of time that elapses between consecutive right and left foot contacts (heel strikes). Both right and left step times should be measured. Measurement is in seconds.
Stride length	The linear distance between two successive points of contact of the same foot. It is measured in centimeters or meters. The average stride length for normal adult males is 1.46 meters.[32] The average stride length for adult females is 1.28 meters.[3]
Swing time	The amount of time during the gait cycle that one foot is off the ground. Swing time should be measured separately for right and left extremities. Measurement is in seconds.
Double support time	The amount of time spent in the gait cycle when both lower extremities are in contact with the supporting surface. Measured in seconds.
Cycle time (stride time)	The amount of time required to complete a gait cycle. Measured in seconds.
Step length	The linear distance between two successive points of contact of the right and left lower extremities. Usually a measurement is taken from the point of heel contact at initial contact of one extremity to the point of heel contact of the opposite extremity. If a patient does not have a heel strike on one or both sides, the measurement can be taken from the heads of the first metatarsals. Measured in centimeters or meters.
Width of walking base (step width)	The width of the walking base (base of support) is the linear distance (in the frontal plane) between one foot and the opposite foot. Measured in centimeters or meters.

Continued

Table 7.11 Gait Variables: Quantitative Gait Analysis—cont'd

Variable	Description
Foot angle (degree of toe out or toe in)	The angle of foot placement with respect to the line of progression. Measured in degrees.
Bilateral stance time (for the FAP)	The length of time up to 30 seconds that a person can stand upright in the parallel bars bearing weight on both lower extremities.
Uninvolved stance time (for the FAP)	The length of time up to 30 seconds that an individual can stand in the parallel bars while bearing weight on the uninvolved lower extremity (involved extremity is raised off the supporting surface).
Involved stance time (for the FAP)	The length of time up to 30 seconds that an individual can stand in the parallel bars on the involved lower extremity (uninvolved lower extremity is raised off the supporting surface).
Dynamic weight transfer rate (for the FAP)	The rate at which an individual standing in the parallel bars can transfer weight from one extremity to another. Measured in seconds from the first lift-off to the last lift-off.
Parallel bar ambulation (for the FAP)	Length of time required for an individual to walk the length of the parallel bars as rapidly as possible. Two trials are averaged to obtain this measurement. Measurement is in seconds.

FAP = Functional Ambulation Profile.

patient to walk a known distance and recording the number of right and left steps during that same period (see Table 7.11). If assessing variables across a short distance (e.g., 20 or 30 ft [6 or 10 m]), patients are often positioned a few steps before the "start line" so that they can achieve a steady state for the data collection.[75,106] They are also encouraged to walk a few steps beyond the "finish line." The "rolling start and finish" mitigates the influence of slow velocities at the initiation and termination of a walk on overall values compared to the "standing start and finish."[75]

Todd et al[98] tested 84 normal children (41 girls and 43 boys) ages 13 months to 12 years, and analyzed data from more than 200 other children ages 11 months to 16 years. A two-dimensional gait graph was developed that provides a visual record of a child's walking performance. Although the gait graph is similar in appearance to graphs used for height and weight, it shows norms for gait dimensions of cadence and stride length adjusted by height (Fig. 7.8).

Two relatively simple and standardized methods that have been used to quantify walking speed in the clinical setting are the *6-Minute Walk Test* (6MWT) and the *10-Meter Walk Test* (10MWT). A stopwatch and tape measure are the tools required to complete the tests. A form for recording temporal and spatial gait parameters is presented in Appendix 7.B.

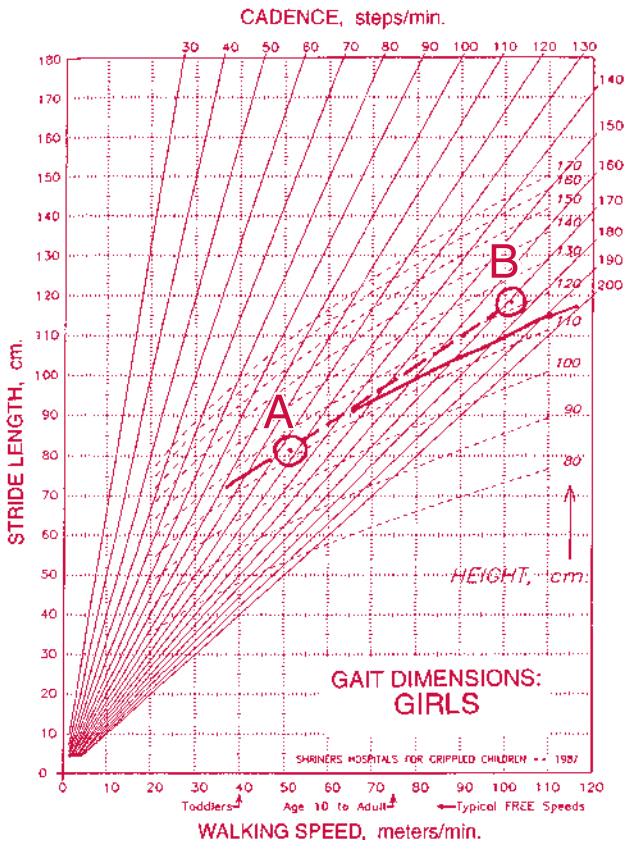

Figure 7.8 The solid line on the gait graph represents normal parameters for height. The dashed line represents data plotted for a normal 6-year-old girl whose height was 45 in (114 cm). A similar chart is available for boys. *(From Todd et al,[98, p. 201] with permission.)*

6-Minute Walk Test

In the 6MWT,[109,110] the distance covered walking at a comfortable pace for 6 minutes is determined. Whereas the tool was initially used as a measure of endurance and

exercise capacity for individuals with cardiac and pulmonary pathology,[109,110] it has since been used to assess walking endurance in clients with a variety of underlying conditions, including Parkinson's disease,[111] acquired brain injury,[112] and stroke.[113] One protocol for performing the 6MWT includes asking clients to walk as far as they can at their usual pace for 6 minutes while using their customary assistive devices and orthotics.[114] Clients walk in a tight oval path around two chairs spaced 18 meters apart, facilitating calculation of the overall distance traveled. Participants stop and rest as needed, but the stopwatch continues. Standardized encouragement is provided periodically. The final distance walked (in meters) is divided by either 6 to determine average velocity in m/min or by 360 if reporting as m/sec.

This simple test, used in combination with other physical performance and impairment measures (e.g., ROM and muscle strength), can either monitor decline or evaluate improvement associated with treatment interventions. Mossberg[112] found that the 6MWT was a reliable measure of functional ambulation (distance walked) for patients with acquired brain injury. Fulk et al[113] identified that the 6MWT score served as a significant predictor of the average number of steps taken per day by community-dwelling individuals with chronic stroke, accounting for 46% of the variance in community walking activity.

Numerous prediction equations have been developed to estimate the expected 6-minute walk distance based on factors such as height, age, weight, and heart rate; however, these equations have accounted for only 20% to 78% of the variance in 6MWT distances in individuals without known disability.[115-122] Variations in the procedures used across studies, as well as variability in the ages studied, likely contributed to differences in predicted outcomes for the distance walked in 6 minutes. Factors that appear to improve reliability between testing sessions include standardizing the instructions given to the patient, the type and amount of verbal encouragement, and the location of testing (e.g., a long corridor or a circular track).[75,115,123] These factors, as well as other patient characteristics such as age, height, weight, and even ethnicity,[115,119,122] should be considered when comparing a patient's value to normative data.

Alternative tests for individuals with limited endurance include the *2-Minute Walk Test*[124,125] and *3-Minute Walk Test*.[63] A *12-Minute Walk Test* also is available for individuals with greater endurance.[110,124]

Timed Walk Tests (5 m, 10 m, and 30 m)

Timed walked tests measure how long it takes to walk a specified distance and then use these data to calculate an average walking speed. Different distances have been used, including 5 m,[126,127] 10 m,[125,128-130] and 30 m.[130] One common protocol for performing a 10-m timed walk test is to have the client ambulate across a 14-m walkway using his or her traditional assistive and LE orthotic devices.[114] The time (seconds) required to traverse the middle 10 m of the walkway is recorded with a stopwatch. Two repetitions are completed at the client's preferred comfortable speed and at a fast pace. Speed (m/sec) is calculated by dividing 10 m by the time (in seconds) required to traverse the path. To determine speed in m/min, the previously calculated speed is multiplied by 60. Average cadence and stride length also can be calculated by recording the number of steps required to traverse the 10 m. Physiological responses (e.g., heart rate, blood pressure, respiratory rate) can be monitored immediately before and after the walking trial.

Despite efforts to standardize the test, some variability still is evident in the published literature, including the path taken (i.e., straight line versus a turn), use of assistive devices, speed (self-selected comfortable versus fast), and use of a rolling start and finish (i.e., capacity to take a few steps before and after start and finish lines, respectively) versus a standing start and finish.[75] Thus, when comparing a patient's speed to published normative data, consideration should be given to procedures used.

Low-Cost Instrumentation for Quantifying Spatial and Temporal Variables

Accelerometers During walking, the body generates forces that can be measured using an **accelerometer**. These data can then be used to calculate spatial and temporal gait features such as cadence, step symmetry, step duration, and stride duration. The methods for measuring the acceleration forces vary widely (e.g., strain gauge, piezoresistive, capacitive, and piezoelectric), but in general, many of these devices provide an affordable, noninvasive, easy to apply means for quantifying select gait characteristics over extended periods (days to weeks) in the home and community.[131]

Triaxial accelerometers have been attached to the trunk in order to measure mean acceleration, cadences, and step and stride lengths.[132-136] Accelerometers have also been attached to the head and pelvis to determine acceleration patterns of these anatomical regions while subjects walked on different surfaces.[137] Simultaneous use of multiple accelerometers has enabled successful differentiation of locomotor activities. For example, one system used five accelerometers (one on each foot and thigh, and one on the sternum) to differentiate walking speeds (slow, medium, and fast) and types of activities (e.g., walking, stair negotiation, running, and jumping) with a high level of accuracy (greater than 94%) in 69 participants free of any known impairments of the locomotor system.[138]

The accuracy of accelerometer data can be impacted by a number of factors.[131,138,139] Devices need to be oriented correctly in relation to the manufacturer's specifications, otherwise the acceleration signals may not correspond correctly with the direction of movement, and interpretation will be confounded. Significant adipose tissue, upper extremity (UE) movement to use assistive devices, or excessively loose mounting of the device can introduce movement artifact into the signal, again confounding

interpretation. Finally, in patient populations, the acceleration signals may be altered if pathology disrupts normal foot-floor contact patterns or contributes to abnormal alignment of body parts (e.g., the impact of a persistent forward trunk lean on a trunk-mounted accelerometer in an individual with Parkinson's disease).[131]

The Step Watch Activity Monitor 3™ (SAM) is on example of a commercially available accelerometer.[140-144] It records the number of strides taken in 1-minute intervals during daily activities for up to 15 consecutive days. The SAM includes a sensor (custom accelerometer) that measures 0.30 × 2 × 0.80 in (7.5 × 50 × 20 mm) and weighs approximately 1.3 oz (37 g) (Fig. 7.9). The battery provides up to 4 to 5 years of continual use.[145] The case is contoured to fit just above the lateral malleolus and is attached by an elastic strap. A personal computer is used to set up the SAM for monitoring, and also for downloading data to a computer file. Michael et al[141] used the SAM to evaluate the walking capacity of adults in the chronic phase of stroke recovery and identified significantly reduced step frequency (mean = 2,837 steps/day) compared to sedentary older adults (5,000 to 6,000 steps/day).

Gyroscopes *Gyroscopes* are another type of instrument that may be used for the estimation of spatial and temporal gait parameters. The gyroscope measures the Coriolis acceleration of a vibrating triangular prism. The signal from the prism is proportional to the angular velocity. The instruments are light, portable, and relatively inexpensive. A single uniaxial gyroscope attached on the skin surface of the lower leg can provide data for calculating cadence, determining number of steps, and estimating stride length and walking speed.[146]

Kotiadis et al developed an integrated system that included accelerometers, gyroscopes, and customized inertial algorithms to replace the footswitches often used to trigger drop foot stimulators.[147] Testing and refinement was performed for an individual after stroke who used a footswitch-driven drop foot stimulator. The combination of accelerometer and gyroscope data was sufficient for defining gait phases and controlling the drop foot stimulator during walking and stair negotiation activities.

Instrumented Systems for Determining Spatial and Temporal Gait Parameters

Examples of instrumented systems for measuring spatial and temporal variables include two walkways (GaitMat™ II and GAITRite®) and two footswitch systems (Krusen Limb Monitor and the Stride Analyzer). Manufacturer contact information for select equipment is presented in Appendix 7.C.

Walkways Compared to more complex systems that require cameras and footswitches, instrumented walkways provide a reliable, valid, and relatively affordable means for rapidly quantifying spatial and temporal gait parameters.[148-154] These portable devices are used by clinics and research facilities to help classify and quantify the severity of a patient's disability, and to guide and assess the effectiveness of treatment interventions. Two walkways widely available are the GaitMat™ II and the GAITRite®.

The GaitMat™ II is a commercially available walkway with embedded pressure-sensitive switches that open and close in response to contact with the patient's feet. The times of openings and closures of the switches are recorded by a computer that provides information on individual footprints; step and stride length; BOS; and step, swing, stance, single support, and double support times for each extremity. The main advantage of this system is that the patient is unencumbered by equipment attached to either the feet or body.

Barker et al[148] examined the reliability of measurements obtained using the GaitMat™ II and the Vicon motion analysis system and reported excellent reliability for temporal measures (0.99), but only poor reliability for spatial measurements (0.24). However, the difference between measurements acquired by the GaitMat™ II and the Vicon system was only 0.5 in (11.7 mm), suggesting that the level of precision would have little impact on most measurements except for BOS measurements. Bowen et al[155] found that the GaitMat™ II was able to detect decreases in velocity and increases in the percentage of double support in dual-task compared to single-task conditions in 11 patients with stroke.[155] Rosano et al[156] examined gray matter volume in the brains of 220 adults over age 65 and identified a number of significant relationships with measures recorded using the GaitMat™ II. In particular, shorter step lengths and longer double limb support times were associated with decreased volume in the sensorimotor and frontoparietal regions, whereas wider steps related to reduced size of the palladium and inferior parietal lobule.

The GAITRite® is another commercially available walkway system (Fig. 7.10). The 1/8-inch-thick, 2-foot-wide, 16-foot-long portable walkway in this system contains 18,482 sensors embedded between a sheet of vinyl and a layer of rubber. Spatial and temporal parameters can be measured, as well as dynamic pressure mapping of footprints during walking. The pressure parameters measured include peak pressure, pressure time, and sectional integrated pressure over time. The walkway system can be used with or without shoes, orthoses, or walking aids, and the GAITRite software is capable of calculating spatial and temporal parameters and displaying them in graphs and tables.

Figure 7.10 Individual with Parkinson's disease walking across the GAITRite® mat while temporal and spatial gait characteristics are recorded including walking velocity, stride length and duration, cadence, and step length and duration. *(Courtesy of Movement and Neurosciences Center, Institute for Rehabilitation Science and Engineering, Madonna Rehabilitation Hospital, Lincoln, NE 68506.)*

In general, the GAITRite® provides a valid means for reliably documenting many gait-related temporal and spatial parameters.[150,151,153] Bilney et al[153] reported high correlations between values recorded on the GAITRite® mat and those recorded using the Clinical Stride Analyzer® for walking speed (0.99), stride length (0.99), and cadence (0.99) for 25 healthy adults walking at three speeds (self-selected, slow, and fast). The reliability of repeated measures appears better at self-selected and fast speeds, compared to slower speeds.[153] Decreased consistency across measurements was documented for BOS[151,152] and toe in and toe out variables,[151,152] particularly in older adults.[152] Strong concurrent validity also has been reported for temporal and spatial gait measures recorded in outpatients recovering from strokes, even when the UE was engaged in using an assistive device.[149] Box 7.1 Evidence Summary provides an overview of selected reliability and validity studies performed using the GAITRite® mat.

Footswitches and Footswitch Systems Footswitches are pressure-sensitive switches placed either on the patient's feet or the inside or outside of the shoes. The switches do not require a walkway, but the patient usually has to carry or wear a data collection device. Footswitches

Bilney et al[153] (2003)	25 healthy adults (13 males, 12 females; mean age = 40.5 years, range = 21–71 years).	The gait variables measured by the GAITRite® were compared with the same variables obtained with the Clinical Stride Analyzer (speed, cadence, stride length, right (R) and left (L) single leg support time and double support as a percentage of the gait cycle).	Intraclass correlation coefficients (ICCs) for speed (ICCs = 0.99), cadence (ICCs = 0.99), and step length (ICCs = 0.99) showed excellent agreement between the two systems for each speed condition (slow, preferred, and fast). Correlations between the two systems for single leg support time were moderate to high across speeds (ICCs = 0.69 to 0.91) in contrast to the weak correlations documented for double limb support times (ICCs = 0.44 to 0.57).	The authors concluded that the GAITRite® had strong concurrent validity and test-retest reliability for selected spatial and temporal variables in normal adults.

McDonough et al[150] (2001)	Single subject: One healthy female with equal leg lengths.	To compare the concurrent validity and reliability of measures recorded with the GAITRite® (cadence, walking speed, R and L step and stride lengths, and R and L step times) to those documented with paper-and-pencil and video-based methods to determine concurrent validity and reliability as the participant walked at various rates and degrees of step symmetry. Additionally, a stride simulator (with predetermined step and stride lengths) was applied to the walkway to simulate 2 steps and 1 stride.	Excellent paper-and-pencil and GAITRite® spatial measure correlations (ICC > 0.95) and video-based and GAITRite® temporal correlations (ICC > 0.93) were reported.	The authors concluded that the GAITRite® was a valid and reliable tool for measuring selected spatial and temporal gait variables.
Menz et al[152] (2004)	Thirty younger adults (12 males, 18 females; mean age = 28.5 years, range 22–40 years) and 31 older adults (13 males, 18 females; mean age = 80.8 years, range = 76–87 years) without known pathology.	Test-retest reliability of temporal and spatial gait parameters was measured using the GAITRite® as subjects walked at a self-selected comfortable speed three times in one session and then repeated the process approximately 2 weeks later. ICCs and coefficients of variation (CV) were calculated.	Reliability of walking speed, cadence, and step length was excellent for younger and older adults (ICCs: 0.82 to 0.92; CVs: 1.4% to 3.5%). Base of support and toe in/out angles also demonstrated high ICCs (0.49 to 0.94); however, CVs were higher in both younger (CVs: 8.3% to 17.7%) and older adults (CVs: 14.3%–33.0%) compared to those calculated for walking speed, cadence, and step length (CVs: 1.4%–3.5% across variables and subject groups).	The authors concluded that the GAITRite® displayed excellent reliability for most temporal and spatial gait parameters in both study groups, but that base of support and toe in/out angles should be interpreted cautiously, particularly in older adults.
Stokic et al[149] (2009)	52 healthy adults (29 males, 23 females; mean age = 47 years, range = 23–87 years) and 20 individuals with chronic stroke (11 males, 9 females; mean age = 58 years, range = 16–90 years).	Gait characteristics (velocity, stride time and length, step length, percent single support, percent total support) were recorded simultaneously by the GAITRite® and an eight-camera motion analysis system as participants performed multiple walks at a self-selected speed.	Mean differences in calculated values between the two methods were ≤ 1.5% of the mean values calculated for each group. For example, healthy adults average gait velocity was 129.1 cm/sec based on GAITRite® calculations compared to 127.7 cm/sec for the motion analysis system. In persons with chronic stroke, the velocity values were 63.9 cm/sec and 63.4 cm/sec, respectively.	The authors concluded that the GAITRite® and motion analysis system provided comparable temporal and spatial measures in healthy adults and those recovering from a stroke.

Box 7.1 Evidence Summary Studies Addressing the Reliability and Validity of Measures of Temporal and Spatial Gait Variables Using the GAITRite® System—cont'd

Reference	Subjects	Design/Intervention	Results	Comments
van Uden and Besser[151] (2004)	Twenty-one adults (12 men, 9 women; mean age = 34 years, range: 19–59 years) without known lower extremity orthopedic disorders or pain that would affect their gait.	Test-retest reliability of GAITRite® temporal and spatial gait measures were recorded at participants' self-selected free and fast speeds on two occasions 1 week apart. Factors evaluated included walking speed, step length, stride length, base of support, step time, stride time, swing time, stance time, single and double support times, and toe in-toe out angle.	At the self-selected walking speed, all measurements had ICCs ≥ 0.92 except base of support (ICC = 0.80). At the fast speed all measurements had ICCs > 0.89 except base of support (ICC = 0.79).	The authors concluded that spatial-temporal gait measurements demonstrated good to excellent test-retest reliability over the 1-week period.
Webster et al[157] (2005)	Five males and five females (mean age = 66.5 years, range = 54–83 years) at least 121 months after unicompartmental knee replacement surgery	Individual step and averaged spatial and temporal variables obtained with the GAITRite® system were compared with the same variables recorded with the Vicon-512 3D motion analysis system.	Walking speed, cadence, step length, and step time variables averaged across one walk using each system revealed an excellent level of agreement between systems (ICCs = 0.92 to 0.99 across variables). No significant systematic differences were found between step length and step time values between the two systems.	The authors concluded that the GAITRite® is a valid tool for measuring both averaged and individual step gait variables. The small number of subjects is one drawback of this study plus the fact that all subjects walked without any problems that were linked to their surgery.

consist of transducers and a semiconductor and are used to signal such events as the heel contacting the ground. One type of footswitch device used to examine both temporal and loading variables is the *Krusen Limb Load Monitor*.[158] This device consists of a pressure-sensitive force plate that can be worn in a patient's shoe. It can be connected to a strip chart recorder to yield a permanent record of temporal and spatial gait variables.[158]

The *Stride Analyzer* is a footswitch system with special insoles containing four pressure-sensitive switches placed under the heel, the heads of the first and fifth metatarsals, and the great toe. The parameters measured by this system include stride length, velocity, cadence, cycle time, single and double limb support time, swing time, and stance time. These measurements are recorded automatically and the information is transmitted to a computer that analyzes the data. The computer can also provide graphic displays of foot–floor contact patterns. Times are presented in seconds and as a percentage of the gait cycle. The computer analysis also includes a percentage of normal using a built-in database (Appendix 7.D). The advantages of the Stride Analyzer system are that measurements from both feet are available, the system is easy to move from place to place, and normative data comparisons are available because it has been used by a large number of physical therapists with different populations.[13-15,20,53,159-167]

The Stride Analyzer is suitable for use with various age groups as well as for patients with neurological or orthopedic involvement. For example, in a study by Mulroy et al,[18] footswitches were taped to the shoe bottoms of 30 individuals recovering from a stroke to assess the effects of three ankle-foot orthosis (AFO) designs on

walking and to determine whether an ankle plantarflexion contracture influenced response to the orthoses. The conditions assessed included walking with usual footwear using three different AFOs, each with unique settings: (1) dorsiflexion assist with a dorsiflexion stop; (2) plantarflexion stop with free dorsiflexion; and (3) a rigid (solid) ankle. The footswitches were used not only to compare stride characteristics across conditions but also to help define gait phases for subsequent analysis of joint kinematics and muscle activation patterns (electromyography [EMG]). Gait parameters were compared across the orthotic conditions and between participants with and without moderate ankle plantarflexion contractures. The authors reported that individuals without a contracture benefitted from AFO designs that allowed stance phase dorsiflexion mobility (e.g., the plantarflexion stop with free dorsiflexion or the dorsiflexion assist with a dorsiflexion stop) as the rigid (solid) ankle inhibited forward progression of the tibia. Those with quadriceps weakness benefitted from an AFO with plantarflexion mobility during loading response (i.e., the dorsiflexion assist with a dorsiflexion stop) as knee flexion motion was diminished compared to the other two AFO conditions.

Powers et al[159] used the Stride Analyzer in an analysis of 22 individuals with transtibial amputations to determine the relationship between isometric muscle force and temporal and spatial gait parameters. Mean walking speed was limited to only 59% of normal, owing to reductions in both cadence (83% normal) and stride length (69% normal). Hip extensor torque of the residual limb served as the only predictor for both free and fast walking speeds. Hip abductor torque of the sound limb was the only predictor of cadence for free and fast walking speeds.

Evaluation of Joint Kinematics (Motion)

Electrogoniometers

Joint displacement can be measured relatively simply by using an electrogoniometer. Early electrogoniometer designs included two rigid links connected by a potentiometer that converted movement into an electrical signal that was proportional to the degree of movement. The rigid links or arms of the electrogoniometer were attached to the proximal and distal limb segments. More recent designs use a flexible shaft and two small end blocks that are affixed to the proximal and distal segments of the joint. The new design allows electrogoniometers to be worn under clothing for extended periods of recording time. Biometrics, Ltd., produces a wide variety of electrogoniometers, including twin-axis designs that simultaneously measure joint motion in multiple planes. Lam et al[168] used these devices to study hip (abduction/adduction) and knee (flexion/extension) during corrective stumbling responses to mechanical perturbations applied to the foot of healthy infants during treadmill stepping. The authors reported that perturbations to the dorsum of the foot during swing resulted in an increase in flexor EMG activity and an increase in knee flexion during swing. Electrogoniometers provide an affordable means of measuring joint motion during walking.[32]

Video-Based Motion Analysis Systems

Two-dimensional (2D) and three-dimensional (3D) video-based motion analysis systems are available for gait analysis; however, their use is limited due to challenges with providing accurate data. Two-dimensional video-based systems use a single digital video camcorder to track subject motion. Computer software programs then assist with identifying points of reference. Unfortunately, joint angles that are out-of-plane (either because of rotation of the limb or due to the position of the individual relative to the camera) will not be calculated accurately. Three-dimensional video-based motion analysis systems use two or more digital video camcorders to gather 3D coordinate data. Hardware is used to synchronize data recorded from the various cameras, and postprocessing is used to identify points of reference either automatically or manually. Markers can be affixed to the skin to help identify anatomical landmarks. Though portable in nature, the accuracy of 2D and 3D video-based systems is a limitation.

Optical Motion Analysis Systems

Imaging-based systems are the most sophisticated and expensive methods of determining joint displacement and patterns of motion. In computerized motion analysis systems, markers placed on body segments such as the hip, knee, and ankle are tracked by automated systems. Motion analysis systems primarily use either *active* or *passive* markers for tracking motion.[31] *Active markers* are usually light-emitting diodes (LEDs) that flash at given frequencies.[169] Each marker is placed over a prespecified location and its individual frequency is used to identify the marker as it moves across space at each instant in time. To power the LED, the participant is either tethered by cable to a central power source or wears a power pack. Fine cables then extend between each LED and the power unit. LEDs are relatively expensive and the thin cables can break. One challenge to the automated labeling of active markers is that reflections from shiny floor surfaces can confound marker identification, particularly for markers located on the feet. Codamotion, Qualisys, and PheoniX Technologies Incorporated are three manufacturers that produce systems that use active markers.

Passive markers (Fig. 7.11) require an external source of illumination that may be provided by external light sources or a ring of infrared emitting diodes located around the lens of the camera. In the latter case, the diodes on the camera pick up the infrared light reflected

Figure 7.11 Oqus Series-3 cameras Qualisys track motion of passive reflective markers placed over known anatomical landmarks and in clusters on body segments as the subject walks along a 6-meter walkway. Marker data will be used to reconstruct joint motions of the upper extremities, trunk, and lower extremities throughout the gait cycle. *(Courtesy of Movement and Neurosciences Center, Institute for Rehabilitation Science and Engineering, Madonna Rehabilitation Hospital, Lincoln, NE 68506.)*

by the markers that they can "see," which means that a large number of cameras are necessary for obtaining unrestricted views of markers. Qualisys, Vicon, and Motion Analysis are three manufacturers that produce systems that use passive markers.

When the systems were first developed, visualization of passive markers was problematic, but now markers are automatically tracked and a computer performs thousands of computations. However, passive marker systems require many cameras, are expensive, and require training to operate the hardware and software. Figure 7.12 provides an example of a computer-generated display of kinematic data recorded using passive markers (Qualisys Motion Analysis System), as well as signals recorded from EMG sensors. In Figure 7.13, the degrees of motion for the ankle and knee are plotted against time. In Figure 7.14, stick figures are shown with accompanying knee angles.

A number of important problems still exist with the use of both active and passive marker systems. Obstruction of markers by body segments, skin/soft tissue motion, marker vibration, and improper placement of markers in relation to the joint center of motion can introduce potential errors. Determining the location of the hip joint center is particularly problematic. The

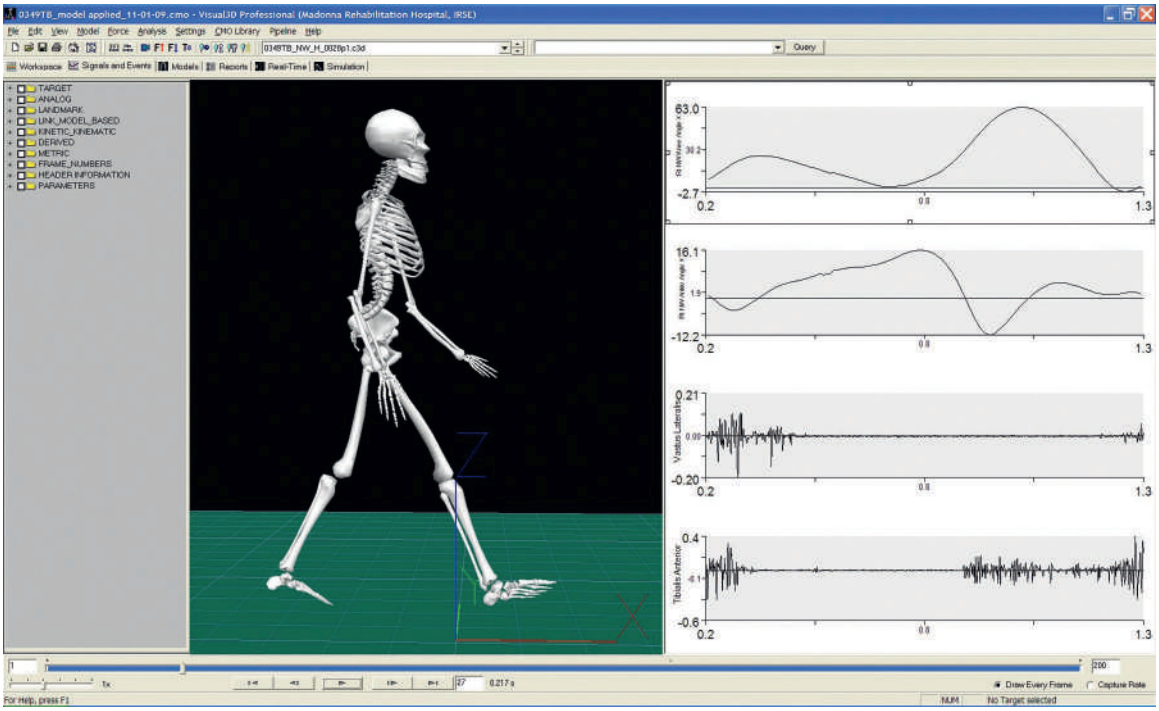

Figure 7.12 Visual 3D computer display of kinematic data recorded using the Qualisys Motion Analysis System and surface electromyographic data recorded using the MA-300 EMG system during overground gait for a 31-year-old male. Reflective markers, applied over known locations, provided the anatomical reference for displayed skeleton and for subsequent analysis of joint motions. To the right of the skeleton, sagittal plane joint motions for the knee and ankle are displayed in the top two rows while surface EMG data for the vastus lateralis and tibialis anterior are displayed in the bottom two rows. *(Courtesy of Dr. Yu Shu, Movement and Neurosciences Center, Institute for Rehabilitation Science and Engineering, Madonna Rehabilitation Hospital, Lincoln, NE 68506.)*

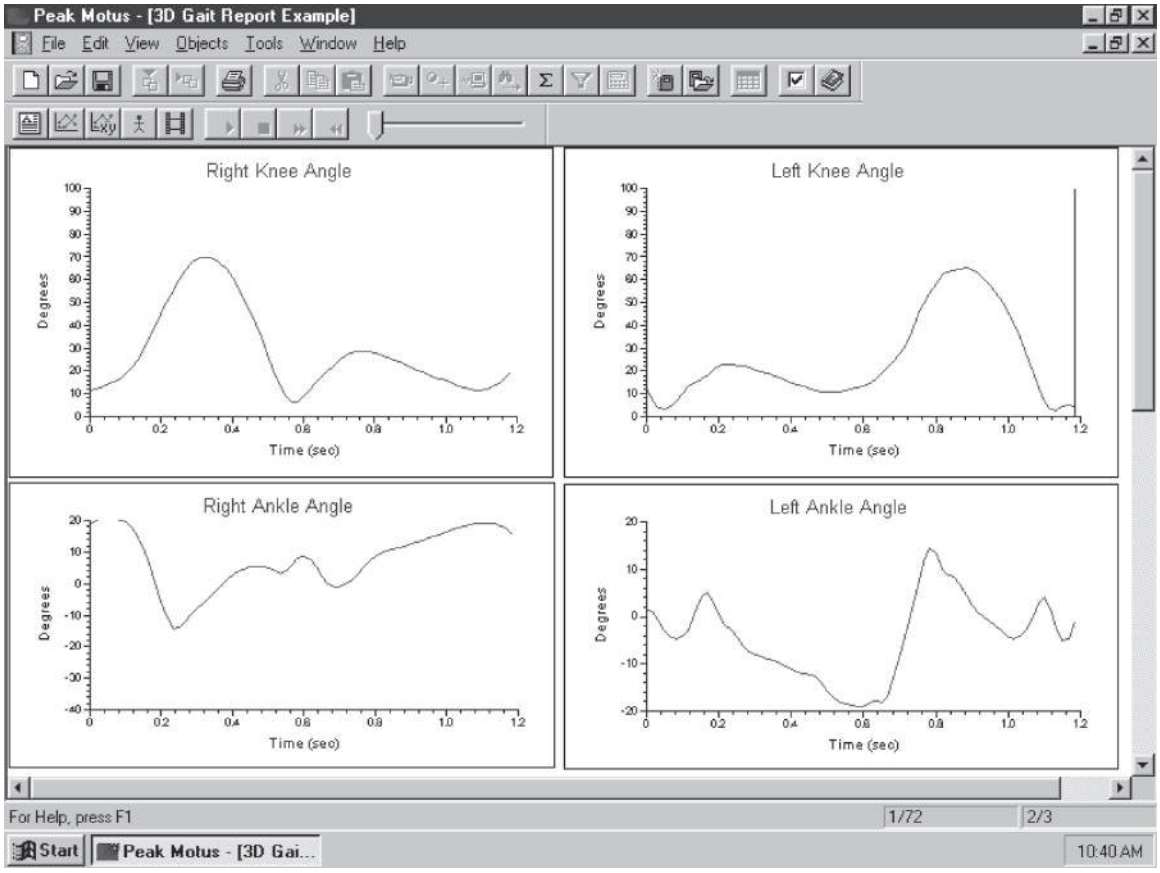

Figure 7.13 A typical computer-generated graph from a motion-analysis system. The graph shows knee and ankle range-of-motion patterns, which are plotted against time for both lower extremities. *(Courtesy of Peak Performance Technologies, Inc., Centennial, CO 80112.)*

ball-and-socket anatomy means that the center of the hip joint is located in the center of the femoral head. Difficulty palpating the femoral head makes accurate marker placement elusive. Radiographic studies have been performed to develop and refine algorithms that can be used to calculate the hip joint center relative to palpable landmarks (e.g., the anterior superior iliac spine, pubic tubercle).[170] Finally, inconsistencies in marker placement have been identified as one of the leading sources of variability in kinematic findings.[171] Following implementation of a standardized protocol for marker placement, Gorton et al[171] reported a 20% average decrease in the standard deviation of 7 of 9 kinematic measures recorded by 24 examiners in 12 motion analysis laboratories using two different camera systems.

As affordable computer processing and storage capabilities rapidly expand, the varying motion analysis products on the market also are evolving. Many video-based systems currently available are able to track markers to within 0.04 in (1 mm) of accuracy, enabling relatively precise tracking of the markers.[172] Most systems have the capacity to integrate with other technology enabling simultaneous acquisition of relevant gait data such as footswitches to identify foot-floor contact patterns and stride characteristics, EMG systems to examine muscle activation patterns, and force plates to determine ground reaction forces. EMG, when recorded simultaneously with stride characteristics data, can be used to identify the particular portion of the gait cycle in which the muscle activity occurs. An example of how EMG is used in combination with a motion analysis system (Vicon) is presented in Figure 7.15. The figure shows the EMG output and ROM on the graph while the computer-generated figures provide a visual image. The differences in muscle activity among the three types of walking patterns are easily seen in the graphs. The deviations from normal ROM at the knee are also easy to identify. A careful observation of the figures in the extension thrust pattern shows an extension thrust of the knee immediately after initial contact and excessive plantarflexion at the ankle both at heel strike and throughout the gait cycle. Refer to Chapter 5, Examination of Motor Function: Motor Control and Motor Learning, for a more detailed discussion of EMG.

Key differentiating features among motion analysis systems include price, marker system options (e.g., active, passive, or both active and passive), and the capabilities and efficiency of postprocessing software. A number

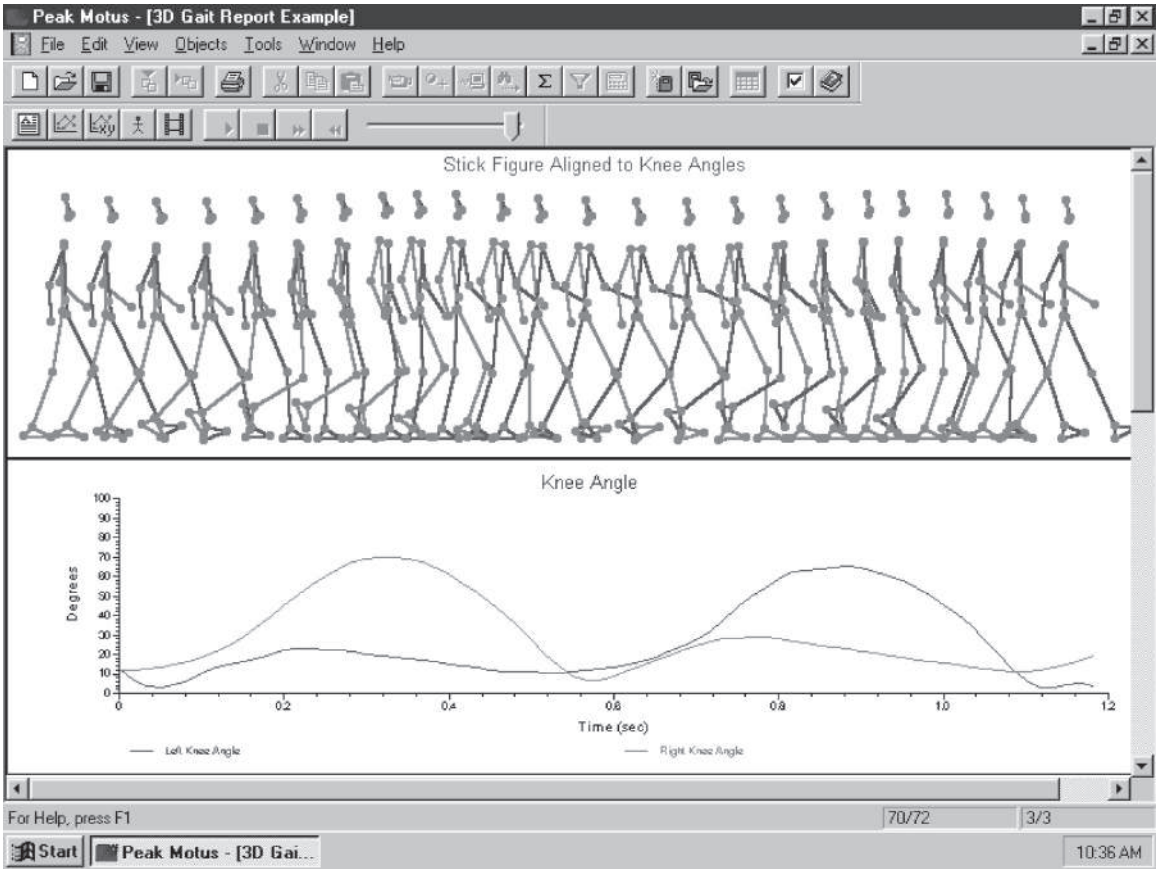

Figure 7.14 Another format for presentation of the data from a motion-analysis system is computer-generated stick figure representations of one complete gait cycle. In this particular case, the pattern of knee motion is graphically presented below the stick figures. *(Courtesy of Peak Performance Technologies, Inc., Centennial, CO 80112.)*

of systems provide manufacturer-generated analysis software that is relatively easy to learn; however, it may be difficult to modify/customize the software to meet the needs of more elaborate studies. Report-generating capabilities differ notably across systems as well, and should be considered depending on the expectations of the laboratory or clinic (e.g., need to produce rapid, easily interpretable reports for inclusion in patient charts versus export of data for statistical analysis for research purposes). Appendix 7.C includes a list of gait analysis software and hardware manufacturers and their contact information. Given the evolving nature of technology, the reader is encouraged to visit the websites provided for the most up-to-date information about the capabilities of different systems.

Electromagnetic Motion Analysis System

One challenge with optical tracking systems is that the motion analysis cameras need to be able to "see" the markers to track their position and subsequently calculate kinematic data. This can be difficult when clients use multiple assistive devices or require substantial physical assistance from one or more therapists to navigate the walkway. An alternative motion analysis technology employs electromagnetic tracking capabilities to determine the 3D coordinates of location and angulation of each sensor. Flock of Birds®, Nest of Birds®, and MotionStar®, all manufactured by Ascension Technology, and FASTRAK® manufactured by Polhemus, are examples of electromagnetic motion analysis technology. MotionStar® allows tracking of up to 120 sensors simultaneously, thus the capacity to perform motion analysis on more than one subject simultaneously. To date, few studies have been published that used electromagnetic motion analysis technology to study gait-related activities.[173,174] The equipment has garnered a following in the virtual reality environments and animation industry.

Kinetic Gait Analysis

Kinetic Variables

Kinetic gait analyses are directed toward determination and analysis of the forces involved in gait, including **ground (floor) reaction forces** (GRFs), joint torques, **center of pressure** (COP), **center of mass** (**COM**), mechanical energy, moments of force, power, support

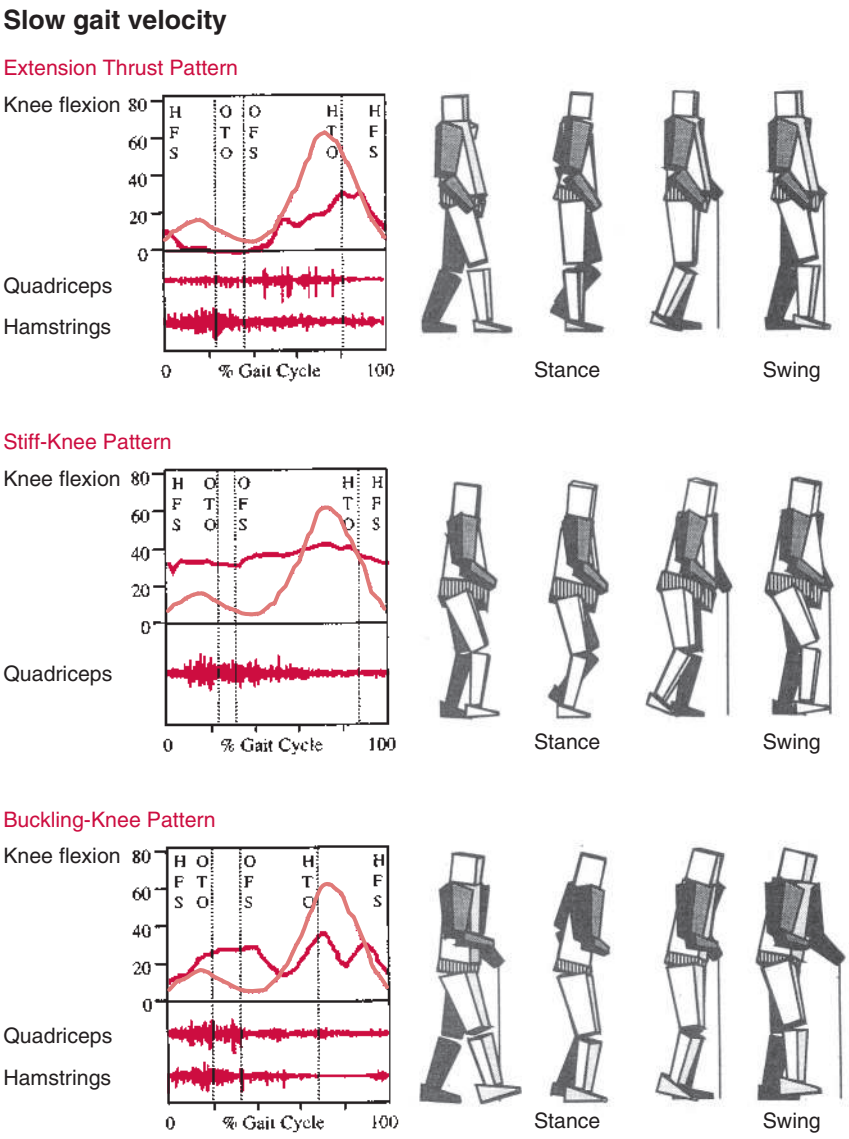

Figure 7.15 Graphs and EMG data for motion of the knee in the sagittal plane for one gait cycle of the three motion patterns. Each patient represents only one of the three motion patterns (extension thrust, stiff knee, and buckling knee) associated with a slow gait velocity. The solid dark red line indicates the motion pattern and the lighter red line represents the normal. HFS, foot strike (initial contact) on the hemiplegic side; OTO, toe off on the contralateral (unaffected) side; OFS, foot strike (initial contact) on the contralateral (unaffected) side; HTO, toe off on the hemiplegic side. *(From De Quervain et al,[6] with permission.)*

moments, work, joint reaction forces, and intrinsic foot pressure (Table 7.12). Although in the past kinetic gait analyses have been used primarily for research purposes, at the present time they are being used clinically as well. Given the risk of foot ulcers arising from high plantar pressures in individuals with diabetic sensory neuropathy, some clinicians are using special pressure mapping insoles to determine if clients may be at risk for developing an ulcer. A patient walks while wearing the special insoles and the pressures are recorded. If high pressures are identified on the bottom of the foot, patients may be referred to have special orthotics and/or shoes fabricated to help redistribute the pressures.

The instrumentation required to examine kinetic variables is complex and expensive because derivation of kinetics requires knowledge of all of the forces acting on the part of the body analyzed (e.g., the foot or the thigh). The analysis usually starts with the forces being applied to the foot, which is determined by a **force plate** embedded in the floor. These plates contain load transducers that measure the **center of pressure** (**COP**), COM, and GRFs during gait. Typically, the force

Table 7.12 Gait Variables: Kinetic Gait Analysis

Ground reaction forces	Vertical, anterior-posterior, and medial-lateral forces created as a result of foot contact with the supporting surface. These forces are equal in magnitude and opposite in direction to the force applied by the foot to the ground. Ground reaction forces are measured with force platforms in newtons (N) or pound force.
Pressure	Pressure = force per unit area. In gait analysis, the parameters that are usually measured include the peak pressure, the pressure-time integral, and the overall pattern of pressure distribution under the foot.
Center of pressure (COP)	The point of application of the resultant force. Movement of the COP as a function of time is used as a measure of stability of a subject who is either standing or walking on a force plate.
Torque (moment of force)	The turning or rotational effect produced by the application of a force. The greater the perpendicular distance from the point of application of a force from the axis of rotation, the greater the turning effect, or torque, produced. Torque is calculated by multiplying the force by the perpendicular distance from the point of application of the force and the axis of rotation. Torque = force × perpendicular distance or moment arm

plates are based on either strain gage or piezoelectric technology.

Calculation of kinetic variables at the ankle requires knowledge of the forces acting on the foot, body mass, and location of the COM (derived from standard anthropometric tables), and knowledge about the acceleration of the COM. Once this knowledge is obtained, equations can be developed to calculate the net forces and net moments occurring at the ankle, at that particular instant in time, in order for the foot to have moved with those particular accelerations. Once forces and moments at the ankle are determined, similar equations can be applied to the adjacent proximal segment (lower leg). One then knows, for each instant in time, whether the dominant internal moment is being caused by the dorsiflexors or the plantarflexors. If the internal moment for each instant in time is multiplied by the net angular velocity between the ankle and the lower leg, the result is knowledge of the net power being produced by the muscles across the ankle. Concentric contractions add power to the limb (power generation), and eccentric contractions reduce power (power absorption). Variations in expected patterns of power generation and absorption are particularly useful in identifying deficiencies and in determining treatment goals. Unfortunately, a detailed explanation of the calculation of COM, COP, and moments and power is beyond the scope of the current chapter. Readers interested in learning more about these concepts are referred to a book written by David Winter included on the supplemental reading list.

The GRF is defined as the net vertical and shear (or horizontal) forces acting between the foot and the supporting surface. The force is three-dimensional and can be resolved into three components: vertical, anterior–posterior, and medial–lateral (Fig. 7.16). Each component varies throughout the gait cycle and is affected by velocity,

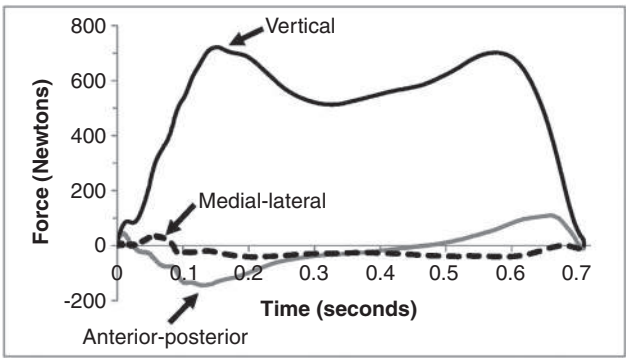

Figure 7.16 Computer-generated graph of the vertical, anterior-posterior and medial-lateral components of the ground-reaction force obtained as an adult walks across an AMTI force plate. *(Courtesy of Movement and Neurosciences Center, Institute for Rehabilitation Science and Engineering, Madonna Rehabilitation Hospital, Lincoln, NE 68506.)*

cadence, and body mass. The averaged wave forms of the vertical and anterior–posterior force components, presented as a percentage of body weight, show consistent patterns across normal subjects for loading rate, peak force, average force, and unloading rate. The vertical force waveform shows a characteristic double hump. The anterior–posterior force has a characteristic negative phase (representing deceleration of the body's mass after the foot hits the ground) followed by a positive phase (reflecting acceleration as body mass moves forward in late stance). In the frontal plane, an initial laterally directed GRF peaks shortly after initial contact. This is most commonly followed by an extended medially directed GRF.

Friction is required while walking and acts in the opposite direction of the desired motion. For example,

during loading response, the foot imparts of forward (anterior) shear force onto the floor as body weight loads onto the limb. Friction resists the tendency of the foot to slip forward. An individual's friction needs during walking, sometimes referred to as *utilized* or *required friction,* can be measured as an individual walks across a force plate. It is calculated as the ratio of the individual's shear (resultant of the anterior–posterior and medial–lateral forces) and vertical GRF components. When an individual's walking friction needs exceed the friction available at the foot-floor interface, a slip is likely to occur.[27,175,176] A tribometer is a device used to measure the friction available on different floor surfaces and in the presence of contaminants (e.g., water or oil). Some floor manufacturers will report on the slip resistance of the surfaces they distribute (e.g., different types of tile). Floor surfaces with a higher available friction (as measured by a tribometer) are generally more slip resistant.

Instruments for Measuring Kinetic Variables

Force Plate Technology

Force plate technology, such as that produced by both Kistler Instrument Corp. and Advanced Mechanical Technology, Inc. (AMTI), is capable of measuring the GRF, as well as calculating the COM, **acceleration, velocity, displacement, power,** and **work**. A graphic display is possible showing the waveforms of the GRF. Kistler Instrument Corp. also markets a treadmill called the Gaitway. The treadmill is capable of measuring the GRF and COP during both walking and running. In addition to graphical presentation and statistical functions, the treadmill system can calculate temporal and spatial parameters.

Cook et al[177] used a force plate to investigate the effect of a knee flexion restriction (using a brace) and walking speed on the GRF. The authors concluded that the application of a brace to restrict knee flexion for the purpose of protection after injury, or while surgically repaired structures were healing, may actually increase the stress on both the braced and unbraced limbs.

Hesse et al[178] compared the trajectories of the COP and the COM in 10 healthy individuals and 14 subjects with hemiparesis. They found that the healthy subjects showed no differences in the behavior of the COP, COM, temporal parameters, and step length when initiating gait with either the right or left extremity. In comparison, patients with hemiparesis showed pronounced asymmetric behavior depending on which limb was the starting limb (affected vs. less affected). Whereas patients who initiated gait with the affected limb were similar to healthy subjects, patients who started gait with the less affected limb showed inconsistent movement of the COP and were incapable of producing directional movement of the body's COM. This suggests therapists should be cautious about promoting that type of gait initiation because the affected leg may be too weak to support starting gait with the less affected LE. Rossi et al[7] investigated the COM, COP, and GRF in a study of gait initiation in patients with transtibial amputations. These authors found that the patients consistently loaded the intact limb more than the prosthetic limb regardless of which limb initiated gait.[7]

Force plates may be used either as part of, or in combination with, motion analysis systems and temporal and spatial analysis systems, as well as in conjunction with EMG and electrogoniometry, for a comprehensive analysis of kinematic and kinetic gait variables. Perry et al[13] incorporated simultaneous recording of GRFs, joint motions, and LE muscle activation patterns to explore an apparent paradox related to the efficiency of toe walking and potential need for therapeutic intervention. Previous researchers identified a lower internal plantarflexor moment during toe walking compared to traditional heel-toe gait and suggested that the plantarflexed foot provided a potential compensatory advantage by reducing the need for plantarflexor strength.[179] However, the earlier researchers had not included measurements of muscle activation (EMG) in their study. The inclusion of EMG into Perry et al's follow-up study,[13] as well as subsequent modeling studies[180,181] of the biomechanical demands of toe walking, highlighted the source of the apparent paradox. Although the internal moments were lower,[13] plantarflexor muscle activation (mean and peak) actually increased because of the biomechanically inefficient position associated with maintaining a plantarflexed foot (less than optimal length–tension of the plantarflexors).[180] The plantarflexed foot also created the need for compensatory adjustments in muscle activation at more proximal joints.[181] This series of studies highlights a potential limitation of using only kinematic and kinetic data to interpret muscle activation patterns; that is, various patterns of muscle co-activation can create the same internal moment. In addition, when a muscle is at an inefficient position on the length–tension curve, it may require greater activation to generate the same internal moment compared to the demands when more optimally aligned.

Plantar Pressure Measurement Systems

Pressure measurement systems may also be used with force plates. Pressure is equal to force divided by area, and is measured by pressure sensors. Therefore, pressure is equal to the force on the sensor divided by the area of the sensor. Plantar pressure measurements are used most commonly in gait analysis to determine the pressure distribution under the foot: foot-to-ground contact, foot-to-shoe contact, and shoe-to-ground contact. Pressure measurements may be used to determine orthotic efficacy, ulceration risk in diabetes, and for regulating weight-bearing following surgery. Many different types of measurement techniques have been developed for measuring contact pressures. Tekscan Inc. has a system called the *F-Scan® Bipedal In-Shoe Plantar Pressure/Force Measurement System* that measures bipedal plantar pressures using paper-thin disposable pressure sensors placed

in a patient's shoes. The sensor is ultrathin, flexible, and can be trimmed to fit; it includes 960 sensing locations distributed across the entire plantar surface. An example of the type of information obtained from the F-scan system is presented in Figure 7.17. Reliability of the F-scan system was determined by Randolph et al[182] to be sufficient for the purpose of designing corrective measures to relieve excessive pressures on the foot. Another system produced by Tekscan, Inc., is called *Mat-Scan System®*, which is a pressure-sensing floor mat that allows the clinician to identify barefoot pressures. Mueller et al[183] used the *F-Scan System* to determine how footwear design impacted plantar pressures in 30 individuals with transmetatarsal amputations who were at risk for additional amputations owing to a history of diabetes. Though all footwear designs reduced plantar pressures under the distal portion of the residual foot compared to traditional footwear with a toe-filler, the most effective design included a full-length shoe with a total contact custom-molded Plastazote insert and a rigid rocker bottom sole. This work has important clinical implications given the high incidence of additional amputations in those with diabetes who have already lost a portion of one limb.[184] Armstrong et al[185] found that patients who have high plantar pressures and wounds greater than 3.12 in (8 cm) took significantly longer to heal than other patients.

Novel Electronics' pedar® and emed® pressure mapping systems provide alternative means for examining pressures. The *pedar®* system consists of insoles (in a variety of lengths and widths) that can be placed inside shoes to measure plantar pressures. Each pressure insole consists of a 0.08 in (2 mm) thick array of 99 capacitive pressure sensors used to calculate a variety of measures including peak pressures, mean pressures, contact area, and pressure-time integral. The insoles can also be used to measure barefoot pressures by securing them to the foot with a thin pair of nylon stockings.[186] Burnfield et al[186] used the pedar® system to study plantar pressures patterns in older adults while walking barefoot and with shoes at three predetermined velocities (187, 262, 295 ft/min [57, 80, 97 m/min]). Compared to slower speeds, fast walking was associated with higher peak pressures under the heel, central and medial metatarsals, and toes, whereas walking barefoot was associated with greater peak pressures under the heel and central metatarsals compared to walking with shoes (Fig. 7.18). These findings suggest that when protection of the plantar surface of the heel and forefoot is important (e.g., with diabetic sensory neuropathy), patients should be encouraged to use shoes and avoid walking at fast speeds for prolonged periods. Subsequent work comparing barefoot walking and wearing shoes examined plantar pressures while walking on grass, carpet, and concrete and identified particularly high pressures when walking barefoot on concrete.[187] Burnfield et al focused on understanding how plantar pressures in young and middle-aged adults vary across common forms of cardiovascular exercise, including treadmill walking, treadmill running, elliptical training, stair stepping, and recumbent cycling. The authors concluded that when protection of the forefoot is important (e.g., diabetic foot neuropathies), biking and stair climbing offer optimal pressure reductions; however, in situations where protection of the heels from high pressures and forces is warranted, recumbent biking, stair climbing, and elliptical training provide greater relief.[188]

The emed® pedography platform is a portable device used to record and evaluate pressure distribution under the foot in static and dynamic conditions. Semple et al[189] used the emed® system to examine COP progression as individuals with rheumatoid arthritis (RA) and individuals without known foot pathology walked. Clients with RA displayed reduced loading of painful regions of the foot as evidenced by delaying progression of the COP across the less painful midfoot followed by rapid progression of the COP across the deformed and painful forefoot.

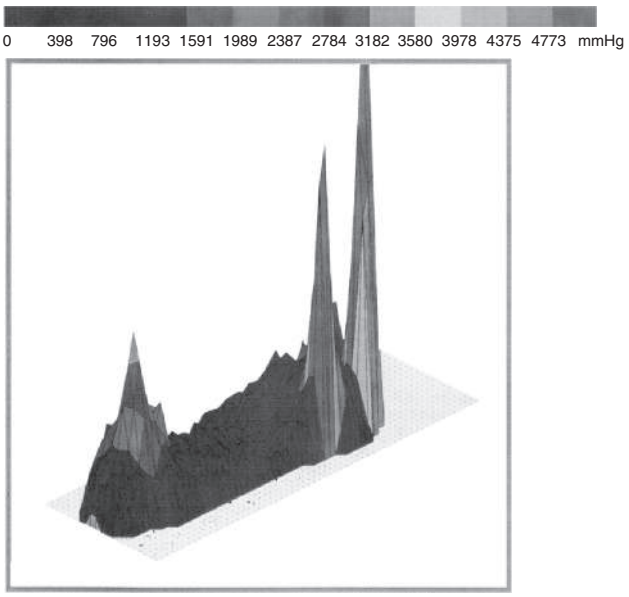

Figure 7.17 Magnitude and location of peak pressure during one complete left foot strike. The highest pressures are shown on the heel, first metatarsal head, and great toe. *(Courtesy of Tekscan, Inc., South Boston, MA 02127.)*

Isokinetic and Isometric Torque Measurement Systems

Simple handheld dynamometers and **isokinetic dynamometer** systems can be used to obtain static and dynamic peak torques before obtaining temporal and spatial measures. Connelly and Vandervoort[104] found that decreases in isometric and dynamic quadriceps strength led to significant decreases in fast-paced and self-selected speed in older women. In a study examining

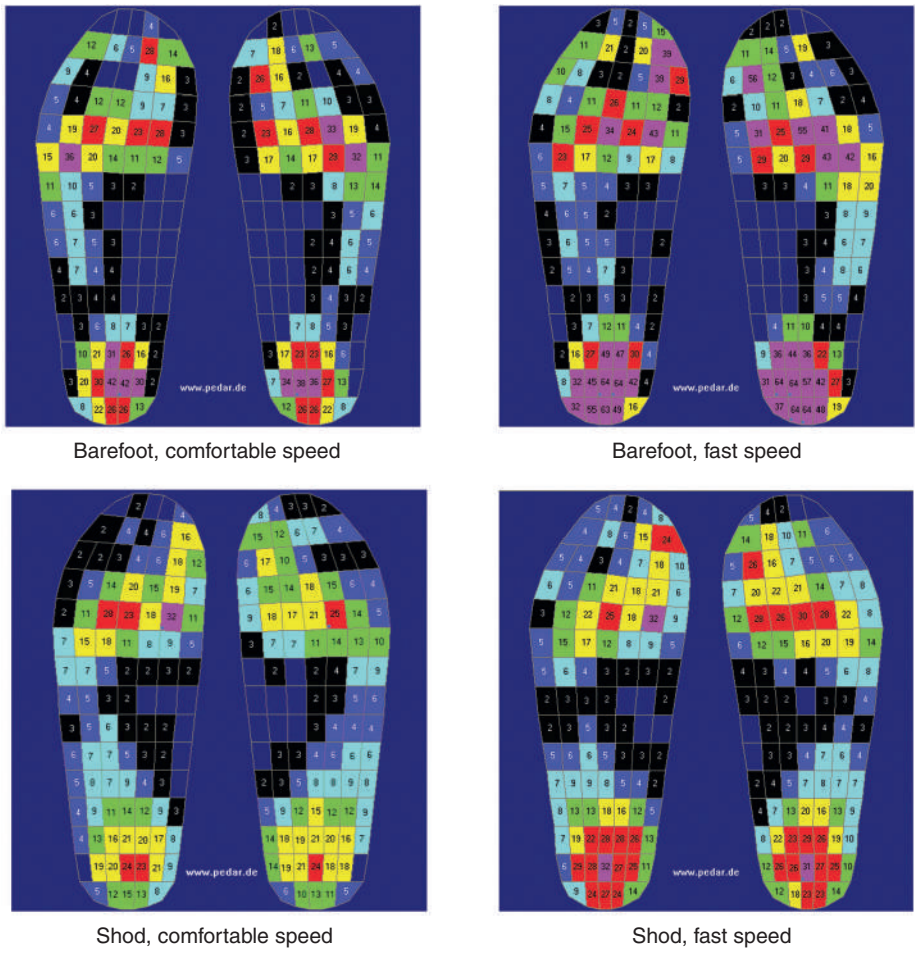

Figure 7.18 Pedar (Novel, Inc.) pressure mapping while walking barefoot (top row) and in shoes (bottom row) at self-selected comfortable (left column) and fast (right column) speeds for a 29-year-old male revealed higher pressures under the heel, metatarsal heads, and great toe during barefoot walking at a fast speed compared to the relatively low pressures while walking in shoes at a comfortable speed. Numbers within each square represent the peak pressure (N/cm^2) experienced during the walking trial. *(Courtesy of Adam Taylor, Movement and Neurosciences Center, Institute for Rehabilitation Science and Engineering, Madonna Rehabilitation Hospital, Lincoln, NE 68506.)*

the relationship between sagittal plane LE isokinetic muscle torques and stride characteristics for a group of elderly ambulatory men, maximal isokinetic hip extensor torque was identified as the only significant independent predictor of stride length, cadence, and free walking velocity.[190] These latter findings highlight the importance of maintaining hip extensor strength in older sedentary males.

Software for Processing, Analyzing, and Displaying Kinematic and Kinetic Data

The Visual 3D, innovative software for biomechanical analysis and modeling, is used to process a variety of gait analysis data (e.g., kinematics, EMG, force plates, gyroscopes). It works with nearly all motion capture systems and has an integrated report generator. It allows users to expand beyond manufacturer predetermined marker sets and analysis rules. However, to fully appreciate the versatility and robustness of the Visual 3D software, it is beneficial to have access to someone with programming skills.

Summary of Kinematic and Kinetic Gait Analysis

Based on the history of gait analysis, one may expect that many gait analysis systems will continue to evolve and more innovative methods of quantifying human gait will be created. However, the most important issues for physical therapists is how reliable and valid the information is and how information can be used to fulfill the four purposes for gait analysis (presented earlier in this chapter under Purposes of Gait Analysis) as described in the *Guide to Physical Therapist Practice*.[1] In brief, these purposes are to assist with understanding the gait characteristics of a particular disorder, to assist with movement diagnosis, to inform selection of intervention(s), and to evaluate the effectiveness of treatment.

The primary advantages of temporal and spatial measures are that they can be determined simply and inexpensively and that they yield objective and reliable baseline data that can be used to formulate anticipated goals and expected outcomes and to evaluate the patient's progress. For example, gait patterns displayed by patients with arthritis often are characterized by a reduced rate and range of knee motion and a slower gait velocity compared to subjects without known pathology. Brinkmann and Perry[191] found that following joint replacement for arthritis, the rate and range of knee motion and gait velocity increased above preoperative levels, but did not reach normal levels.

Usually, increases in measures such as cadence and velocity indicate improvement in a patient's gait. However, comparisons with normal standards are appropriate only if the goal of treatment is to restore a normal gait pattern (e.g., for a patient recovering from a meniscectomy). Comparison with normative standards may not be appropriate for a patient who has had a cerebral vascular accident (CVA). The appropriate norms for examining the gait of a patient with hemiplegia may be either a population of patients with hemiplegia who are of similar age, gender, and involvement, or the patient's pretreatment gait.

Therapists must be cautious when selecting a norm or standard by which to measure patient progress. Significant age, gender, weight, and activity level–related differences have been found in both temporal and spatial measures.[192-194] Himann et al[193] found that an older group (63 to 102 years) of 289 subjects had a significantly slower self-selected walking speed and smaller step length in comparison to a younger group. Age was a significant determinant of walking speed after age 62, but height was a significant determinant before age 62. Step length has been found to be significantly shorter and the double support stance period significantly increased in an elderly sample compared to a database of young adults.[94] Cho et al[195] found a number of gender differences in kinematic and kinetic gait variables. For example, females had shorter stride lengths and narrower step widths, a more anteriorly tilted pelvis, greater hip flexion and internal rotation, greater knee valgus, and smaller ankle joint moment compared to males. Some of these changes were attributed to the anatomically wider female pelvis.[195]

Few disadvantages exist regarding kinematic quantitative gait analysis, except for the possible expense involved in instrumentation, the time required to apply the markers accurately to ensure valid and reliable data, and the fact that a certain amount of uncertainty exists about how to normalize for leg length, height, age, gender, weight, level of maturation, and disability. The interpretation of motion patterns obtained through motion analysis systems usually involves comparisons of an individual's data with a mean curve for normal subjects using one standard deviation (SD) for boundaries. Sutherland et al[196] suggest that motion patterns cannot be fully analyzed without consideration of all points along the curve. They propose the use of prediction regions (multiples of the SD above and below the mean curve of data for each point in the gait cycle). Within a prediction region (Fig. 7.19), if any point along the curve of joint motion falls outside of the

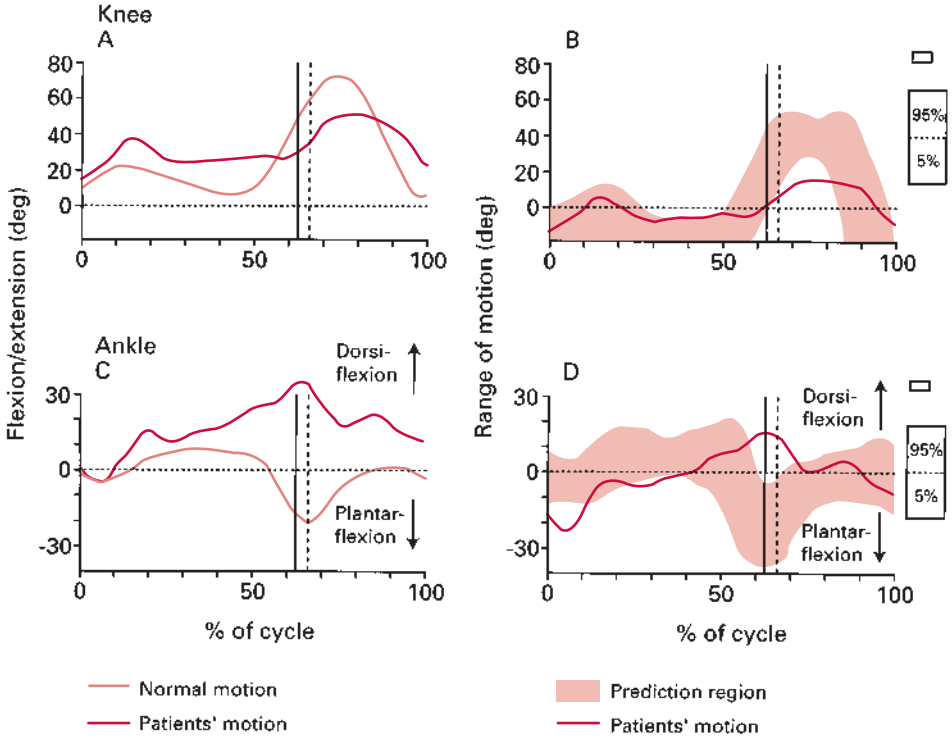

Figure 7.19 Prediction regions. *(Sutherland et al,[196] with permission.)*

defined region, the patient's gait is considered to be abnormal.

Gait Pattern Classification

Identification of gait parameters that deviate widely from a norm is a fairly simple outcome of gait analysis. However, identification of groups or clusters of gait deviations that characterize a known disorder is more complicated and represents one of the very urgent needs in gait analysis. In an attempt to classify gait disorders, a number of statistical techniques are being used for both kinematic and kinetic gait variables. The *bootstrap technique*[197] is used to establish the boundaries (prediction regions) about the mean curve for healthy control subjects in order to establish the limits of normal variability. *Discriminant analysis* is used to recognize gait patterns of healthy people and persons with gait deviations. *Principal components analysis* is useful to reduce the large quantities of data acquired in a gait analysis to a set of features that accurately describe gait patterns. *Cluster analysis* is used to place subjects in homogeneous groups, or clusters, based on specified input parameters.

Normalcy Index

Principal components analysis was used to develop the *Normalcy Index (NI),* which was able to quantify the amount of deviation in a subject's gait compared to the gait of an average unimpaired person.[198] The *NI* has been found to be sensitive enough to distinguish unimpaired subjects from idiopathic toe walkers and to distinguish between involved and less involved limbs of subjects following stroke. However, the gait pathology of non-independent walkers was not well categorized. The authors suggested that perhaps the inclusion of kinetic variables along with kinematic variables might be helpful.

The principal components method derived the NI by assigning weighted factors inversely proportional to the amount of variation exhibited by each gait measure in the unimpaired population. However, since the data come from a motion analysis system they are subject to sources of error such as soft tissue artifacts and marker misplacement.[198]

Cluster Analysis

Cluster analysis is a commonly used statistical technique in the social sciences, but only relatively recently has been used to create an objective classification system of gait patterns. Cluster analysis has been used to classify gait patterns of patients with stroke based on temporal and spatial parameters for each phase of the gait cycle. Four clusters of gait patterns were identified: *fast*, *moderate*, *flexed*, and *extended*.[199] The authors suggested that clinicians use critical parameters to categorize patients with stroke, so that intervention programs could be more specifically targeted to underlying impairments.

Energy Cost Analysis During Gait

Walking at constant speed is a cyclical activity that requires the body to add energy by means of concentric contractions, and absorb energy by means of eccentric contractions. These energy transfers and exchanges are cleverly designed to make walking efficient.[24] Generally, conditions that affect either the motor control of gait and posture or conditions that affect joint and muscle structure and function will increase the energy cost of gait.[14,200-204] The type of footwear,[205] use of assistive devices, and speed of gait affect energy expenditure as well.[206] Energy expenditure is an important consideration in gait analyses, particularly in neurological conditions in which muscular resources may be low. There are three general approaches in determining energy costs: *physiological measurement, mechanical energy analysis,* and *heart rate data.* The selection of a particular approach should be based on the purpose of taking the measure and the relative importance of test characteristics outlined earlier in this chapter under Types of Gait Analyses.

Physiological Energy Cost Measures

Physiological cost measures estimate the heat (energy) produced by a subject at rest and during exercise by indirect calorimetry, based on the assumption that all energy-using reactions of the body depend on oxygen uptake. The most common method of measuring oxygen uptake during walking is open-loop spirometry in which exhaled air is sampled and analyzed for its oxygen content, classically using the Douglas bag method.[24] More recently, stationary or moving metabolic carts or lightweight portable devices perform breath-by-breath oxygen and carbon dioxide analysis. Two parameters of prime interest are *oxygen cost* and *oxygen rate.* One may be interested in the oxygen cost or energy expenditure per unit of distance walked (in mL/kg/m), which relates to the physiological work involved in the task and reflects gait efficiency. Alternatively, the oxygen rate, or energy expenditure per unit of time (in mL/kg/min), reflects the power of walking and is interpreted using knowledge of walking speed.[201,207] Perry et al[14] used a modified Douglas bag assembly to compare the energy expenditure required for an individual with bilateral transfemoral amputations and bilateral transradial (below elbow) amputations to walk at a self-selected speed using different prosthetic devices. When wearing the microprocessor-controlled C-Leg prostheses, the subject walked the farthest and fastest compared to the traditional non–microprocessor-controlled articulating prostheses and stubbies (nonarticulating, short prosthetic limbs). The overall rate of oxygen consumption and oxygen cost was lower while using the C-Legs compared with walking with either of the other prostheses.

Physiological cost analysis methods are most useful in comparing the energy cost of walking with normal values or an individual's maximum capacity, and for

determining the effects on energy costs of interventions such as the use of orthoses, prostheses, or assistive devices. Physiological cost analyses reflect overall costs of walking with respect to time or distance, but they cannot discern the possible causes. If insight into the particular movements is needed, mechanical energy analysis can be helpful.

Mechanical Energy Cost Determination

There are two methods of obtaining mechanical energy costs. In the first method, kinematic data alone are required, using estimates of masses of body parts and of locations of the COM of these parts. By employing a spatial motion analysis system with basic equations of motion and anthropometric constants for masses of body parts, the potential energy and translational and rotational kinetic energy levels of each body part can be calculated. The differences between values obtained at each time increment indicate energy cost. Various equations are used to combine the costs across body parts to yield the total body cost. The large head-arms-and-trunk segment shows excellent exchanges between kinetic and potential energy types, providing the body with energy efficiency. When the body is at its highest position (mid stance), it is also moving most slowly, but as the head-arms-and-trunk "roll down the hill" into initial contact of the foot, this potential energy is changed into kinetic energy, and the head-arms-and-trunk picks up speed. In this way, a great deal of energy is saved and the movement is efficient. However, if the person walks very slowly or very quickly, or has a stiff knee and has to lift one side of the body excessively to clear the floor, the energies are no longer complementary in size and/or shape; less energy exchange can take place.[208] These modes of walking are less efficient than normal walking.

The second method of obtaining mechanical energy costs uses a kinetic approach. Briefly stated, the energy changes in a body part between subsequent instants in time are calculated (1) from the product of the forces on each end of the joint and the velocity of the point of application and (2) from the muscle powers, which are the product of each muscle moment and the angular velocity of the body part. In some cases, the muscle is adding energy to the part (generation), and, in other cases, it is absorbing energy. There are a number of different methods of handling the calculations of mechanical energy, exchanges, and transfers, but a sound approach is described by McGibbon et al.[209]

Heart Rate Data

A third general approach to determining the relative energy cost of gait is by measuring the heart rate (HR) during ambulation. Relative energy consumption has been found to be highly correlated with HR and absolute level of energy consumption has been found to be highly correlated with HR and maximum walking speed. The most accurate way to determine HR is to use a telemetry system that produces beat-by-beat information as well as electrocardiographic activity. Many inexpensive HR monitors are also available and some are designed to download stored information to a computer (see Chapter 2, Examination of Vital Signs). HR responses to ambulation can also be determined by palpation of the radial or carotid arteries, though somewhat more error may be present.

HR measures have been shown to be adequately sensitive for some applications. For example, simple measures of HR and maximum ambulatory velocity allowed accurate prediction ($r = 0.89$) of energy consumption in children with myelomeningocele based on measures recorded from 21 children treadmill walking, 8 children using wheelchairs, and 5 children using both modes.[210] However, Herbert et al[202] found no difference in HR between children with transtibial amputations and those with intact LEs even though energy consumption was 15% higher in the children with amputations. Perhaps because the conditions were more disparate, Waters et al[200] found that in patients with hip arthrodesis, oxygen consumption was 32% greater than normal and that HR was significantly greater than normal.

An energy index based on HR called the *Physiological Cost Index (PCI)* was developed specifically to determine the relative costs of walking per unit of distance walked.[211] Calculated as the difference between the walking HR and the resting HR divided by the average speed, it is expressed in beats per meter. The reliability of PCI has been investigated in individuals without known pathology,[212-214] as well as people with spinal cord[214,215] and brain injuries.[112] The index has been used to quantify improvements following an intervention in individuals with spinal cord injury (SCI),[216,217] RA,[218] and stroke.[219-221] For example, PCI was used as a key outcome measure in a study assessing the effects of a 12-week intervention that combined functional electrical stimulation (FES) with conventional rehabilitation to manage dropfoot in individuals recovering from a stroke.[221] While walking speed increased 38.7% between the initiation and end of the trial, PCI decreased 34.6%, suggesting not only improved function but also efficiency. The relationship between PCI and oxygen consumption has been studied across a variety of populations, including individuals with amputations,[222] individuals with SCIs,[223] and individuals without known disabilities.[212] Some researchers have found oxygen uptake measures to be more repeatable and less variable than PCI.[213,215,224,225] One concern that has been raised is that HR measures may be affected by altered vagal or sympathetic regulation due to brain injury[226-229] or medication.[230]

The *Total Heart Beat Index* provides an alternative approach for determining the relative energy efficiency of walking. It is calculated by dividing the total

(cumulative) number of heart beats during exercise by the total distance traveled in a given time period.[214] It has been used to study walking efficiency in individuals with diabetic foot ulcers and amputations,[231] chronic incomplete SCIs,[232] and intellectual and developmental disabilities.[233] Reliable and valid use of the measure with populations with blunted HR responses requires study.

SUMMARY

An overview of select methods for kinematic and kinetic gait analyses has been presented in this chapter. Many of the common variables examined in gait analyses have been defined and described, and examples of studies using gait analyses have been presented. OGA and temporal and spatial variables have been emphasized, because they appear to be the most common types of analyses used in the clinical setting. A brief overview of some of the motion analysis systems has been provided. Readers are encouraged to investigate the capabilities of individual motion analysis systems, and to consult the gait literature for reliability and validity studies regarding these systems. The ability to perform a gait analysis that accurately describes a patient's gait will provide important quantifiable information necessary for optimal treatment planning.

Questions for Review

1. Describe the three different types of gait analyses (kinematic qualitative, kinematic quantitative, and kinetic) and list the variables examined in each type. Identify at least one variable from each type of analysis and describe a technique/technology that could be used to examine the variable.
2. Compare the advantages and disadvantages of a kinematic qualitative gait analysis with the advantages and disadvantages of a kinematic quantitative analysis.
3. Describe how a therapist would determine the concurrent validity of temporal and spatial gait measures recorded using the GAITRite® with values calculated using the Stride Analyzer.
4. A new client is referred to physical therapy with gait dysfunction arising from severe diabetic sensory and motor neuropathy. The patient has a history of recurrent ulcers, bilaterally, under his first metatarsal heads that have impaired his ability to stand/walk at work for prolonged periods of time. He recently received a new pair of custom-molded orthotic shoe inserts and was instructed to use them in his shoes to help reduce plantar pressures. Unfortunately, he is unable to feel whether they are fitting or not, secondary to the sensory neuropathy. What technology could be used to assess the effectiveness of the inserts at reducing plantar pressures? What activities should be assessed and why?
5. A person walks with excessive dorsiflexion, no heel-off, and limited toe extension in terminal stance. Hip and knee analysis reveals excess flexion during stance with absence of the normal "trailing limb" posture characteristic of terminal stance. Identify potential causes for these deviations. What additional tests or measures should be performed?
6. Identify methods that can be used to determine the energy costs that a patient incurs while walking.
7. How could a gait analysis of temporal parameters be used to demonstrate a patient's progress or lack of progress?

CASE STUDY

HISTORY

This 65-year-old woman is 5 days post–right total hip arthroplasty. The surgery was performed following a femoral neck fracture incurred during a fall on the ice in front of her home. She has had daily bedside physical therapy for the past 3 days and now is independent in transfers. However, she needs to be independent in walking before she goes home.

She has a past history of diabetes mellitus (onset age 50), which is controlled with daily insulin injections. She has a recurrent history of foot ulcers and has been hospitalized on two occasions to manage infected foot ulcers. She denies any history of "heart problems." She does not participate in any regular exercise program and spends a great deal of time sitting during her work as a seamstress. She is alert and oriented to time and place and has a pleasant demeanor. She is 5 feet 3 inches tall and weighs 160 pounds.

	Eversion	F+	F
Toes	Flexion	F	F
	Extension	P	P

Upper extremities: All muscle grades are within the G to G– range.

Sensory Examination

	Plantar Aspect Left Foot	Plantar Aspect Right Foot
Sharp/dull	5	5
Light touch	5	5
Temperature	5	5
Proprioceptive sensation	4	4

NUMERIC VALUES REFER TO THE SENSATION SCALE BELOW.

SENSATION SCALE

1. Intact: normal, accurate
2. Decreased: delayed response
3. Exaggerated: increased sensitivity
4. Inaccurate: inappropriate perception of stimuli
5. Absent: no response
6. Inconsistent or ambiguous

INSPECTION

Patient has an ulcer on the medial aspect of the right plantar surface which is 0.7 × 6.0 cm in diameter and 1.5 mm deep.

FUNCTIONAL EXAMINATION

Locomotion

FIM level = 5

Transfers

FIM level = 7

Activities of Daily Living

Eating: FIM = 7
Bathing: FIM = 7
Dressing: FIM = 7

GUIDING QUESTIONS

1. Develop a physical therapy problem list.
2. Complete the sample OGA form for the right lower extremity based on the information presented (see Appendix 7.A). What deviations would you expect to see for the right lower extremity and why? How might gait change if the client is instructed to not bear weight on the right forefoot secondary to the plantar ulcer?
3. Present your recommendations for physical therapy intervention.

For additional resources, including answers to the questions for review and case study guiding questions, please visit **http://davisplus.fadavis.com**

	Increased forward rotation																		
	Limited backward rotation																		
	Limited forward rotation																		
	Drops on contralateral side																		
Trunk	None																		
Frontal plane observations	Backward rotation																		
	Lateral lean																		
	Forward rotation																		
	Backward lean																		
	Forward lean																		

Key: IC = initial contact; LR = loading response; MSt = mid stance; TSt = terminal stance; PSw = pre-swing; ISw = initial swing; MSw = mid swing; TSw = terminal swing.

appendix
7.B Temporal and Spatial Measures Gait Analysis Form

Patient's name_____ Age_____ Gender _____ Height_____ Weight_____

Diagnosis _____

Ambulatory aids: Yes _____ No _____

Type: Crutch(es) _____ Cane(s): R _____ Walker: _____

L _____

Other: _____

Instructions: Distance walked, elapsed time and walking velocity can be calculated for a single walking trial or averaged across multiple walking trials if the patient's endurance permits. Therapist should provide an average value (calculated across multiple complete steps/strides) for the stride and step lengths, width of walking base, and foot angles.

Date	
Therapist's initials	
Distance walked (distance from first to last heel strike)	
Elapsed time (time from first to last heel strike)	
Walking velocity (distance walked divided by elapsed time)	
Left stride length (distance between two consecutive left heel strikes)	
Right stride length (distance between two consecutive right heel strikes)	
Left step length (distance between a right heel strike and the next consecutive left heel strike)	
Right step length (distance between a left heel strike and the next consecutive right heel strike)	
Step length difference (difference between right and left step lengths)	
Cadence (total number of steps taken divided by the elapsed time)	
Width of walking base (perpendicular distance between right and left heel strike)	
Left foot angle (angle formed between a line bisecting the left foot and the line of progression)	
Right foot angle (angle formed between a line bisecting the right foot and the line of progression)	
Right stride length to right lower extremity length (right stride length divided by right lower extremity length)	
Left stride length to left lower extremity length (left stride length divided by left lower extremity length)

Chapter 8

Examination of Function

David A. Scalzitti, PT, PhD, OCS

LEARNING OBJECTIVES

1. Discuss the concepts of health status, function, activity, participation, disability, impairment, activity limitations, and participation restrictions.
2. Define *function,* and discuss the purposes and components of the examination of function.
3. Select activities and roles appropriate to an individual's particular characteristics and condition to guide examination of function.
4. Compare and contrast characteristics of various formal tests of function, including physical function tests and multidimensional functional assessment instruments.
5. Identify factors to be considered in the selection of formal instruments for testing function.
6. Compare and contrast various scoring methods used in instruments to measure function.
7. Discuss the issues of reliability, validity, and meaningful change as they relate to the measurement of function.
8. Using the case study example, apply clinical decision making skills in evaluating data from the examination of function.

CHAPTER OUTLINE

A CONCEPTUAL FRAMEWORK *309*
EXAMINATION OF FUNCTION *312*
- Purpose of Examination of Function *312*
- General Considerations *312*
- Testing Perspectives *313*
- Types of Instruments *314*
- Instrument Parameters and Formats *315*
- Response Formats *317*

INTERPRETING TEST RESULTS *318*
- Determining the Quality of Instruments *319*
- Considerations in Selection of Instruments *321*
- SINGLE DIMENSION VERSUS MULTIDIMENSIONAL MEASURES OF FUNCTION *322*

SAMPLE INSTRUMENTS TO ASSESS FUNCTION *323*
- The Barthel Index *323*
- The Functional Independence Measure *325*
- The Outcome and Assessment Information Set *325*
- The SF-36 *326*

SUMMARY *334*

A clinician needs to consider the purposes of obtaining the measurement in deciding which measure of function to use. For example, is the measure to describe a specific activity limitation or describe an individual's overall level of function? Will the measure be used to assess outcomes of an episode of care, determine the destination at discharge, obtain reimbursement, meet regulatory requirements, or a combination of all of the above? As function may incorporate performance at the level of body systems, the person, and society, or a combination of these, and the clinician should be cognizant of the ability of the measure to capture the appropriate information.

The ultimate objective of any rehabilitation program is to return the individual to a lifestyle that is as close to the premorbid level of function as possible or, alternatively, to maximize the current potential for function and maintain it. For an otherwise healthy person with a fractured arm, this may be a reasonably simple process: improving range of motion, strength, and impairments in body function will reestablish skills in the performance of activities, such as dressing and feeding. However, considering the person with a stroke as an example, the task is much more complex because the problems are much more extensive, complicated, and interwoven. The two cases, however, are broadly similar. In both instances, the therapist begins by describing the problem in functional terms obtained from the history, performing a systems review and detailed examination using selected tests and measures, evaluating the data, establishing a diagnosis and prognosis, implementing interventions to reduce or to eliminate the problems identified, and documenting the progress toward the desired functional outcome.[1]

Every individual values the ability to live independently. The construct of function encompasses all those tasks, activities, and roles that identify a person as an independent adult or as a child progressing toward adult independence. These activities require the integration of both cognitive and affective abilities with motor skills. Functional activity is a patient-referenced concept and is dependent on what the individual self-identifies as essential to support physical and psychological well-being, as well as to create a personal sense of meaningful living. Function is not totally individualistic, however; there are certain categories of activities that are common to everyone. Eating, sleeping, elimination, and hygiene are major components of survival and protection common to all animals. Particular to humans are the evolutionary advancements of bipedal locomotion and complex hand activities, which permit independence in the personal environment. Work and recreation are functional activities in a social context.

This chapter presents a conceptual framework for examining functional status based on the International Classification of Functioning, Disability, and Health (ICF) and introduces the reader to terminology used in the field (see also Chapter 1). It presents an overview of the purposes of the examination of function and the range and rigor of formal test instruments currently available to clinicians and researchers. Considerations in test selection and principles of administration are also presented.

A CONCEPTUAL FRAMEWORK

Chronically ill and disabled persons represent a large segment of the population in the United States. In 2008, approximately 37 million Americans (12%) were considered to have a disability (limited in their usual activities due to one or more chronic health conditions).[2] Traditionally, these individuals have been categorized or classified according to their medical diseases or conditions. Medical procedures such as physical examination and laboratory tests are the primary tools to delineate the problems created by disease. Strict focus on a biomedical model, with its emphasis on the characteristics of *disease* (etiology, pathology, and clinical manifestations), may contribute to reducing patients to the *medical labeling* of these individuals; for example, referring to people as amputees, paraplegics, or arthritics rather than as individuals with these conditions. This model virtually ignores the equally important psychological, social, and behavioral dimensions of the **illness**, which accompanies the disease. Illness refers to the personal behaviors that emerge when the reality of having a disease is internalized and experienced by an individual. Factors related to illness often play a key role in determining the success or failure of rehabilitation efforts well beyond the nature of the medical condition that prompted a patient's referral to physical therapy. In helping the individual with a disease, physical therapists come to understand each person's illness as well.

A broad conceptual framework is necessary to fully understand the concept of health and its relationship to function and disability. Terms such as *well-being, health-related quality of life,* and *functional status* are often used interchangeably to describe health status. The most global definition of **health** has been provided by the World Health Organization (WHO), which defined health as "a state of complete physical, mental, and social well-being, and not merely the absence of diseases and infirmity."[3, p. 459] Although such global definitions are useful as philosophical statements, they lack the precision necessary for a clinician or researcher.

In order to describe the components of health and provide a unified and standard language and framework for the description of health and health-related states, the *International Classification of Functioning, Disability, and Health (ICF)* was developed.[4] The ICF was endorsed by the World Health Assembly on May 22, 2001, for international use and complements other classifications of the WHO such as the *International Classification of Diseases,* 10th revision (ICD-10).[5] Whereas the ICD-10 is a classification of diseases, disorders, and other health conditions, the ICF attempts to provide a meaningful description of the components of health and its relationship to a person with the health condition. Since its development the use of the ICF has been endorsed by the physical therapy community, including the World Confederation of Physical Therapy (WCPT) and the American Physical Therapy Association (APTA), and is gradually replacing other frameworks.[6] Table 8.1 presents an overview of some of these other frameworks, including of the ICF's predecessor, the WHO's International Classification of Impairments, Disability and Handicaps (ICIDH)[7] and the Nagi model[8] on which the process of disablement in APTA's *Guide to Physical Therapist Practice*[1] is based.

Function in the ICF is an umbrella term encompassing all **body functions and structures**, **activities,** and **participation**, whereas **disability** is a term that encompasses **impairments** in body functions and structures, **activity limitations**, and **participation restrictions**. Both function and disability are represented in the ICF, in contrast to previous frameworks, to provide for the description of a continuum of the components of health from positive aspects to items an individual is not able to perform or perform in a limited manner or with assistance.

The ICF framework consists of two parts. The first part describes components of function and disability in the context of health, whereas the second part describes contextual factors which may interact with the components of the first part (Fig. 8.1). These components of the ICF do not model a process of disablement, such as in previous frameworks; rather, the ICF provides an approach to classification of function and disability from

Table 8.1 Terminology Used In Historical Disablement Frameworks

ICIDH[7]	Nagi[8]
Disease The intrinsic pathology or disorder	**Active pathology** Interruption or interference with normal processes, and efforts of the organism to regain normal state
Impairments Any loss or abnormality of psychological, physiological, or anatomical structure or function	**Impairments** Anatomical, physiological, mental, or emotional abnormalities or loss
Disability Any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner or within the range considered normal for a human being	**Functional limitations** Limitation in performance at the level of the whole organism or person
Handicaps A disadvantage for a given individual, resulting from an impairment or disability, that limits or prevents the fulfillment of a role that is normal (depending on age, sex, and social and cultural factors) for that individual	**Disability** Limitation in performance of socially defined roles and tasks within a sociocultural and physical environment

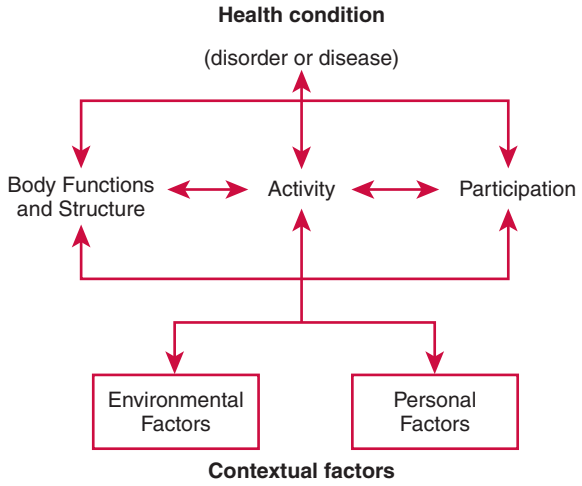

Figure 8.1 Schematic representation of the ICF. *(From World Health Organization: ICF: International Classification of Functioning, Disability, and Health. World Health Organization, Geneva, Switzerland, 2002, p 18, with permission.)*

multiple perspectives. The relationship between components and parts of the ICF does not imply causality. Bidirectional arrows are used in Figure 8.1 to represent a complex relationship. For example, a health condition such as angina may influence aspects of mobility such as gait, whereas at the same time increasing one's mobility by performing a regular walking program may influence the management of the health condition. In addition, a limitation in one component of the framework does not imply limitations in other components.

Body functions are defined by the ICF as the physiological functions of body systems, and body structures are parts of the body such as organs, limbs, and their components. *Impairment* is the term used to refer to problems in body function or structure. Although two separate sections are used to classify body functions and structures in the ICF, the classifications are designed to be used together. For example, the chapter titled "Neuromuscular and Movement-related Functions" in the body functions classification correlates with the chapter titled "Structures Related to Movement" in the body structures classification. Hence, for a person with rheumatoid arthritis a clinician may use aspects of the body functions classification to describe range of motion of the interphalangeal joints and muscle performance of the hand intrinsic muscles and the body structures classification to describe the integrity of the joints of the hand. The headings for the chapters in the ICF classification of body functions and structures are in Table 8.2.

The ICF defines activity as the execution of a task or action by an individual and participation as involvement in a life situation. The terms used to describe problems in these domains are *activity limitations* and *participation restrictions.* Through the definitions of activity and participation an attempt is made to differentiate what a person can do because of characteristics of the individual and those of society. In the ICF, however, a single list covers both activity and participation. In contrast, a draft of the ICF, the ICIDH-2, used separate lists to distinguish activity from participation.[9] Instead of separate lists, the ICF allows users to operationally differentiate activities and participation. Possibilities suggested in the ICF include (a) designating some domains as activities and others as participation with no overlap, (b) designating some domains as activities and others as participation allowing for overlap, (c) designating all detailed domains as activities and the broad categories as participation, and (d) using all

Table 8.2 ICF Classification of Body Functions and Body Structures

Body Functions	Body Structures
Mental functions	Structures of the nervous system
Sensory functions and pain	The eye, ear, and related structures
Voice and speech functions	Structures involved in voice and speech
Functions of the cardiovascular, hematological, immunological, and respiratory systems	Structures of the cardiovascular, immunological, and respiratory systems
Functions of the digestive, metabolic, and endocrine systems	Structures related to the digestive, metabolic, and endocrine systems
Genitourinary and reproductive functions	Structures related to the genitourinary and reproductive systems
Neuromusculoskeletal and movement-related functions	Structures related to movement
Functions of the skin and related structures	Skin and related structures

domains as both activities and participation.[4, pp. 234-237] To date, no standard exists for the distinction of the classification of activity and participation, and physical therapists should be aware of the potential uses of the classification for practice and research.[10]

The headings for the nine chapters in the ICF classification of activities and participation and examples of classification within a chapter are presented in Figure 8.2. The chapters are considered the first-level of classification and can be used to categorize positive and negative aspects of function. The second-level of classification includes categories of different actions, tasks, and activities. Subcategories provide additional detail for the main categories. For example, moving around is a category within the mobility domain of the ICF, and crawling is a subcategory of the moving around category.

The second part of the ICF is labeled "contextual factors," which represent the complete background of an individual's life and are included to represent factors that may interact as facilitators or barriers to the components of function. The contextual factors are considered as either barriers or facilitators to function from the perspective of the individual whose situation is being described. Contextual factors have two components: environmental factors, which are external to the individual and can have positive or negative influence on performance, and personal factors, which are features of the individual such as age, gender, and race that are not part of a health condition or health state. Due to the bidirectional nature of the ICF framework contextual factors may also be modified by the components of part 1. Environmental factors are classified by the ICF; however, a classification of personal factors is notably omitted (Table 8.3).

The ICF, and models such as the Institute of Medicine's enabling-disabling process (Fig. 8.3),[1] emphasize the interaction between the person and the environment as critical to understanding functioning and disability. Physical therapists can help change discriminatory social attitudes and environmental restrictions such as architectural barriers that stigmatize individuals and restrict participation in all aspects of society. The modification of factors that are barriers and incorporation of factors that are facilitators is as important to functioning as the amelioration of activity limitations.[11]

In addition to providing a framework for the classification of function, the ICF provides a classification scheme for coding, which, although not yet in widespread use by physical therapists, may be particularly intriguing in its delineation of actions, tasks, and activities in an implicit hierarchy of functioning. Within this hierarchy, actions (e.g., rolling, bending, sitting, standing, lifting, and reaching) are constituents of tasks and activities (e.g., bathing, dressing, and grooming). Tests and measures of actions are particularly relevant to physical therapist practice as they capture the complex integration of systems that permits an individual to maintain a posture, transition to other postures, or sustain safe and efficient movement.

Although typical patterns of deficits in body functions and problems in activities may typically exist in certain disease categories, the exact empirical relationship between a particular set of impairments in body functions and structure and activity limitations is not yet known.[12] The cause-and-effect relationship between an impairment and an activity limitation is most often inferred in the clinic from empirical evidence. For example, physical therapists may assume that the reason a patient cannot transfer independently is causally linked to the fact that the individual has lost enough lower extremity range of motion at the hip (e.g., hip flexion contractures) to prevent balancing in a fully upright posture. The return of activity following remediation of the impairment of joint mobility is then considered clinical evidence of a relationship between the impairment and the limitation. For data to be

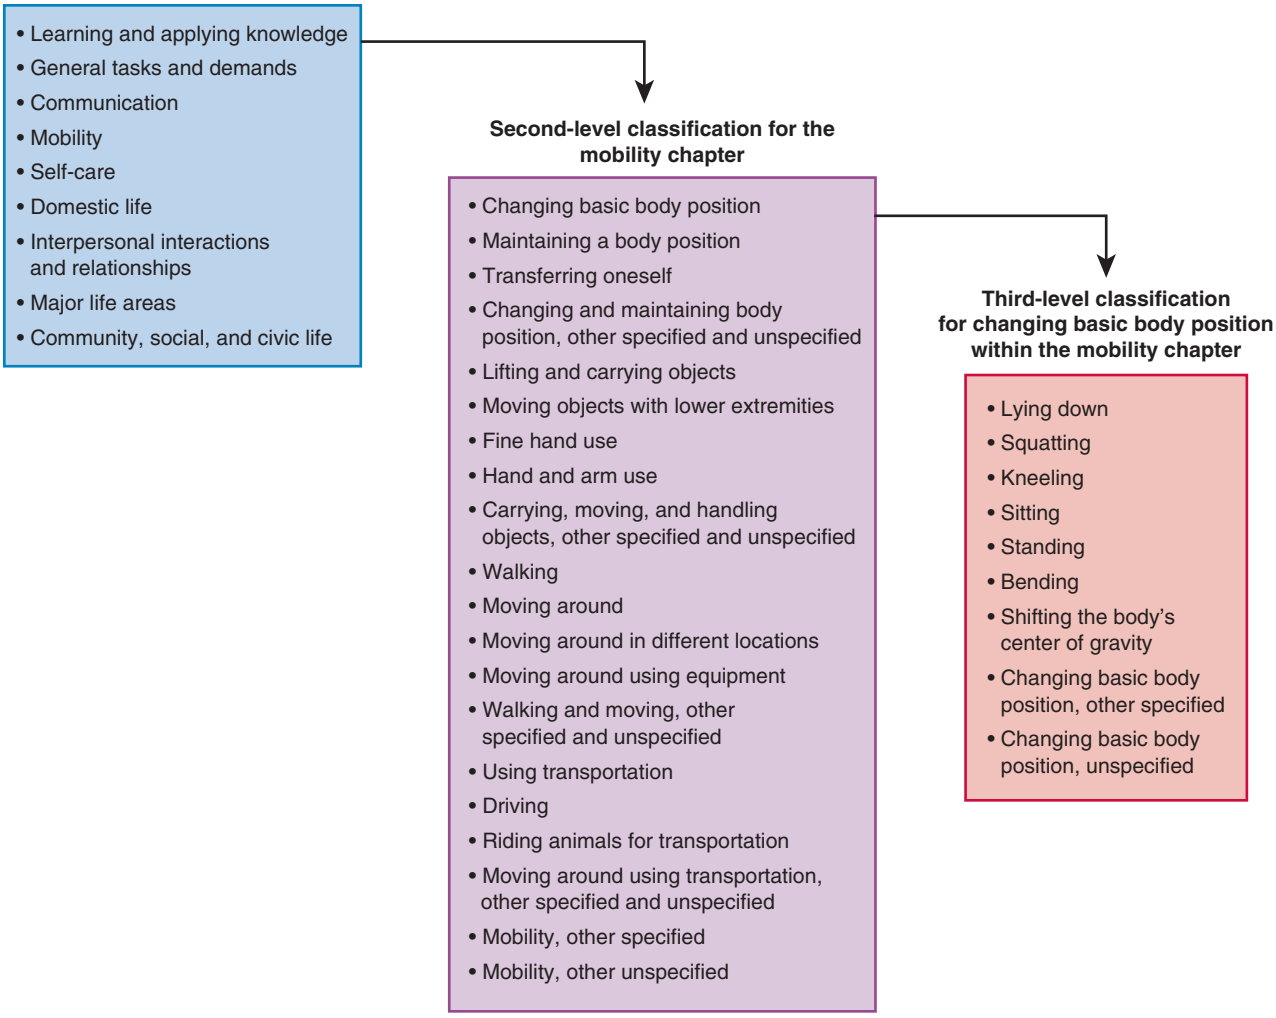

Figure 8.2 ICF Classification of Activities and Participation.

clinically useful, assessment of a patient's function by a physical therapist must include all of the appropriate components.

EXAMINATION OF FUNCTION

Purpose of Examination of Function

Analysis of function focuses on the identification of pertinent activities and measurement of an individual's ability to successfully engage in them. In essence, functional testing measures how a person does certain tasks or fulfills certain roles in the various dimensions of living described in the framework of the ICF. Application of selected functional tests and measures yield data that can be used as (1) baseline information for setting function-oriented goals and outcomes of intervention; (2) indicators of a patient's initial abilities and progression toward more complex functional levels; (3) criteria for placement decisions, for example, the need for inpatient rehabilitation, extended care, or community services; (4) manifestations of an individual's level of safety in performing a particular task and the risk of injury with continued performance; and (5) evidence of the effectiveness of a specific intervention (medical, surgical, or rehabilitative) on function.

General Considerations

Physical therapists possess a unique body of knowledge related to the identification, remediation, and prevention of movement dysfunction. Thus, they have traditionally been involved in the examination of physical function. Other members of the rehabilitation team, including the occupational therapist, nurse, rehabilitation counselor, and recreational therapist, are also typically involved in administering and interpreting functional tests. Some formal instruments were designed to be completed collectively by the team. Other tests are compiled in separate sections by specific health professionals and housed together in the patient's chart. Where teams exist, physical therapists are typically responsible for the testing of aspects of function related to mobility, such as bed mobility, transfers, and locomotion (wheelchair mobility, ambulation, negotiation of stairs and graded

Table 8.3 Environmental Factors in the ICF

First-Level Classification	Examples
Products and technology	Medications, clothes, prosthetics, walking devices, scooters, hearing aids, ramps, assets
Natural environment and human-made changes to environment	Geography, climate, light, air quality
Support and relationships	Immediate family, extended family, friends, persons in positions of authority, personal assistants, domesticated animals, health professionals
Attitudes	Individual attitudes of immediate family members, individual attitudes of health professionals, societal attitudes
Services, systems, and policies	Housing, transportation, legal, associations, health, education, political

elevations, walking for longer distances in the community, and so forth). Instruments to measure activities of daily living (ADL) may be administered by a physical therapist alone or cooperatively with other health professionals. When overlap among team members exists, for example, the performance of toilet transfers, the data may be collected by the physical therapist, an occupational therapist, or a nurse. In these instances, testing should be coordinated to reduce duplication and unnecessary patient stress. In noninstitutional settings or where there is no team, the physical therapist is often responsible for determining all aspects of these instruments.

Testing Perspectives

Function tests can utilize two highly divergent perspectives on what is to be tested or measured by the physical therapist. It is extremely important that the therapist determine in advance whether data are needed to describe the *habitual level* of a patient's ability to do certain tasks and activities, or to identify the patient's *capacity* to perform certain tasks and activities, whether the patient habitually performs up to that level or not, or even performs them at all. These perspectives are incorporated within the ICF by the constructs of performance and capacity and the ICF allows for the separate coding of both constructs.

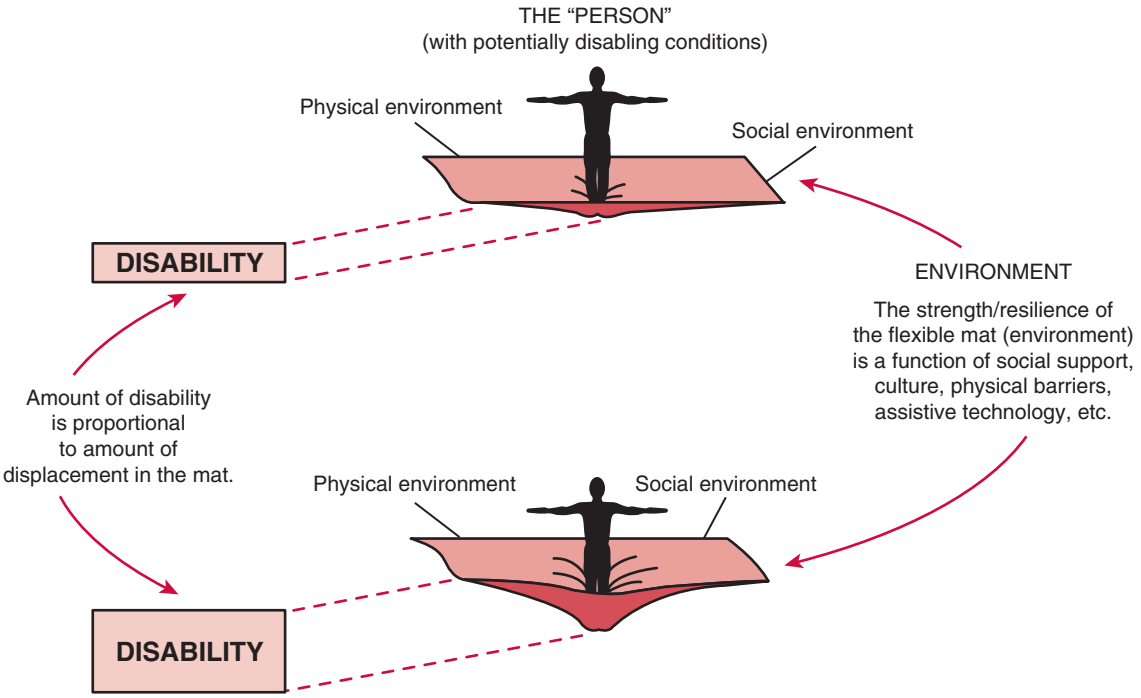

Figure 8.3 The Institute of Medicine model of the enabling-disabling process. Disability is a function of the interaction between the person and the environment. The amount of displacement represents the amount of disability that is experienced by the individual. Displacement is a function of the strength of the physical and social environments that support an individual and the magnitude of the potentially disabling condition. *(From Brandt, EN, Jr, and Pope, AM (eds): Enabling America: Assessing the Role of Rehabilitation Science and Engineering. National Academy Press, Washington, DC, 1997, p 9, with permission.)*

These divergent viewpoints directly affect what types of tests and measures should be chosen and what parameters of measurement are appropriate to yield data useful to making clinical judgments. Most important, physical therapists must consider the differences between capacity for function and habitual function in determining the prognosis for rehabilitation and estimating the likelihood of the success of an intervention. Patients accept a therapist's recommendations regarding the anticipated goals of treatment only if there is the perceived need and motivation to function habitually at the highest level of ability. Understanding the difference between what a person actually does or would be willing to do and what that person potentially could do is an essential component of designing realistic, and achievable, functional goals. For example, even though a person might have the capacity to climb stairs, there may not be any willingness to do so. Ultimately, physical therapists must abide by each patient's own decision regarding which tasks and activities will be incorporated into a daily routine and what is a meaningful level of function, regardless of the therapist's professional opinion.

Irrespective of the particular instrument used, there are several basic considerations to be kept in mind. The setting chosen must be conducive to the type of testing and free of distractions. Instructions should be precise and unambiguous. Testing may be biased by fatigue. If a patient performs best in the morning but tires by afternoon, an accurate determination of functional ability must consider the variation in the patient's performance. Therapists should be aware of patients whose energy fluctuates during the day, and interpret the data accordingly. In general, information related to body functions and body structure, activities, and participation, as well as personal and environmental factors, should be generated during the initial examination (or as soon as feasible) so the information may be considered together to develop a picture of a patient's function. Retesting should occur at regular intervals during treatment to document progress and before discharge from the episode of care.

Types of Instruments

Performance-Based Tests

A performance-based test involves **observing the patient during the performance of an activity**. Generally speaking, the therapist who chooses a performance-based test is searching for an indication of what a patient can do under a specific set of circumstances, which may or may not be similar to the natural environment in which the patient functions. If a performance-based test is chosen with the intention of making inferences about how the patient will perform at home, the conditions and setting should be as similar as possible to the actual environment in which the patient usually performs the tasks and activities. A performance-based approach may be used either to describe the patient's current level of function or to identify the maximum level of function possible.

During the administration of the test, each task is presented and the patient is asked to perform it. For example, to examine current level of function in wheelchair mobility, a patient would receive this instruction: "Push your wheelchair over to that red chair and stop." To determine the patient's maximum level of function in this activity, the instruction might specify a particular manner of performance: "Push your wheelchair over to that red chair *as quickly as you can* and stop." Understanding the difference between these two commands, even though both are observation-based performance of wheelchair mobility, is essential to sound clinical decision making. Data from the first example identify only what the patient can do under specific circumstances, but does not support the inference that the patient will be able to wheel across a busy intersection in the short time span allotted to a typical pedestrian walkway. The form of the instruction determines whether an inference can be made about the patient's maximal level of function in formulating the goals for intervention and the plan of care.

In either case, a patient is given no additional instructions or assistance unless he or she is unable or unsure of how to perform. Then only as much direction or assistance as is needed is given. Appropriate safety precautions should be taken during the session so that the patient does not attempt tasks that are potentially dangerous.

A number of tests of impairments are sometimes also referred to as functional performance measures, including the *6-Minute Walk Test*,[13] the *Physical Performance and Mobility Examination*,[14] the *Functional Reach Test*,[15,16] the *Get Up and Go Test*,[17] the *Timed Up and Go Test*,[18] and the *Physical Performance Battery*.[19] A performance instrument of this sort typically measures either a complex integration of impairments, the performance of actions, or a combination of both by direct observation. Overall, the tests do provide some insight into the individual's capabilities to maintain a posture, transition to other postures, or sustain safe and efficient movement. The data from such a test, gathered under controlled conditions, characterize a person's performance limitations as a result of impairments, and may purport to predict the success or failure of an individual in performing goal-directed tasks or activities under natural conditions, using a score that summates the combined effects of impairments throughout and across systems on movement dysfunction. Each of these tests can contribute to an understanding of an aspect of a person's function, but they should not be used to represent all aspects of function. Although these tests employ the method of direct observation of performance, they most often do not measure the task or activity as it might be

accomplished in the "real" world of the patient, which is also influenced by motivation and habit.

Self-Reports

In contrast to the method of direct observation, useful data on how a person functions may also be gathered by *self-report,* in which the patient is asked directly either by the therapist or a trained interviewer (*interviewer report*) or through the use of a *self-administered report* instrument. The critical issue in the ability of a self-report to capture function correctly and completely lies in providing clearly worded questions without language bias, concise directions on completing the questions, and a format that encourages accurate reporting of answers to all questions. Self-report is a valid method of determining function and may be preferable to performance-based methods in some circumstances.[20] Self-reports should be designed so that questions are asked in a standard format and answers are recorded as specified by the predetermined choices. Long paper-and-pencil tests may be difficult for those with upper extremity disability.

Clinical personnel who will act as interviewers must be trained to administer a questionnaire. Interviewers should practice until they have reached a high degree of agreement with expert examiners of the same cases. Periodic retraining may be necessary if interviewers do not have frequent practice administering the instrument. The interview should be scheduled with the patient in advance and conducted in an environment conducive to complete concentration. Interviews may be conducted by phone or in person, but the mode of administration should be kept consistent if comparisons of the data are to be made. Ad lib prompting by the interviewer or caregivers for answers is discouraged because these intrusions into the patient's self-report tend to bias results. If the patient has had help in filling out a form or responding to questions, this should be noted. Similarly, if the data have been provided by a spouse, family member, or caregiver, this should be documented as well.

The distinction in perspectives on function that was discussed regarding performance-based measures of function also holds for self-reports. It is extremely important to distinguish between questions that indicate a person's habitual performance (e.g., "*Do* you cook your own meals?") and those that identify a person's perceived capacity to perform a task (e.g., "If you had to, *could* you cook your own meals?"). It may also be important to distinguish between an individual's performance of an activity and his or her confidence in performance of an activity. For example, confidence and performance for 21 items are measured in separate scales in APTA's *Outpatient Physical Therapy Improvement in Movement Assessment Log (OPTIMAL)*.[21]

The time frame reference of self-reporting is also a relevant consideration. A therapist should decide in advance if the relevant "window" on a person's functional level is the past 24 hours, last week, last month, or the previous year. One can easily imagine how the same person might respond differently regarding the same functional activity depending on frame of reference. Instruments that examine only short-term objectives may not relate well to the long-term objectives of a rehabilitation program.

Instrument Parameters and Formats

Performance-based and self-report instruments grade performance on a number of different criteria in a variety of formats. There is no one parameter or format that is perfect for every type of clinical encounter or research need. It is particularly important that documentation of a patient's progress not be blunted by *floor* or *ceiling* effects. For example, if a therapist wishes to measure changes in function among generally well elderly patients and the most advanced functional activity on an instrument measures "independent ambulation on level surfaces," there would be no room to demonstrate either progression or decline except around ambulation on level surfaces. Similarly, a patient who was severely debilitated might improve in transfers from needing the maximum assistance of two persons to maximum assistance of one. If the instrument only measures change from "maximum assistance" to "moderate assistance," this patient's real improvement will not be recorded.

Descriptive Parameters

Therapists should use descriptive terms that are well defined and unambiguous. Meanings of descriptive terms should be clear to all others using the medical record. Box 8.1 provides a sample set of acceptable terms and definitions. Additional terms used to qualify function include *dependence* and *difficulty*. Most often, the term *independent* refers to the complete absence of a need for human or mechanical assistance to accomplish a task, but some scoring systems consider reliance on devices and aids as a modified form of independence when used without the help of another person. The use of equipment during the performance of a functional task should be explicitly noted; for example, "independent in ambulation with axillary crutches" or "independent in dressing with adapted clothing and a long-handled shoe horn."

Difficulty is a hybrid term that suggests an activity poses an extra burden for the patient, regardless of dependence level. It is unclear whether it is a measure of overall perceptual-motor skill, coordination, endurance, efficiency, or a combination of measures. Difficulty can be measured in two ways. One approach assumes that difficulty is likely to be present and quantifies the degree of difficulty that the individual experiences while performing the activity (e.g., "How much difficulty do you have while doing household chores? None, some, or a

Box 8.1 Functional Examination and Impairment Terminology

Definitions

1. **Independent:** patient is able consistently to perform skill safety with no one present.
2. **Supervision:** patient requires someone within arm's reach as a precaution; low probability of patient having a problem requiring assistance.
3. **Close guarding:** person assisting is positioned as if to assist, with hands raised but not touching patient; full attention on patient; fair probability of patient requiring assistance.
4. **Contact guarding:** therapist is positioned as with close guarding, with hands on patient but not giving any assistance; high probability of patient requiring assistance.
5. **Minimum assistance:** patient is able to complete majority of the activity without assistance.
6. **Moderate assistance:** patient is able to complete part of the activity without assistance.
7. **Maximum assistance:** patient is unable to assist in any part of the activity.

Descriptive Terminology

- **6.** Moderate assistance
- **7.** Maximum assistance

} may require cues

C. Functional Balance Grades

1. Normal	Patient able to maintain steady balance without support (static). Accepts maximal challenge and can shift weight easily and within full range in all directions (dynamic).
2. Good	Patient able to maintain balance without support, limited postural sway (static). Accepts moderate challenge; able to maintain balance while picking object off floor (dynamic).
3. Fair	Patient able to maintain balance with handhold support; may require occasional minimal assistance (static). Accepts minimal challenge; able to maintain balance while turning head/trunk (dynamic).
4. Poor	Patient requires handhold and moderate to maximal assistance to maintain posture (static). Unable to accept challenge or move without loss of balance (dynamic).
5. No balance	

[a]Types of cues: verbal, visual, or tactile. In some instances (e.g., a person with a memory deficit, short attention, learning disability, visual loss), a decrease in the number of cues may represent treatment progress, even though the level of dependence remains the same. Interim progress notes can denote these changes by citing frequencies (e.g., 2 out of 3 tries) or an arbitrarily defined rank order scale (e.g., always/occasionally/rarely).

great deal?"). The other approach quantifies the frequency that the difficulty is encountered (e.g., "How often do you have difficulty putting on your shoes? Never, sometimes, very often, or always?").

Often it is helpful to qualify a person's performance by linking observations with nonspecific indicators of impairments such as the energy consumption required to complete the functional task and the degree to which patients must exert themselves to engage in the activity. Simple measurements of a patient's physiological response to activity generally include heart rate, respiratory rate, and blood pressure, obtained at rest (baseline measurements), during (as possible), or immediately after completion of the most stressful elements of the activity. For example, "heart rate increased to 100 beats per minute with independent ambulation on stairs; no increase in respiratory rate." In addition, the patient's perceived fatigue, perception of exertion, and overt signs of physiological stress, such as shortness of breath, also should be noted. These notations may assist the therapist

in a quick identification of some obvious impairments that limit function, which should be followed by more specific tests and measures of impairment.

Additional descriptors frequently used to qualify functional performance further include (1) pain, (2) fluctuations according to the time of day, (3) medication level, and (4) environmental influences. Any factors that modify a patient's function should be carefully noted and considered by the physical therapist evaluating examination data.

Quantitative Parameters

The time it takes to complete a series of activities is often used to enhance a therapist's quantification of function when a given speed of performance is required or an improvement in performance speed is expected. A common example of timed functional skills is found in premedication and postmedication performance of individuals with Parkinson disease who are placed on l-dopa therapy. Examples of activities that may be timed include (1) walking a set distance; (2) writing one's signature; (3) donning an article of clothing; and (4) crossing a street during the time of a "Walk" light. Scores of timed tests should not be taken as absolute, but rather as one dimension of performance. Although the ability to complete a particular activity in a specified period of time does provide one kind of important data on a patient's overall ability, it may not always be correct to conclude that what is being measured as "quicker" can be interpreted as "better." For example, the patient may get dressed quickly (within seconds), but do so with poorly coordinated movements and a haphazard outcome. When the task is slowed down, the movements may become more coordinated, with a more satisfactory functional outcome, even though the time taken to do the task increases. Similarly, certain medical conditions that affect energy expenditure may require that the patient properly pace a functional activity to complete it successfully. Thus, time scores alone do not always yield the complete functional picture. When interpreted in light of other aspects of the patient's clinical presentation, they do provide an added dimension to the evaluation of data collected during a functional examination.

Response Formats

Function can be measured with tests that report data as nominal, ordinal, interval, and ratio measures. The clinician should consider the uses of the measure when deciding which format to use. In cases where the clinical decision is nominal, such as is the patient ready for discharged to home, a nominal measure such as whether the patient can independently ascend 10 stairs may be adequate. When ratio measures are obtained, such as the score on a Berg Balance scale, the clinician may interpret the score as a dichotomous measure related to the decision (e.g., Does the patient have or not have adequate balance for discharge to home?). In cases where the clinical decision is more complex, such as the amount of assistance a patient needs with activities, nominal measures cannot be used and the measure should reflect the type and amount of information needed for the decision.

Nominal Measures

One of the simplest formats in functional tests uses a **nominal** level of measurement by presenting a **checklist** of various functional tasks on which the patient is simply scored as able to do/not able to do, independent/dependent, completed/incomplete, or the like. The results are not particularly descriptive of the exact nature of an individual's limitations and usually require further examination before interpretation. Nominal measures, however, may be helpful in making dichotomous decisions. For example, knowledge of the ability to perform ADL skills by themselves is important in deciding if a patient can be discharged, or not, to living independently at home.

Ordinal Measures

A few tests use descriptive scales that describe a range of performance or the degree to which a person can perform the task. Most commonly, the scales are **ordinal or rank-order scales** (e.g., "no difficulty," "some difficulty," or "unable to do"; or "always," "sometimes," "rarely," or "never"). Scales may be graded in ascending or descending order. The primary drawback in using such a system to score function is that these grades do not define categories that are separated by equal intervals. For example, it is not possible to tell whether the patient who went from maximal assistance to moderate assistance changed as much as a patient who also went one level between moderate assistance and minimal assistance.

Interval Measures

Summary or **additive measures** grade a specific series of skills, award points for part or full performance, and sum the subscores as a proportion of the total possible points, such as 60/100 or 6/24 and so forth. Although the scales typically may include a score of zero, this value represents a floor effect of the scale and not necessarily the absence of the construct. One example of a summary measure, which is well known to physical therapists, is the Barthel Index.[22]

Some formal, standardized instruments for testing function summarize detailed information about a complex area of function into an overall index score. Use of these instruments facilitates the interpretation of complex data and enables the clinician to perform cross-disease, cross-program, and cross-population comparisons of function. Caution must be exercised in considering only summated scores, however, because potentially important individual differences in functional ability can be masked.[23] A patient who is limited in only a few of

the many tasks covered on a functional test will most likely score well, despite what could be substantial limitations in discrete functional activities that are pertinent to the physical therapist's anticipated goals of treatment. Similarly, two patients with the same numeric score might be quite different in their functional deficits, having gained (or lost) their points on different activities. Although these measures yield a "hard number," which is regarded statistically as an interval level of measurement, the degree to which "points" are truly equal intervals or only ordinal should be carefully scrutinized.

Ratio Measures

Visual or linear analog scales attempt to represent measurement quantities in terms of a straight line placed horizontally or vertically on paper (Fig. 8.4). The endpoints of the line are labeled with descriptive or numeric terms to anchor the extremes of the scale and provide a frame of reference for any point in the continuum between them. Some scales will also use descriptors or numeric intervals between the endpoints to assist the individual in grading responses. Commonly a visual analog line of 10 centimeters (100 millimeters) is used. The patient is asked to bisect the line at a point representing self-reported position on the scale. The patient's score is then obtained by measuring from the zero mark to the mark bisecting the scale.

Examples of the use of visual analog scales in rehabilitation settings may be to measure pain, dyspnea, function, or satisfaction with care. Since visual analog scales include a true zero and equal intervals (e.g., mm) they may be analyzed as ratio measures. In contrast, some clinicians may use a numeric rating scale (e.g., rate your function on a scale from 0 to 10) to measure similar impairments. Although providing a numeric rating may be quicker to obtain in clinical settings, scores obtained may not represent interval or ratio data as the reporting of a numeric value may not represent equal intervals. For example, a 4 reported by a patient may not be twice as much function as a 2 reported by another patient. This is due to the nature of interval and ratio scales because a ratio scale allows for the comparison of scores using addition, subtraction, multiplication, or division and an interval scale allows for the comparison of scores using addition or subtraction. These mathematical functions cannot be performed with ordinal or nominal scores.

Figure 8.4 A visual analog scale for measuring pain or other symptoms. The patient is instructed to mark the line at the point that corresponds to the degree of pain or severity of symptoms that are experienced.

Knowledge of the level of measurement is important in analyzing data from groups of patients, such as a rehabilitation unit wishing to summarize the functional status of patients admitted during a specified time period. For interval and ratio measures, means and standard deviations may be calculated (assuming the data follow a normal distribution). For ordinal measures, medians and interquartile ranges are appropriate, whereas nominal measures should be reported as modes or frequency counts.

INTERPRETING TEST RESULTS

Clearly, the single most important consideration in examining functional status is using the test results correctly to establish and revise the anticipated goals and expected outcomes of intervention and the plan of care. The therapist should carefully delineate the contributing factors that result in the functional deficit. When diminished ability is evident, the therapist must attempt to ascertain the cause of the problem. Some important questions to ask include the following:

1. What are the normal movements necessary to perform the task?
2. Which impairments inhibit performance or completion of the task? For example, do factors such as poor motor planning and execution, decreased strength, decreased range of motion, or altered joint integrity impede function? Does fatigue hamper functional ability?
3. Are the patient's functional deficits the result of impaired communication, perception, vision, hearing, or cognition?

Examples of the kinds of questions a therapist must pose to assess function and integrate findings into a comprehensive treatment program are found using the case vignettes in Table 8.4:

Table 8.4 Sample Case Vignettes

Case A	Case B
36-year-old male construction worker Dx: traumatic right transtibial amputation; following fracture left femur	72-year-old female homemaker Dx: CVA with right hemiplegia with global aphasia
Partial Examination Findings	
Motor Control and Muscle Performance	
Decreased in all extremities following prolonged immobilization	Flaccid paralysis right extremities
Activity Limitations	
Unable to transfer from bed to wheelchair	Unable to transfer from bed to wheelchair

Dx = Diagnosis.

Although the activity limitation in each case is in fact identical, the contributing factors, goals and outcomes, and the interventions would be markedly different. In case A, the patient's inability to transfer can reasonably be attributed to decreased strength. When ameliorated, it is likely that the patient will go on to achieve an outcome of independent ambulation with a prosthesis. The patient in case B has factors that cannot be addressed solely through physical therapy. In addition, it may be difficult to determine whether it is the paralysis or the aphasia that compromises efforts to assess and improve function. Although a similar goal of independence in wheelchair mobility and transfers may be proposed, reexamination throughout the episode of care may demonstrate that functional deficits persist, despite improvement in motor function. In that case, the impairments in comprehension and language function may be the more important factors contributing to functional limitation. Thus, the design of rehabilitation programs is based on the impairments that presumably underlie the functional deficits. If remediation of the impairment does not solve the functional problem, the therapist needs to reexamine the initial clinical impression by looking for other potentially causative factors.

Some functional tasks may need to be analyzed more precisely. Activities can be broken down into subordinate parts, or subroutines. A **subordinate part** is defined as an element of movement without which the task cannot proceed safely or efficiently. For example, bed mobility includes the following subordinate parts: (1) scooting in bed (changing position for comfort or skin care and getting to the edge), (2) rolling onto the side, (3) lowering the legs, (4) sitting up, and (5) balancing at the edge of the bed. A functional loss of independent bed mobility may result from an inability to perform any or all of these subroutines. These are not only checkpoints for examining patients, but they also later represent the anticipated goals of various interventions. The more involved the patient, the slower the learner, or complex the task, the more the functional task may need to be broken down into subordinate parts.

Determining the Quality of Instruments

Within the rehabilitation setting, many tools exist for the measurement of function or its components. For example, the Catalog of Tests and Measures in APTA's *Guide to Physical Therapist Practice* includes close to 500 tests and measures.[24] In deciding which measure to use the instrument's **reliability** and **validity** should be considered. If the reliability and validity of an instrument have not been established, little faith can be put in the results obtained or in the conclusions drawn from the results. A poorly constructed instrument can produce data that are questionable, if not worthless. In light of the fact that the viability of physical therapy as a reimbursable service rests on the demonstration of functional outcomes, the importance of these concepts to functional testing becomes clear. In accordance with APTA's Standards of Measurement, physical therapists should use only those instruments whose reliability and validity are known.[25] Although no instrument will have perfect reliability or validity, therapists must be able to gauge the certainty of their data and the appropriate scope of inferences drawn from the data.

Reliability

A reliable instrument measures a phenomenon dependably, time after time, accurately, predictably, and without variation. If a functional test is not reliable, the patient's initial baseline status or the true effect of treatment can be concealed. An instrument with acceptable *test–retest reliability* is stable and will not indicate change when none has occurred. Tests performed by the same therapist of the same performance should be highly correlated (*intrarater reliability*). Instruments should also have strong *interrater reliability*, or agreement among multiple observers of the same event. If a particular patient is examined by several therapists in the course of treatment, or reexamined over time to determine long-term change, the reliability of the functional tool must be known.

A flaw in the clinical use of most types of standardized tests and measures is the tendency to disregard interrater reliability. To use functional tests with maximum accuracy, (1) scoring criteria must be defined clearly and must be mutually exclusive; (2) criteria must be strictly applied to each clinical situation; and (3) all therapists in a facility must be retrained periodically in the use of the instrument to ensure similarity.

Values for reliability coefficients have been recommended. For example, Portney and Watkins suggest less than 0.50 as poor reliability, 0.50 to 0.75 as moderate reliability, and greater than 0.75 as good reliability.[26, p. 82] These cutoffs must be based on the precision of the measured variable and how the results of the reliability test will be applied. A clinician should use these values as guidelines, and not as absolutes, in determining the accuracy of the measurement and needs to consider the use of the instrument. If high precision is needed in the instrument for clinical decision making, values of a reliability coefficient higher than the minimal threshold for "good" reliability should be used. In addition to the value of the reliability coefficient, the clinician should consider the variability of the measurement that may be expressed as a standard deviation (SD) or confidence interval (CI).

Validity

Validity is a multifaceted concept and established in many different ways. Questions regarding an instrument's validity attempt to determine (1) whether an instrument designed to measure function truly does just that; (2) what the appropriate applications of the instrument are; and (3) how the data should be interpreted.

First, the valid instrument should, on the face of it, appear to measure what it purports to measure (*face validity*).[25,26] For example, an instrument claiming to measure balance should appear to measure some aspect of balance. Another critical dimension is whether the assessment instrument measures all the important or specified dimensions of function (*content validity*). If there were a **gold standard** (an unimpeachable measure of a phenomenon, such as a laboratory test with normative values), then a new instrument could be tested against the results of this standard (*criterion-related validity*). Such a gold standard does not exist for functional instruments. New functional measurement tools can, however, be compared to existing ones that are accepted measures of the same functional activities. The degree to which the two instruments agree helps to establish *concurrent validity*. Concurrent validity can also be demonstrated by showing that an instrument corresponds appropriately to measures of other phenomena. This method is particularly relevant for self-report instruments. The concurrent validity of some self-report instruments has been determined by comparison with clinician ratings and other clinical findings; for example, a person's level of function as indicated by an instrument correlates directly with clinician's ratings of improvement and inversely with the patient's reports of pain.

Sensitivity and Specificity

In the comparison of a test of function to a gold standard or to another existing instrument one should be concerned with the ability of the measure to make an accurate classification. *Sensitivity* of a test refers to the proportion of individuals with a limitation in function (as identified by the gold standard or existing instrument) who are correctly classified. In other words, sensitivity is an indication of how well a test identifies persons who should have a positive finding on the test. In contrast, s*pecificity* of a test refers to the proportion of individuals who do not have a limitation in function who are correctly classified. Additional properties of a test are the positive predictive value and the negative predictive value. The *positive predictive value* is the proportion of people who have a positive finding on a test who actually have a limitation in function as classified by the comparison test; the *negative predictive value* is the proportion of people who have a negative finding on a test who do not have a limitation in function.

Both sensitivity and specificity are expressed as values between 0 and 1. Ideally, both sensitivity and specificity should be as close to 1 as possible, but this is very rare in reality. Different tests, however, will be better at identifying those with the condition and others will be better at identifying those without the condition. This will be reflected in the magnitude of their sensitivity and specificity scores. When values of sensitivity or specificity are close to 1, the SpPIn and SnNOut acronyms may help with interpretation.[27] The acronym SpPIn refers to tests that have very high specificity: a positive finding helps to rule in the condition. SnNOut, on the other hand, refers to tests that have very high sensitivity: a negative finding helps to rule out the condition. In general, sensitivity and specificity values greater than 0.95 are considered very high.

Sensitivity and specificity values may be combined to obtain a likelihood ratio (LR) with the following equations. The calculation of likelihood ratios may be helpful in determining how much the test result influences the identification of a patient's condition or identification of a limitation in function. This is especially helpful in cases when sensitivity and specificity are not high enough to apply the SpPIn and SnNOut rules.

$$\text{Positive LR} = (\text{Sensitivity})/(1 - \text{Specificity})$$
$$\text{Negative LR} = (1 - \text{Sensitivity})/(\text{Specificity})$$

The larger the value of a positive likelihood ratio, the more helpful the finding of a positive test is in identification of the condition. Likewise, the smaller the value of a negative likelihood ratio (e.g., close to zero), the more helpful the finding of a negative test is in ruling out the condition. In contrast, a positive or negative likelihood ratio close to 1 is not helpful in identifying the condition. Likelihood ratios can be helpful in determination of post-test odds through their application in Bayes' theorem (i.e., the pretest odds (the likelihood ratio = the post-test odds).[27]

There is also the *predictive validity* of a test or measure, which indicates the likelihood of a subsequent phenomenon or event (e.g., return to work) on the basis of a prior phenomenon (e.g., a baseline measure of function). Finally, the degree to which an instrument measures abstract concepts such as physical mobility or social interaction can be established over time (*construct validity*). Construct validation, using a variety of statistical procedures, is a never-ending process as our understanding of the construct is further refined as instruments are developed to measure it.

Meaningful Change

In addition to reliability and validity, a measure of functional status should be sufficiently sensitive to reflect meaningful changes in a patient's status. The change should exceed the **minimal detectable change** (MDC) of the instrument and a **minimal clinical important difference** (MCID). The MDC can be described as the smallest amount of change in a measurement that exceeds the measurement error of the instrument. A physical therapist should be aware of published MDC values for the instruments used to measure function. A sample of MDC and MCID values is presented in Table 8.5. The clinician should keep in mind that MDC values are specific for the patient population in whom the instrument was investigated.

In cases where MDC values may not exist in the literature, values may be calculated if the reliability

Table 8.5 Examples of MDC and MCID Values

Measure of Function and Population of Interest	MDC or MCID Value	Reference
6-Minute Walk Test in persons following total hip and knee arthroplasty	61.34 m	Kennedy et al (2005)[28]
6-Minute Walk Test in persons with COPD	37-71 m	Make (2007)[29]
6-Minute Walk Test in older adults	~50 m	Perera et al (2006)[30]
6-Minute Walk Test in persons with Alzheimer disease	33.5 m	Ries et al (2009)[31]
6-Minute Walk Test in persons following stroke	54.1 m	Fulk et al (2008)[32]
Timed Up and Go Test in persons with Alzheimer disease	4.09 sec	Ries et al (2009)[31]
Timed Up and Go Test in persons following total hip and knee arthroplasty	2.49 sec	Kennedy et al (2005)[28]
Gait speed in persons following stroke	0.1 m/sec	Fulk and Echternach (2008)[33]
Gait speed in persons following hip fracture	0.1 m/sec	Palombaro et al (2006)[34]
Berg Balance Scale in persons following stroke	7 points	Liaw et al (2008)[35]
Berg Balance Scale in persons with Parkinson disease	5 points	Steffen and Seney (2008)[36]
FEV_1 in persons with COPD	100 ml	Make (2007)[29]

COPD = chronic obstructive pulmonary disease; FEV_1 = forced expiratory volume in 1 second.

coefficient, such as an intraclass correlation coefficient (ICC), and a measure of its variability is known, such as the SD. The following equations present the relationship between the MDC95 (the amount of change with 95% confidence beyond measurement error) and the standard error of the measurement (SEM). The second equation can be used to determine the SEM if the value of the reliability coefficient and the standard deviation (SD) from one of the groups used to determine reliability is known. Note that because the ICC and the SD are from a specific sample, the calculated SEM and MDC95 are only generalizable to persons with similar conditions.

$$MDC95 = 1.96 \times SEM \times \sqrt{2} \text{ where } SEM = SD \times \sqrt{(1 - ICC)}$$

For example, if a study of persons after total knee arthroplasty reported an ICC of 0.75 for knee flexion with an SD of 5 degrees, the SEM is equal to 2.5 degrees. Using this value in the first equation, the MDC95 is 6.925 degrees. In other words, the measure of knee flexion would need to change more than 7 degrees to have 95% confidence that this change was due to something other than measurement error.

The MCID is the smallest difference in a measured variable that signifies an important rather than a trivial difference in the patient's condition. The value of the MCID should exceed the value of the MDC; in other words, the MCID needs to exceed the measurement error. For example, a 50-meter change in distance on the 6-minute walk test may be beyond measurement error; however, is the ability to walk 50 meters during 6 minutes meaningful to an individual patient's function? A number of different ways have been suggested to determine values for the MCID.[26, pp. 646-652] No universal method exists. Controversies exist among the strategies to determine MCID based on the perspective of what is meaningful, as well as issues related to measurement.[37,38] The clinician should consult the literature for recommended values of the MCID for measures of function. Additionally, online resources are being developed to help clinicians locate values for a number of tests.[39,40] Similar to the interpretation of the MDC, in consulting published values for the MCID for a measure of function the clinician needs to consider the sample for which the values were established.

Considerations in Selection of Instruments

A large number of instruments have been developed to assess and to classify function. Given the plethora of instruments that currently exist, it is quite reasonable to ask how these instruments compare with one another. It is important to remember that no instrument is perfect for all patients or all situations. No instrument can measure all the items potentially relevant to a particular individual and provide the perfect composite picture. For example, one instrument may provide an extensive measure of ADL, but not deal with psychological or social dimensions of function. Another instrument may investigate social functioning while omitting some ADL tasks. Many items overlap from instrument to instrument. For example, a question on the ability to ambulate is a common item found in most physical function instruments. Although instruments may cover the same kind of activity, the questions posed about the performance of the same activity may be quite different. For

example, one instrument may investigate the degree of difficulty and of human assistance required to "dress yourself, including handling of closures, buttons, zippers, snaps." Another may ask, "How much help do you need in getting dressed?" As discussed, differences also may exist in the time frames sampled in the various instruments. Critical questions to ask in selecting an instrument are presented in Box 8.2.

Extrapolating items from a variety of instruments may provide the kind of data desired but should be considered with extreme caution inasmuch as this process changes reliability or validity of the measurements. Factors such as the theoretic orientation of the user, the purpose for using the instrument, and the relevance of particular functional items to certain patient populations all enter into the decision making process. In the final analysis, the choice of instrument may be dictated by practical considerations. For example, self-report instruments, which rely on information from the patient, are limited in use to mentally competent individuals. Time and resources for administration also may influence test selection, or some rehabilitation facilities may adopt the use of a specific instrument for all patients (e.g., the Functional Independence Measure [FIM]). In any case, many suitable instruments are available for assessing functional status, some of which are commonly used by clinicians as well as researchers.

Box 8.2 Critical Questions to Ask in Selecting an Instrument

1. What are the domains or categories that the assessment instrument focuses on?
2. How adequately does the instrument measure the domain or domains being sampled?
3. What areas of physical function are included? Does the instrument measure ADL? Does the instrument measure instrumental activities of daily living (IADL), for example, more advanced skills such as managing personal affairs, cooking, and driving? Mobility skills?
4. What aspect of function is being measured? Is the level of dependence–independence considered? What is the length of time required to complete the functional task? Degree of difficulty? Influence of pain?
5. What is the time frame sampled in the instrument?
6. What is the mode of administration?
7. What type of scoring system is used?
8. Are multiple instruments necessary to provide a more complete picture of functional status?
9. Who completes the instrument—the clinician, the patient (self-report), or family member (proxy)?
10. How long does the instrument take to complete?

SINGLE DIMENSION VERSUS MULTIDIMENSIONAL MEASURES OF FUNCTION

Among the factors to consider in selecting a measure of function is whether a single dimension measure or a multidimensional measure should be used. For example, single dimension measures may include a specific construct such as balance, gait, or reaching; whereas multidimensional measures would include a combination of these constructs or have items that represent impairments, activity limitations, and participation restrictions. As an example of a single test, gait speed may be used to represent function. This test may frequently be used in clinical settings because it require a minimal amount of time to perform and little equipment other than a stopwatch and a hallway free of obstructions. For the test, the time for the patient to ambulate a specified distance, such as 10 meters, is recorded and speed is calculated as distance divided by time and frequently reported as meters per second. Although this is a test of a specific mobility item, walking, one might make inferences in regard to a patient's function based on this test. The clinician, however, is responsible to check with the literature to determine if the inferences are supported by evidence, because there are some specific populations where gait speed may be representative of a patient's ability to function. For example, in a study of persons after hip arthroplasty it was demonstrated that gait speed was more representative of the capacity to ambulate than performance because when the patients were tested in real world environments their gait speed was slower than in the clinic. However, in this case the measure of capacity versus performance was highly correlated ($\rho = 0.440$).[41] Recent evidence among older persons also suggests that the measure of gait speed is highly related to overall health.[42] For populations that have not been tested, however, a clinician should be cautious in using gait speed to make inferences regarding function.

Other tests may use multiple items to measure a single dimension, such as the items in the Barthel Index to measure ADL or the 14 items in the Berg Balance Scale to calculate a balance score. A clinician is justified using these instruments to describe the dimension of interest related to the patient's problem. However, unless data exist, they should not be used to make inferences regarding other impairments, activity limitations, or participation restrictions. Other instruments specific to those dimensions should be used as appropriate to the patient's presentation.

Alternatively, a clinician may take an approach to understand a patient's health status in all its domains. Further instrument development has resulted in the emergence of multidimensional health status instruments to measure the spectrum of health status more comprehensively. Used in conjunction with traditional clinical methods of examining signs and symptoms,

multidimensional functional status instruments can add an important comprehensive view of a patient's function to the overall health status. In this respect they add a crucial, and previously missing, component in evaluating the health of individuals.

Recently, more comprehensive instruments are being developed to measure multiple dimensions of the ICF to present an overall view of a person's function. Specifically, a number of *ICF Core Sets* are being developed for specific patient conditions, such as stroke,[43] or by settings such as postacute rehabilitation settings.[44] Each core set includes items related to body functions, body structures, activities, participation, and contextual factors important to the specific condition or setting. These core sets are being developed using expert opinion and are being empirically tested to determine if representative items are included.[45,46] These core sets potentially may allow a clinician to focus on the most relevant items from the myriad of specific items in the ICF classification.

The final section of this chapter briefly discusses one single dimension instrument and three multidimensional instruments a physical therapist may use in practice. Many other instruments exist, some of which were mentioned previously in this chapter and some of which are included in other chapters. For a selection of instruments, the reader is referred to the APTA's *Catalog of Tests and Measures*.[24]

For the purposes of illustration, three multidimensional instruments, the *Functional Independence Measure* (FIM), the *Outcome and Assessment Information Set* (OASIS), and the *SF-36* are presented. Choice of a multidimensional instrument carries the same caveats mentioned for instruments a single dimension.[47] No instrument measures all potentially relevant items. In addition, depending on how an item is worded, items that may appear to measure the same aspect of function may be measuring different aspects of performance.[48] Table 8.6 presents a comparison of items covered. In the area of physical function, questions on the ability to ambulate are the only items these instruments have in common. Aspects of physical function not covered in any of these instruments include bed mobility and dexterity. The FIM and the OASIS include more ADL items than either the Sickness Impact Profile (SIP) or the SF-36. The SIP and the SF-36 investigate work performance, whereas the FIM and the OASIS do not. This is not surprising, given that the FIM was originally developed as a tool for the inpatient rehabilitation setting and the OASIS was expressly designed for home health agencies, both generally serving older patients. In contrast, the development of the SIP and SF-36 was focused on younger adult populations in ambulatory care. Anxiety and depression are addressed as areas of psychological function in the SIP, the SF-36, and the OASIS, but not in the FIM. The OASIS does not explore social function, whereas the other three instruments do. Finally, only the SF-36 records general health perceptions.

SAMPLE INSTRUMENTS TO ASSESS FUNCTION

The Barthel Index

The *Barthel Index* was developed by a physical therapist over 45 years ago.[22] Although not as commonly used today in practice as some other instruments, this instrument is still used to measure function in clinical research, and this assessment tool represents one of the earliest contributions to the functional status literature and identifies physical therapists' long-standing inclusion of functional mobility and ADL measurement within their scope of practice. The Barthel Index specifically measures the degree of assistance required by an individual on 10 items of mobility and self-care ADL (Table 8.7). Levels of measurement are limited to either complete independence or needing assistance. Each performance item

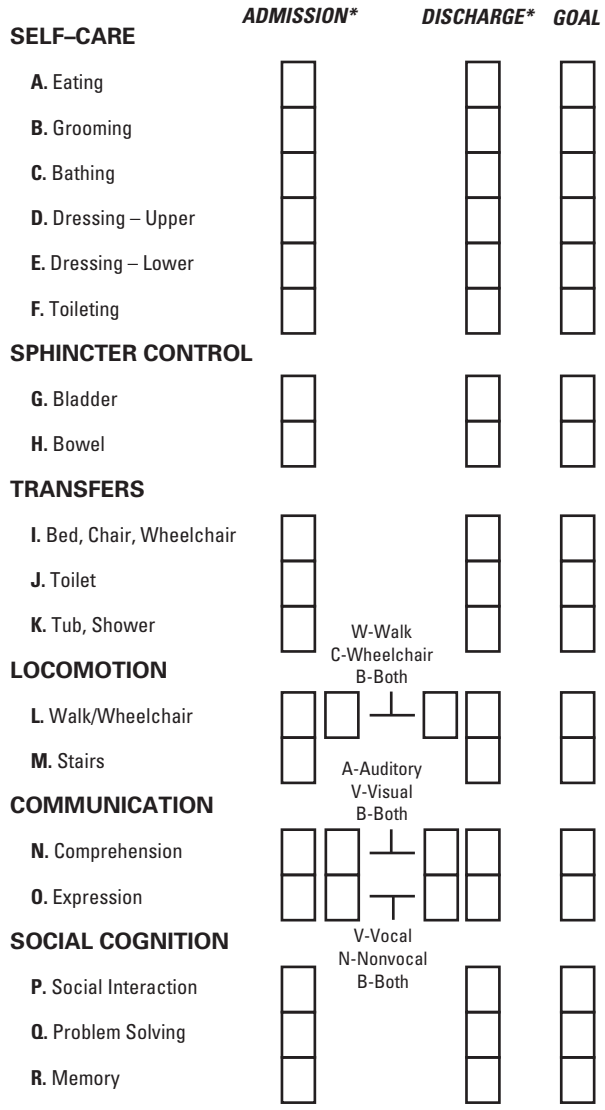
Table 8.7 Items Included in the Barthel Index

Feeding: scores range from independent (able to use utensils and other apparatus) to dependent (needs assistance)
Bathing: scores range from independent to dependent
Personal Toilet: scores range from independent (able to wash, comb hair, brush teeth or shave) to dependent (needs assistance)
Dressing: scores range from independent (able to dress, fasten closures, tie shoes, apply orthosis as needed) to dependent (needs assistance)
Bowels: scores range from independent (accident-free, able to use suppositories or enemas as needed) to dependent (occasional accidents, needs assistance)
Bladder: scores range from independent (accident-free, able to use collection device as needed) to dependent (occasional accidents, needs assistance)
Transfers–Toilet: independent (able to use toilet or bedpan) to dependent (needs assistance)
Transfers–Chair and Bed: scores range from independent (able to manage wheelchair as needed) to dependent (needs assistance)
Ambulation: scores range from independent (able to use assistive devices as needed) to dependent (needs assistance)
Stair Climbing: scores range from independent (able to use assistive devices as needed) to dependent (needs assistance)

Adapted from Mahoney and Barthel.[22]

is scored on an ordinal scale with a specified number of points assigned to each level or ranking. Variable weightings were established by the developers of the Barthel Index for each item based on clinical judgment or other implicit criteria. An individual who uses human assistance in eating, for example, would receive 5 points; independence in eating would receive a score of 10 points. A single global score, ranging from 0 to 100, is calculated from the sum of all weighted individual item scores, so that 0 equals complete dependence for all 10 activities, and 100 equals complete independence in all 10 activities. The Barthel Index has been used widely to monitor functional changes in individuals receiving inpatient rehabilitation, particularly in predicting the functional outcomes associated with stroke.[49,50] Although its psychometric properties have never been fully examined, the Barthel Index has demonstrated strong interrater reliability (0.95) and test–retest reliability (0.89), as well as high correlations (0.74 to 0.80) with other measures of physical disability.[51]

The Functional Independence Measure



The *Functional Independence Measure (FIM)*[52,53] is an 18-item measure of physical, psychological, and social function that is part of the Uniform Data System for Medical Rehabilitation (UDSMR).[54] The UDSMR collects data from participating rehabilitation facilities and issues summary reports of the records that have been entered into the UDSMR database. The FIM uses the level of assistance an individual needs to grade functional status from total independence to total assistance (Fig. 8.5). A person may be regarded as independent if a device is used, but this is recorded separately from "complete" independence. The instrument lists six self-care activities: feeding, grooming, bathing, upper body dressing, lower body dressing, and toileting. Bowel and bladder control, aspects of which some may consider as impairments rather than function, are categorized separately. Functional mobility is tested through three items on transfers. Under the category of locomotion, walking and using a wheelchair are listed equivalently, whereas stairs are considered separately. The FIM also includes two items on communication and three on social cognition.

The FIM measures what the individual does, not what that person could do under certain circumstances. The interrater reliability of the FIM has been established at an acceptable level of psychometric performance (intraclass correlation coefficients ranging from 0.86 to 0.88).[53] The face and content validity of the FIM, as well as its ability to capture change in a patient's level of function, have also been determined. Any clinical worker can administer the FIM after appropriate training in using the response set for each item.

For persons with stroke, the motor scale of the FIM has been shown to have high concurrent validity with the Barthel Index (ICC ≥ 0.83).[55] Gosman-Hedstrom and Svensson[56] have shown strong construct validity between items on the Barthel and items on the FIM that measure functional limitations. Rasch analysis has been applied to the scale scores of the FIM, which are ordinal measures, in order to create interval scale measurements.[57] In addition, the *WeeFIM*, an 18-item instrument based on the FIM, has been developed for use for children between the ages of 6 months and 18 years.[58]

The Outcome and Assessment Information Set

The *Outcome and Assessment Information Set (OASIS)* was designed to ensure the collection of pertinent data on the adult patient in the home care setting that would allow home health agencies to assess the quality of care by measuring the outcomes of care.[59,60] During the years of its initial development, use of the OASIS by home health agencies had been voluntary. However, as of January 1, 1999, home health agencies were mandated to use the OASIS as a *Condition of Participation in*

** Leave no blanks. Enter 1 if not testable due to risk.*

FIM LEVELS

No Helper
- **7** Complete Independence (Timely, Safety)
- **6** Modified Independence (Device)

Helper – Modified Dependence
- **5** Supervision (Subject = 100%)
- **4** Minimal Assistance (Subject = 75% or more)
- **3** Moderate Assistance (Subject = 50% or more)

Helper – Complete Dependence
- **2** Maximal Assistance (Subject = 25% or more)
- **1** Total Assistance or not testable (Subject less than 25%)

Figure 8.5 The Functional Independence Measure (FIM) instrument scores function using a seven-point scale based on percentage(s) of active participation from patient. *(From the Uniform Data System for Medical Rehabilitation, a division of UB Foundation Activities, Inc. the Medicare program by the Health Care Financing Administration. The current version of OASIS, known as OASIS-C, contains core items covering sociodemographic characteristics, environmental factors, social support, health status, and functional status.[61] This version of the instrument was approved in 2009 and represents a substantial change from preceding versions. OASIS is not designed to be a comprehensive examination of a patient or an "add-on" measurement. OASIS items are meant to be integrated into the clinical record to highlight various aspects of a patient's status that identify particular needs for care on admission to the home health service, at follow-up every 60 days, and at discharge. The OASIS was intended to be a discipline-neutral record, administered by any health professional, including physical therapists. Created as part of a research program to develop outcome measures applicable to home health, the OASIS has been field-tested through demonstration projects and refined by a panel of experts. Reliability testing is ongoing.

Ease of administration increases with familiarity with the instrument. Unlike most other instruments, the response sets that accompany each item are specifically matched to the item. Some response sets have only two possible descriptions of behavior, whereas others have as many as nine possible descriptions of behavior. Therefore, the user must be familiar with the possible response set to each item and anticipate that comfort level in using this instrument will increase over a learning curve. The ADL/instrumental ADL (IADL) section is composed of 13 different items (Table 8.8): grooming, dressing the upper body, dressing the lower body, bathing, transferring to the toilet, toileting, transfers, ambulation/locomotion, feeding, meal preparation, ability to use the telephone, prior functioning, and falls risk.

The SF-36

The *SF-36* contains 36 items based on questions used in the RAND Health Insurance Study. These 36 items were culled from the 113 questions used by RAND in the Medical Outcomes Study (MOS) to explore the relationship between physician practice styles and patient outcomes.[62] Thus, it was named the SF-36, because it was a short form of the MOS instrument with only 36 questions. The MOS provided important data

Table 8.8 Outcome and Assessment Information Set (Oasis): ADL/IADL

(M0640) Grooming: Ability to tend to personal hygiene needs (i.e., washing face and hands, hair care, shaving or make up, teeth or denture care, fingernail care).

Prior	Current	
☐	☐	0—Able to groom self-unaided, with or without the use of assistive devices or adapted methods.
☐	☐	1—Grooming utensils must be placed within reach before able to complete grooming activities.
☐	☐	2—Someone must assist the patient to groom self.
☐	☐	3—Patient depends entirely upon someone else for grooming needs.
☐		UK—Unknown

(M0650) Ability to Dress *Upper* Body (with or without dressing aids) including undergarments, pullovers, front-opening shirts and blouses, managing zippers, buttons, and snaps:

Prior	Current	
☐	☐	0—Able to get clothes out of closets and drawers, put them on, and remove them from the upper body without assistance.
☐	☐	1—Able to dress upper body without assistance if clothing is laid out or handed to the patient.
☐	☐	2—Someone must help the patient put on upper body clothing.
☐	☐	3—Patient depends entirely upon another person to dress the upper body.
☐		UK—Unknown

(M0660) Ability to Dress *Lower* Body (with or without dressing aids) including undergarments, slacks, socks or nylons, shoes:

Prior	Current	
☐	☐	0—Able to obtain, put on, and remove clothing and shoes without assistance.
☐	☐	1—Able to dress lower body without assistance if clothing and shoes are laid out or handed to the patient.
☐	☐	2—Someone must help the patient put on undergarments, slacks, socks or nylons, and shoes.
☐	☐	3—Patient depends entirely upon another person to dress lower body.
☐		UK—Unknown

Table 8.8 Outcome and Assessment Information Set (Oasis): ADL/IADL—cont'd

(M0670) Bathing: Ability to wash entire body. ***Excludes* grooming (washing face and hands only).**

Prior	Current	
☐	☐	0—Able to bathe self in *shower or tub* independently.
☐	☐	1—With the use of devices, is able to bathe self in shower or tub independently.
☐	☐	2—Able to bathe in shower or tub with the assistance of another person:
		(a) for intermittent supervision or encouragement or reminders, *OR*
		(b) to get in and out of the shower or tub, *OR*
		(c) for washing difficult to reach areas.
☐	☐	3—Participates in bathing self in shower or tub, *but* requires presence of another person throughout the bath for assistance or supervision.
☐	☐	4—*Unable* to use the shower or tub and is bathed in *bed or bedside chair*.
☐	☐	5—Unable to effectively participate in bathing and is totally bathed by another person.
☐		UK—Unknown

(M0680) Toileting: Ability to get to and from the toilet or bedside commode.

Prior	Current	
☐	☐	0—Able to get to and from the toilet independently with or without a device.
☐	☐	1—When reminded, assisted, or supervised by another person, able to get to and from the toilet.
☐	☐	2—*Unable* to get to and from the toilet but is able to use a bedside commode (with or without assistance).
☐	☐	3—*Unable* to get to and from the toilet or bedside commode but is able to use a bedpan/urinal independently.
☐	☐	4—Is totally dependent in toileting.
☐		UK—Unknown

(M0690) Transferring: Ability to move from bed to chair, on and off toilet or commode, into and out of tub or shower, and ability to turn and position self in bed if patient is bedfast.

Prior	Current	
☐	☐	0—Able to independently transfer.
☐	☐	1—Transfers with minimal human assistance or with use of an assistive device.
☐	☐	2—*Unable* to transfer self but is able to bear weight and pivot during the transfer process.
☐	☐	3—Unable to transfer self and is *unable* to bear weight or pivot when transferred by another person.
☐	☐	4—Bedfast, unable to transfer but is able to turn and position self in bed.
☐	☐	5—Bedfast, unable to transfer and is *unable* to turn and position self.
☐		UK—Unknown

(M0700) Ambulation/Locomotion: Ability to *SAFELY* walk, once in a standing position, or use a wheelchair, once in a seated position, on a variety of surfaces.

Prior	Current	
☐	☐	0—Able to independently walk on even and uneven surfaces and climb stairs with or without railings (i.e., needs no human assistance or assistive device).
☐	☐	1—Requires use of a device (e.g., cane, walker) to walk alone *or* requires human supervision or assistance to negotiate stairs or steps or uneven surfaces.
☐	☐	2—Able to walk only with the supervision or assistance of another person at all times.
☐	☐	3—Chairfast, *unable* to ambulate but is able to wheel self independently.

Continued

Table 8.8 Outcome and Assessment Information Set (Oasis): ADL/IADL—cont'd

☐	☐	4—Chairfast, unable to ambulate and is *unable* to wheel self.
☐	☐	5—Bedfast, unable to ambulate or be up in a chair.
☐		UK—Unknown

(M0710) Feeding or Eating: Ability to feed self meals and snacks. **Note: This refers only to the process of *eating, chewing,* and *swallowing, not preparing* the food to be eaten.**

Prior	Current	
☐	☐	0—Able to independently feed self.
☐	☐	1—Able to feed self independently but requires:
		(a) meal setup; *OR*
		(b) intermittent assistance or supervision from another person; *OR*
		(c) a liquid, pureed, or ground meat diet.
☐	☐	2—*Unable* to feed self and must be assisted or supervised throughout the meal/snack.
☐	☐	3—Able to take in nutrients orally *and* receives supplemental nutrients through a nasogastric tube or gastrostomy.
☐	☐	4—*Unable* to take in nutrients orally and is fed nutrients through a nasogastric tube or gastrostomy.
☐	☐	5—Unable to take in nutrients orally or by tube feeding.
☐		UK—Unknown

(M0720) Planning and Preparing Light Meals (e.g., cereal, sandwich) or reheat delivered meals:

Prior	Current	
☐	☐	0—(a) Able to independently plan and prepare all light meals for self or reheat delivered meals; *OR*
		(b) Is physically, cognitively, and mentally able to prepare light meals on a regular basis but has not routinely performed light meal preparation in the past (i.e., prior to this home care admission).
☐	☐	1—*Unable* to prepare light meals on a regular basis due to physical, cognitive, or mental limitations.
☐	☐	2—Unable to prepare any light meals or reheat any delivered meals.
☐		UK—Unknown

(M0730) Transportation: Physical and mental ability to *safely* use a car, taxi, or public transportation (bus, train, subway).

Prior	Current	
☐	☐	0—Able to independently drive a regular or adapted car; *OR* uses a regular or handicap-accessible public bus.
☐	☐	1—Able to ride in a car only when driven by another person; *OR* able to use a bus or handicap van only when assisted or accompanied by another person.
☐	☐	2—*Unable* to ride in a car, taxi, bus, or van, and requires transportation by ambulance.
☐		UK—Unknown

(M0740) Laundry: Ability to do own laundry—to carry laundry to and from washing machine, to use washer and dryer, to wash small items by hand.

Prior	Current	
☐	☐	0—(a) Able to independently take care of all laundry tasks; *OR*
		(b) Physically, cognitively, and mentally able to do laundry and access facilities, *but* has not routinely performed laundry tasks in the past (i.e., prior to this home care admission).
☐	☐	1—Able to do only light laundry, such as minor hand wash or light washer loads. Due to physical, cognitive, or mental limitations, needs assistance with heavy laundry such as carrying large loads of laundry.

Table 8.8 Outcome and Assessment Information Set (Oasis): ADL/IADL—cont'd

☐	☐	2—*Unable* to do any laundry due to physical limitation or needs continual supervision and assistance due to cognitive or mental limitation.
☐		UK—Unknown

(M0750) Housekeeping: Ability to safely and effectively perform light housekeeping and heavier cleaning tasks.

Prior	Current	
☐	☐	0—(a) Able to independently perform all housekeeping tasks; *OR*
		(b) Physically, cognitively, and mentally able to perform *all* housekeeping tasks but has not routinely participated in housekeeping tasks in the past (i.e., prior to this home care admission).
☐	☐	1—Able to perform only *light* housekeeping (e.g., dusting, wiping kitchen counters) tasks independently.
☐	☐	2—Able to perform housekeeping tasks with intermittent assistance or supervision from another person.
☐	☐	3—*Unable* to consistently perform any housekeeping tasks unless assisted by another person throughout the process.
☐	☐	4—Unable to effectively participate in any housekeeping tasks.
☐		UK—Unknown

(M0760) Shopping: Ability to plan for, select, and purchase items in a store and to carry them home or arrange delivery.

Prior	Current	
☐	☐	0—(a) Able to plan for shopping needs and independently perform shopping tasks, including carrying packages; *OR*
		(b) Physically, cognitively, and mentally able to take care of shopping, but has not done shopping in the past (i.e., prior to this home care admission).
☐	☐	1—Able to go shopping, but needs some assistance:
		(a) By self is able to do only light shopping and carry small packages, but needs someone to do occasional major shopping; *OR*
		(b) *Unable* to go shopping alone, but can go with someone to assist.
☐	☐	2—*Unable* to go shopping, but is able to identify items needed, place orders, and arrange home delivery.
☐	☐	3—Needs someone to do all shopping and errands.
☐		UK—Unknown

(M0770) Ability to Use Telephone: Ability to answer the phone, dial numbers, and *effectively* use the telephone to communicate.

Prior	Current	
☐	☐	0—Able to dial numbers and answer calls appropriately and as desired.
☐	☐	1—Able to use a specially adapted telephone (i.e., large numbers on the dial, teletype phone for the deaf) and call essential numbers.
☐	☐	2—Able to answer the telephone and carry on a normal conversation but has difficulty with placing calls.
☐	☐	3—Able to answer the telephone only some of the time or is able to carry on only a limited conversation.
☐	☐	4—*Unable* to answer the telephone at all but can listen if assisted with equipment.
☐	☐	5—Totally unable to use the telephone.
☐	☐	NA—Patient does not have a telephone.
☐		UK—Unknown

From OASIS-B, Center for Health Services and Policy Research, Denver, CO, 1997, with permission.

on the functional status of adults with specific chronic conditions[63] and the well-being of patients experiencing depression compared to subjects with a chronic medical condition.[64] The SF-36 demonstrated high reliability and validity (correlation coefficients ranging from 0.81 to 0.88).[65–68] Normative data for these self-report items have been collected.[69]

All but one of the 36 questions of the SF-36 are used to form eight different scales: physical function, social function, role function, mental health, energy/fatigue, pain, and general health perceptions. The last question considers self-perceived change in health during the past year. Items are scored on nominal (yes/no) or ordinal scales. Each possible response to an item on a scale is assigned a number of points. The total points for all items within a scale are then added and transformed mathematically to yield a percentage score, with 100% representing optimal health. Sample items on physical function and role function are presented in Table 8.9.

The SF-36 has been used in a number of studies that describe the health status and physical functioning of patients with a variety of impairments receiving physical therapy services.[70–75]

A shortened version has been developed that uses a subset of items from the SF-36.[76] This version, known as SF-12, includes items from each of the eight concepts represented in the SF-36 and allows for the calculation of physical and mental subscale scores. An advantage to using fewer questions is that less time is required to complete the survey. This, however, may be at the expense of having a less precise score that may not be as sensitive to change for an individual patient.[77] The development of the SF-36 stands as the premier example, to date, of a complete and published exploration of the psychometric properties of an instrument as an essential part of its development, and a testament to the responsibility of its creators in verifying the quality of the SF-36 as a scientific tool (Box 8.3 Evidence Summary).

Table 8.9 The SF-36: Physical and Role Function

The following questions are about activities you might do during a typical day. Does *your health* limit you in these activities? If so, how much? (Mark one box on each line.)	Yes, limited a lot	Yes limited a little	No, not limited at all
a. *Vigorous activities*, such as running, lifting heavy objects, participating in strenuous sports	1 ☐	2 ☐	3 ☐
b. *Moderate activities*, such as moving a table, pushing a vacuum cleaner, bowling, or playing golf	1 ☐	2 ☐	3 ☐
c. Lifting or carrying groceries	1 ☐	2 ☐	3 ☐
d. Climbing *several* flights of stairs	1 ☐	2 ☐	3 ☐
e. Climbing *one* flight of stairs	1 ☐	2 ☐	3 ☐
f. Bending, kneeling, or stooping	1 ☐	2 ☐	3 ☐
g. Walking *more than a mile*	1 ☐	2 ☐	3 ☐
h. Walking *several blocks*	1 ☐	2 ☐	3 ☐
i. Walking *one block*	1 ☐	2 ☐	3 ☐
j. Bathing or dressing yourself	1 ☐	2 ☐	3 ☐
During the *past 4 weeks*, have you had any of the following problems with your work or other regular daily activities *as a result of your physical health*? (Mark one box on each line.)		Yes	No
a. Cut down the *amount of time* you spent on work or other activities		1 ☐	2 ☐
b. *Accomplished less* than you would like		1 ☐	2 ☐
c. Were limited in the *kind* of work or other activities		1 ☐	2 ☐
d. Had *difficulty* performing the work or other activities (for example, it took extra effort)		1 ☐	2 ☐

From Ware et al.[69]

Box 8.3 Evidence Summary Reliability and Validity of the SF-36

Study	Study Design	Sample	Setting	Reliability	Validity	Comments
Stewart et al[63] (1989)	Cross-sectional	9,385 persons 18 years and older who had visited a physician	Ambulatory care	Internal consistency of scale scores .67 to .88	Not addressed	Used MOS SF-20
Stewart et al[65] (1988)	Cross-sectional	11,186 English-speaking persons 18 years and older who had visited a physician	Ambulatory care in three large cities	Internal consistency of scale scores .81 to .88	Used internal consistency as a validity measure; also compared good and poor health samples to discriminate; also correlated to sociodemographic factors.	Used MOS SF-20
McHorney et al[68] (1994)	Cross-sectional and longitudinal	3,445 English-speaking persons 18 years and older with chronic medical and psychiatric conditions	Ambulatory care in three large cities	Internal consistency reliability of scale scores .78 to .93	Item discriminant validity from .09–.58 to .20–.62	SF-36
Ware et al[76] (1996)	Longitudinal	$n = 2,333$, including adults with chronic conditions	Participants in the National Survey of Functional Health Status and the Medical Outcomes Study	2-week test–retest. 89 for physical component score and .76 for mental component score, in the general U.S. population	Discriminant validity of SF-12 similar to SF-36 in groups of patients known to differ in physical and mental conditions.	Article on construction of SF-12
Riddle et al[77] (2001)	Longitudinal	101 consecutive patients with low back pain	Three physical therapy clinics in the Richmond, VA area	Not addressed	SF-36 completed before initial examination and at time of discharge. SF-12 items extracted from SF-36. No significant differences were found for the comparison of change scores between the physical component score of the SF-36 and SF-12.

Box 8.3 Evidence Summary Reliability and Validity of the SF-36—cont'd

Study	Study Design	Sample	Setting	Reliability	Validity	Comments
King and Roberts[78] (2002)	Cross-sectional	88 persons with cervical spondylotic myelopathy	Outpatient neurosurgery clinic	Internal consistency reliability (Cronbach's alpha) of scale scores .79 to .92	Construct validity was demonstrated using myelopathy scales constructed by Nurick, Cooper, and Harsh, as well as a Western modification of the scale developed by the Japanese Orthopedic Association.	
Kosinski et al[79] (1999)	Cross-sectional	1,016 persons with osteoarthritis or rheumatoid arthritis	Outpatient or inpatient setting	Internal consistency reliability of baseline scale scores .75 to .91	Not addressed	
Kosinski et al[80] (1999)	Longitudinal	1,016 persons with osteoarthritis or rheumatoid arthritis	Outpatient or inpatient setting	Not addressed	SF-36 administered before treatment and 2 weeks after treatment. Discriminant validity was demonstrated in groups of patients with clinical measures of arthritis severity and across patients who improved with treatment.	
Hagen et al[81] (2003)	Prospective, observational	153 persons recruited within 1 month of a recent stroke. SF-36 administered at 1, 3, and 6 months.	24 general practices in Scotland	Internal consistency of scale scores >.7 at all time points except for Vitality at 1 month = .68 and General Health at 3 months = .66	Construct validity examined with Barthel Index, Canadian Neurological Scale, and Mini-Mental State Examination. Strongest correlations were between Barthel Index and Physical Functioning and Social Functioning subscales.	

Box 8.3 Evidence Summary Reliability and Validity of the SF-36—cont'd

Study	Study Design	Sample	Setting	Reliability	Validity	Comments
Findler et al[82] (2001)	Cross-sectional	597 participants of whom 326 had a traumatic brain injury (TBI) who were at least 1 year post injury	Residents of New York State	Internal consistency of scale scores for individuals with TBI .79 to .92	Compared with Beck Depression Inventory, TIRR Symptom Checklist, and Health Problems List. Significant correlations were found between the SF-36 scales and the other measures.	
Yip et al[83] (2001)	Cross-sectional	32 persons 60 years of age and older and their proxy respondents	Community-dwelling older adults recruited from senior housing programs, assisted living facilities, and senior centers	Correlations for scale scores of respondents and their proxies .31 to .84	Not addressed	
Andresen et al[84] (1999)	Longitudinal	128 nursing home residents with scores of 17 or more on the Mini-Mental State Examination and at least 3 months residence	Nursing home	1 week test-retest for scales from .55 to .82 (ICC)	Convergent validity of physical health scales with activities of daily living index f rom –0.37 to –0.43. Mental health scales correlated with Geriatric Depression Scale (–0.63 to –0.71). No SF-36 scales correlated strongly with the Mini-Mental State Examination.	
Hobart et al[85] (2002)	Cross-sectional	126 males and 51 females with stroke at time of admission; mean age 62 years	Three hospitals in Indianapolis	Not addressed	Limited discriminant validity in this sample of persons with stroke due to floor and ceiling effects. Assumptions for generating 5 of the 8 scales and for the 2 summary scores not satisfied.	

SUMMARY

This chapter has presented a conceptual framework for understanding function and for the examination of functional status. The traditional medical model, with its narrow focus on disease and its symptoms, fails to consider the impact of the condition on the person, as well as the broader social, psychological, and behavioral dimensions of illness. All these factors have an impact on an individual's activity and participation. Although individual aspects of function may be assessed, examination of functional status must be viewed as a broad, multidimensional process. Finally, specific aspects of functional examination have been discussed, including purpose, selection of instruments, aspects of test administration, interpretation of test results, and determination of instrument quality.

Questions for Review

1. How does the measurement of function relate to health status?
2. Your rehabilitation facility uses the FIM. How can reliability be ensured so that the results can be used with confidence in both treatment planning and research?
3. What criteria can be used in the selection of a functional instrument?
4. Discuss the uses, advantages, and disadvantages of performance-based instruments, interviewer reports, and self-administered reports.
5. Explain how environment, fatigue, and other related issues affect measurement of function. Suggest ways to control these factors in the clinic.
6. Identify the major types of scoring systems used in functional instruments. What are some common errors in interpretation of testing results?
7. Review Tables 8.4, 8.6, 8.7, and 8.8. Hypothesize a caseload in a particular setting and indicate how and when you could use each of these instruments with the proposed population. Describe the advantages and disadvantages of each. Imagine that you are looking to follow the progress of these same patients to another setting. Which instruments would you choose?
8. Using one of the instruments, develop a set of results and use them to identify treatment goals and outcomes and to formulate a plan of care.
9. For each of the following, identify particular physical tasks relevant to that individual's functional status:
   - A 22-year-old female file clerk
   - A 31-year-old male physical therapist assistant
   - A 39-year-old female homemaker with children
   - A 45-year-old male construction worker
   - A 56-year-old female school teacher
   - A 65-year-old male journalist
10. Discuss the relationship among disease, body structures, body functions, activity, participation, environmental factors, and personal factors.

CASE STUDY

A 78-year-old woman with a diagnosis of osteoarthritis was admitted for a right total hip replacement. The patient reported a long-standing history of discomfort. She described the hip pain as radiating posteriorly to the buttock and low back and exacerbated by weight-bearing and stair climbing. Over the past 12 months she has experienced a very marked increase in pain and stiffness. Radiographic findings demonstrated degenerative changes of both the acetabulum and femoral head consistent with osteoarthritis. The surgical intervention replaced the right femoral head and neck with a metallic prosthesis and the acetabulum was resurfaced with a plastic cup. Past medical history is unremarkable.

SOCIAL HISTORY

The patient is a retired manager of a small accounting firm that she and her husband established. Her husband is deceased. She has three grown children who all live in neighboring communities. Before the functional limitations imposed by the hip pain, the patient had been independent in all ADL and IADL. She also volunteered her accounting services 1 day per week to a local charity that provides meals to homebound individuals. She was a regular participant in family outings, enjoyed going to

the theater, concerts, and special museum events, and was an active member of the community historical preservation society. Recently, these activities had to be curtailed owing to the increased hip discomfort. She essentially had no activities outside the home for 3 months before admission and used a walker to minimize weight-bearing and reduce pain. She also required the assistance of a home care aide 4 hours a day two times per week (primarily for shopping, errands, and some household management tasks). She expressed considerable distress at being unable to take a bath and having to rely on the assistance of another person for some basic care activities. She had been using aspirin for its analgesic and anti-inflammatory effects. However, the pain experienced in recent months was not alleviated by the aspirin and other conservative measures. She has been instructed to use local applications of heat, periodic rest intervals, and gentle range-of-motion (ROM) exercises. The patient has extensive medical insurance coverage and is without financial concerns.

POSTSURGICAL RIGHT HIP PRECAUTIONS

No hip flexion beyond 90°.
Avoid crossing one leg or ankle over the other.
Avoid internal rotation of right lower extremity.

REVIEW OF SYSTEMS

Communication, Affect, Cognition, Learning Style: Fully communicative and oriented × 3. Cooperative and motivated. Hearing intact. Wears corrective lens; experiences "night blindness," which she describes as seeing poorly in dim light and her eyes take several seconds longer than normal to adjust from brightness to dimness.

Cardiopulmonary: Heart rate (HR) = 84 beats/minute; blood pressure (BP) = 130/78 mm Hg; respiratory rate (RR) = 16 breaths/minute; no appreciable increases with activity.

Integumentary: Surgical wound healing well; staples removed.

Strength: Upper extremity gross ROM is within normal limits (WNL). Gross strength generally good to normal, except hands. Left hip, knee, and ankle at least good on break test. Partial weight-bearing on right lower extremity.

Joint Integrity and Mobility: Patient reports some sporadic episodes of wrist and finger stiffness on awakening in the morning and after periods of immobility. Crepitus noted in right knee. Heberden's nodes noted at the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints of the left index finger.

Range of Motion: Right knee and ankle within functional limits; right hip not tested.

Muscle Performance: Grip strength is reduced bilaterally (4–15).

Pain: Patient denies pain in wrist or fingers, or right hip.

Gait, Locomotion, and Balance: The patient is ambulating on level surfaces with supervision using bilateral standard aluminum axillary crutches with partial weight-bearing on the right lower extremity. Stair climbing also requires minimal assistance. It is anticipated that the patient will be independent with ambulation on level surfaces at time of discharge from the hospital.

Functional Status: Impaired bed mobility (modified independence device), sit-to-stand, transfers (minimum assistance).

Home Environment: The patient lives alone in a fifth-floor apartment in a building with an elevator. The living space is a one-bedroom apartment on a single level.

Patient Goals: The patient is extremely motivated to once again be an independent manager of her personal care and household management needs. The prosthetic replacement has successfully relieved much of the pain experienced in the hip before surgery (most of her current discomfort is described as minor and associated with the surgical incision). She would also like to return to her family, volunteer, social, and leisure activities. She is very determined to discontinue the home care assistance as soon as possible.

GUIDING QUESTIONS

1. Based on the findings of the initial examination, discuss the links between the condition, impairments in body structures and body functions, activity limitations, participation restrictions, and contextual factors using the ICF model.
2. Identify the specific ADL and IADL skills that would need to be examined to return this patient to the highest level of function and achieve the patient's goals for rehabilitation. Discuss the appropriateness of the instruments presented in this chapter for measuring her function and documenting the outcomes of patient management.

Chapter 9

Examination of the Environment

Thomas J. Schmitz, PT, PhD

LEARNING OBJECTIVES

1. Identify the roles and responsibilities of the physical therapist in examination of the physical environment.
2. Understand the importance of environmental accessibility in optimizing patient function.
3. Identify common home, workplace, and community environmental barriers that affect patient function.
4. Identify the tests and measures, tools used for gathering data, and data generated during examination of environmental, home, and work barriers.
5. Describe examination instruments used to measure environmental impact on patient function.
6. Identify strategies to improve patient function through environmental modifications.
7. Describe the scope of adaptive equipment and assistive technology options available for individuals with activity limitations and disability.
8. Recognize the importance of an examination of the environment within the context of a comprehensive plan of care.

SUMMARY *372*

A variety of both built and natural objects comprise the *physical environment* in which an individual functions. Built objects refer to buildings and structures created by humans; natural objects include other humans, as well as geographical objects such as vegetation, mountains, rivers, uneven terrain, and so forth.[1] The environment encompasses a substantial range of components that affect human function and includes the individual's home, neighborhood, community, and method(s) of transportation, in addition to the individual's educational, workplace, entertainment, commercial, and natural settings.[2]

Environmental barriers are defined as physical impediments that prevent individuals from functioning optimally in their surroundings and include safety hazards, access problems, and home or workplace design difficulties.[3] **Accessibility** is the degree to which an environment affords use of its resources with respect to an individual's level of function. **Accessible design** typically refers to structures that meet prescribed standards for accessibility. In the United States, these standards are available from the American National Standards Institute,[4] the Fair Housing Amendments Act of 1988, and the Uniform Federal Accessibility Standards (UFAS). Requirements for public and commercial buildings are regulated by the guidelines of the Americans with Disabilities Act (ADA) Standards for Accessible Design.[5]

UNIVERSAL DESIGN

Universal design (UD) refers to "the design of products and environments to be usable by all people, to the greatest extent possible, without the need for adaptation or specialized design."[6, p. 1] This design concept emphasizes social inclusion by creating products and environments that are

usable by a wide range of individuals of different ages, stature, sizes, and abilities, and it addresses the changing needs of human beings across the life span. Other terms associated with this design concept include *inclusive design, design-for-all, accessible design, barrier-free design, life span design, aging-in-place design,* and *sustainable* and *transgenerational design*. Joines suggests that "although the individual's capabilities do not change as a result of the design, his/her abilities do. By redefining problems, changing environments, and selecting different products, the quality of life of the individual may be enhanced."[7, p. 155]

Universal design has been identified as an outgrowth of the disability rights movement in the 1960s, although some earlier recognition of the concepts has been identified. Its foundational elements of ensuring equal opportunity and eliminating discrimination based on disability has been embraced in many parts of the world.[8] The design principles not only involve residential or commercial dwellings but also elders and those with disabilities. They provide a human-centered framework for creating spaces, furniture, landscapes, products, and services that can seamlessly accommodate diverse ability levels across generations.[9,10]

Evidence-based design (EBD) supports and informs UD. EBD is defined by the Center for Health Design (CHD) "as the process of basing decisions about the built environment on credible research to achieve the best possible outcomes."[11, p. 2] It emphasizes use of research to influence the design process and evaluate design innovations. Traditionally associated with health care architecture, EBD now supports design decisions for many structures in the built environment, including schools, office spaces, performance centers, restaurants, museums, and prisons.[12]

Although UD is both accessible and free of barriers, it is not the same as bringing existing buildings or structures into compliance with the ADA Standards for Accessible Design[5] or other building codes or laws. Applying such standards to existing structures often results in important but selective accessibility. In contrast, UD is applied from the *inception* of a building design plan versus creating new structures and then approaching the task of eliminating environmental barriers. For example, the need to retrofit a new structure with a ramp would not be needed had the original design plan considered the needs of all users. Ostroff suggests that such thoughtless add-ons "have a stigmatizing quality similar to the 'back of the bus' practices that were once the norm in the United States."[13, p. 1.4]

Incorporated into initial planning, UD elements are essentially "invisible" as compared to adaptations made to existing structures. They apply to all features and spaces of a dwelling. Several examples of UD elements include stepless entrances, wide hallways and doorways, level transitions between rooms (no doorway thresholds), use of nonslip floors, lever door handles, rocker light switches, single-handle sink faucets, and no-step shower access. Reinforced walls capable of supporting handrails or grab bars and large closets aligned from floor-to-floor suitable for housing a residential elevator are examples of UD elements intended to meet the future needs of residents.[4,5,14]

Bjork suggests that UD is empowered by three important characteristics. "First, it expands the focus of design from people with disabilities to a much broader population. Second, UD focuses on striving for new thinking in the development of initiatives and strategies for creating new solutions, instead of focusing on reconstruction and adaptation; an innovative approach. Third, UD strives for full social participation for everybody over a whole life span, through the creation of flexible products and environments with good usability. It is not about one universal solution that fits everybody. It is about solutions that provide flexibility in use and handling."[15, pp. 118-119]

Principles of Universal Design

The Principles of Universal Design (Appendix 9.A) were developed at the Center for Universal Design (CUD) at North Carolina State University by a group of experts that included architects, product designers, engineers, and environmental design researchers. The principles provide guidance for the design of products and environments. They are also intended to educate designers and consumers about characteristics that increase usability for everyone.[16] Key elements of the principles include the following:

- *Equitable Use*. The design is useful and marketable to people with diverse abilities.
- *Flexibility in Use*. The design accommodates a wide range of individual preferences and abilities.
- *Simple and Intuitive*. Use of the design is easy to understand, regardless of the user's experience, knowledge, language skills, or current concentration level.
- *Perceptible Information*. The design communicates necessary information effectively to the user, regardless of ambient conditions or the user's sensory abilities.
- *Tolerance for Error*. The design minimizes hazards and the adverse consequences of accidental or unintended actions.
- *Low Physical Effort*. The design can be used efficiently, comfortably, and with a minimum of fatigue.
- *Size and Space for Approach and Use*. Appropriate size and space is provided for approach, reach, manipulation, and use regardless of the user's body size, posture, or mobility.

Although UD originated in response to the need for environmental access for individuals with activity limitations and disability, many of its design elements proved useful and have been embraced by the general public. Riley[14] provides a fitting example of this development: "Think for a moment of the automatic garage door, which originated out of necessity for a client whose disability prevented him from lifting a heavy door. Now a staple of living for nearly all of us so-called

'able-bodied' people as well as those with disabilities, it is but one of many examples of how Universal Design has raised the bar for home design of all kind."[14, p. XII]

DISABILITY ACCESS SYMBOLS

Reflective of the importance of **environmental accessibility**, an internationally recognized *wheelchair symbol* identifies buildings accessible to individuals with a disability. The Rehabilitation Act of 1973 (Sections 503 and 504) requires that all organizations receiving federal funding provide accessible programs and activities. The Americans with Disabilities Act (1990) expanded accessibility to the private sector to improve employment opportunities, as well as environmental access to retail businesses, cultural events, movie theaters, restaurants, travel, and so forth. Other access symbols identify the availability of assistive listening devices, telephones with interactive text capabilities (TTY), which allow the user to communicate using a keyboard and visual display, volume-controlled telephones, availability of sign language interpretation, and so forth. The Disability Access Symbols are presented in Figure 9.1. These symbols are prominently displayed to identify and make public the availability of accessible services.

PURPOSE OF EXAMINATION

A primary outcome of rehabilitation is for the patient to be fully functional in a former environment and lifestyle. To achieve this outcome, continuity of accessibility must exist within the individual's environmental context. With full accessibility as a goal, examination of the environment must address the patient–environment relationship relative to accessibility, safety, usability, and function. The purposes of an environmental examination are multiple and serve to:

1. Determine the degree of patient safety and level of function in the physical environment.
2. Identify design barriers that may affect usability or compromise performance of customary tasks or activities.
3. Make realistic recommendations regarding environmental accessibility and accommodations to the patient, family/caregivers, employer, government agencies or other potential funding sources, and third-party payers.
4. Determine the need for adaptive equipment or assistive technology to support and promote function.
5. Assist in preparing the patient and family/caregivers for the patient's return to a former environment and to help determine whether further services may be required (e.g., outpatient treatment, home care services, and so forth).

EXAMINATION STRATEGIES

Physical therapists use a variety of tests and measures to examine physical impediments (e.g., safety hazards, access problems, design barriers) affecting the patient–environment relationship. The data generated are used to suggest modifications to the environment, guide recommendations for adaptive equipment and assistive technology, and/or propose alternative approaches to performing a task or activity (e.g., improve safety, conserve energy) to promote optimum function. The *Guide to Physical Therapist Practice*[3] includes examination of environmental, home, and work (job/school/play) barriers among the list of 24 categories of tests and measures that may be used by physical therapists. Table 9.1 presents an overview of examination components, including the types of tests and measures used, tools used for gathering data, and types of data generated.

Depending on the nature of the patient's activity limitation or disability, data collection tools used for examination of the environmental may include (1) interviews, (2) self-reports (checklists, questionnaires) and performance-based measures (observation) of function, (3) measures of environmental impact on function, (4) visual depictions (photographs, videotapes) and dimensions of physical space (structural specifications), (5) viewing the environment from a remote site, and (6) on-site visits.

A combination of two or more of these strategies may be warranted to generate all needed data. The current era of cost containment has placed restrictions on time and travel allocations for on-site visits. In such situations, several data collection alternatives (e.g., interview, self-report, and performance-based measures; and use of photographs and/or diagrams [with dimensions] of the physical space) can be implemented to achieve the goals of the environmental examination.

Telehealth (telecommunication technology) offers considerable potential to view an environment at a remote site using a voice-over-Internet Protocol (voIP) service and software application (e.g., Skype, Linphone) or other videoconferencing protocol. A large and expanding body of literature addresses the extensive application of telehealth in providing health care services,[17-29] including physical therapy.[30-33] In a document titled *Telehealth—Definitions and Guidelines* the Board of Directors of the American Physical Therapy Association (APTA) defines telehealth as "the use of electronic communications to provide and deliver a host of health-related information and health care services, including, but not limited to, physical therapy–related information and services, over large and small distances. Telehealth encompasses a variety of health care and health promotion activities, including, but not limited to, education, advice, reminders, interventions, and monitoring of interventions."[34, p. 1]

Sanford et al[35] reported on an early application of telehealth to examination of the home environment. The authors compared data from an actual on-site home examination with those obtained from remote videoconferencing technology. The data suggested that videoconferencing has the potential for enabling therapists to examine the patient's environment regardless of distance or location. The data from the remote examination identified 51 of the 59 problems (86.4%) documented from the

	**Symbol for Accessibility** The wheelchair symbol should only be used to indicate access for individuals with limited mobility including wheelchair users. For example, the symbol is used to indicate an accessible entrance, bathroom or that a phone is lowered for wheelchair users. Remember that a ramped entrance is not completely accessible if there are no curb cuts, and an elevator is not accessible if it can only be reached via steps.
	**Access (Other Than Print or Braille) for Individuals Who Are Blind or Have Low Vision** This symbol may be used to indicate access for people who are blind or have low vision, including: a guided tour, a path to a nature trail or a scent garden in a park; and a tactile tour or a museum exhibition that may be touched.
	**Audio Description** A service for persons who are blind or have low vision that makes the performing arts, visual arts, television, video, and film more accessible. Description of visual elements is provided by a trained Audio Describer through the Secondary Audio Program (SAP) of televisions and monitors equipped with stereo sound. An adapter for non-stereo TVs is available through the American Foundation for the Blind, (800) 829-0500. For live Audio Description, a trained Audio Describer offers live commentary or narration (via headphones and a small transmitter) consisting of concise, objective descriptions of visual elements (e.g., a theater performance or a visual arts exhibition).
	**Telephone Typewriter (TTY)** This device is also known as a text telephone (TT), or telecommunications device for the deaf (TDD). TTY indicates a device used with the telephone for communication with and between deaf, hard of hearing, speech impaired and/or hearing persons.
	**Volume Control Telephone** This symbol indicates the location of telephones that have handsets with amplified sound and/or adjustable volume controls.
	**Assistive Listening Systems** These systems transmit amplified sound via hearing aids, headsets or other devices. They include infrared, loop and FM systems. Portable systems may be available from the same audiovisual equipment suppliers that service conferences and meetings.
	**Sign Language Interpretation** The symbol indicates that Sign Language Interpretation is provided for a lecture, tour, film, performance, conference or other program.
	**Accessible Print (18 pt. or Larger)** The symbol for large print is "Large Print" printed in 18 pt. or larger text. In addition to indicating that large print versions of books, pamphlets, museum guides and theater programs are available, you may use the symbol on conference or membership forms to indicate that print materials may be provided in large print. Sans serif or modified serif print with good contrast is important, and special attention should be paid to letter and word spacing.
	**The Information Symbol** The most valuable commodity of today's society is information; to a person with a disability it is essential. For example, the symbol may be used on signage or on a floor plan to indicate the location of the information or security desk, where there is more specific information or materials concerning access accommodations and services such as "LARGE PRINT" materials, audio cassette recordings of materials, or sign interpreted tours.
	**Closed Captioning (CC)** This symbol indicates a choice for whether or not to display captions for a television program or videotape. TV sets that have a built-in or a separate decoder are equipped to display dialogue for programs that are captioned when selected by the viewer. The Television Decoder Circuitry Act of 1990 requires TV sets (with screens 13" or larger) to have built-in decoders as of July, 1993. Also, videos that are part of exhibitions may be closed captioned using the symbol with instruction to press a button for captioning.
	**Opened Captioning (OC)** This symbol indicates that captions, which translate dialogue and other sounds in print, are always displayed on the videotape, movie or television program. Open Captioning is preferred by many including deaf and hard-of-hearing individuals, and people whose second language is English. In addition, it is helpful in teaching children how to read and in keeping sound levels to a minimum in museums and restaurants.
	**Braille Symbol** This symbol indicates that printed material is available in Braille, including exhibition labeling, publications, and signage.

The Disability Access Symbols were produced by the Graphic Artists Guild Foundation with support and technical assistance from the Office for Special Constituencies, National Endowment for the Arts. Special thanks to the National Endowment for the Arts. Graphic design assistance by the Society of Environmental Graphic Design. Consultant: Jacqueline Ann Clipsham, with permission.

Figure 9.1 Disability access symbols.

on-site visit and 54 of the 60 quantitative measures (90%) obtained from the on-site visit.

Interview

Exploration of the environment is typically initiated by interviewing the patient and family/caregivers. If the patient's activity limitations or disability affects only isolated tasks or activities or if accessibility issues involve limited environmental barriers, an interview may be all that is needed to determine the physical impediments and provide suggestions and guidelines for improving performance and resolving access problems. In the presence of more formidable activity limitations or disability, the interview may be the first of several strategies used

Table 9.1 Environmental, Home, and Work (Job/School/Play) Barriers: Types of Tests and Measures Used, Tools Used for Gathering Data, and Types of Data Generated

Environmental, home, and work (job/school/play) barriers are the physical impediments that keep patients/clients from functioning optimally in their surroundings. The physical therapist uses the results of tests and measures to identify any of a variety of possible impediments, including safety hazards (e.g., throw rugs, slippery surfaces), access problems (e.g., narrow doors, thresholds, high steps, absence of power doors and elevators), and home or office design barriers (e.g., excessive distances to negotiate, multistory environments, sinks, bathrooms, counters, placement of controls or switches). The physical therapist also uses the results to suggest modification to the environment (e.g., grab bars in the shower, ramps, raised toilet seats, increased lighting) that will also allow the patient/client to improve functioning in the home, workplace, and other settings.

Tests and Measures	Tools Used for Gathering Data	Data Generated
Tests and measures may include those that characterize or quantify: • Current and potential barriers (e.g., checklists, interviews, observations, questionnaires) • Physical space and environment (e.g., compliance standards, observations, photographic assessments, questionnaires, structural specifications, technology-assisted assessments, videographic assessments)	Tools for gathering data include: • Cameras and photographs • Checklists • Interviews • Observations • Questionnaires • Structural specifications • Technology-assisted analysis systems • Video cameras and videotapes	Data are used in providing documentation and may include: • Descriptions of: —Barriers —Environment • Documentation and description of compliance with regulatory standards • Observations of environment • Quantifications of physical space

From American Physical Therapy Association,[3, p. 68] with permission.

to collect data about the patient's environment. The interview can be used to establish the general characteristics of the environment (number of levels, stairs, railings, and so forth), identify any special problems previously encountered by the patient, alert the therapist to potential safety hazards, and determine the need for further tests and measures to obtain essential information. The interview process also provides the therapist an opportunity to gain knowledge of family/caregiver characteristics, including (1) attitude toward the patient; (2) the extent of their desire to have the patient return to his or her environment; (3) their caregiving goals and capabilities; and (4) attitude toward rehabilitation team members, which may influence receptivity to suggested environmental modifications.

Self-Report and Performance-Based Measures of Function

Self-reports involve asking the patient to provide information about the ability to perform certain tasks and activities in specific environments. Administration can be either in a paper-and-pencil format or by way of an interview conducted by the therapist. An inherent shortcoming of self-report instruments is that an individual may overestimate performance capabilities or underestimate the impact of environmental barriers. Accuracy of reporting can be improved by requesting that the patient (1) focus the performance information on a recent time interval (e.g., *within* the previous week) and (2) distinguish between actual performance of an activity (e.g., *daily* use of shower for bathing) versus perceived ability in the absence of consistent execution of the task.

Performance-based measures address classification of functional abilities and identification of activity limitations. The therapist administers these measures while observing patient performance of an activity. A variety of instruments are available that include quantitative scoring systems. Examples of instruments used to examine balance, mobility, and fall risk include the *Functional Reach (FR) Test*[36-38] and *Multidirectional Reach Test (MDFR),*[39,40] the *Get Up and Go (GUG) Test*[41] and *Timed Up and Go (TUG) Test*,[42] the *Performance-Oriented Mobility Assessment (POMA)*,[43-45] timed[46] and distance walking tests,[47-50] and the *Berg Balance Scale (BBS).*[51-54] The therapist interprets the data by comparison to normative performance. The measures yield important information about the impact of impairments on function and help predict patient performance within his or her natural environment. Self-report and performance-based measures of function are discussed in Chapter 8, Examination of Function.

Measures of Environmental Impact on Function

The environment directly affects the ability to perform tasks and activities that support physical, social, and psychological well-being. Environmental factors can

either *constrain* or *promote* patients' abilities to perform customary actions within their social/cultural contexts. A variety of instruments have been developed that address the impact of environmental determinants on function. Examples of these instruments include the following:

- The *Physical Activity Resource Assessment (PARA)*.[55] Based on the close link between aspects of the physical environment and physical activity levels, this instrument was designed to examine and document the available resources that promote activity within a neighborhood or community environment. The PARA is used to examine the type, quantity, accessibility, quality, and features of physical activity resources within a patient's environment. The assessment, together with protocol and definitions, is available online.[56]
- *Home and Community Environment (HACE)* instrument.[57] The HACE is a self-report instrument used to identify features of the patient's home or community that may affect level of function. The environmental domains examined include home and community mobility, basic mobility and communication devices, transportation factors, and attitudes. The instrument and scoring manual are available online.[58]
- *Safety Assessment of Function and the Environment for Rehabilitation (SAFER)* tool.[59-61] A comprehensive functional and environmental examination tool designed for use with the elderly. It includes 15 areas of concern: living situation, mobility, kitchen, eating, household management, fire hazards, dressing, grooming, bathroom, medication, communication, recreation, general items, wandering, and memory aids. Each category is examined within the content of the home environment and the functional capabilities of the patient.
- *Usability in My Home (UIMH)*.[62-65] This self-report instrument examines features of the home environment that either constrain or promote activity performance (see Appendix 9.B). It addresses aspects of both basic activities of daily living (BADL) and instrumental activities of daily living (IADL) and consists of 23 items, 16 of which are scored on a scale of 1 to 7 (1 representing the most negative response, 7 the most positive response). In addition, the instrument includes seven open-ended questions (six for description of specific usability problems and one for expressing additional opinions). Usability is conceptually defined as the extent to which a patient's needs and preferences can be met within the home. The UIMH includes a personal, environmental, and activity component.
- *Housing Enabler*.[62,64] This instrument is administered using a combination of interview and observation and is designed to examine home accessibility. It includes three steps: (1) determination of activity limitations (13 items) and dependence on mobility devices (2 items); (2) examination of environmental barriers (188 items), including indoor and outdoor accessibility, entrances, and communication features; and (3) calculation of an accessibility score (higher scores reflect greater accessibility problems). A content-valid Nordic version of the Housing Enabler has also been developed.[66]
- *Environmental Analysis of Mobility Questionnaire (EAMQ)*.[67,68] The EAMQ is a self-report instrument that examines the impact of the environment on community mobility. It includes 24 characteristics of the environment grouped into 8 dimensions. Each characteristic includes both an encounter question ("How often do you…?") and an avoidance question ("How often do you avoid…?"). A five-item ordinal scale is used to document frequency of encounter and avoidance responses (never, rarely, sometimes, often, always).[68, p. 394] Encounter and avoidance scores are averaged to generate a *summary environmental score* and a *summary avoidance score.*
- *Craig Handicap Assessment and Reporting Technique (CHART)*.[69] This instrument was developed to document an individual's functioning within his or her societal context. It examines level of involvement within six domains of function: physical independence, cognitive independence, mobility, occupation, social integration, and economic self-sufficiency. Each area is scored based on 100 points (600 points maximum) with greater levels of participation receiving higher scores. The CHART Short Form (CHART-SF)[70,71] is a 19-item shortened version of the CHART.
- *Craig Hospital Inventory of Environmental Factors (CHIEF)*.[72,73] This inventory rates frequency and impact of 25 environmental barriers defined as any impediments that prevent functioning within the home and community. In addition to physical and architectural barriers, the instrument includes social, attitudinal, and policy barriers; response items carry numeric values. The CHIEF gathers information about the frequency of encounters with each barrier (daily = 4, weekly = 3, monthly = 2, less than monthly = 1, never = 0) and the magnitude of the problem (big problem = 2 or little problem = 1). Scores are calculated by multiplying the frequency of occurrence by the magnitude of the problem to provide an *impact score.* Higher scores indicate greater impact of environmental barriers. A CHIEF short form (CHIEF-SF) contains 12 items from the original inventory.[74] The CHIEF Manual, containing information about instrument development as well as both the CHIEF and the CHIEF-SF, is available online.[75]
- *ADL-Staircase*.[76-83] Based on the original Katz ADL-Index,[84] the ADL-Staircase (see Appendix 9.C) is an index of four instrumental activities (cleaning, shopping, transportation, and cooking)[80,81] combined with six personal daily life activities (bathing, dressing, going to the toilet, transfer, continence, and

feeding).[84] The ability to perform each activity is scored using a three-point scale: *independent, partly dependent,* and *dependent. Partly dependent* means that assistance from another person is required. The ratings can then be dichotomized into *independent* or *dependent,* and arranged into one conditional ordered scale of ADL-steps 0 to 9 or 10 (when continence is included there are 10 steps and when it is excluded there are 9 steps). ADL-step 0 means independent in all activities, and ADL-step 9 (or 10) dependent in all activities. The reliability and validity of the instrument have been established. The 10-step ADL scale has shown good validity and reliability in an elderly population.[82] In a study using three different age groups, findings indicated that the ADL-Staircase is most valid and reliable for age groups between 18–29 and 75–89 years.[79] A version of this instrument has been developed for use in rural areas.[85]

Visual Depictions and Dimensions of Physical Space

The therapist may request that family members or caregivers provide visual depictions (e.g., streaming video using a computer, smart phone, or tablet, photographs, videotapes, diagrams, floor plans) and physical dimensions (structural specifications obtained with a tape measure) of the environment in which the patient is expected to function. If resources for obtaining visuals are limited, an inexpensive disposable camera works well for this purpose.

Suggestions for modifications can be made from the visual representations and measured dimensions of the patient's environment. Such environmental information will allow the therapist to simulate aspects of the patient's surroundings (before discharge) for practicing tasks while directing attention to maximizing safety and function. This will also assist the therapist to determine the need for adaptive equipment.

On-Site Visits

On-site visits require that rehabilitation team members together with the patient travel to the physical location where the patient will be required to function (home, community, and/or work [job/school/play]). A major advantage of the on-site visit is that it allows observation of performance in the actual environment in which the activities must be accomplished. On-site visits are often useful in reducing patient, family, caregiver, and/or employer apprehension concerning the patient's ability to function within the environment. The on-site visit also provides an important opportunity for the therapist to identify safety hazards and make recommendations regarding altering, coping with, or adapting specific environmental barriers. During the visit, patient activity should be interspersed with adequate rest intervals to ensure that fatigue is not an influencing factor.

Whichever examination strategy or combination of strategies are applied, the scope and breadth of the information gathered will be enhanced by involvement of family members and caregivers. Because it is usually not feasible for the therapist to examine all aspects of the patient's total environment, involvement of other individuals can be instrumental in ensuring that the goal of maximum accessibility is met. This is particularly important for determination of general community access. The therapist can direct and guide an investigation of access to community recreational, educational, and commercial facilities, as well as availability of public transportation. The therapist can also provide guidance in the essential role of exploring funding sources for needed environmental modifications (potential funding sources are addressed later in this chapter).

Data from an examination of the environment are used to evaluate the need for specific access, usability, and safety interventions. Corcoran and Gitlin[1] identify five major areas of environmental intervention strategies: (1) *assistive* or *adaptive devices* such as grab bars, reachers, adapted eating utensils (e.g., rocker knife), canes, or walkers; (2) *safety devices* such as lighting, smoke detectors, or sensing devices; (3) *structural alterations,* which include widening doors, installing railings or ramps, or removing a doorway threshold; (4) *modification* or *altered location of environmental objects* such as disabling a stove, placing locks on doors, use of extension levers on door handles, removing throw rugs, or moving furniture; and (5) *task modification* such as use of visual, auditory, or other sensory cueing, work simplification, and energy conservation or joint preservation techniques.

The following sections offer suggestions for examination and modification of the home and workplace environment. The information presented is neither exhaustive nor inclusive of the needs of every patient. The environmental considerations are intended to direct attention to some of the more common access, usability, and safety concerns.

EXAMINATION OF THE HOME

Preparation for On-Site Visit

Before an on-site visit to the patient's home, occupational and physical therapy treatment sessions should be scheduled that will include participation from family and caregivers. These visits serve several functions. They provide an opportunity to become familiar with the patient's capabilities and activity limitations. They give the family/caregivers time to learn safe methods (e.g., proper body mechanics, guarding techniques) for assisting with ambulation, transfers, exercise, and functional activities. During these treatment sessions the occupational and physical therapists will have an opportunity to provide instruction in the use of assistive devices, adaptive equipment, and assistive technology. The time spent in education of family and caregivers is often pivotal in facilitating the patient's successful return to the home, community, and/or work (job/school/play) environments.

Clinical Note: Although sometimes restricted by reimbursement issues, when feasible, a day or weekend patient visit to his or her home should be encouraged and arranged before the on-site visit. During such a visit, problems not previously anticipated by the therapist or family and/or caregivers may be uncovered. Emphasis can then be placed on initial development of a plan to solve these problems before the on-site visit and the patient's actual return to the environment.

Preceding the on-site visit, information should be gathered about several important areas that will influence both the preparation for and the types of suggestions made during the visit. This information includes the following:

- Detailed information about present level of function (e.g., communication skills, bed mobility, transfers, gait, and so forth); data should be gathered from all involved disciplines (occupational therapist, physical therapist, speech-language pathologist, and so forth).
- Knowledge of physical assistance or verbal cueing required for activity performance.
- Characteristics and dimensions of adaptive devices and/or assistive technology (e.g., raised toilet seat, long-handled reachers, environmental controls) and ambulatory assistive devices (e.g., canes, crutches, walkers).
- Information about predicted level of optimum function or improvement (expected outcomes).
- Nature of the activity limitations or disability (i.e., static or progressive).
- Insurance coverage, financial resources, and availability of potential funding sources (in terms of capacity to modify environment or obtain needed adaptive and assistive devices or assistive technology).
- Knowledge of the patient's future plans (household management, family care, employment outside the home, school, vocational training, and so forth).
- Knowledge of whether the house or apartment is owned or rented; the type and ownership of the home can affect or preclude the type of modifications the patient may require. However, it should be noted that the Fair Housing Act requires landlords to allow individuals with disabilities to make reasonable access modifications to both personal living space and common space such as entryways.
- Information about the relative permanence of the dwelling; if the patient plans to move in the near future, it will influence the type of modifications recommended (e.g., installing permanent ramps versus removable ones, or paving a gravel driveway).

This information can be obtained from a variety of sources, including the patient, rehabilitation team conferences, patient/family and caregiver conferences or interviews, medical record documentation from all disciplines involved, and social service interviews. Once this information is gathered, decisions can be made concerning what adaptive or assistive devices will be needed and the appropriate team members to accompany the patient on the visit.

Ideally, given their complementary expertise and skills, both the physical and occupational therapist accompany the patient on the home visit. They assume shared responsibility for examining the patient–environment interface. Depending on the specific needs of the patient, family, and/or caregivers, a speech-language pathologist, social worker, or nurse also may be among the rehabilitation team members visiting the home. For purposes of organization and structure, home visits are often divided into two global elements: (1) accessibility of the dwelling's *exterior* and (2) examination of the home's *interior*. An inexpensive disposable camera is useful for providing images of architectural barriers to accompany letters of justification for needed modifications. A tape measure and home examination form are also important tools during the visit. Many rehabilitation departments develop their own home examination forms to meet the particular needs of their patient population. The forms (or checklists) help to organize the visit and are useful in directing attention to all necessary details. An example of a Home Examination Form is provided in Appendix 9.D. This form can be expanded or modified, depending on the specific needs of the individual or patient population. Some caution must be used in interpreting data from home examination forms that have not been standardized or examined for reliability.

On-Site Visit

On arrival at the home for the on-site visit, the patient may need to rest for a short while before beginning the home examination. This is an important consideration, because patients may become very excited or emotional when returning to a cherished home environment after a lengthy absence. This may be true even if a day or weekend visit occurred before the formal home visit.

One method of gathering data about the interior of the home is to begin with the patient in bed as though it were morning. Simulation of all daily tasks and activities, including dressing, grooming, bathroom activities, and preparation of meals, can ensue. The patient should attempt to perform all transfer, exercise, locomotion, self-care, and homemaking activities as independently as possible. This will provide an additional opportunity to teach the family and caregivers how and when to assist the patient.

Exterior Accessibility

Route of Entry

1. If there is more than one entry to the dwelling, the most accessible should be selected (closest to driveway, most level walking surface, fewest stairs, available handrails, and so forth).

2. Ideally, the driveway should be a smooth, level surface with easy access to the home. Walking surfaces to the entrance should be carefully examined. Cracked and uneven surfaces should be repaired or an alternate route selected.
3. The route to entrance should be level, be well lighted, and provide adequate cover from adverse weather conditions. Package shelves near the entrance are useful for freeing hands to unlock and/or open doors.
4. The height, number, and condition of stairs should be noted. Ideally, steps should not be greater than 7 in (180 mm) high with a minimum depth of 11 in (280 mm).[4] *Nosings,* also referred to as "lips," are the 0.5 in (13 mm) curved overhangs on the front edge of stairs. These overhangs are often problematic because they can cause a patient's toe to "catch" and prevent smooth transition to the next step. Nosings should be removed or reduced, if possible. Installing small wood bevels under the overhangs that taper down toward the lower step and provide a smoother contour can minimize nosing (Fig. 9.2A). The steps also should have a nonslip surface to improve traction. This can be accomplished by adding abrasive strips (Fig. 9.2B).
5. Handrails should be installed, if needed. In general, handrail height should measure between a minimum of 34 in (865 mm) and a maximum of 38 in (965 mm) high for stairs, ramps, and level walking surfaces (Fig. 9.3). This range in handrail height allows for modifications to accommodate needs of particularly tall or short individuals. At least one handrail should extend a minimum of 12 in (305 mm) beyond the foot and top of the stairs (Fig. 9.4). Outside cross-sectional diameter of circular handrails should be between a minimum of 1.25 in (32 mm) and a maximum of 2 in (51 mm). If mounted adjacent to a wall, clearance between the handrail and wall should be a minimum of 1.50 in (38 mm).[4,5]
6. Installation of a ramp requires adequate space. Large ramps are typically constructed of wood or concrete; smaller ramps can be made from aluminum or fiberglass. The minimum **ramp grade** (incline or slope) for a wheelchair ramp is that for every inch of threshold height there is a corresponding 12 in (305 mm) of ramp length (a running slope of 1:12).[4] Outdoor ramps exposed to inclement weather such as snow or ice formation require a more gradual running slope of approximately 1:20. Ramps should be a minimum of 36 in (915 mm) wide, with a nonslip surface. The overall rise of any ramp should be no greater than 30 in (760 mm). Handrails also should be included on the ramp with a minimum height of 34 in (865 mm) and a maximum height of 38 in (965 mm) and extend 12 in (305 mm) beyond the top and bottom of the ramp (Fig. 9.5).[4,5] Small, commercially available ramps can be used for traversing curbs and small step heights.
7. *Vertical platform lifts* and *stairway lifts* are commercially available and may be a consideration when inadequate space is available for a ramp. Vertical platform lifts (Fig. 9.6) travel approximately 8 ft (243.84 cm) straight up and down. Both open and enclosed models are available. Platform lifts are often installed adjacent to stairs with an upper landing and are available in a variety of dimensions with lengths ranging from 54 to 60 in (137.16 to 152.4 cm) and widths ranging from 34 to 42 in (86.36 to 106.68 cm). The lift brings the wheelchair user from the ground level to the landing level to access the entrance to the home (these lifts can be used indoors as well). Stairway lifts are installed directly onto existing outdoor stairways; however, they are more frequently used indoors. The stairway lifts are mounted on runners that traverse the length of the stairs and slightly beyond. Many models allow the platform to fold up against an adjacent wall to allow free stair access for others entering the home.

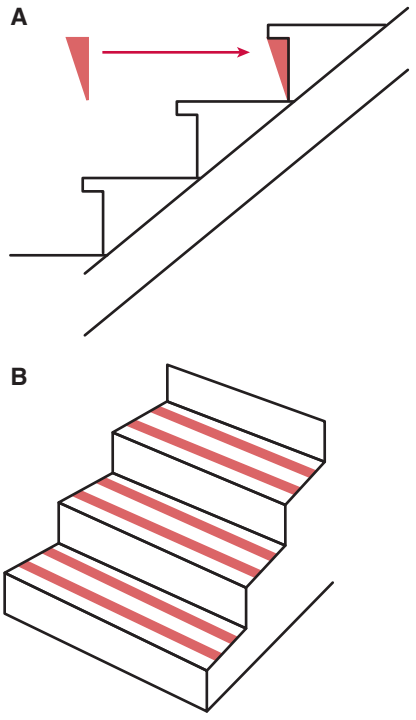

Figure 9.2 **(A)** Wood bevels placed under nosings minimize the danger of "toe-catching" during transition to the next step. **(B)** Abrasive strips improve traction and depth perception.

Entrance

1. For individuals using a wheelchair, the entrance should have a platform large enough to allow the patient to rest and to prepare for entry. This platform area is particularly important when a ramp is

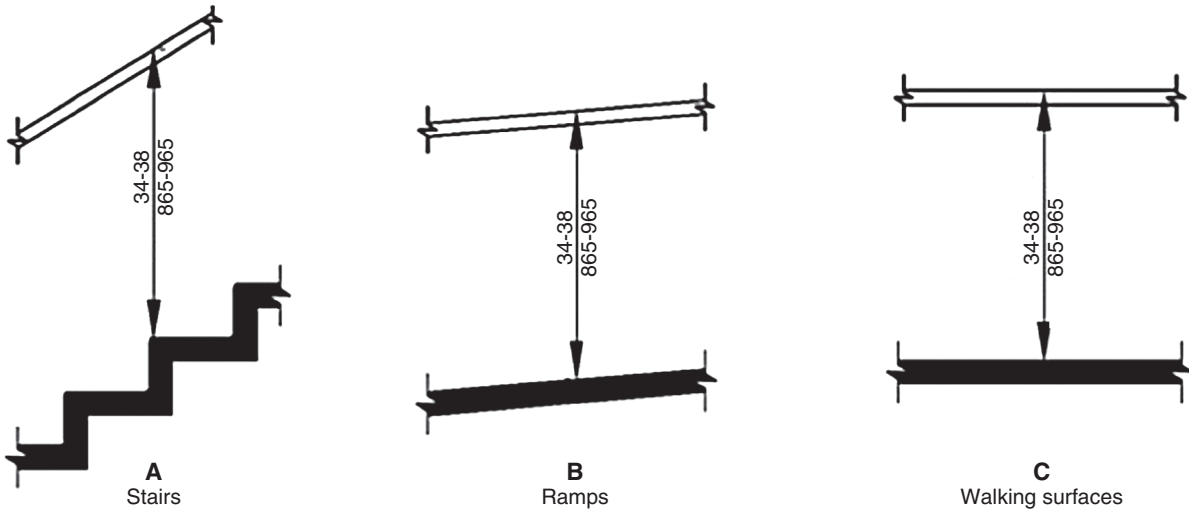

Figure 9.3 Handrail height for (a) stairs, (b) ramps, and (c) level walking surfaces in inches and millimeters. *(From 2010 ADA Standards for Accessible Design.[5, p. 145])*

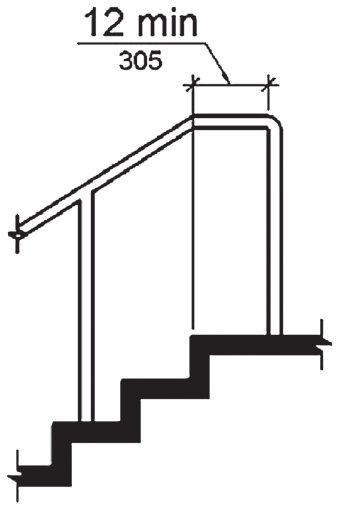

Figure 9.4 Handrail extension at top of stairs. A similar handrail extension of 12 in (305 mm) is placed at bottom of stairs. *(From 2010 ADA Standards for Accessible Design.[5, p. 157])*

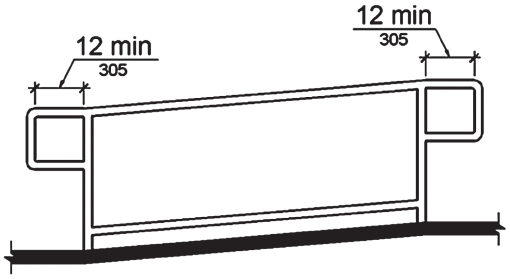

Figure 9.5 Handrail extensions should run a minimum of 12 in (305 mm) beyond the top and bottom edge of ramp. *(From 2010 ADA Standards for Accessible Design.[5, p. 157])*

Figure 9.6 Powered residential vertical lift. This lift has a 600-lb weight capacity. The platform measures approximately 36 inches wide and 48 inches deep (91.44 × 121.92 cm). *(Courtesy of AmeriGlide, Inc., Raleigh, NC 27610.)*

in use. It provides for safe transit from the inclined surface to the level surface. If an individual using a wheelchair is required to open a door that swings out, this area should be at least 5 × 5 ft (153 × 153 cm). If the door swings in and away from the patient, a space at least 3 ft (91.5 cm) deep and 5 ft (153 cm) wide is required.

2. The door locks should be accessible to the patient. The height of the locks should be determined, as well as the amount of force required to turn the key. Alternative lock systems (e.g., voice- or card-activated locks, remote control locks, keypad electronic security systems, and push-button padlocks) may be an important consideration for some patients. Particular attention should be directed toward ensuring that the locking mechanism on the door is sufficiently illuminated.
3. The door handle should be turned easily by the patient. Rubber doorknob covers (that stretch over a round doorknob and provide a textured grip) or lever-type handles (Fig. 9.7) are often easier to use for patients with limited grip strength (screw fastened, slip-on levers are also available that convert a round doorknob to lever-type handle). Lever handles do not require the same strength or range of motion (ROM) needed for traditional round doorknobs.[7]
4. The door should open and close in a direction that is functional for the patient. A long canvas "door strap" may be attached to the outside of the door (or around the door handle) to help an individual using a wheelchair close the door when leaving. A long, sturdy belt can be also be used as a door strap.
5. Remote control automatic door openers are available that attach to existing doors that can open, close, and lock the door; some are equipped with customized "stay-open" features to accommodate the time required to enter or exit. A handheld remote control or a touch pad can be used to activate these devices.
6. Installation of an intercom system allows the patient to see and/or hear who is at the door. Some allow remote control opening of a door from any location in the home.

Figure 9.7 Lever-style door handle (a frequent universal design element) is particularly useful for individuals with limited grip strength because they can be activated with other body parts (e.g., fisted hand, forearm, elbow).

7. If there is a raised threshold in the doorway, it should be removed. If removal is not possible, the threshold should be lowered to no greater than 1/2 in (13 mm) in height, with beveled edges;[4] alternatively, a threshold ramp may be installed (see section titled *Doors*). If needed, weather-stripping the door will help prevent drafts.
8. The doorway width should be measured. Generally, 32 to 34 in (815 to 865 mm) is an acceptable doorway width to accommodate most wheelchairs. Bariatric chairs require increased width. (See Box 9.1 for bariatric considerations.)
9. If the door is weighted to aid in closing, the pressure should not exceed 8 lb (3.6 kg) to be functional for the patient.
10. A kick plate (metal guard) may be added to doors frequently entered by individuals using a wheelchair or ambulatory assistive devices. The kick plate should measure 12 in (305 mm) in height from the bottom of the door.

General Considerations: Interior Accessibility

Furniture Arrangement and Features

1. Sufficient room should be made available for maneuvering a wheelchair or ambulating with an assistive device. An initial step is to move as much furniture as possible against the walls to increase clearance and stability (i.e., prevent sliding of furniture during movement transitions). Further stability can be achieved by placing rubber cups (floor guards) under the legs of sofas and chairs. Items such as coffee tables, footstools, or telephone or electrical wires should not obstruct access to furniture.
2. Clear passage must be allowed from one room to the next.
3. Typically, overstuffed sofas and chairs do not provide the needed support for sit-to-stand movement transitions. Although generally not the case, living room chairs should have double arm rests, a firm seating surface, and an upright back. Sometimes a suitable chair can be found in a different location within the home and moved to the living room. Another option is to modify the current furniture by placing a fitted wooden board under the seat cushion and behind the seat back (if removable). If a new chair is to be purchased, recommended features of the chair should be provided to the patient, family member, and/or caregiver (e.g., the height of the seat should allow the knees to flex approximately 90° with the feet flat on the floor, a firm cushioned seat, a firm cushioned back that provides adequate upright support, and double arm rests).
4. Use of any unstable furniture such as rocking chairs should be discouraged for most patients. Use of leather furniture should also be avoided because the increased friction can hinder movement. Chairs that

Box 9.1 Bariatric Considerations

Obese or morbidly obese individuals present unique environmental needs. Obesity is generally defined using body mass index (BMI) and can be divided into three classes:[1]

Class	BMI
I Obesity (Moderate)	30-34
II Obesity (Severe)	35-39
III Obesity (Very Severe) (morbidly obese)	>40

Patients who are obese often require specialized equipment for being lifted, moved, transferred, or transported. Bariatric equipment is space consuming; this is often exacerbated by older homes designed and built when the statistical averages for adult height and weight were less than today. The following are environmental considerations specific to this population.

- ***Patient, Family, and Caregiver Training:*** Specific training in the use of bariatric equipment and patient handling is critical. Patients who are obese often require assistance throughout the day for many routine activities (e.g., positional changes, supine-to-sit, sit-to-stand, bathing, toileting, and dressing). These care requirements emphasize the need for highly trained caregivers able to promote safety and injury prevention for both patient and themselves. When possible, the patient should be encouraged to assume the lead in directing those responsible for care.
- ***Physical Assistance:*** More than one individual may be required to assist the patient. There may be situations where as many as three or four people are needed for patient handling. Third-party payers challenge reimbursement for more than one support person in the home simultaneously (duplication of services). This may require involvement from extended family members and/or require the patient and family to seek creative funding sources to meet this need (see section titled Funding for Environmental Modifications).
- ***Bariatric Equipment:*** Inherent to its purpose, bariatric equipment is oversized, is designed for increased weight capacity, and is generally heavier and more costly than the nonbariatric equivalent. Bariatric equipment is extensive and includes beds (some with built-in scales), bedside commodes, standard and overhead lifts, reclining chairs, steel-framed chairs, powered lift chairs with a 1,000 lb (453.59 kg) weight capacity, bathroom equipment, adaptive equipment, wheelchairs (widths up to 48 in [121.92 cm]), scooters, and ambulatory assistive devices. Providers of durable medical equipment (DME) typically offer instruction for in-home use. Some provide ongoing support should additional caregivers require training.
- ***Risk of Ulceration:*** Patients who are obese are at increased risk for developing pressure ulcers secondary to their size and immobility. They may be unable to effectively change positions, creating excess pressure on susceptible areas for long periods. This may require use of a specialized mattress (e.g., low air loss with alternating pressure). Moisture or perspiration may contribute to ulcer formation.
- ***Care Environment:*** Large beds (e.g., 42 to 54 in [106.68 to 137.16 cm] wide, 80 to 90 in [203.2 to 228.6 cm] long, and up to 1,000 lb [453.59 kg] weight capacity), lifts, and other large bariatric equipment require larger room dimensions. Passage of bariatric equipment generally requires a door width of 60 in (152.4 cm). A large window may need to be temporarily removed to allow passage of oversized items. Ample floor space is also needed for caregivers to interface with the patient in and around the equipment. Five feet of clear floor space is recommended on each side and at the foot of the bed.[2] The floor surface and support structures beneath need to be carefully examined. They must be able to support a patient weight ranging from 500 to 1,000 lb (226.8 to 453.59 kg) together with all needed equipment and supplies. Often space is made available on the first level of a dwelling (versus navigating patient and equipment up a narrow staircase to a small second floor bedroom). This may require conversion of the living room to a patient care area. An environmental control unit is an important consideration.
- ***Bathroom:*** Space is a primary concern in gaining access to a standard residential bathroom. Sufficient door width is needed to accommodate patient size, an assistive device, and/or the individual(s) guarding the patient. A 60 in (152.4 cm) door width and turning radius is recommended.[2] To place a bariatric commode with armrests over a toilet or allow a two-person assist, ample space of 24 in (60.96 cm) is needed on each side with a 44 in (111.76 cm) front clearance.[2] A bidet may be recommended to assist cleansing. The toilet and sink should be floor mounted with a 1,000 lb (543.59 kg) weight capacity.[2] Longer than typical grab bars with a 1,000 lb (543.59 kg) weight capacity should be installed on reinforced walls. The shower stall should be a minimum of 4 × 6 ft (1.22 × 1.83 m) and include a level entrance, a bariatric shower seat, a shower hand spray, and grab bars with a 1,000 lb (543.59 kg) weight capacity. The use of shower curtains is recommended over solid doors to facilitate caregiver assistance.

provide mechanized elevation of the back of the seat are commercially available but should be used with caution. It may be difficult for a patient to stabilize the feet as the seat is elevating. This causes the feet (and pelvis) to slide forward, resulting in a fall.

Electrical Controls

1. Unrestricted access should be provided to wall switches and electrical outlets. Power strips (surge protectors) can be used to increase the number of outlets, as well as improve access. Outlets may need to be raised and wall switches lowered. For individuals using a wheelchair, use of pull cord extensions may allow control of some high electrical switches.
2. Some patients may benefit from replacement of standard toggle electric switches (e.g., overhead fixtures) with rocker switches that require less fine motor skill to activate (Fig. 9.8). Rocker switches are available with lighted surfaces and with occupancy (motion) sensor devices that automatically turn on or off. Light-switch plates come in a variety of colors and will be easier to see if they contrast with the existing wall color. For example, in rooms with light-colored walls (white, off-white, beige), darker electrical outlet and light-switch plates can be selected. A ground fault circuit interrupter (GFCI) should be installed in wet locations such as bathrooms to prevent against electrical shock. A GFCI outlet acts as a monitor for current imbalance between the hot and neutral wires and breaks the circuit if that situation occurs (e.g., faulty appliances, worn cords, or appliance contact with water).
3. For some patients, vision may be enhanced by use of higher wattage bulbs, fluorescent lighting, full-spectrum bulbs, daylight bulbs, or high-intensity halogen lamps. Use of long-life, energy-efficient light bulbs reduces the frequency of required bulb changes.
4. Inexpensive, programmable electrical timers can be used to regularly turn lights on and off throughout the day and night.
5. Inexpensive night-lights with motion sensors can be placed in strategic locations to provide additional illumination.
6. Touch pad dimmer switches can be used to activate lamps with small control knobs. The dimmer module is plugged into a wall outlet and the lamp attached to the module. The lamp can be turned "on" or "off" or level of brightness changed by touching the pad. Voice-activated dimmers are also available.
7. Inexpensive remote control units can be used in any room of the home to control lights or small appliances. The simplest designs of these remote control units send signals through existing wires (receiver modules are plugged into existing outlets and appliances are plugged into the receiver and controlled by a handheld remote); others are wireless and utilize radio signals. Receiver modules can also be wired directly into the electrical system of the dwelling. Remote control units are available with large-print buttons and numbers.

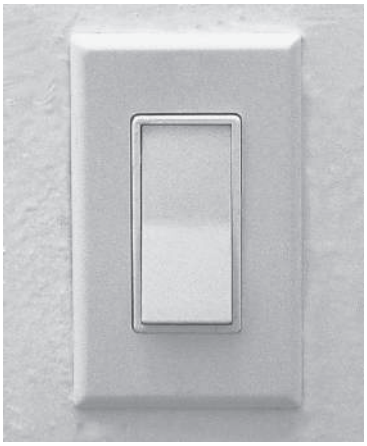

Figure 9.8 Rocker switches do not require fine motor skill and can be activated without using fingers (e.g., fisted hand, lateral aspect of hand, distal forearm). Rocker switches are available with an illuminated surface and with occupancy light sensor that turns on or off upon entering or leaving the room.

Floors

1. Floors should be nonslip and level. All floor coverings should be glued or tacked to the floor. This will prevent bunching or rippling under wheelchair use. When carpeting is used, a dense, low pile (0.25 to 0.5 in [0.635 to 1.27 cm]), low-level loop generally provides for easiest movement of a wheelchair or ambulatory assistive device. Industrial-style or "indoor/outdoor" carpeting typically meet these requirements. High pile carpeting and carpet padding

increases roll resistance (e.g., wheelchair, rolling walker); firmer carpeting decreases roll resistance. Carpeting with bold patterns of mixed colors may be visually confusing and impair judgment of spatial distances.[86] Padding under carpet is generally not recommended; if used, it should be very firm.[5]

2. Floors should be examined for uneven or unlevel areas. This may be particularly problematic with older wooden floors. Joints in wood flooring should be shallow and no more that 0.25 to 0.5 in (0.635 to 1.27 cm) wide. Deep joints wider than 0.75 in (1.9 cm) will cause wheelchair casters to turn and lodge, blocking movement.[86] Optimally, problem areas should be repaired or replaced. If restoration is not possible, several other solutions might be recommended: (1) establish a path of movement for the patient that eliminates use of the problematic area; (2) place a piece of furniture over the offending area; or (3) place brightly colored tape along the borders of the area to continually remind the patient to avoid this area of potential danger.
3. Scatter rugs should be removed; larger area rugs can be secured with a good-quality carpet tape. Use of nonskid waxes should be encouraged.
4. If flooring is to be replaced, matte finishes should be recommended to reduce glare. Patients with visual impairments will benefit from a contrasting colored border along the perimeter of the room to help mark the boundaries of the space. Wide, colored tape can also be used effectively.

Doors

1. Raised thresholds should be removed to provide a flush, level surface. If structural elements prevent removal, threshold ramps ("transition wedges") can be easily installed (Fig. 9.9).
2. Doorways may need to be widened (if less than 32 in [815 mm] wide) to allow clearance for a wheelchair or assistive device. Doors may have to be removed, reversed (e.g., to open outward for easier exit, especially in the case of an emergency), or replaced with folding doors. Several other options are available to increase door clearance:
   - Installation of pocket doors, which slide into the adjacent wall when not in use; some sliding doors allow installation on the outside of the door frame and wall to minimize structural changes.
   - Removal of the wood strips on the inside of a doorframe will add approximately 0.75 to 1 in (19 to 25.4 mm) of clearance.
   - Use of *offset* hinges (also called *swing-clear* hinges), which swing the open door clear of the frame provide approximately 2 additional inches (51 mm) of space.
   - Removal of the door with installation of a curtain (inexpensive spring-loaded curtain rods and a fabric or plastic shower curtain can be used); if used for a bathroom door, this option is less than optimal because it compromises privacy.
3. As mentioned in regard to exterior doors, handles inside the home should also be examined. Rubber doorknob covers or lever-type handles may be important considerations. Knurled (roughened) surface door handles are used on interiors of buildings and dwellings when frequented by persons with visual impairments. These abrasive, knurled surfaces provide tactile clues that the door leads to a hazardous area and alerts the individual to danger. (Note: Brightly colored roughened areas are also used on flooring to indicate potential danger; for example, the edge of a train or subway platform.)

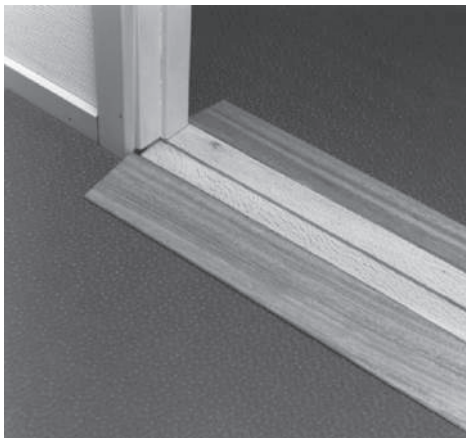

Figure 9.9 Common materials used for threshold ramps are wood (shown) and aluminum with a lacquered nonslip surface. They can be used between rooms, if threshold cannot be removed. *(Courtesy of Guldmann, Inc., Tampa, FL 33634.)*

Windows

1. To reduce glare, window films can be installed; frosted films are effective at diffusing light without appreciably reducing ambient light.
2. Heavy draperies or shades can also be used with the added benefit of absorbing internal background noise to improve hearing and conversation.
3. Remote control systems for closing or opening window coverings either partially or fully are commercially available.
4. Although not frequently seen in older dwellings, casement windows provide several important features for individuals using a wheelchair or for patients with limited upper extremity function. Casement windows open using a crank-style handle and can be locked with a single lever locking mechanism located near the bottom of the window. Automatic openers can be installed on these windows.

Stairs

1. All indoor stairwells should have handrails and should be well lighted. Ideally, handrails should extend a minimum of 12 in (305 mm) past the top and bottom of the stairs for added safety.[4,5] Battery-operated touch switch lamps are a practical supplement where electrical light sources are unavailable. Inexpensive track lighting provides multiple adjustable lamps and requires only a single electrical source. Lighting should be bright with glare and reflection minimized. Motion detection lights that automatically turn on when the patient approaches the stairs (or other area of the home) can also be an important safety consideration.
2. Stairs should be free of clutter. Rather than climbing the stairs to move a single item to the next level, patients sometimes "store" or collect items on the stairs. This creates several safety hazards: (1) initially bending over to pick up the items before stair climbing can alter postural stability; (2) negotiating stairs holding several objects can impair balance and limit use of the handrail; and (3) other household members may not see the item(s), precipitating a fall. As an alternative, a canvas bag or "stair basket" with handles (that can be held in one hand) can be placed near the stairs to collect the items until the patient is ready to move to another floor level.
3. For individuals with decreased visual acuity or age-related visual changes, adhesive, light-reflective *tactile warning strips* provide contrasting textures on the surface of the top and bottom stair(s) to alert them that the end of the stairwell is near. They can also be used on each step to identify its edge. Circular bands of tape also can be placed at the top and bottom of the handrail for the same purpose. Tactile warning strips placed on the floor can also be used to signal a change in level of the walking surface or entrance to another area or room of the dwelling.
4. Many patients with visual impairment will benefit also from bright, contrasting color tape on the border of each stair. Warm colors (reds, oranges, and yellows) are generally easier to see than cool colors (blues, greens, and violets).
5. For patients unable to negotiate stairs who require access to the second floor of a dwelling, a motorized stairlift may be an option (Fig. 9.10). These battery-powered units are available with a variety of options such as swing-away arms for wheelchair transfers, wide adjustable seat width (22.5 to 25.5 in [572 mm to 648 mm]), and wireless call/send controls. Outdoor models are also available, as well as units to accommodate curves or turns in the stairwell. Residential elevators are another, more costly option; they require construction of an enclosed shaft. If the residence has "stacked" closets (same position on different floors), these closet spaces can be combined to form an elevator shaft.

Figure 9.10 Powered stairlift. When not in use, the stairlift folds up against wall. It has a rack-and-pinion drive system that can safely transport up to 350 lb. The seat measures 19 inches (48.26 cm) wide and 14 inches (35.56 cm) deep. *(Courtesy of AmeriGlide, Inc., Raleigh, NC 27610).*

Heating Units

1. All radiators, heating vents, and hot water pipes should be appropriately screened off or insulated with pipe covers to prevent burns, especially for patients who have sensory impairments. Adaptations may be required to allow patient access to heat controls (e.g., remote thermostat control, use of reachers or enlarged, extended, or adapted handles on heat control valves).
2. The heating source should be clear of combustible material and clutter. Use of space heaters should be discouraged.
3. Smoke alarms and carbon monoxide detectors should be in the home and checked regularly by pressing the test button. Some newer models allow testing the unit using a flashlight or remote control.

Specific Considerations: Interior Accessibility

Bedroom Area

1. The bed should be stationary and positioned to provide ample space for transfers. Stability may be improved by placing the bed against a wall or in the corner of the room (except when the patient plans to make the bed). Additional stability may be achieved by placing rubber cups under each leg.
2. The height of the sleeping surface must be optimal for transfers. Furniture risers can be used to raise bed height. Wooden and high-density rubber furniture risers are commercially available in a variety of heights with routed depressions to hold each leg of

the bed (or other furniture such as chairs or tables). The use of an extra-thick mattress or box spring can also provide additional height to the bed. Using reduced-height box springs can lower the bed height.

3. The mattress should be carefully examined. It should provide a firm, comfortable surface. If the mattress is in relatively good condition, a firm bed board inserted between the mattress and box spring may suffice to improve the sleeping surface adequately. If the mattress is badly worn, a new one should be suggested.
4. A bedside nightstand (or small table) should be available; it can be used to hold a lamp, telephone (preferably cordless with a memory dial for frequently used numbers or emergency phone numbers; cellular phones have the added advantage of always remaining with the patient), necessary medications, and call bell if assistance is needed from a caregiver. Brooks et al[87] examined the type of items patients kept in their nightstands and their willingness to consider use of a smart nightstand. Findings indicated that the top surface and upper drawer were used most often. The categories of items most frequently kept on or in nightstands included personal hygiene (e.g., deodorant, eye drops, facial clothes), trash, clothing (e.g., belt, gloves, handkerchief), food accessories (e.g., fork, glass), telephone, book/magazine, water container, lotion, tissue box, and medical items (e.g., alcohol swabs, call button, cold pack). The vast majority of patients were willing to consider use of a smart nightstand. Participant preferences for design features included ability to raise and lower height, contemporary design, well-designed storage space, and voice activation.
5. The closet clothes bar may require lowering to provide wheelchair accessibility. The bar should be lowered to 52 in (132 cm) from the floor. Nonslip hangers are often recommended. Wall hooks also may be a useful addition to the closet area and should be placed between 40 in (101.6 cm) and 56 in (142.2 cm) from the floor. *Wardrobe lifts* can increase closet storage capacity while maintaining accessibility (Fig. 9.11). They consist of a clothes bar attached by hinged supports; using an extended handle, the bar is pulled down and out to access clothing. Electrically powered and hydraulic wardrobe lifts are also commercially available. Shelves also can be installed at various levels in the closet. The highest shelf should not exceed 45 in (115.5 cm). Clothing and grooming articles frequently used by the patient should be placed in the most easily accessible bureau drawer. Freestanding modular closet units are also available in a variety of dimensions. These units typically provide clothes bar, shelves, and drawers that can be adjusted to meet the needs of the user. Figure 9.12 illustrates the basic components and dimensions of an accessible bedroom.

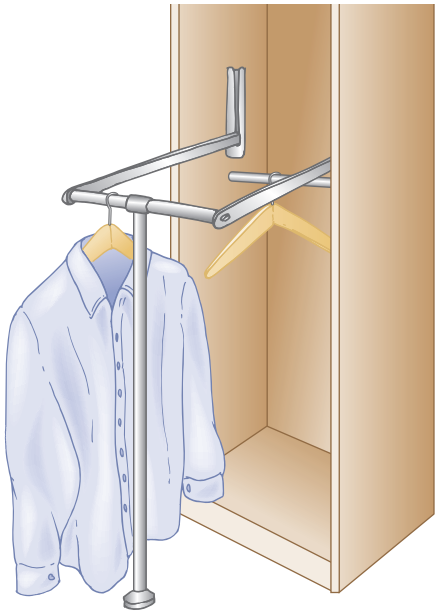

Figure 9.11 Manually operated wardrobe lift. Wardrobe lifts are available in a variety of sizes and some allow placement on either back wall or sidewalls.

Bathroom

1. If the doorframe prohibits passage of a wheelchair, the patient may transfer at the door to a chair with casters attached. As mentioned, several other solutions are available to address the problem of narrow doorframes (see Interior Accessibility: General Considerations, Doors).
2. An elevated toilet seat can be used to facilitate transfers. Some models allow the height to be custom adjusted whereas others provide a fixed height elevation. They are also available with grab bars. Power-lift toilet seats with grab bars are designed to assist the patient to standing (elevation initiated from the posterior aspect of the seat). As with other types of mechanized seat elevators, they should be used with caution, because it may be difficult to stabilize one's feet as the seat is elevating. For new construction, a wall-mounted toilet seat may be recommended that can be placed at the optimum height for the user and provide more floor space for transfer positioning.
3. Grab bars securely fastened to a reinforced wall will assist in both toilet and tub transfers. Grab bars should have a circular cross-section diameter of 1.25 in (32 mm) minimum and 2 in (51 mm) maximum and be knurled. For use in toilet transfers, the bars should be mounted horizontally 33 to 36 in (840 to 915 mm) from floor. The length of the grab bars should be between 42 and 54 in (1,065 and 1,370 mm) on sidewall and between 24 and 36 in (610 and 915 mm) on the back wall (Fig. 9.13). Ideally, two grab bars are secured horizontally to the back wall for use in tub transfers. One is placed

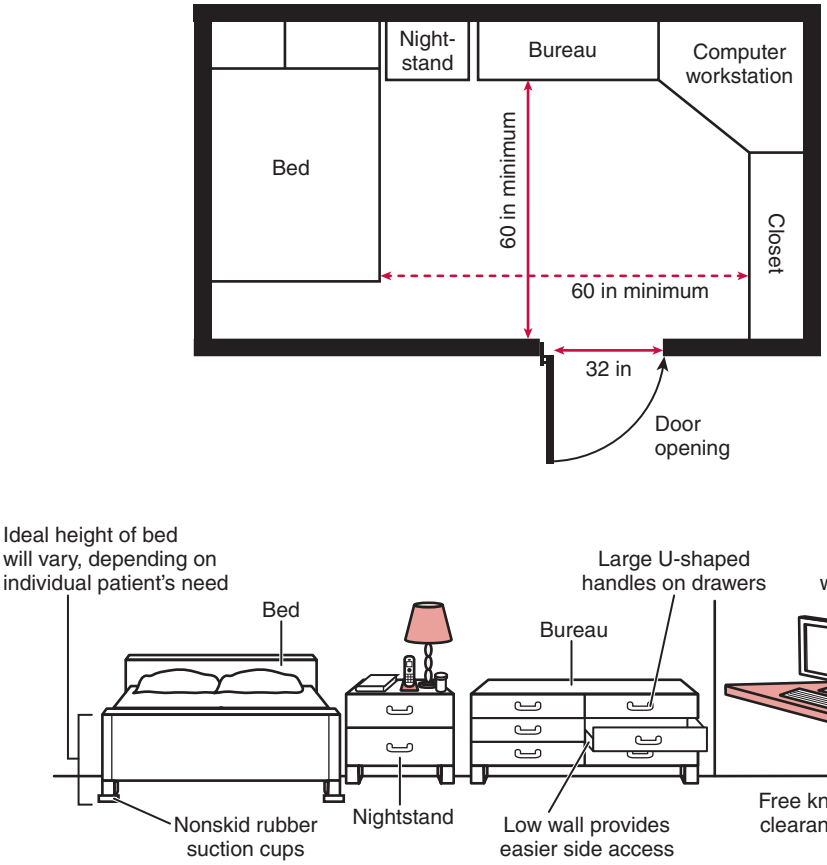

Figure 9.12 Sample dimensions and features of an accessible bedroom.

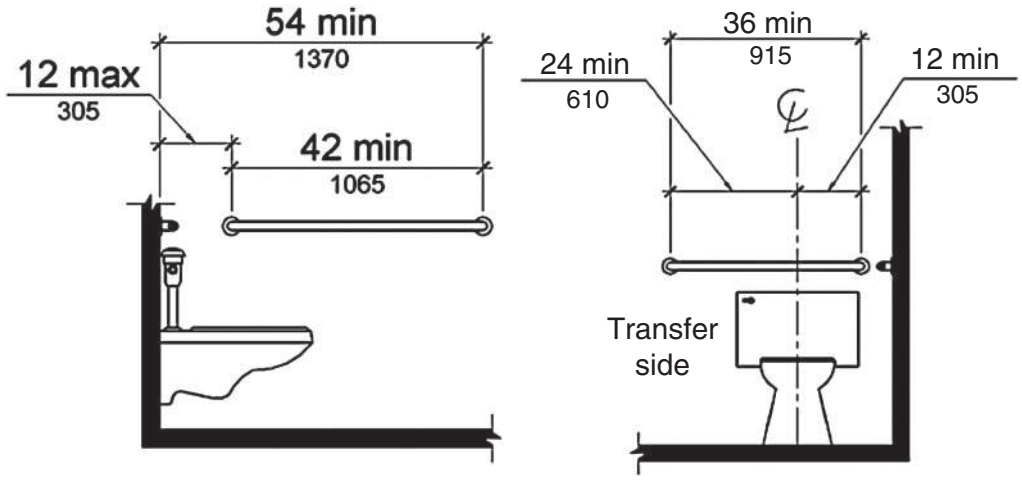

Figure 9.13 Location and dimensions of bathroom grab bars. Values denoted in inches and millimeters. The bars should be mounted horizontally 33 in (840 mm) to 36 in (915 mm) from the floor.[4] *(Left)* The sidewall grab bar is 42–54 in wide placed at a maximum of 12 in (305 mm) from rear wall. If anchored on or near rear wall, it should extend 54 in (1,370 mm) from the wall. *(Right)* The rear wall grab bar is 24–36 in wide (36 in is considered minimum if wall space allows). When 36 in long, 24 in of the bar (from center of toilet) is placed toward the side used for transfers. *(From 2010 ADA Standards for Accessible Design,[5]* Left, *p 163,* Right, *p 164.)*

33 to 36 in (840 to 915 mm) from tub floor and the second 9 in (230 mm) above top rim of the bathtub. Grab bars may also be mounted horizontally at the foot-end wall of the bathtub (recommended length is 24 in [610 mm] with placement at the front edge of the bathtub) and at the head-end wall of the bathtub (recommended length is 12 in [305 mm] with placement at the front edge of the bathtub) (Fig. 9.14). Knurled surfaces are typically used on grab bars to improve grasp and prevent slipping.

Figure 9.14 Bathtub with grab bars secured to back, foot-end, and head-end walls. The hand-spray faucet attachment facilitates control of water flow direction from a sitting position. *(Courtesy of The Swan Corporation, St. Louis, MO 63101.)*

4. A tub transfer bench (tub seat) may be recommended for bathing. Many types of commercially produced benches are available. In selecting a tub transfer bench (tub seat), function and safety are primary considerations. The bench should provide a wide base of support (some are designed with suction feet, and some provide height adjustment), a backrest, and an appropriate seating surface to facilitate transfers in and out of the tub (Fig. 9.15). Tub transfer benches with relatively long seating surfaces are typically positioned with two legs in the tub and two legs on the floor adjacent to the tub. Smaller benches are available that require all four legs to be placed inside the bathtub.
5. A space-saving design combines a toilet and shower seat into one assembled seat (Fig. 9.16). The design has the potential benefit of allowing creation of an accessible toilet and shower area in a relatively small bathroom as well as cost reduction since installation generally requires no wall demolition.
6. In shower stall areas, a collapsible seat may be permanently attached to the wall (Fig. 9.17). When not in use it folds flat against the wall, allowing easy shower access from a standing position as well. Many new extended shower designs incorporate a permanent, built-in seat.
7. Nonskid adhesive strips may be placed on the floor of the tub or shower area.

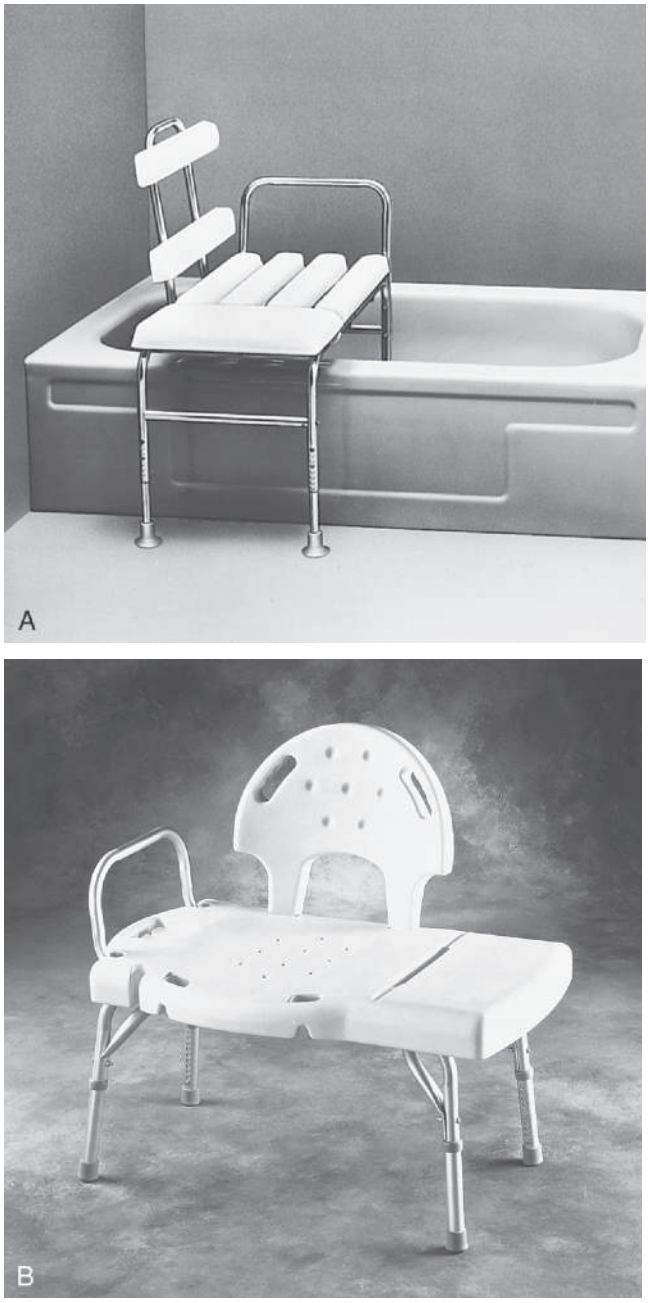

Figure 9.15 Two tub transfer bench designs each providing a wide base of support, a secure back rest, and a long seating surface to facilitate transfers. *(Courtesy of Lumex, Inc., Bay Shore, NY 11706.)*

8. Additional bathroom considerations may include a hand-spray attachment to the bathtub or shower faucet (see Fig. 9.14 and Fig. 9.17), antiscald valves to prevent water temperature from rising above a preset limit (also called *scald-guard valves* or *high temperature stops*), water volume–control mechanisms (to prevent a sudden surge of water with resultant change in temperature), enlarged faucet handles on the tub or sink (single-lever system faucets are optimal owing to their ease of use),

Figure 9.16 Combined toilet and shower seat into a single assembled seat. *(Courtesy of WYNG® Products, The Woodlands, TX 77380).*

Figure 9.17 Shower stall with collapsible shower seat, grab bars, and hand-spray attachment.

motion-sensor faucets, a spray attachment at the sink (allows washing hair without entering the bathtub or shower), a towel rack and small shelf for toiletry articles, and a call bell within easy reach of the patient.

Clinical Note: To prevent injury in the presence of sensory impairments, patient, family, and caregiver education should include using a thermometer to test water temperature before bathing.

9. Ideally, sinks should provide clear knee space below and any exposed hot water pipes should be insulated to prevent burns (Fig. 9.18). In new construction, shallow sinks may be installed to increase knee clearance with faucets placed on the side for easier access. Storage space lost from beneath the sink can be partially compensated for by an under-the-sink rollout cabinet that can be easily moved for wheelchair access. An enlarged mirror over the sink with the top tilted away from the wall facilitates use from a sitting position (Fig. 9.19). Forward-tilting mirrors are also available with adjustable hinges for alternating placement against and away from the wall. Hinged-wall, gooseneck, or accordion fold-up mirrors (with one side magnified) are also helpful for close work.

Figure 9.20 illustrates the minimum space requirements of a wheelchair-accessible bathroom.

Kitchen

1. The height of countertops (work space) should be appropriate for the individual. When using a wheelchair, the armrests should be able to fit under the working surface. The ideal height of counter surfaces should be no greater than 31 in (794 mm) from the floor with a knee clearance of 27.5 to 30 in (705 to 769 mm). Counter space should provide a depth of at least 24 in (615 mm). All surfaces should be smooth to facilitate sliding of heavy items from one area to another. Slide-out counter spaces are useful in providing an over-the-lap working surface (Fig. 9.21). A section of base cabinetry can be removed to provide a seated countertop workspace. For patients who are ambulatory, stools (preferably with back and footrests) may be placed strategically at the main work area(s). For patients with visual impairments, placing colored tape along the border of the countertop that contrasts sharply with the color of the counter surface will help identify boundaries of the workspace. Under-the-counter cabinets with glide-out height-adjustable shelves improve access to storage areas (Fig. 9.22).

2. Improved function and safety may be provided by a sink equipped with large blade-type handles or a single-lever style faucet, scald-guard valves, or electronic sensors that allow hands-free operation by automatically turning water off and on. A spray-hose fixture allows filling heavy pots without needing to lift them from a sink. Pressure-balanced valves can be used to equalize hot and cold water; other faucets allow pre-programming desired water temperature. Hot water dispensers are helpful for preparing coffee or tea and

Figure 9.18 Accessible bathroom with knee clearance below sink and insulated piping. The shower entrance includes a small ramp to accommodate a difference in floor surface heights. Note that the shower hand-spray is held by a vertical slide-bar (to change height) allowing for a seated shower. Alternately, the hand-spray can be handheld to direct water flow to specific areas. *(Courtesy of The Swan Corporation, St. Louis, MO 63101.)*

Figure 9.19 Over-sink mirror with top tilted away from wall to allow use from a seated position.

instant soups or cereals, minimizing the need for using the stove. Shallow sinks 5 to 6 in (128 to 153 mm) deep will improve knee clearance below. Providing sink access to an individual using a wheelchair may require removal of under-the-sink cabinets. As in the bathroom, hot water pipes under the kitchen sink should be insulated to prevent burns. Motorized adjustable sinks (Fig. 9.23) are mounted against a wall between two stationary cabinets with free space beneath. By activating the control switch, the sink height can be adjusted for the individual user whether seated in a wheelchair or standing.

3. A small cart with casters may be helpful to improve ease of moving articles from refrigerator to counter or table.
4. The height of tables also should be checked and the tables may have to be raised or lowered.
5. Equipment and food storage areas should be selected with optimum energy conservation in mind. All frequently used articles should be within easy reach, and unnecessary items should be eliminated. Additional storage space may be achieved by installation of open shelving or use of pegboards for pots and pans. If shelving is added, adjustable shelves are preferable and should be placed 16 in (410 mm) above the countertop.[88] Electronically powered storage cabinets are also available that automatically lower for countertop access (Fig. 9.24).
6. Electric stoves are generally preferable to open-flame gas burners. For optimum safety, controls should be located on the front or side border of the stove to eliminate the need for reaching across the burners. Burners that are placed beside each other provide a safer arrangement than those placed one behind the other. A heat-resistant burn-proof counter surface adjacent to the burners

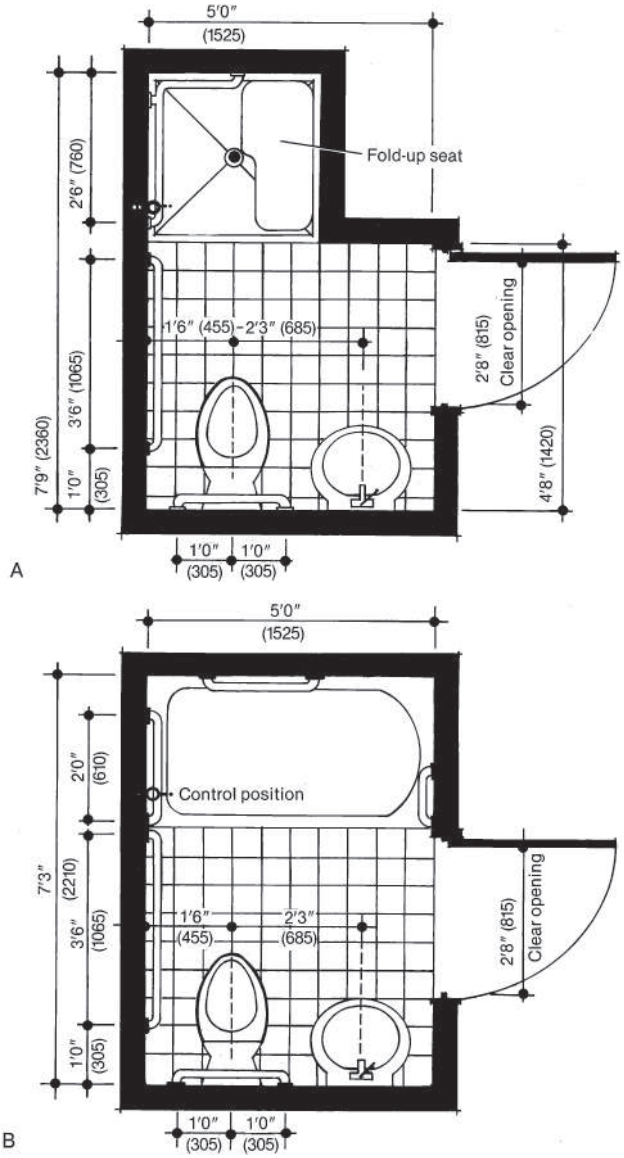

Figure 9.20 Minimum space requirements of a residential bathroom with **(A)** a shower stall and **(B)** a bathtub. The dotted line indicates lengths of wall that require reinforcement to receive grab bars or supports. *(From Nixon, V: Spinal Cord Injury: A Guide to Functional Outcomes in Physical Therapy Management. Aspen Systems Corporation, Rockville, MD, p 186, with permission.)*

Figure 9.21 Slide-out counter spaces provide over-the-lap working surfaces. Positioned here below a built-in wall oven, the pullout surface allows for ease of transfer of hot dishes. *(Courtesy of General Electric, Appliance Park, Louisville, KY, 40225.)*

Figure 9.22 Glide-out under-cabinet shelves improve ability to see and access stored items. *(Courtesy of General Electric, Appliance Park, Louisville, KY, 40225.)*

will facilitate movement of hot items once cooking is completed. Smooth, ceramic cooktop surfaces also reduce the amount of lifting required while cooking (Fig. 9.25). If cooktops provide knee clearance beneath, exposed or potential contact surfaces must be insulated. Induction (electromagnetic) stoves are also available that heat food without flames or heating elements.

7. For patients with visual impairments, large-print label-making devices and large-print stencil overlays can be used to enlarge appliance control indicators and dials (e.g., on/off or temperature indicators on thermostats, microwaves, stoves, and ovens). Timers, wall clocks, and telephones with large-print numbers are also available.
8. Wall-mounted ovens (separate from the stove) should be placed 30 to 34 in (76 to 102 cm) from the floor with a side-opening door. These cooking units are generally more easily accessible than a

Figure 9.23 A motorized adjustable-height sink can be raised or lowered for comfortable use from either a seated or standing position. Height-adjustment controls are located on the anterior panel of the sink. *(Courtesy of General Electric, Appliance Park, Louisville, KY, 40225.)*

Figure 9.25 Cooktop with front-mounted controls and smooth surface that allows sliding (rather than lifting) from burner to heat-resistant countertop. Knee clearance beneath is accessed by folding doors. *(Courtesy of General Electric, Appliance Park, Louisville, KY, 40225.)*

Figure 9.24 Motorized storage cabinets that can be lowered from the resting position to allow countertop access. Height-adjustment controls (***[A]*** high and ***[B]*** low) are located on the right anterior panel of the cabinet. *(Courtesy of AD-AS, Boise, ID 83709.)*

single, low-level combined oven and burner unit. Oven units should be self-cleaning.

9. For many individuals, a countertop microwave oven is essential for food preparation.
10. Dishwashers should be elevated 9 in (228.6 mm) and be front-loading, with pullout shelves and front-mounted controls (Fig. 9.26). Elevated (9 in [228.6 mm]) side-by-side clothes washers and dryers should also be front-loading with front-mounted controls (Fig. 9.27).
11. Access to the refrigerator will be enhanced by use of a side-by-side (refrigerator-freezer) model.
12. A standard or remote control smoke and carbon monoxide detector and one or more, easily accessible, portable fire extinguishers should be available. It is generally recommended that fire extinguishers be mounted in open view near an exit and away from cooking appliances. For patients with hearing impairments, the smoke detector can be attached to a signaling system that activates both an audible and strobe light response to visually warn of danger. These signaling systems also can be used to activate flashing lights in response to a doorbell, knock on the door, telephone ring, or burglar alarm.

Although important for many patients, an examination of the home environment is often essential for older adults with specific areas of the home presenting greater hazards than others. Gitlin et al[89] addressed the types of difficulties older adults experience in their home. Data were collected from 296 participants (mean age 73.24 years) using interviews, self-reports, clinical assessment, and direct observation of the home environment. The researchers focused on nine areas of the home: bathroom, kitchen, bedrooms, entry to home, dining/living/family room, outdoor spaces, common rooms, stairs, and the area from street to house. The areas where subjects encountered the greatest environmental difficulties were bathrooms (88%), kitchens (76%), bedrooms (61%), and entryways (58%).

ADAPTIVE EQUIPMENT

A large variety of **adaptive equipment** is commercially available to increase independence, speed, skill, and efficiency in performing activities of daily living (ADL). Adaptive equipment is available to assist performance in such areas as bathing, personal care, dressing, meal preparation, and general household tasks (e.g., built-up handles on eating utensils and personal care items, suction devices to stabilize bowls and dishes, long-handled reacher, sponge, duster, dustpan and brush, rocker knife, adapted cutting board). Typically, adaptive equipment is a component of a *compensatory training approach* that focuses on achieving the highest level of function possible by using remaining abilities. This approach involves considering alternative ways to accomplish a task, use of intact segments to compensate for those lost, use of energy conservation and joint preservation techniques, and adapting the environment to optimize performance.

ASSISTIVE TECHNOLOGY

In the Technology-Related Assistance for Individuals with Disabilities Act of 1988, assistive technology is defined as "any item, piece of equipment, or product system, whether acquired commercially off the shelf,

modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities."[90] Assistive technologies can be simple mechanical or mobility devices but the term usually denotes some type of electronic, computer (e.g., hardware, software, peripherals), tablet application, or microprocessor-based (e.g., prosthetic knee control) device.

Assistive technologies (ATs) enable individuals with disabilities to perform daily activities by compensating for lost or impaired function. They promote greater independence and typically improve quality of life by assisting in such areas as communication, education, environmental accessibility, and work or recreational activities. Three important considerations in determining the need for ATs are (1) the individual's available function, (2) the nature of the tasks or activities that will be performed, and (3) the environmental context in which it will be used.

An enormous variety of ATs are commercially available. Ideally, an interdisciplinary rehabilitation team is responsible for examination, evaluation, and prescription recommendation for specific items. Although influenced by the care setting, participating individuals typically include the patient, family member(s) and/or caregiver(s), physical and occupational therapists, a speech-language pathologist, and an assistive technology professional (see below). Depending on the needs of the patient, other contributors may include a special education teacher, seating specialist, rehabilitation technology supplier, augmentative communication specialist, and social worker or funding specialist. Box 9.2 provides an overview of the general categories of AT.

An assistive technology professional (ATP) or rehabilitation technology specialist is responsible for analyzing the AT needs of the patient. Through the systematic application of technology and engineering principles, this individual addresses the patient's needs in multiple contexts including, but not limited to, education, employment, independent living, transportation, and recreation/leisure activities. The ATP recommends and guides selection of appropriate assistive technology and educates the patient family/caregivers in use of the technology. The ATP or rehabilitation technology specialist may hold a degree in areas such as Assistive Technology Engineering, Assistive Technology and Human Services, Physical or Occupational Therapy, Engineering, Human Factors and Ergonomics, or other related field. In addition, they typically hold a certificate in assistive technology. Many such certification programs have developed across the country. An example of such a certification program is the Rehabilitation Engineering and Assistive Technology Society of North America's (RESNA's) Assistive Technology Professional (ATP) certification program.

Environmental control units (ECUs) are an important example of how ATs can enhance function and improve independence. ECUs are electronic interfaces that allow the user to control a variety of appliances and devices (e.g., telephones, bed controls, various components of an entertainment unit, room temperature and lighting, open and close curtains, open doors). These devices combine operation of all appliances into a central control panel, providing increased independence for individuals with severe disability.

The three main components of an ECU are (1) the input device, (2) the control unit, and (3) the appliance. The *input device* controls the ECU using whatever voluntary movement the individual has available (e.g., joystick, control panel, keypad, keyboard [ECU computer software programs are available], a series of switches, touch pads and screens, light pen, optical pointers, brain implants [e.g., patients with high-level spinal cord injuries] and voice, mouth-stick, and eye control). The *control unit* is the central processor that translates the input signal to an output signal to regulate the target appliance. The *appliance* can be virtually any device that can be controlled electronically.

EXAMINATION OF THE WORKPLACE

An investigation of the workplace is an important component of a comprehensive examination of the environment. It is used to explore the *worker–job–environment relationship* and to determine the feasibility of returning to a former job or if reasonable accommodations will provide the needed support to resume work. The tests and measures used by physical therapists to examine the workplace fall into two broad categories: (1) *ergonomics,* which is the application of scientific and engineering principles to the worker–job–environment relationship to improve safety, efficiency, and quality of movement; and (2) *body mechanics,* which is the interaction of muscles and joints in response to forces placed on or generated by the body.[3] Within the context of these two examination categories, Table 9.2 presents the tests and measures used by physical therapists together with the tools for gathering data, and the types of data generated.

Interview

An initial component of the workplace examination is a preliminary *job analysis interview.* The purpose of the interview is to gather information about (1) the functional requirements of the job based on a review of duties and responsibilities and (2) the characteristics of the physical space in which the individual is required to work (job analysis will continue during the on-site visit). Interview questions are developed based on the type of employment (e.g., assembly work, food service tasks, clerical work, motor vehicle operation, manual material handling, factory work, and so forth). During the interview, the patient/client should be encouraged to provide detailed information about responsibilities

Box 9.2 Categories of Assistive Technology

Aids for Daily Living

Aids or devices that enhance performance of ADL and level of independence in such activities as eating, meal preparation, dressing, personal hygiene, bathing, or household management. *Examples*: Grab bars, ramps, stairlifts, lowered counters, bathtub seats, adapted doorknobs, eating utensils, personal hygiene items, nonslip surface to stabilize dishes or other objects, and alternative doorbells.

Augmentative Communication

Devices used to enhance personal expressive and receptive communication. *Examples*: Communication enhancement devices (electronic), book holders, communication boards, eye gaze boards, electric page turners, head wands, mouth sticks, light pointers, reading machines, personal voice amplification, signal systems, and telephone adaptations.

Computer Applications

Hardware, software, and devices to enhance computer access. *Examples*: Modified, chording, expanded or alternate keyboards; voice recognition software; alternate workstations (electrically powered height and tilt adjustments); Braille translation software (conversion from print and Braille); Braille printers; access aids (head-control sticks, light pointers, eye gaze input); alternative switches (minimal pressure, voice activated) and cursor (mouse) control; voice synthesizers, large-print software that allows user to alter background and text colors (e.g., electronic books, magazines, and newspapers); magnification screens, touch screens, onscreen keyboard, screen reader; keyguards, forearm supports; text-to-speech software; speech-to-text software; optical character recognition (OCR) system that scans written text to a computer and is read by a speech synthesis/screen review system; and robotic wheelchair mounting to support a laptop computer.

Environmental Control Systems

Electronic systems that enhance ability to control various devices. *Examples*: Electronic control of appliances, lights, doors, and security systems in the home.

Hearing Technology

Devices designed to enhance receptive communication (assistive listening devices). *Examples*: Closed captioning, FM amplification systems (isolate and amplify a sound source), hearing aids, infrared amplification systems, personal amplification systems, TDDs/TTYs, television amplifiers, telephone adaptations, and visual and tactile alerting systems.

Mobility Technology

Devices designed to provide an alternative means for walking or moving within the environment. *Examples*: Manual or powered wheelchairs; powered scooters; vehicle modification (driving adaptations, hand controls, wheelchair lifts); stairlifts; bus lifts; kneeling buses; and ambulatory assistive devices.

Seating and Positioning

Wheelchair (or other seating system) interventions to improve postural alignment, stability, and head control and reduce skin pressure. *Examples*: Custom-fitted wheelchair (reclining back, elevating leg rests), tilt in space wheelchair, custom-molded seating surface, control blocks, pressure-relieving seat cushions, head and neck supports, adductor cushions, abductor pommel, lumbar supports, torso supports, and pelvic and foot positioners.

Vision Technology

Devices designed to enhance interaction with the environment for individuals with visual impairments. *Examples*: Talking devices (clocks, watches, calculators, thermometers, scales, handheld spell checkers, dictionaries, and thesauruses), magnifiers, speech output devices, large-print screens, mini pocket tape recorders, voice-activated daily planners, large-button phone, large-print books, magazines, and newspapers, audio books, and books on disc (can be loaded onto a computer and read to user with a voice synthesizer).

and tasks performed while on duty (e.g., duration of performance, weight and distance of items lifted, carried, or pulled, body positions used, and so forth). A sample of suggested job analysis interview questions appropriate for a clerical position is presented in Table 9.3.[91]

Job Analysis

A **job analysis** provides the basis for accommodating individuals with disabilities. It typically includes a job function statement that identifies the overall purpose as well as a description of (1) the essential functions

Table 9.2 Ergonomics and Body Mechanics: Tests and Measures, Tools Used for Gathering Data, and Data Generated

Ergonomics is the relationship among the worker; the work that is done; the actions, tasks, or activities inherent in that work (job/school/play); and the environment in which the work (job/school/play) is performed. Ergonomics uses scientific and engineering principles to improve safety, efficiency, and quality of movement involved in work (job/school/play). Body mechanics are the interrelationships of the muscles and joints as they maintain or adjust posture in response to forces placed on or generated by the body. The physical therapist uses these tests and measures in examining both the worker and the work (job/school/play) environment and in determining the potential for trauma or repetitive stress injuries from inappropriate workplace design. These tests and measures may be conducted after a work injury or as a preventive step. The physical therapist may conduct tests and measures as part of work hardening or work conditioning programs and may use the results of tests and measures to develop such programs.

Tests and Measures	Tools Used for Gathering Data	Data Generated
Tests and measures may include those that characterize or quantify: Ergonomics • Dexterity and coordination during work (job/school/play) (e.g., hand function tests, impairment rating scales, manipulative ability tests)	Tools for gathering data include: • Accelerometers • Cameras and photographs • Checklists for exposure standards, hazards, lifting standards	Data are used in providing documentation and may include: Ergonomics • Characterizations of efficiency and effectiveness of use of tools, devices, and workstations
• Functional capacity and performance during work actions, tasks, or activities (e.g., accelerometry, dynamometry, electroneuromyography, endurance tests, force platform tests, goniometry, interviews, observations, photographic assessments, physical capacity tests, postural loading analyses, technology-assisted assessments, videographic assessments, work analyses)	• Dynamometers • Electroneuromyographs • Environmental tests • Force platforms • Functional capacity evaluations • Goniometers • Hand function tests • Indexes • Interviews • Muscle tests • Observations • Physical capacity and endurance tests	• Characterizations of environmental hazards, health risks, and safety risks • Descriptions of tools, devices, equipment, and workstations • Descriptions and quantification of: —Abnormal movement patterns associated with work actions, tasks, or activities —Dexterity and coordination —Functional capacity —Repetition and work/rest cycle in work actions, tasks, or activities —Work actions, tasks, or activities
• Safety in work environments (e.g., hazard identification checklists, job severity indexes, lifting standards, risk assessment scales, standards for exposure limits)	• Postural loading tests • Questionnaires • Scales • Screenings • Technology-assisted analysis systems • Video cameras and videotapes • Work analyses	• Presence or absence of actual, potential, or repetitive trauma in the work environment
• Specific work conditions or activities (e.g., handling checklists, job simulations, lifting models, preemployment screenings, task analysis checklists, workstation checklists) • Tools, devices, equipment, and workstations related to work actions, tasks, or activities (e.g., observations, tool analysis checklists, vibration assessments)		Body mechanics • Characterizations of abnormal or unsafe body mechanics • Descriptions and quantifications of limitations in self-care, home management, work, community, and leisure actions, tasks, or activities

Continued

Table 9.2 Ergonomics and Body Mechanics: Tests and Measures, Tools Used for Gathering Data, and Data Generated—cont'd

Tests and Measures	Tools Used for Gathering Data	Data Generated
Body mechanics • Body mechanics during self-care, home management, work, community, or leisure actions, tasks, or activities (e.g., activities of daily living [ADL] and instrumental activities of daily living [IADL] scales, observations, photographic assessments, technology-assisted assessments, videographic assessments)

Table 9.3 Suggested Interview Questions Appropriate for a Clerical Position

Interview questions are used to gather general data about functional requirements of the job and the physical space in which the individual is required to work.

1. Y N Do you frequently lift more than 35 pounds?
2. Y N Are you required to lift objects from below knee level or above shoulder level on an occasional or frequent basis?
3. Y N When you lift, do you reach across other objects or at arms' length in order to accomplish the lift?
4. Y N Do you frequently reach for objects above shoulder level during the day?
5. Y N Do you sit for more than 4 hours per day?
6. Y N Does your job require you to maintain one position or posture for 30 to 60 minutes or longer at one time? If yes, what posture is it?_____
7. Y N Are repetitive exertions required on a regular basis (e.g., typing)?
8. Y N Does your job require frequent motions of the fingers, wrists, elbows, or shoulders? (If yes, circle all that apply.)
9. Y N Do you feel that your desk height is at a comfortable level?
10. Y N (a) Is your chair comfortable for you?
    Y N (b) Do you feel that it fits you properly?
    Y N (c) Do you know how to adjust your chair?
11. Y N Is there ample space for you to perform your job?
12. Y N Does your job involve frequent bending, twisting, or jerking movements?

From Hunter,[91, p. 68] with permission.

of a job and relative time spent on each; (2) the physical environment in which the essential functions are performed (e.g., indoors, outdoors, temperature fluctuations, noise levels); (3) the physical requirements (e.g., lifting, push/pull activities, bending, reaching); (4) the skills needed (cognitive processes, language, writing, or computer skills); and (5) the social context of the job (level of supervision, independent, contact with the public).

Job analyses provide a description of the job (not the potential employee). They are typically performed when a job is created to guide hiring of individuals with disabilities. (A sample job analysis form is presented in Appendix 9.E.) The physical therapist may also be called on to analyze a patient/client's current job following the onset of disability to make recommendations for reasonable accommodations.

Functional Capacity Evaluation (FCE)

Typically, the most effective means of examining the patient/client–work environment interface is an on-site visit. However, a variety of standardized functional capacity evaluation (FCE) instruments are commercially available that can be used to gather preliminary data before an on-site visit. The APTA defines FCE as "a comprehensive battery of performance-based tests that are commonly used to determine ability for work, activities of daily living, or leisure activities."[92] Depending on the job task requirements, the FCE may be all that is needed to determine ability to return to a previous job or to assume alternative job placement. The FCE provides a series of objective tests and measures designed to identify both work-related capabilities and activity limitations. Measurement parameters typically include endurance, ROM, flexibility, strength, force generation, posture, coordination, manual dexterity, and consistency of performance.[93-95]

The FCE is used to measure performance in specific components of work-related tasks. The specificity of the job will dictate the functional movements required. FCE instrument capabilities are then selected based on these requirements in order to examine the specific group of skills that comprise the employment tasks (e.g., lifting, stooping, trunk rotation, reaching). An example of an FCE instrument is the *Simulator II* functional testing system (Baltimore Therapeutic Equipment [BTE] Co., Hanover, MD 21076-3105). This computer-integrated system (Fig. 9.28) allows replication of physical task

Figure 9.28 Simulator II Functional Capacity Evaluation System. *(Courtesy of BTE Technologies, Inc., Hanover, MD 21076.)*

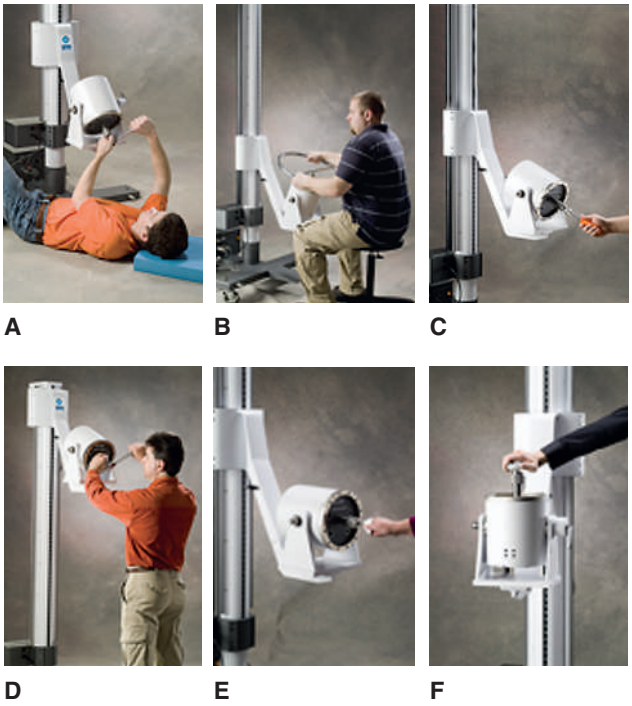

Figure 9.29 Examples of task simulations: (a) auto repair; (b) driving a bus; (c) using a screwdriver; (d) working overhead; (e) turning and (f) opening a jar. *(Courtesy of BTE Technologies, Inc., Hanover, MD 21076.)*

demands required of an individual's work environment using either standardized testing protocols or customized physical tests. A variety of tasks can be simulated, including, but not limited to, lifting, pushing, pulling, carrying capacity, turning a valve, and using a variety of tools (e.g., swinging a hammer, using a paint roller, using a manual saw). Additional examples are provided in Figure 9.29. This system may also be used for strengthening and retraining using task-specific strategies that simulate requirements of the client's real environment. Other examples of physical work capacity instruments include the *Joule Functional Capacity Evaluation System* (Valpar International Corporation, Tucson, AZ 85703-5767), the *Arcon Functional Capacity Evaluation System* (Arcon Vernova, Inc., Saline, MI 48176), the *ErgoMed Work Systems* (ErgoMed USA, San Antonio, TX 78269) and the *Isernhagen Work Systems Functional Capacity Evaluation* (WorkWell Systems, Inc., Aliso, CA 92656).

Software programs allow comparison of FCE data with normative values such as strength and ROM. Data from the FCE assist the physical therapist with the following tasks:

- Predicting the individual's work capacity and ability to safely return to work
- Identifying parameters of the physical environment needed to optimize function and prevent further injury (reasonable accommodations)
- Identifying extent of activity limitations (e.g., compensation process)
- Matching abilities to appropriate job placement
- Projecting potential benefits of a work hardening program

An additional resource is the *Occupational Information Network* (O*NET) available from the U.S. Department of Labor.[96] It provides a database of occupational job requirements (e.g., required skills and knowledge, how and where the work is performed) and worker attributes. The O*NET system includes the O*NET database (files available as free downloads for application development), O*NET OnLine (access to O*NET information), and the O*NET Career Exploration Tools (career investigation and assessment tools).

Work Hardening/Conditioning

Work hardening/conditioning refers to treatment interventions aimed at improving worker capabilities and function. The APTA defines work hardening/conditioning as "a work related, intensive, goal-oriented treatment program specifically designed to restore an individual's systemic, neuromusculoskeletal and cardiopulmonary functions. The objective of the work conditioning program is to restore the injured employee's physical capacity and function for return to work."[92]

Work hardening/conditioning programs typically involve progressive function-based exercise programs established from an analysis of work-related activities with careful attention to ergonomic and body mechanic principles. The anticipated goals and expected outcomes of work hardening programs are based on specific job requirements. Elements of the program may include (1) interventions to improve joint and soft tissue

mobility, improve motor function, increase functional skill and coordination at work-related tasks, improve muscle performance (i.e., strength, power, endurance), ROM, flexibility, and cardiovascular/pulmonary status; (2) guided practice and instruction in simulated work activities (replication of physical demands); (3) education (e.g., body mechanics, safety and injury prevention, behavioral education programs); and (4) promotion of self-management strategies.[97-99]

Work hardening/conditioning products (Fig. 9.30) are commercially available that allow the therapist to progressively challenge the patient/client using simulated work activities such as lifting and moving tasks using objects of different shapes and weight (Fig. 9.31A) to and from different heights, assembly tasks (Fig. 9.31B), sorting tasks, shoveling, pushing and pulling activities, use of tabletop and wall-mounted workstations, and so forth.

On-Site Visit

The on-site visit to the workplace typically includes (1) further refinement of the job analysis by observation of the patient/client performing work tasks within the environment in which they must be accomplished and (2) application of ergonomic principles to identify the immediate or predicted risks of musculoskeletal injury for an individual worker. Data from the on-site visit will allow the therapist to establish a *plan for risk reduction* that provides recommendations to eliminate the potential for injury, and a *plan to optimize function* that may include suggestions for fitting the job to the patient/client's anatomical and physiological characteristics in a way that enhances efficiency and performance within the work environment and addresses fear avoidance beliefs.[100,101]

When examining level of function during an on-site visit to the work environment, the principles of energy conservation, ergonomics, body mechanics, and anthropometrics are of prime importance in prevention of injury and maximizing the worker's efficiency and comfort. Capabilities should be weighed against the physical demands of the work environment, and the therapist, using knowledge of adaptive equipment and applied biomechanics, may suggest changes appropriate to the situation.

Many of the areas examined, recommendations made, and adaptive strategies employed in the home may be used in the work environment as well. Several considerations specific to the work setting are described below.

Figure 9.30 Work hardening equipment allows development of progressive therapeutic exercise (conditioning) programs based on simulation of a variety of tasks and assembly activities using sound ergonomic and body mechanic principles. *(Courtesy of Bailey Mfg. Co., Lodi, OH 44254.)*

External Accessibility

A parking space should be available within a short distance of the building if the patient/client plans to drive to and from work. For wheelchair users, parking spaces should be a minimum of 96 in (2440 mm) wide, with an adjacent access aisle 60 in (1525 mm) wide. The location should be clearly marked as a reserved parking area.

External accessibility of the building should be addressed using guidelines similar to those presented for home exteriors.

Internal Accessibility

Initially, the component requirements of the work task are identified. The complexity of some tasks or the needed interface with the work environment may render the analysis of such tasks before the on-site visit inappropriate. This will include determination of mobility requirements (movement within and outside the primary work area), as well as determination of demands or skill required in each of the following areas: muscle performance (including strength, power, and endurance [trunk, upper versus lower extremities]), ROM, posture, manual dexterity, eye–hand coordination, vision, hearing, and communication.

The immediate work area should be carefully examined. This includes lighting; temperature; seating surface (if other than a wheelchair); the height and size of the workstation (some patients may benefit from a variable height or tilting work surface); and exposure to noise, vibration, or fumes. Access to supplies, materials, or equipment should be considered with respect to the patient's vertical and horizontal reaching capabilities. Access to public telephones, drinking fountains, and bathrooms should also be addressed.

Owing to the prevalence of computer workstations in many employment settings, therapists may be called on to make recommendations to optimize efficiency and reduce the potential for trauma or repetitive stress injury from poorly designed work areas. A fully adjustable chair is an integral component of an ergonomic workstation.[102] The foundational requirements for workstation chairs are depicted in Figure 9.32. Although individual client parameters may require variations, the general principles for positioning at a computer workstation include screen slightly below eye level, body centered directly in front of monitor and keyboard, forearms level or tilted slightly upward, wrists free while typing, lower back well-supported, thighs horizontal on seating surface, and feet resting flat on the floor (Fig. 9.33).[102]

During examination of workstations for individuals using a wheelchair, functional sitting reach is an important consideration. From an upright wheelchair sitting position, the unobstructed high forward reach is a maximum of 48 in (1,220 mm) from the floor and the low forward reach is a minimum of 15 in (380 mm) from the floor (Fig. 9.34A). When the high forward reach is over a work surface of not greater than 20 in (510 mm), the maximum reach distance is 48 in (1,220 mm) from the floor (Fig. 9.34B). Progressively deeper work surfaces will alter the forward reach accordingly. For example, a work surface depth between 20 and 25 in allows a maximum forward reach of not greater than 44 in (1,120 mm) (Fig. 9.34C). With a floor obstruction of 10 in (255 mm), the high side reach is a maximum of 48 in (1,220 mm) and a low side reach of 15 in (380 mm) minimum (Fig. 9. 34D). With an obstruction of a maximum of 24 in (610 mm), the high side reach is a maximum of 46 in (1,170 mm).[5] For individuals with good trunk control, reaching capacity will be increased.

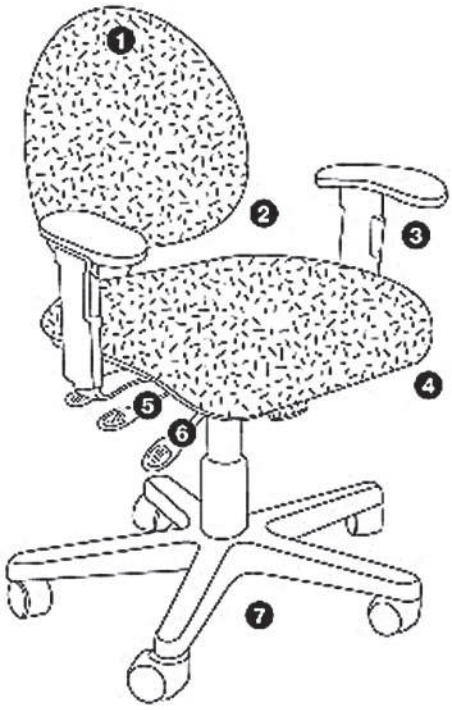

Figure 9.32 Overview of recommended features of workstation chair: (1) breathable, medium-texture upholstery; (2) adjustable lumbar support that moves up/down; (3) adjustable armrests; (4) seat with rounded front border (waterfall design); (5) adjustable seat that moves up and down and tilts forward and backward; (6) a tilt mechanism that tilts forward and backward; and (7) five-caster base with a full 360-degree swivel. *(From Workplace Ergonomics Reference Guide.[102, p. 4])*

Detailed resources are available to guide examination of the workplace. These include the *Americans with Disabilities Act (ADA) Regulations and Technical Assistance Materials*,[103] the *ADA Accessibility Guidelines for Buildings and Facilities* (ADAAG),[104] and the *2010 ADA Standard for Accessible Design*.[5] These documents are freely available and include the technical requirements for accessibility to buildings and facilities by individuals with disabilities under the Americans with Disabilities Act of 1990. A comprehensive source of information about the ADA is provided at the U.S. Department of Justice's *ADA Home Page*.[105]

COMMUNITY ACCESS

To attain the goal of full accessibility, the viability of community resources, services, and facilities must be investigated. When direct involvement by the therapist is not possible, this may best be accomplished by providing the patient and family/caregivers with guidelines for exploring access to local facilities.

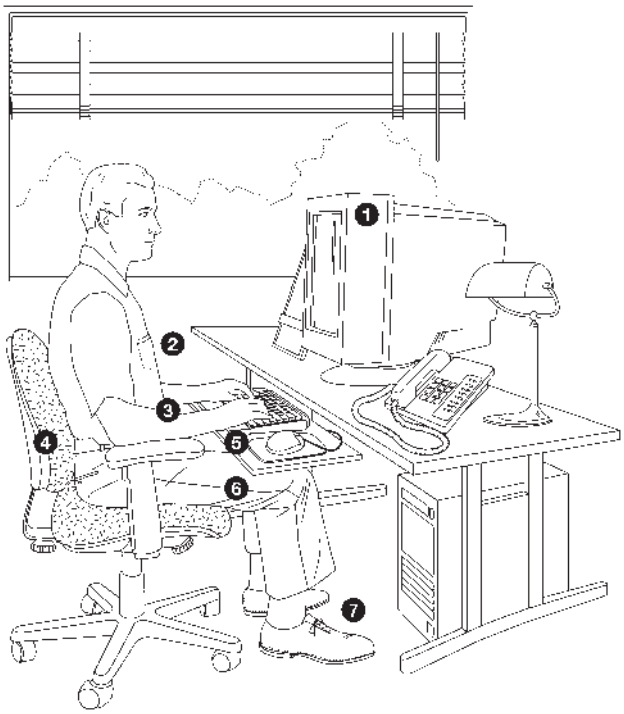

Figure 9.33 Overview of positioning recommendations for computer workstations: (1) monitor screen top slightly below eye level; (2) body centered in from of the monitor and keyboard; (3) forearms level or tilted-up slightly; (4) lower back supported by chair; (5) wrists free while typing; (6) thighs horizontal; and (7) feet resting flat on the floor. *(From Workplace Ergonomics Reference Guide.[102, p. 2])*

Another important consideration is to refer the patient, family, and/or caregivers to community organizations such as the Arthritis Foundation, National Easter Seal Society, Multiple Sclerosis Society, the Mayor's Office, Chamber of Commerce, or the Veterans Administration. These groups can provide information on services available to individuals with a disability who reside in the community. Individuals who are returning to school should be encouraged to contact the campus student services office, which addresses the needs of students with disabilities. Information will be offered on housing, special services, and general campus resources.

Transportation

Currently the availability of accessible public transportation varies considerably among geographical areas. As such, careful exploration by the patient, family, and/or caregivers will be needed to determine what resources are obtainable in specific locales. Many communities provide at least part-time service of partially or completely accessible buses. These include the so-called "kneeling buses" equipped with a hydraulic unit that lowers the entrance to curb level for easier boarding (Fig. 9.35). Many buses are now designed with hydraulic lifts to allow direct entry by an individual using a wheelchair (Fig. 9.36).

Not all public transportation systems in the United States allow use by individuals who are nonambulatory or by those with limited ambulatory capacity. However, many urban transit systems are gradually making accommodations for individuals with mobility impairments (e.g., installation of elevators, alternatives to turnstile entrances, identified space for wheelchair riders). In many areas where public transportation is unavailable, door-to-door accessible van transportation is provided to residents with disabilities. Again, availability of such services may be limited in some rural locations.

Some patients will want to master driving an adapted automobile or van. This, of course, will improve opportunities for community travel significantly. Motor vehicle adaptations are selected based on the physical capabilities

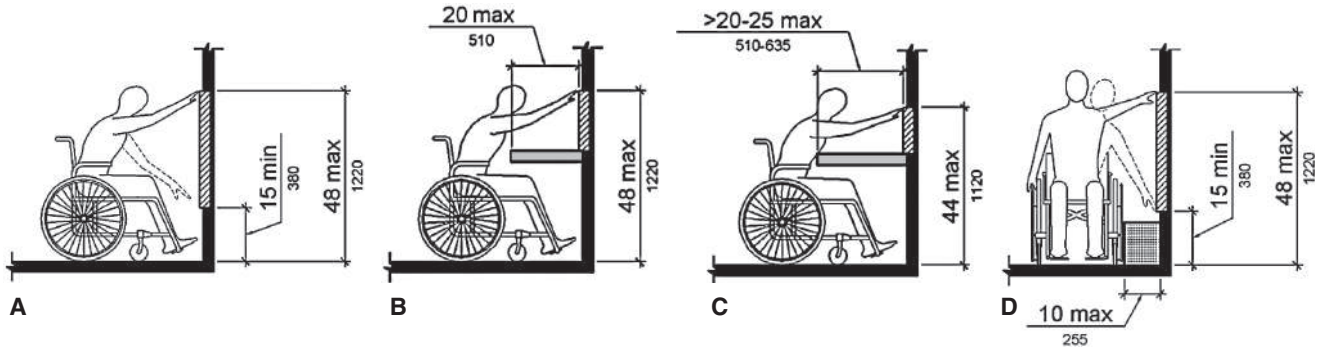

Figure 9.34 (a) Unobstructed high forward reach is a maximum of 48 in (1,220 mm) from the floor and the low forward reach is a minimum of 15 in (380 mm) from the floor. (b) High forward reach over a 20-inch-deep (510-mm-deep) work surface is a maximum of 48 in (1,220 mm) from the floor. (c) A work surface depth of 20 to 25 in (510 to 635 mm) allows a maximum forward reach of not greater than 44 in (1,120 mm) from the floor. (d) For a reach depth of 10 in (255 mm), the high side reach is a maximum of 48 in (1,220 mm). With a floor obstruction of 10 in (225 mm), the high side reach is a maximum of 48 in (1,220 mm) and a low reach of 15 in (380 mm) minimum. Values denoted in inches and millimeters. *(From 2010 ADA Standards for Accessible Design.[5, pp. 114-115])*

Figure 9.35 A kneeling bus lowers the steps to within 3 to 6 in of the curb. Buses designed to kneel typically display a sign (Kneeling ↓ Bus) either on or next to the door.

Figure 9.36 Bus lifts are able to accommodate wheelchairs and motorized scooters. The international wheelchair symbol for accessibility is typically displayed on the doors of the bus.

of the individual. Common adaptive equipment includes hand controls to operate the brakes and the accelerator; control panels mounted directly on steering wheel to control windshield wipers, turn indicators, and high/low beams; steering wheel attachments, such as knobs or universal cuffs, for individuals with limited grip strength; lifting units to assist with placement of the wheelchair into the vehicle; and, for patients with tetraplegia or high-level paraplegia, self-contained lifting platforms for entry to a van while remaining seated in a wheelchair. Driver training programs are taught by occupational therapists and offered in most large rehabilitation centers.

For patients whose capacity for long-distance ambulation is limited and/or whose endurance is low, community-going battery-powered scooters (Fig. 9.37) may be a practical alternative for travel within a reasonable proximity of the home.

Access to Community Facilities

Several considerations incorporated into examination of the workplace warrant attention for general community access, as well. Briefly stated, area facilities used by the patient should be explored for the availability of appropriate parking areas; beveled curbs; external and internal structural accessibility of buildings; and availability of accessible public telephones, drinking fountains, bathrooms, and restaurants. Theaters, auditoriums, and lecture halls must be considered with respect to accessible seating areas. Many such public presentation spaces are now designed with an accessible isle leading to open floor space interspersed within a row of standard seats to accommodate a wheelchair. This allows the individual using a wheelchair the option of either sitting next to a person who is ambulatory or someone using a wheelchair. Locations of emergency exits should also be noted for all facilities. In addition to these general considerations, stores and shopping areas should also be inspected for access to merchandise (especially for individuals using a wheelchair), appropriate aisle widths, and adequate space at checkout counters.

Some theater companies offer "touch tours" for individuals who are blind or have impaired vision, allowing them to learn about the visual elements of the production. These multisensory experiences supplement for the lack of detail provided by a live performance and are led by cast, crew, and/or management. They provide an opportunity for participants to touch and handle theatre pieces while tour guides explain the significance of individual pieces.[106]

Another useful source of information on community access is the guidebook offered by many larger cities (often funded by the Mayor's Office or as a community service by local businesses). These guides provide information on accessibility of local cultural, civic, and religious institutions; government offices; theaters; hotels; restaurants; shopping areas; transportation; and social and recreational facilities. These publications usually can be obtained from the city's chamber of commerce, the mayor's office, or the office of tourism. Combined use of such guides and phoning ahead for details of accessibility will facilitate travel both within and outside the local community. Many of these guides are available online (e.g., Accessible NYC!![107] and the Disability Guide for Washington, DC[108]).

DOCUMENTATION

Once examination of the environment is complete, a final collaborative report is prepared that includes information from each participating team member. This report consists of information obtained from the home and, if applicable, the workplace or school setting. Information should also be included about the measures taken to explore general community accessibility.

Additional information that should be provided includes (1) a description of the methods used to assist the patient in ambulation or functional activities,

Figure 9.37 Examples of motorized scooters suitable for outdoor travel. **(A)** This lightweight scooter has a weight capacity of 275 lb (124.74 kg), a maximum speed of 4.25 miles per hour (MPH), and a turning radius of 35.5 in (90.17 cm). **(B)** This model includes a heavy-duty drivetrain with a weight capacity of 500 lb (226.8 kg), a maximum speed of 5.25 MPH, with a turning radius of 50.38 in (127.96 cm). **(C)** This unit features a reclining back with headrest, large pneumatic tires, a weight capacity of 400 lb (181.44 kg), a maximum speed of 8.25 MPH, with a turning radius of 82.5 in (209.55 cm). *(Courtesy of Pride Mobility Products, Exeter, PA, 18643.)*

(2) identification of the type and quantity of adaptive equipment required (including source and cost), (3) AT recommendations, and (4) suggested environmental modifications with precise specifications. If an examination form, survey, or checklist was used during the on-site visit, it should be included with documentation or the data summarized in narrative form.

Documentation related to community access should include verification of the patient's knowledge of available community resources. The sources of this information, as well as whether the therapist was directly or indirectly involved in the community investigation, should be reported.

The completed report is then included as part of the patient's medical record. Copies of the report are typically submitted to the patient's family/caregivers, the physician, third-party payer(s) or other potential funding sources, and any community-based health care or social service agencies that will be providing care.

FUNDING FOR ENVIRONMENTAL MODIFICATIONS

The patient and family/caregivers may require assistance in locating appropriate financial resources to achieve environmental accessibility. Typically, the social worker within the patient care facility will provide direction in this area. Information on resource organizations can also be obtained from the National Council on Disabilities. Potential sources of funding include private medical insurance companies, home equity or other types of bank loans, Veterans Administration, the Division of Vocational Rehabilitation (DVR), the Workers' Compensation Commission, and local chapters of national groups (e.g., Kiwanis International, Veterans of Foreign Wars, Masons/Shriners Lodges, and Lions International) or diagnosis-specific organizations (e.g., National Stroke Association, National Multiple Sclerosis Society, National Parkinson Foundation).

An important consideration is that not all patients will have current housing that is amenable to modification (e.g., an individual who previously lived in a third-floor walk-up apartment and now uses a wheelchair). In such instances, the local Housing and Urban Development (HUD) office will be an important resource. This office can provide a listing of accessible housing within the community. Because there are often waiting lists for such dwellings, early application is warranted.

Finally, creative funding for specific items (such as specialized adaptive equipment not covered by other resources) may be available through private organizations or foundations. Considerable time, research, and perseverance may be required in locating a receptive organization. General suggestions the patient, family, and/or caregiver(s) might consider in seeking assistance include contacting local businesses or corporate giving offices, civic or service clubs, churches or synagogues, labor unions, Jaycees, and the Knights of Columbus.

LEGISLATION

Much attention has been focused on the importance of environmental accessibility. Through legislation and a variety of private organizations, significant strides have been made in this area. In 1990 the *Americans with*

Disabilities Act was signed into law. This legislation is among the most comprehensive of the civil rights laws enacted for individuals with disabilities. It guarantees civil rights protection and equal opportunity in the areas of government services, employment, public transportation, privately owned transportation available to the public, telephone service, and public accommodations.[109] This law requires that all "public places of accommodation" be made accessible to people with a disability unless it imposes "undue hardship" to the establishment. This law specifies that restaurants, movie theaters, hotels, professional offices, retail stores, and so forth make reasonable accommodations.

With respect to an individual, disability is defined in the ADA as "a physical or mental impairment that substantially limits one or more major life activities of such an individual; a record of such impairment; or being regarded as having such impairment."[109, p. 4] Undue hardship includes excessive direct cost of adapting the environment, limited resources of the establishment, or situations where these changes would fundamentally alter the nature or daily operation of a business. The ADA also provides a federal tax credit incentive for measures taken by businesses to comply with this law.

The *Fair Housing Amendment Act of 1988* prohibits discrimination in housing on the basis of race, color, religion, gender, disability, familial status, and national origin. The Act includes private housing, state and local government housing, and any housing that receives federal financial support. The Act requires that accessible units be included in all new multiple-dwelling buildings with four or more units. It requires landlords to allow individuals with disabilities to make reasonable, access-related modifications to their living space, as well as common areas of the building. However, the landlord is not required to pay for these modifications. To promote adherence, the Fair Housing Amendment Act also provides accessible construction standards for multifamily housing units built for first occupancy after March 1991.

The *Rehabilitation Act of 1973* provided that access must be established in all federally funded buildings and transportation facilities constructed after 1968. The law prohibits discrimination in federal employment, stipulates accessibility within federal buildings, and established the Architectural Transportation Barriers and Compliance Board. Because many federally funded institutions provided low compliance with the 1973 Rehabilitation Act, an amendment was passed in 1978. The Comprehensive Rehabilitation Services Amendments (P.L. 95-602) of 1978 strengthened the enforcement of the original 1973 Rehabilitation Act. The Architectural and Transportation Barriers Compliance Board is the governing body responsible for enforcing this legislation.

The *Architectural Barrier Act of 1968* (P.L. 90-480) provided that certain buildings that were financed by federal funds be designed and constructed "to insure that physically handicapped persons will have ready access to, and use of, such buildings."[110, p. 719] Another important item of legislation related to environmental accessibility is the Public Buildings Act of 1983, which functioned to establish public building policies for the federal government. This Act (section 307) provided several amendments to the Architectural Barrier Act of 1968 to further strengthen and delineate the importance of accessibility. The term *fully accessible* in this Act was defined as "the absence or elimination of physical and communications barriers to the ingress, egress, movement within, and use of a building by handicapped persons and the incorporation of such equipment as is necessary to provide such ingress, egress, movement, and use and, in a building of historic, architectural, or cultural significance, the elimination of such barriers and the incorporation of such equipment in such a manner as to be compatible with the significant architectural features of the building to the maximum extent possible."[111, p. 373]

The *Telecommunications Act of 1996* applies to all telecommunication equipment and services. It stipulates that manufacturers of "telecommunications equipment or customer premises equipment shall ensure that the equipment is designed, developed, and fabricated to be accessible to and usable by individuals with disabilities, if readily achievable."[112, p. s.652-20] The Act also provides a similar accessibility directive to providers of telecommunications services.

Despite the recent gains made in architectural accessibility, barriers continue to exist. Inasmuch as most public transportation systems were built before 1968, accessibility is not required by law. However, the ADA indicates that all concerns that offer public transit along a fixed route must also provide buses that are accessible to individuals with disabilities, including access by wheelchairs. Other areas that continue to be problematic include revolving doors, the design of many supermarkets and shopping areas (barriers imposed by checkout areas and items displayed on high shelves), lack of available parking spaces, multiple levels of stairs at the entrance to some buildings, and the design of some theaters and auditoriums that do not have specifically designated areas for individuals using a wheelchair.

The ADA homepage (www.ada.gov) provides an extensive listing of links to available ADA publications, as well as links to federal resources.

Although increasing numbers of buildings are being designed to provide accessibility, this area warrants further involvement from therapists. Physical therapists can be effective advocates and are equipped to provide a leadership role in compliance with existing and new laws. They have important knowledge and skills to enable them to provide valuable input into the initial planning and/or modification of barrier-free designs. Appendix 9.F provides Web-based accessibility resources for clinicians, patients, and families.

SUMMARY

Examination of the environment is an important factor in facilitating the patient's transition to the home, work, and community. The rehabilitation team uses the data to determine the level of patient access, safety, and function within the environment. The information is also used to determine the need for additional treatment interventions, ATs, environmental modifications, outpatient services, and adaptive equipment. In addition, the examination assists in preparing the patient, family, caregivers, and/or work colleagues and employer for the individual's return to a given setting.

This chapter has presented a sample approach to examination of the environment. Common environmental features that typically warrant consideration have been highlighted. Inasmuch as a return to a former environment is often a primary goal of rehabilitation, early consideration of these issues is warranted. Collaboration among team members, the patient, and the patient's family and/or caregivers will ensure an optimum and highly individualized patient–environment interface.

Questions for Review

1. Explain the concept of universal design.
2. What are the purposes for performing an examination of the environment?
3. What data collection tools are used for examination of the environment?
4. Identify an inherent shortcoming of self-report instruments. How can accuracy of reporting be improved?
5. Before an on-site visit to a patient's home, what preliminary information is needed?
6. What specific aspects of the exterior of a patient's home should be examined during an on-site visit? Your response should address the *route of entry* to the home and actual *entrance* to home and include suggestions for potential access problems.
7. During a home visit, you find that a wheelchair user's bathroom door width measures 31 in wide (77.74 cm). The patient owns the 50-year-old home and plans to remain in the dwelling. What options are available to increase the bathroom door width?
8. What is included in a job analysis?
9. What is a functional capacity evaluation (FCE)? How are data from the FCE used (i.e., what decisions are informed by the data)?
10. What is work hardening/conditioning? Describe the elements included in a work hardening/conditioning program.

CASE STUDY

A 78-year-old woman with a diagnosis of osteoarthritis was admitted for a right total hip replacement. The patient reported a long-standing history of discomfort. She described the hip pain as radiating posteriorly to the buttock and low back and was exacerbated by weightbearing and stair climbing. Over the past 12 months she has experienced a very marked increase in pain and stiffness. Radiographic findings demonstrated degenerative changes of both the acetabulum and femoral head consistent with osteoarthritis. The surgical intervention replaced the right femoral head and neck with a metallic prosthesis and the acetabulum was resurfaced with a plastic cup. Past medical history is unremarkable.

SOCIAL HISTORY

The patient is a retired manager of a small accounting firm that she and her husband established. Her husband is deceased. She has three grown children who all live in neighboring communities. Before the activity limitations imposed by the hip pain, the patient had been independent in all BADL and IADL. She also volunteered her accounting services one day per week to a local charity that provides meals to homebound individuals. She was a regular participant in family outings; enjoyed going to the theater, concerts, and special museum events; and was an active member of the community historical preservation society. Recently, these activities had to be curtailed owing to the increased hip discomfort.

She essentially had no activities outside the home for 3 months before admission and used a walker to minimize weight-bearing and reduce pain. She also required the assistance of a home care aide 4 hours a day two times per week (primarily for shopping, errands, and some household

management tasks). She expressed considerable distress at being unable to take a bath and having to rely on the assistance of another person for some basic care activities. She had been using aspirin for its analgesic and anti-inflammatory effects. However, the pain experienced in recent months was not alleviated by the aspirin and other conservative measures she has been instructed to use (e.g., local applications of heat, periodic rest intervals, and gentle ROM exercises). The patient has medical insurance coverage and is without financial concerns.

REVIEW OF SYSTEMS

Cognitive function: Intact.

Vision: Wears corrective lens; experiences night blindness, which she describes as seeing poorly in dim light and her eyes take several seconds longer than normal to adjust from brightness to dimness.

Hearing: Intact.

Strength—upper extremities:

- Generally within functional limits; patient reports some sporadic episodes of wrist and finger stiffness on awakening in the morning and after periods of immobility.
- Grip strength is reduced bilaterally (manual muscle testing [MMT] of finger flexors = G–).
- Heberden's nodes noted at the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints of the left index finger. Patient denies pain in wrist or fingers.

Strength—lower extremities:

- Left: within functional limits.
- Right: within functional limits (hip motions not tested owing to surgical intervention); crepitus noted in right knee.
- Weight-bearing status on right lower extremity: partial weight-bearing

Range of motion: Within functional limits (with the exception of the right hip, which was not tested).

Postsurgical right hip precautions: No hip flexion beyond 90°. Avoid crossing one leg or ankle over the other. Avoid internal rotation of right lower extremity.

Coordination: Within normal limits.

Sensation: Intact.

Gait: The patient is ambulating on level surfaces with supervision using bilateral standard aluminum axillary crutches with partial weight-bearing on the right lower extremity. Stair climbing also requires minimal assistance. It is anticipated the patient will be independent with household ambulation on level surfaces at time of discharge from the hospital.

PATIENT GOALS

The patient is extremely motivated to be independent in her personal care and household management. The prosthetic replacement has successfully relieved much of the pain experienced in the hip before surgery (most of her current discomfort is described as "minor" and associated with the surgical incision). She would also like to return to her family, volunteer, social, and leisure activities. She is very determined to discontinue the home care assistance as soon as possible.

HOME ENVIRONMENT

The patient lives alone in a fifth floor apartment in a building with an elevator. The living space is a one-bedroom apartment on a single level. At your request, one of the patient's children has provided dimensions of doorframes and height of sleeping and seating surfaces together with several photographs of each room of the patient's home. The physical dimensions and photographs indicate the following:

- Bedroom: two small area rugs, a nightstand with an alarm clock, a bureau, an old wooden four-poster bed in the middle of room with a sleeping surface 1.5 ft from the floor, and a ceiling lamp fixture controlled by a switch adjacent to the door.
- Bathroom: an area rug, standard toilet and sink, bathtub does not include a shower, a doorway entrance 30 in wide.
- Kitchen: polished linoleum floors, adequate counter space, and a dining table in the center of the room with standard kitchen chairs.
- Living room: overstuffed upholstered furniture with low seating surfaces, a favorite rocking chair, a large carpet that appears to ripple in several areas, a centered coffee table, a telephone with an extra-long extension wire placed on the coffee table, a remote controlled television, two end tables, and a bookcase.
- Hallway (between rooms): poorly lit with a long, narrow area rug.

GUIDING QUESTIONS

With general knowledge of the patient's living space, what environmental modifications, adaptive equipment, or additional instruction would you suggest or provide to optimize safety and function in each of the following areas of the home?

1. Bedroom
2. Bathroom
3. Kitchen
4. Living room
5. Hallway

The Principles of Universal Design

appendix
9.A

The Principles of Universal Design

PRINCIPLE

1 Equitable Use

The design is useful and marketable to people with diverse abilities.

2 Flexibility in Use

The design accommodates a wide range of individual preferences and abilities.

3 Simple and Intuitive Use

Use of the design is easy to understand, regardless of the user's experience, knowledge, language skills, or education level.

GUIDELINES

1

- 1a. Provide the same means of use for all users: identical whenever possible; equivalent when not.
- 1b. Avoid segregating or stigmatizing any users.
- 1c. Provisions for privacy, security, and safety should be equally available to all users.
- 1d. Make the design appealing to all users.

2

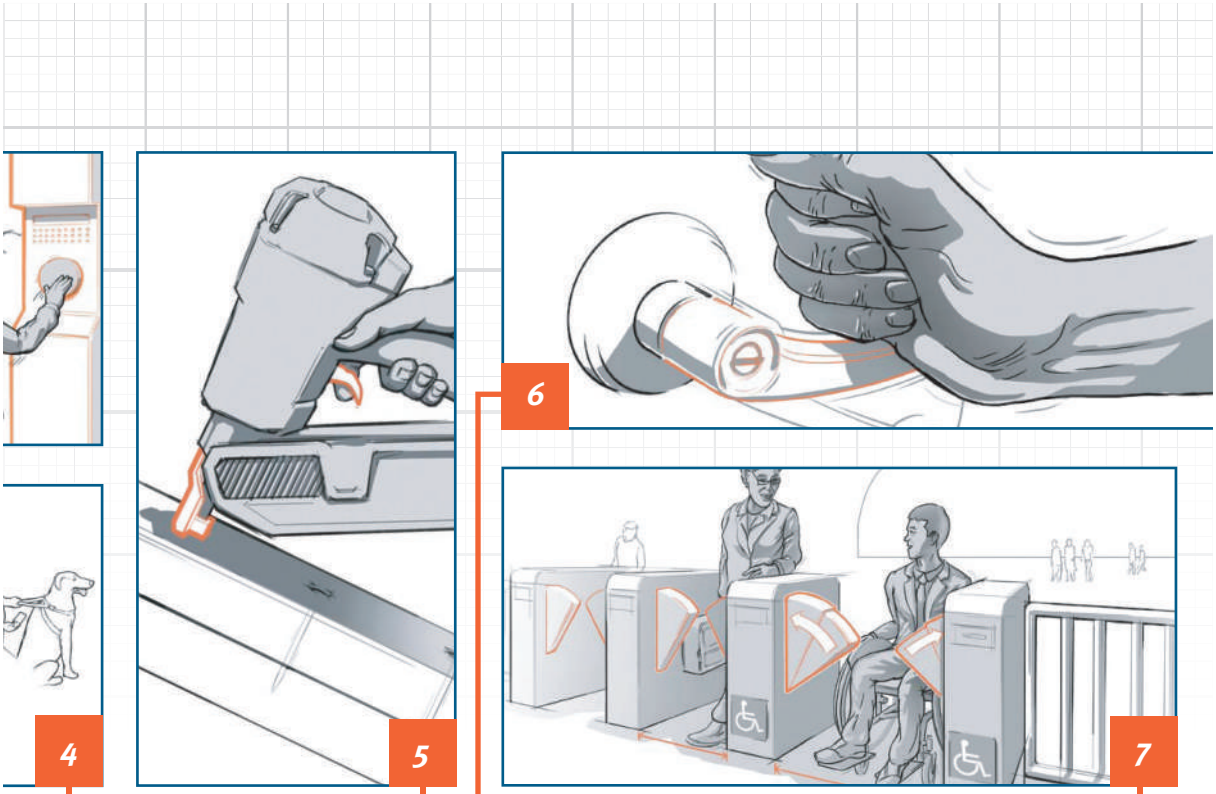
- 2a. Provide choice in methods of use.
- 2b. Accommodate right- or left-handed access and use.
- 2c. Facilitate the user's accuracy and precision.
- 2d. Provide adaptability to the user's pace.

3

- 3a. Eliminate unnecessary complexity.
- 3b. Be consistent with user expectations and intuition.
- 3c. Accommodate a wide range of literacy and language skills.
- 3d. Arrange information consistent with its importance.
- 3e. Provide effective prompting and feedback during and after task completion.

EXAMPLES

1



- Power doors make visiting public spaces easier for all users.
- E-mail makes communication easier for everyone, including people who have trouble communicating via phone.

2

Large grip scissors accommodates use with either hand and allows alternation between the two in repetitive tasks.

3

- Public emergency stations utilize recognized emergency colors and a simple design to quickly convey function to passers-by.
- Intuitive ATM interfaces allow use without instruction or training.

Perceptible Information	Tolerance for Error	Low Physical Effort	Size and Space for Approach and Use
The design communicates necessary information effectively to the user, regardless of ambient conditions or the user's sensory abilities.	The design minimizes hazards and the adverse consequences of accidental or unintended actions.	The design can be used efficiently and comfortably and with a minimum of fatigue.	Appropriate size and space is provided for approach, reach, manipulation, and use regardless of user's body size, posture, or mobility.
4a. Use different modes (pictorial, verbal, tactile) for redundant presentation of essential information. 4b. Provide adequate contrast between essential information and its surroundings. 4c. Maximize "legibility" of essential information. 4d. Differentiate elements in ways that can be described (i.e., make it easy to give instructions or directions). 4e. Provide compatibility with a variety of techniques or devices used by people with sensory limitations.	5a. Arrange elements to minimize hazards and errors: most used elements, most accessible; hazardous elements eliminated, isolated, or shielded. 5b. Provide warnings of hazards and errors. 5c. Provide fail safe features. 5d. Discourage unconscious action in tasks that require vigilance.	6a. Allow user to maintain a neutral body position. 6b. Use reasonable operating forces. 6c. Minimize repetitive actions. 6d. Minimize sustained physical effort.	7a. Provide a clear line of sight to important elements for any seated or standing user. 7b. Make reach to all components comfortable for any seated or standing user. 7c. Accommodate variations in hand and grip size. 7d. Provide adequate space for the use of assistive devices or personal assistance.
Small bumps on a cell phone keypad tell the user where important keys are without requiring the user to look at the keys.	The "sequential trip" mechanism on a nail gun prevents accidental firing when the tool is not pressed against an object.	Door lever does not require grip strength to operate, and can even be operated by a closed fist or elbow.	Wide gates at subway stations accommodate wheelchair users as well as commuters with packages or luggage.

Usability in My Home—A Self-Report Instrument

appendix **9.B**

Directions: The questionnaire consists of two parts, with a number of questions about the design of the *physical housing environment* in which you live. You are asked to answer the questions by assessing how you feel that the design and form of the physical housing environment suits you, your needs, and your wishes.

By physical housing environment is meant here your home, the car park, garage, or parking space that you use if you have a car, your own letterbox, the dustbin/refuse storage place, the storage space, and the shared laundry, if there is one. This includes all the routes along which you move on the site to and from these places. It also includes a balcony, patio, and garden where applicable.

The questions are very general, and the aim is to capture your immediate perception of how the physical housing environment suits you.

For each question there are seven response alternatives in the form of the numbers 1 to 7. The number 1 stands for what is the worst and lowest alternative for you, and 7 stands for the best and highest alternative. The numbers 2 to 6 describe the positions that lie between the best and the worst alternatives. The number 4 is the neutral point on the scale, neither good nor bad. Put a circle round the alternative that agrees best with your perception.

Example: If you are so dissatisfied with your physical housing environment that it could not, in your opinion, be worse for you, then circle the number 1. If you are so satisfied with the design of your physical housing environment that it could not, in your opinion, be better, then circle the number 7. You use the numbers 2 to 7 to describe how close to the best or worst alternative you find the features of your housing environment.

There now follow a number of questions about how well you feel that the design of your physical housing environment suits your needs and wishes. Some questions concern security, social interaction, and so forth, while others concern how the design of the housing environment makes it easy or difficult to do the everyday tasks you wish and need to perform.

Draw a circle round the number that you think agrees best with your own perception.

1. In relation to how you normally manage your personal hygiene, dressing, visiting the toilet, or how you eat; to what extent is the housing environment suitably designed? *(If you do not manage any of these at all, cross out the whole question.)*

1 2 3 4 5 6 7
Not at all suitable — Very suitable

2. In relation to how you normally manage your cooking/heating of food or preparation of snacks; to what extent is the housing environment suitably designed? *(If you do not manage any of these at all, cross out the whole question.)*

1 2 3 4 5 6 7
Not at all suitable — Very suitable

3. In relation to how you normally manage your washing up, cleaning, care of flowers; to what extent is the housing environment suitably designed? (*If you do not manage any of these at all, cross out the whole question.*)

1 2 3 4 5 6 7
Not at all suitable — Very suitable

4. In relation to how you normally manage your washing, ironing, or repair of clothes; to what extent is the housing environment suitably designed? (*If you do not manage any of these at all, cross out the whole question.*)

1 2 3 4 5 6 7
Not at all suitable — Very suitable

5. How secure do you feel in your housing environment?

1 2 3 4 5 6 7
Not at all secure — Completely secure

6. To what extent does the design of the housing environment allow you to be by yourself when you so wish?

1 2 3 4 5 6 7
Not at all — As much as I want to

From Fänge, A: Usability in My Home: Manual and Instrument Form. Division of Occupational Therapy, Lund University, Sweden, 2002. © Agneta Fänge, 2002, with permission.

7. To what extent does the design of the housing environment allow you to socialize with the friends and acquaintances you want to meet?

1 2 3 4 5 6 7
Not at all — As much as I want to

8. To what extent does the design of the housing environment allow you to do hobbies/leisure pursuits and relax?

1 2 3 4 5 6 7
Not at all — As much as I want to

9. If your health should change, to what extent would it be possible for you to make simple changes to your housing environment (e.g., to use a different parking place, to use a different toilet, to rearrange the furniture, to use a different room as a bedroom, and so forth)?

1 2 3 4 5 6 7
Not at all — As much as I need to

There now follow a number of questions about how usable you feel that your housing environment is. First you make an overall assessment (question 10). This is followed by a number of more detailed questions about usability in different parts of the housing environment. State the problems you perceive and make an assessment of how accessible each part of the housing environment is, with regard to the problems you have stated (questions 11 to 22). If you do not feel that there are any special problems, please say so. Do not forget to assess each part of the physical housing environment, even if you have not stated any specific problem.

10. How usable do you feel that your housing environment is in general?

1 2 3 4 5 6 7
Not at all usable — Fully usable

11. What problems do you perceive in the physical environment just outside your home (e.g., paths and pavements, car park/garage/carport, the design of the refuse storage place, the placing of your letterbox, and so forth)?

_____

_____

12. In view of the above problems in question 11, how usable do you feel that the environment outside your home is?

1 2 3 4 5 6 7
Not at all usable — Fully usable

13. What problems do you find in the design of the entrance to your home (e.g. heavy doors, narrow stairs, ramps, cramped lift, poor lighting, and so forth)?

_____

_____

14. In view of the above problems in question 13, how usable do you feel that the entrance to your home is?

1 2 3 4 5 6 7
Not at all usable — Fully usable

15. What problems do you find in the design of the secondary spaces in your home (e.g., store rooms, attic/basement, refuse storage place, laundry [if any], and the routes you have to follow indoors to reach these places)?

_____

_____

16. In view of the above problems in question 15, how usable do you feel that the secondary spaces in your home are?

1 2 3 4 5 6 7
Not at all usable — Fully usable

17. What problems do you have in reading and understanding markings and signs outside the building or at the entrance? (For example, are lift buttons fully visible and easy to use? Are the signs at the waste sorting station clear and easy to understand? Are the markings in staircases easy to see?) (*The questions should only be answered by people living in apartments. If you live in your own house, omit this question and question 18.*)

_____

_____

18. In view of the above problems in question 17, to what extent would you say that the markings and signs outside the building and at the entrance can be read and understood?

1 2 3 4 5 6 7
Not at all — Perfectly easily

19. What problems do you find in the design of your balcony, patio, or garden? (*If you do not have any balcony, patio, or garden, please say so. You may then omit question 20.*)

20. In view of the above problems in question 19, how usable do you feel that the balcony, patio, or garden are?

1 2 3 4 5 6 7
Not at all usable Fully usable

21. What problems do you find in the design of the interior of your home?

22. In view of the above problems in question 21, how usable do you feel that the interior of your home is?

1 2 3 4 5 6 7
Not at all usable Fully usable

To conclude, there is a general question that allows you to express your wishes and needs.

23. If you were able to wish for anything at all concerning your home and your housing environment, what would you wish for?

appendix
9.C The ADL-Staircase

Note: In this instrument, the term **personal activities of daily living (P-ADL)** is synonymous with **basic activities of daily living (BADL)**.

DEFINITIONS

Cleaning: ***performs house cleaning, vacuum cleaning, washing floors***
Independent: Performs the activity when necessary.
Partly dependent: Gets assistance in taking the carpets outdoors or assistance very seldom.
Dependent: Does not perform the activity or gets assistance with some part of the activity regularly.

Shopping: ***gets to the store, manages stairs and other obstacles, takes out groceries, pays for them and carries them home***
Independent: Performs the activity when necessary.
Partly dependent: Performs the activity but together with another person.
Dependent: Does not perform the activity or needs assistance with some part of the activity.

Transportation: ***gets to the stop for public transportation, gets on and goes by bus, tram, or train***
Independent: Performs the activity when needed.
Partly dependent: Performs the activity but together with another person.
Dependent: Does not perform the activity.

Cooking: ***gets to the kitchen, prepares the food, manages the stove***
Independent: Performs the activity when needed.
Partly dependent: Does not prepare dinner-food or only heating up prepared food.
Dependent: Does not perform the activity.

Bathing: ***means sponge bath, tub bath, or shower***
Independent: Receives no assistance (gets in and out of tub by self if tub is usual means of bathing).
Partly dependent: Receives assistance in bathing only one part of the body (such as back or leg).
Dependent: Receives assistance in bathing more than one part of the body (or does not bathe self).

Dressing: ***means getting all needed clothing from closets and drawers and getting dressed, includes using fasteners, and putting on brace if worn***
Independent: Gets clothes and gets completely dressed without assistance.
Partly dependent: Gets clothes and gets dressed without assistance except for help with tying shoes.
Dependent: Receives assistance in getting clothes or in getting dressed, or stays partly or incompletely dressed.

Toileting: ***means going to the "toilet room" for bowel and urine elimination, cleaning self after elimination, and arranging clothes***
Independent: Goes to the "toilet room," cleans self and arranges clothes without assistance. (May use support object such as cane, walker, or wheelchair, and may manage a night bedpan or commode, emptying it in the morning.)
Partly dependent: Receives assistance in going to the "toilet room" or in cleaning self or in arranging clothes after elimination, or using the night bedpan or commode.
Dependent: Does not go to the "toilet room" for elimination.

Transfer: ***means moving in and out of bed and in and out of chair***
Independent: Moves in and out of bed and out of chair without assistance. (May use support object such as cane or walker.)
Partly dependent: Moves in and out of bed or chair with assistance.
Dependent: Does not get out of bed.

Continence: ***means function of controlling elimination from the bladder and bowel***
Independent: Controls urination and bowel movement completely by self.
Partly dependent: Has occasional "accidents."
Dependent: Supervision helps keep urine or bowel control, or catheter is used, or is incontinent.

© Sonn, U, and Hulter Asberg, K, 1990, with permission.

Feeding: ***means the basic process of getting food from plate or equivalent into the mouth***

Independent: Feeds self without assistance.

Partly dependent: Feeds self except for getting assistance in cutting meat or buttering bread.

Dependent: Receives assistance in feeding or is fed partly or completely through tubes or with intravenous fluids.

Definitions of personal (P-) and instrumental (I-) ADL according to a cumulative scale of conditional ADL-steps (the ADL Staircase)

ADL-STEPS IN I AND P-ADL

Step 0 Independent in all activities
Step 1 Dependent on one activity
Step 2 Dependent on cleaning and one more activity
Step 3 Dependent on cleaning, shopping, and one more activity
Step 4 Dependent on cleaning, shopping, transportation, and one more activity
Step 5 Dependent in all I-ADLs and one P-ADL
Step 6 Dependent in all I-ADLs, bathing, and one more P-ADL
Step 7 Dependent in all I-ADLs, bathing, dressing, and one more P-ADL
Step 8 Dependent in all I-ADLs, bathing, dressing, going to the toilet, and one more P-ADL
Step 9 Dependent in all activities
"Others" Dependent in two or more activities but not classifiable as above

If the item continence is included, the definitions of the last two steps will be as follows:

Step 9 Dependent in all I-ADLs, bathing, dressing, going to the toilet, transfer, and one more P-ADL
Step 10 Dependent in all activities

ADL-step 0
ADL-step 1 Cleaning
ADL-step 2 Shopping
ADL-step 3 Transportation
ADL-step 4 Cooking
ADL-step 5 Bathing
ADL-step 6 Dressing
ADL-step 7 Toileting
ADL-step 8 Transfer
ADL-step 9 Continence
ADL-step 10 Feeding

appendix
9.D Home Examination Form

Type of Home
(Indicate apartment or single family home)

☐ ***Apartment***
Owned _____ Rented _____
Is elevator available? _____
What floor does patient live on? _____
☐ ***Single family home***
Two or more floors_____
Does patient live on only one floor, or use all floors of home?_____
Basement. Does patient have or use basement area? _____

Entrances to Building or Home

Location
Front Back Side (Circle one)
Which entrance is used most frequently or easily? _____
Can patient get to entrance? _____

Stairs
Does patient manage outside stairs? _____
Width of stairway_____
Number of steps _____ Height of steps _____
Railing present as you go up? R _____ L _____ Both _____
Is ramp available for wheelchair? _____

Door
Can patient unlock, open, close, lock door? (Circle for yes)
If doorsill is present, give height _____ and material _____
Width of doorway _____
Can patient enter _____ leave _____ via door?

Hallway
Width of hallway _____
Are any objects obstructing the way? _____

Approach to Apartment or Living Area
(Omit if not applicable)
Obstructions? _____
_____

Steps
Width of stairway _____
Number of steps _____ Height of steps _____
Railing present as you go up? R _____ L _____ Both _____
Is ramp available? _____

Door
Can patient unlock, open, close, lock door? (Circle one)
Doorsill? Give height _____ material _____
Width of doorway _____
Can patient enter _____ leave _____ via door?

Elevator
Is elevator present? _____ Does it land flush with floor? _____
Width of door opening _____
Height of control buttons _____
Can patient use elevator alone? _____

Inside Home
Note width of hallways and of door entrances.
Note presence of doorsills and height.
Note if patient must climb stairs to reach room.
Can patient move from one part of the house to another?
Hallways _____
Bedroom _____
Bathroom _____
Kitchen _____
Living room _____
Others _____
Can patient move safely?
Loose rugs _____
Electrical cords _____
Faulty floors _____
Highly waxed floors _____
Sharp-edged furniture _____
Note areas of particular danger for patient.
Hot water pipes _____
Radiators _____

Bedroom
Is light switch accessible? _____
Can patient open and close windows? _____

Bed

Height _____ Width _____
Both sides of bed accessible? _____ headboard present? _____ footboard? _____
Is bed on wheels? _____ Is it stable? _____
Can patient transfer from wheelchair-to-bed? _____
And bed-to-wheelchair? _____
Is night table within patient's reach from bed ____
Is telephone on it? _____

Clothing

Is patient's clothing located in bedroom? _____
Can patient get clothes from dresser? _____
Closet? _____ Elsewhere? _____

Bathroom

Does patient use wheelchair _____ walker _____ in bathroom?
Does wheelchair _____ walker _____ fit into bathroom?
Light switch accessible? _____ Can patient open and close window? _____
What material are bathroom walls made of? _____
If tile, how many inches does tile extend from the floor beside the toilet? _____
How many inches does tile extend from the top of the rim of the bathtub? _____
Does patient use toilet? _____
Can patient transfer independently to and from toilet? _____
Does wheelchair wheel directly to toilet for transfers? _____
What is height of toilet seat from floor? _____
Are there bars or sturdy supports near toilet? _____
Is there room for grab bars? _____
Can patient use sink? _____ What is height of sink? _____
Is patient able to reach and turn off faucets? _____
Is there knee space beneath sink? _____
Is patient able to reach necessary articles? _____
Mirror? _____ Electrical outlet? _____

Bathing

Does patient take tub bath? _____ Shower? _____
Sponge bath? _____
If using tub, can patient safely transfer without assistance? _____
Bars or sturdy supports present beside tub? _____
Is equipment necessary? (tub seat, hand-spray attachment, tub rail, no-skid strips, grab rails, other: _____)
Can patient manage faucets and drain plug? _____
Height of tub from floor to rim _____
Is tub built-in _____ or on legs? _____
Width of tub from the inside _____
If uses separate shower stall, can patient transfer independently and manage faucets? _____
If patient takes sponge bath, describe method. _____
_____
_____

Living Room Area

Light switch accessible? _____ Can patient open and close window? _____
Can furniture be rearranged to allow manipulation of wheelchair? _____
Can patient transfer from wheelchair to and from sturdy chair? _____
Height of chair _____
Can patient transfer from wheelchair to and from sofa? _____
Height of sofa _____
Can ambulatory patient transfer to and from chair or sofa? _____
Can patient manage television and radio? _____

Dining Room

Light switch accessible? _____
Is patient able to use table? _____ Height of table _____

Kitchen

What is the table height? _____ Can wheelchair fit under? _____
Can patient open refrigerator door and take food? _____
Can patient open freezer door and take food? _____

Sink

Can patient be seated at sink? _____
Can patient reach faucets? _____ Turn them on and off? _____
Can patient reach bottom of basin? _____

Shelves and cabinets

Can patient open and close? _____
Can patient reach dishes, pots, eating utensils, and food? _____
Comments: _____
_____
_____

Transport

Can patient carry items from one part of kitchen to another? _____

Stove

Can patient reach and manipulate controls? _____
Manage oven door? _____
Place food in oven and remove? _____
Manage broiler door? _____
Put food in and remove? _____

Other Appliances

Can patient reach and turn on appliances? _____
Can patient use outlets? _____

Counter space

Is there enough for storage and work area? _____
Diagram (include stove, refrigerator, microwave, sink, table, counters, others if applicable)

Laundry

If patient has no facilities, how will laundry be managed?
_____
_____

Location of facilities in home or apartment and description of facilities present:
Can patient reach laundry area? _____
Can patient use washing machine and dryer? _____
Load and empty? _____
Manage doors and controls? _____
Can patient use sink? _____
What is height of sink? _____
Able to reach and turn on faucets? _____
Knee space beneath sink? _____
Able to reach necessary articles? _____
Is laundry cart available? _____
Can patient hang clothing on line? _____
Ironing board _____
Location: _____
Is it kept open? _____
If not kept open, can patient set up and take down ironing board? _____
Can patient reach outlet? _____

Cleaning

Can patient remove mop, broom, vacuum, pail from storage? _____
Use equipment? (mop, broom, vacuum and so forth)
_____

Emergency

Location of telephone in house: _____
Could patient use fire escape or back door in a hurry if alone? _____
Does patient have numbers for neighbors, police, fire, and physician? _____

Other

Will patient be responsible for child care? _____
If so, give number of children _____ and ages: _____
Will patient do own shopping? _____
Is family member or friend available? _____
Is delivery service available? _____
Does family have automobile? _____
Is family member or friend available to help with lawn care, changing high light bulbs, and so forth?
_____
_____
_____

Guidelines for Completing Essential and Marginal Job Function Analysis Form

appendix **9.E**

Purpose and Use

- It qualifies a position, describing the purposes and needs within the respective department.
- It is a comprehensive job description describing both the tasks performed and the physical and cognitive needs of the job.
- It maximizes interview information to determine the candidate's ability to perform the *Essential Functions.*
- It identifies performance evaluation criteria.
- It is required for all job accommodation requests when a health condition necessitates ADA modification/accommodation.
- It must accompany all new positions that need to be advertised and a reclassification request if the position is currently vacant and needs to be advertised.

Help Table

Department: The department where the position is performed.
Position/Job Code Title: Merit classification or professional and scientific classification.
Job Code: University of Iowa Job Code (EX: GB11, PC67).
Incumbent: Name of person currently in position or "vacant."
Position Number: HRIS assigned 8-digit position number (EX: 00000755).
Requisition Number: For advertising, match Requisition Number to Functional Analysis.
Position Summary: Basic purpose of job and rationale for existence.
Function Statements: Action outcome statements, starting with a verb, either essential (primary) or marginal (secondary) to the position, identified by percentage of time performed to add up to 100%.
Essential Function: Functions defined by the frequency with which they are performed, the amount of time it takes to perform them, how the job is affected if not performed by this position, or whether these functions could be assigned to another position.
Marginal Function: Function that needs to be performed only infrequently, with usually minimal consequence to the mission of the job if performed by another person.
Position Context Variables: Needed for the performance of essential functions. Check "YES" even if only one variable applies at this time.
Comments: Add anything not already covered that is needed to perform the essential functions of the job, or to further explain context variables.
Cognitive Processes: Level of training needed to perform the essential functions of the position, split between high school level training and post high school college/technical training. Check "YES" even if only one variable applies at this time.
Bilingual Requirements: Foreign languages used in the performance of the position.
Degree of Push–Pull Activity: Designate all forms of push–pull on the job to add up to a total of 100% for performance of the essential functions.
Physical Requirements: Movements that **CANNOT** be performed concurrently and reflect the essential functions on pages 1 and 2.
Physical Requirements: Movement that **CAN** be performed concurrently to reflect the essential functions of the job.
Vision Clarity: With corrected vision to perform the essential functions.
Equipment, Tools, Electronic Devices and Software: Equipment, tools, electronic devices, and software operated to perform the essential functions.
Physical Surroundings and Hazards: Applicable to all areas where essential functions of a position are performed (e.g., office, job site, lab, hospital, kitchen, and so forth).
Comments: Any that pertain to the physical surroundings or possible hazards involved in the performance of the essential functions of the position.
Vehicle Driven: Only if needed to perform the essential functions (out-of-town work, delivery, and so forth).

Locations: All job sites where essential functions are performed.
Day/Hour Schedule: The work shift or shifts if rotating.
Name and Title of Supervisor: Name of person to whom this incumbent reports.
Person Completing this Form: Incumbent or supervisor (print or type).
Signature of Incumbent: Signature of person currently in position. If "vacant" or "new," leave blank.

ESSENTIAL AND MARGINAL JOB FUNCTION ANALYSIS

Tab field-to-field to enter data (or click with mouse). Press the F1 key at any field to see a description of that field.

Department: _____ **Position Title:** _____ **Job Code:** _____
Incumbent: _____ **Position #:** _____ **Requisition #:** _____

POSITION SUMMARY:

Provide a position summary. If you need more space, please attach a separate sheet. A position summary consists of concise, qualitative statements crystallizing the basic purpose of the job and rationale for its existence.

FUNCTION STATEMENTS:

A job function statement should focus on the purpose, the result to be accomplished, and the productivity required rather than the manner in which the function is performed. Begin each statement with a verb. Each statement is to contain one action that produces the desired outcome. Identify whether the functions are essential or marginal (primary or secondary) to the position. Provide the projected percent of time to be devoted to each job function during a typical time period.

Essential (Primary) Functions	%	Marginal (Secondary) Functions	%
1.	0.00	1.	0.00
2.	0.00	2.	0.00
3.	0.00	3.	0.00
4.	0.00	4.	0.00
5.	0.00	5.	0.00
6.	0.00	6.	0.00
7.	0.00	7.	0.00
8.	0.00	8.	0.00
9.	0.00	9.	0.00
10.	0.00	10.	0.00
11.	0.00	11.	0.00
12.	0.00	12.	0.00
13.	0.00	13.	0.00
14.	0.00	14.	0.00
Essential Column Total**	0.00%	Marginal Column Total**	0.00%

**Essential and Marginal Column Totals must total 100%.

POSITION CONTEXT VARIABLES:

Indicate the responsibilities and aptitudes required to perform the essential/primary functions for this position.

Yes	No	Place an "X" in the appropriate box (or click box with mouse to use as toggle).
☐	☐	Work with frustrating situations: Job objectives are hindered by events beyond the employee's control.
☐	☐	Advise: Counsel others based on legal, financial, scientific, technical, or other specialized areas; recommend, guide caution.
☐	☐	Coordinate: Negotiate, monitor and organize activities of others to achieve objectives, but without direct authority.
☐	☐	Instruct: Teach others, formally or informally.
☐	☐	Group activities: Participate in activities requiring interpersonal skills and cooperation with others.
☐	☐	Work under time pressure: Rush or urgent time lines.
☐	☐	Work on an irregular schedule: Unscheduled overtime, called in to work, unanticipated changes in work pace.
☐	☐	Work with numerous distractions: Telephone calls, visitors, coworkers.
☐	☐	Handle multiple assignments, conflicting demands or priorities.
☐	☐	Concentration: Maintain attention to detail over extended period of time, continually aware of variations in changing situations.
☐	☐	Reaction or response: Quick reaction/immediate response to emergencies of severe consequences.
☐	☐	Research and analysis: Fact-finding, interpretation, investigation in preparing reports or evaluations.
☐	☐	Accountability and consequence of error: Responsible for money, equipment, or personnel. Severe consequences to department, University, or coworkers if work objectives are not met.
☐	☐	Work independence: Work is performed independently or with minimal on-site supervision.
☐	☐	Supervise: Recruit, screen, hire, assign and/or review work, train and/or evaluate other employees.
☐	☐	Confidentiality: Work with confidential information, materials, records.

Comments:

COGNITIVE PROCESSES:

Indicate cognitive abilities required to complete the essential functions.

Yes	No	Type an "X" in the appropriate box (or click box with mouse to use as toggle).
☐	☐	Inspect products, objects, or materials.
☐	☐	Analyze information or data.
☐	☐	Plan sequence of operations or actions.
☐	☐	Make decisions of moderate to substantial effects, with variety of alternatives and moderate to substantial consequences.
☐	☐	Use logic to define problems, collect information, establish facts, draw valid conclusions, interpret information, and deal with abstract variables.
☐	☐	Perform basic counting, addition, and subtraction of numbers.
☐	☐	Perform calculations using algebra, geometry, and statistics.
		Comprehend written communication:
☐	☐	a. Basic instructions, safety rules, office memoranda at high school graduate level.
☐	☐	b. Technical or professional materials, financial or legal reports at postsecondary level.
		Compose written communication:
☐	☐	a. Compose letters or memos using standard business English at high school graduate level.
☐	☐	b. Compose and edit report or technical, professional material at postsecondary level.
		Verbal comprehension:
☐	☐	a. Comprehend simple verbal sentences and instructions at high school graduate level.
☐	☐	b. Comprehend technical and complex information at postsecondary level.
		Verbal communication:
☐	☐	a. Converse in Standard English at high school graduate level.
☐	☐	b. Converse using complex technical or professional English at postsecondary level.

Foreign Language Requirements:

Comments:

DEGREE OF PUSH/PULL ACTIVITY:

Indicate the percent of time that pushing and pulling activities are performed. The total should equal 100%.

		N/A	<25%	25%–49%	50%–74%	>75%
SEDENTARY	Exert up to 10 lb of force occasionally* and/or a minute amount frequently**	☐	☐	☐	☐	☐
LIGHT	Exert up to 20 lb of force occasionally* and/or up to 10 lb of force frequently**	☐	☐	☐	☐	☐
MEDIUM	Exert 20–50 lb of force occasionally* and/or 10–15 lb of force frequently**	☐	☐	☐	☐	☐
HEAVY	Exert 50–100 lb of force occasionally* and/or 25–50 lb of force frequently**	☐	☐	☐	☐	☐
VERY HEAVY	Exert 100 lb of force occasionally* and/or 50 lb of force frequently**	☐	☐	☐	☐	☐

*Occasionally: activity or conditions exist up to 1/3 of the time
**Frequently: activity or conditions exist from 1/3 to 2/3 of the time

PHYSICAL REQUIREMENTS:

Indicate the percent of time the following are performed.

The following activities CANNOT be performed concurrently, so the total should equal 100%.		N/A	<25%	25%–49%	50%–74%	>75%
KNEEL	To bend legs at the knee, come to rest on knees	☐	☐	☐	☐	☐
CROUCH	To bend the body down and forward, bending the legs and spine	☐	☐	☐	☐	☐
CRAWL	Move on the hands, knees, and feet					
CLIMB	Ascend/descend ladders, stairs, ramps	☐	☐	☐	☐	☐
SIT	For up to 2 hours at a time	☐	☐	☐	☐	☐
STAND	**For up to 2 hours at a time**	☐	☐	☐	☐	☐
WALK	**Move about on foot**	☐	☐	☐	☐	☐

The following CAN be performed concurrently, so the amounts need not be totaled.		N/A	<25%	25%–49%	50%–74%	>75%
LIFT	To raise or lower an object >10 lb from one level to another	☐	☐	☐	☐	☐
LIFT	To raise or lower an object >25 lb from one level to another	☐	☐	☐	☐	☐
CARRY	To transport an object	☐	☐	☐	☐	☐
PUSH	To press with steady force, thrust objects forward, downward, outward	☐	☐	☐	☐	☐
PULL	To drag or tug objects	☐	☐	☐	☐	☐
BEND	To bend downward and forward by bending the spine at the waist	☐	☐	☐	☐	☐
BALANCE	Exceeding ordinary body equilibrium	☐	☐	☐	☐	☐
REACH	Extend hands and arms, in any direction	☐	☐	☐	☐	☐
HANDLE	Seize, hold, turn with hands	☐	☐	☐	☐	☐
FINGER	Pinch, type, activity with fingers	☐	☐	☐	☐	☐
REPETITIVE MOTION	Repetitious movements of arms, hands, wrists, and so forth	☐	☐	☐	☐	☐
TALK	Express or exchange ideas verbally	☐	☐	☐	☐	☐
HEAR	Perceiving sound by ear	☐	☐	☐	☐	☐
SEE***	Obtain impressions through the eye	☐	☐	☐	☐	☐

***Check all that apply:
- ☐ Vision clarity greater than 20 inches
- ☐ Vision clarity less than 20 inches
- ☐ Ability to distinguish color

EQUIPMENT, TOOLS, ELECTRONIC AND COMMUNICATION DEVICES, AND SOFTWARE:

List the items the employee will use to perform the essential/primary functions.

1.		**4.**	
2.		**5.**	
3.		**6.**	

PHYSICAL SURROUNDINGS AND HAZARDS:

Indicate which statements are applicable.

☐ Spends approximately 80% or more of time indoors.
☐ Spends approximately 80% or more of time outdoors.
☐ Activities occur inside or outside in approximately equal amounts.
☐ Temperatures may be below 32 degrees for more than 1 hour at a time.
☐ Temperatures may be above 100 degrees for more than 1 hour at a time.
☐ Noise is sufficient to cause the employee to shout in order to be heard.
☐ Exposure to vibrating movements to the extremities or entire body.
☐ Risk of bodily injury due to proximity to moving mechanical parts, electrical current, animals, and so forth.
☐ Conditions that affect the respiratory system or the skin, for example, fumes, odors, air particles.

GENERAL INFORMATION:

Comments: _____
Must a vehicle be driven to perform the essential/primary functions? ☐ YES ☐ NO
Location(s) where work is performed: _____
Day/Hour schedule: _____
Name/phone of Supervisor to whom this position reports: _____
Title of Supervisor: _____
Name of person completing form: _____ Date _____
Signature of incumbent:* _____ Date _____

***Signature of person currently in position. If "vacant" or "new," leave blank.**
If you are requesting the establishment of a new Merit position or reclassification of existing Merit position, submit this form to:
Compensation and Classification, 121-11 USB.
All merit requisitions must have an EFMA on file in the hiring department before the requisition will be processed.
It is recommended all P & S requisitions have an EFMA on file in the hiring department at the time of advertising.

SECTION TWO

Intervention Strategies for Rehabilitation

Strategies to Improve Motor Function

Susan B. O'Sullivan, PT, EdD

Chapter 10

LEARNING OBJECTIVES

1. Describe a model for clinical decision making that incorporates components of normal motor control and motor learning.
2. Identify factors critical to motor control and describe intervention strategies designed to optimize the acquisition of motor control.
3. Identify key factors in recovery of function and describe intervention strategies designed to optimize recovery.
4. Identify factors critical to motor learning and describe intervention strategies designed to optimize motor learning.
5. Differentiate among the following: functional task-oriented, augmented, and compensatory interventions.
6. Analyze and interpret patient data, formulate anticipated goals and expected outcomes, and develop a plan of care that presents an integrated approach to treatment when presented with a clinical case study.

SUMMARY *436*

Developing strategies to improve motor function (motor control and motor learning) requires a thorough understanding of the neural processes involved in producing movement and learning and the pathologies that may affect the central nervous system (CNS). In addition, knowledge of recovery and neuroplasticity processes following CNS insult is essential. Treatment based on theories of motor control, motor learning, and recovery allows the therapist to organize thinking and approach clinical decision making in a coherent manner. Patients with disorders of the CNS frequently demonstrate impaired motor function with a wide variety of impairments, activity limitations, and restrictions in the ability to participate in normal roles. Careful examination of cognitive, sensoriperceptual, motor, and learning behaviors, along with the environmental contexts in which they occur, provides an appropriate base for planning (see Chapter 5, Examination of

Motor Function: Motor Control and Motor Learning). Different intervention strategies and techniques have been developed by physical therapists to address disorders of motor function. An optimal plan of care (POC) must address the individual needs of the patient. This includes minimizing or eliminating impairments, reducing activity limitations and physical disabilities, and promoting full participation in life roles to the maximum extent possible. An effective POC also enhances overall quality of life.

MOTOR CONTROL

Information Processing

Motor control has been defined as "an area of study dealing with the understanding of the neural, physical, and behavioral aspects of biological (e.g., human) movement."[1, p. 497] Information processing of human motor behavior occurs in stages (Fig. 10.1). In the initial stage, *stimulus identification,* relevant stimuli about current body state, movement, and environment, are selected and identified. This includes somatosensory, visual, and vestibular inputs. Meaning is attached based on past sensorimotor experiences. Perceptual and cognitive processes including memory, attention, motivation, and emotional control all play an integral role in ensuring the ease and accuracy of information processing during this stage. Selection of relevant sensory input is sensitive to the clarity and intensity of the stimuli received. Thus, precise and stronger stimuli result in enhanced attentional mechanisms and information processing. Processing is also influenced by stimulus pattern complexity. Complicated and novel patterns of stimuli prolong stimulus identification. An intrinsic knowledge of movement (e.g., position of limb, length of limb, distance to goal, and so forth) is a critical characteristic of motor behavior.

In the *response selection stage* the plan for movement is developed. A **motor plan** is defined as an idea or plan for purposeful movement and is made up of component motor programs. A general rather than detailed response is selected; that is, a prototype of the final movement. Decision making during this stage is sensitive to the number of different movement alternatives possible and the overall compatibility between the stimulus and response. A natural or firmly linked association between stimulus and response enhances the ease of the decision making. For example, in a well-learned movement such as crossing at a streetlight, an individual easily responds to the green light by moving forward. If a crossing guard signals the individual to move forward even though the light is red, the individual is likely to be more hesitant in responding.

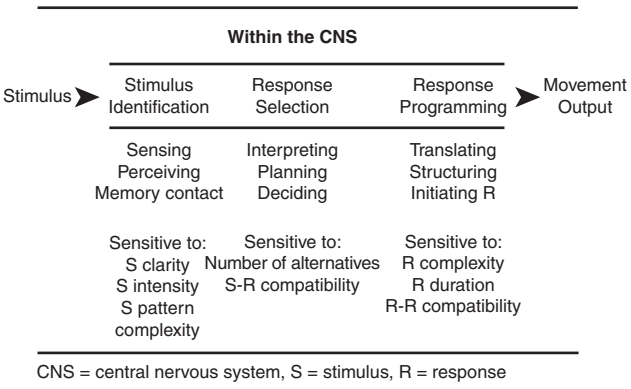

Figure 10.1 Model of information-processing stages of movement control.

The final stage is termed *response programming.* Neural control centers translate and change the idea for movement into muscular actions defined by a motor program. A **motor program** is defined as "an abstract representation that, when initiated, results in the production of a coordinated movement sequence."[1, p. 497] The structuring of motor programs includes attention to specific parameters such as synergistic component parts, force, direction, timing, duration, and extent of movement. Parametric specification is based on the constraints of the individual, the task, and the environment. Information processing during this stage is sensitive to the complexity of the desired movement and duration. Thus, complex and lengthier movement sequences increase the duration of processing during this stage. Programming can also be affected by *response–response compatibility.* This is the compatibility for dual movement tasks that either occur simultaneously (e.g., bouncing a ball while walking) or when choices are required (e.g., one paired movement response must occur before another). During *response execution* (movement output), muscles are selected against an appropriate background of postural control. **Feedforward control** is the sending of signals in advance of movement to ready a part of the system for incoming sensory feedback or for a future motor command.[1] It allows for anticipatory adjustments in postural activity. **Feedback** is response-produced sensory information received during or after the movement and is used to monitor movement output for corrective actions.[1] Although this simplified model gives the appearance that the information flow is linear, actual processing by the CNS is both serial and parallel. Thus, information flows in a specific pathway (serial order) and in multiple pathways (parallel order) in order to process information to more than one center. Many times processing occurs using both serial and parallel order depending on the complexity of the movement.

The association areas of the cortex decide that a movement is called for. The premotor area (PMA) and supplementary motor areas (SMA) (collectively known as Area 6) devise a plan for the movement. The primary motor cortex (Area 4) is located just anterior to the precentral sulcus and issues the motor commands to the descending motor neurons either directly or indirectly

by way of nuclei and interneurons in the brainstem and spinal cord. A major source of subcortical input arises from the loop from the cortex through the basal ganglia (BG) and back to the cortex, primarily to the SMA via the ventral lateral nucleus (VL) of the dorsal thalamus. This loop functions in assisting in the selection and initiation of voluntary movements. A second motor loop arises from the cortex through the lateral cerebellum and back to the cortex via the VL. This loop also functions in the production of voluntary movement and is concerned with execution of planned, coordinated multijoint movements (i.e., direction, timing, and force). Neurons that give rise to descending pathways are **termed upper motor neurons (UMNs)**. Lateral UMN pathways are involved in the control of voluntary movements through the corticospinal tract. UMN pathways are also involved in indirect control by way of neural subsystems in the brainstem. The reticulospinal tracts and to a lesser extent rubrospinal tracts are the primary alternate route for the mediation of voluntary movement. The tectospinal tract descends from the superior colliculus to the cervical levels and is important for reflex turning of the head. The vestibulospinal tracts are involved in control of postural adjustments and head movements. The ventral horn of the spinal cord gives rise to the peripheral nerve (**lower motor neuron** [**LMN**]). Activation of muscle fibers is from the motor unit.

Systems Theory

Contemporary theory of motor control has evolved over time, and reflects current understanding and interpretation of nervous system function. The reader is referred to the work of Schmidt and Lee[1] and Shumway-Cook and Woollacott[2] for excellent reviews of this topic. The term **systems theory** is used to describe the process by which various brain and spinal centers work cooperatively to accommodate the demands of intended movements. Both internal factors (joint stiffness, inertia, movement-dependent forces) and external factors (gravity) must be taken into consideration in the planning of movements. Systems theory assumes a shifting locus of neural control, referred to as a *distributed model of control.* Thus, large areas of the CNS may be engaged for complex motor tasks whereas relatively few centers are engaged for more discrete movements. This type of multilevel control allows for the control of a number of separate independent dimensions of movement, termed *degrees of freedom*.[3] The executive level (cortex) can be freed from the responsibility of control of some movements or the demands of having to control many degrees of freedom at one time.[4] For example, the use of central pattern generators (CPGs) in the spinal cord to initiate multijoint and intralimb coordination (coupling) for locomotion is well documented.[5,6] This is in contrast to an older theory of motor control, *hierarchical theory*, in which control was viewed as proceeding only in a descending, top-down direction from higher to lower centers, with the cortex always in control. Multiple descending systems are engaged for control movement and posture. These include corticospinal/corticobulbar, medial (e.g., medial vestibulospinal) and lateral (e.g., reticulospinal, lateral vestibulospinal) descending pathways. Thus, both voluntary (conscious) and involuntary (automatic) pathways regulate posture and movement.

Coordinative Structures

Motor programs allow for movements to occur in the absence of sensation (deafferentation) or in situations in which limitations in speed of processing feedback negate control. Motor programs also free the nervous system from conscious decisions about movement, reducing the problem of multiple degrees of freedom. Preprogrammed instructions to a set of effectors (motor program) run virtually without the influence of peripheral feedback or error detection processes, termed an **open-loop system**.[7] For example, rapid and skilled movements during piano playing occur too rapidly to benefit from feedback and function in an open-loop control system. This is in contrast to a **closed-loop control system**, which employs feedback and a reference for correctness to compute error and initiate subsequent corrections.[1] Feedback and closed-loop processes play a critical role in the learning of new motor skills (response selection) and in the shaping and correction of ongoing movements (response execution). Feedback is also essential for the ongoing maintenance of body posture and balance.[8]

The complexity of human movement negates any simplistic model of movement control. An *intermittent control hypothesis* described by Schmidt and Lee[1] proposes a blending of both open-loop and closed-loop control processes, in which both operate in concert as part of the larger system. Motor programs provide the generalized code for motor events (**schema**) rather than having every specific motor act stored in the brain. Feedback is used to refine and perfect movements.[8] Either may assume a dominant role, depending on the task at hand. Both may operate within a given movement but at different times and with different functions. Generalized motor programs include both invariant characteristics and parameters. *Invariant characteristics* are the unique features of the stored code: relative force, relative timing, and order of components. *Parameters* are the changeable features that ensure flexibility of motor programs and variations in movements from one performance to the next. These include overall force and overall duration of the movement. For example, speeding up or slowing down can change walking performance (changes in speed) while the basic order of stepping cycle and relative timing of the components (invariant characteristics) are maintained.

Muscle **synergies** are used to simplify control, to reduce or constrain the degrees of freedom, and to initiate

coordinated patterns of movement. Synergies are functionally linked muscles that are constrained by the CNS to act cooperatively to produce an intended motor action. Control is flexible with the cerebellum acting to generate the appropriate sequence of precise force, timing, and direction. A synergy can act in isolation for discrete movements. More frequently, synergies are combined to produce an appropriate sequence of muscle actions required for a functional task (e.g., the sequence of actions required during a transfer). Synergies are learned through motor skill practice, are flexible, and can be adapted to changes in the task or environment. For example, basic movement strategies (synergies) are well defined for postural control and balance, and include ankle, hip, and stepping strategies.[9-11] The organization and utilization of these strategies varies from quiet to perturbed stance and positions of instability.

MOTOR LEARNING

Motor learning has been defined as "a set of internal processes associated with practice or experience leading to relatively permanent changes in the capability for motor skill."[1, p. 497] Learning a motor skill is a complex process that requires spatial, temporal, and hierarchical organization of the CNS. Changes in the CNS are not directly observable but rather are inferred from changes in motor behavior. Improvements in **performance** result from an understanding of the task and practice and are a frequently used measure of learning. For example, with practice an individual is able to develop appropriate sequencing of movement components with improved timing and reduced effort and concentration. A **performance curve** can be used to plot the average performance of a subject or group of subjects across a number of practice trials. Performance, however, is not always an accurate reflection of learning. It is possible to practice enough to temporarily improve performance but not retain the learning. Conversely, factors such as fatigue, anxiety, poor motivation, or medications may cause performance to deteriorate while learning may still occur. Because performance can be affected by a number of factors, it should be viewed as a temporary change in motor behavior observed during practice. **Retention** provides a better measure of learning. Retention, as measured by a **retention test**, refers to the ability of the learner to demonstrate the skill over time and after a period of no practice (**retention interval**).[1] Performance after a retention interval may decrease slightly, but should return to original performance levels within relatively few practice trials. This is referred to as a *warm-up decrement* in performance. For example, riding a bike is a well-learned skill that is generally retained even though an individual may not have ridden for years. The ability to adapt and refine a learned skill to changing task and environmental demands is termed **adaptability**.[2] This is another important measure of motor learning. Individuals who learn to transfer from wheelchair to platform mat can apply that learning to other types of transfers (e.g., wheelchair to car, wheelchair to tub). The time and effort required to organize and learn these new types of transfers is reduced. Finally, *resistance to contextual change* can be used to measure learning. This is the adaptability required to perform a motor task in altered environmental situations. Thus, an individual who has learned a skill (e.g., walking with a cane on indoor level surfaces) should be able to apply that learning to new and variable situations (e.g., walking outdoors, walking in a busy mall). Motor learning is the direct result of practice and is highly dependent on sensory information and feedback processes. The relative importance of the different types of sensory information varies according to task and to the phase of learning. Individual differences exist in **motor ability**, a relatively stable characteristic or trait that is largely unmodifiable by practice. Abilities underlie and support the development of skills.[1]

Theories of Motor Learning

Adams'[7] theory of motor learning was based on closed-loop control (closed-loop theory). He postulated that sensory feedback from ongoing movement is compared with stored memory of the intended movement (perceptual trace) to provide the CNS with a *reference of correctness* and error detection. Memory traces are then used to produce an appropriate action and to evaluate outcomes. The stronger the perceptual trace developed through practice, the greater the capability of the learner to use closed-loop processes for learning movements. This theory helps to explain learning that occurs during slow, linear-positioning responses. It does not, however, adequately explain learning under conditions of rapid movements (open-loop control processes) or learning that occurs in the absence of sensory feedback (deafferentation studies).

Schema theory, proposed by Schmidt,[8] is an essential concept in motor learning theory. **Schema** is defined as "a rule, concept, or relationship formed on the basis of experience."[1, p. 499] It can be viewed as a generalized motor program (GMP).

Schema allows storage into short-term memory of such things as initial conditions (body position, weight of objects, and so forth), relationships between movement elements, movement outcomes, and sensory consequences of movement. This information is then abstracted into motor memory (**procedural memory**), defined as "the memory for movement or motor information."[1, p. 497] According to schema theory, it consists of two schema, recall and recognition schema. *Recall schema* are used to select and define the relationship among past parameters, past initial conditions, and past movement outcomes produced by these combinations. *Recognition schema* are used to evaluate movement responses and are based on information of the

relationships among past initial conditions, past movement outcomes, and the sensory consequences produced by these combinations.[1] Clinically, schema theory supports the concept that "we learn skills by learning rules about the functioning of our bodies—forming relationships between how our muscles are activated, what they actually do, and how these actions feel."[1, p. 448] Practicing a variety of movement tasks and outcomes would improve learning through the development of expanded rules or schema. It also enhances our understanding of how novel and open skills performed in a variable and changing environment are learned.

Stages of Motor Learning

The process of motor learning has been described by Fitts and Posner[12] as occurring in relatively distinct stages, termed *cognitive, associated,* and *autonomous.* These stages provide a useful framework for describing the learning process and for organizing training strategies during rehabilitation. Table 10.1 provides a summary.

Table 10.1 Characteristics of Motor Learning Stages and Training Strategies

Cognitive Stage Characteristics	Training Strategies
The learner develops an understanding of task; **cognitive mapping** assesses abilities, task demands; identifies stimuli, contacts memory; selects response; performs initial approximations of task; structures motor program; modifies initial responses *"What to do"* decision	Highlight purpose of task in functionally relevant terms. Demonstrate ideal performance of task to establish a **reference of correctness.** Have patient verbalize task components and requirements. Point out similarities to other learned tasks. Direct attention to critical task elements. Select appropriate feedback. • Emphasize intact sensory systems, intrinsic feedback systems. • Carefully pair extrinsic feedback with intrinsic feedback. • High dependence on vision: have patient watch movement. • **Knowledge of performance (KP):** focus on errors as they become consistent; do not cue on large number of random errors. • **Knowledge of results (KR):** focus on success of movement outcome. Ask learner to evaluate performance, outcomes; identify problems, solutions. Use reinforcements (praise) for correct performance, continuing motivation. Organize feedback schedule. • Feedback after every trial improves performance during early learning. • Variable feedback (summed, fading, bandwidth designs) increases depth of cognitive processing, improves retention; may decrease performance initially. Organize initial practice. • Stress controlled movement to minimize errors. • Provide adequate rest periods (distributed practice) if task is complex, long, or energy costly or if learner fatigues easily, has short attention, or poor concentration. • Use manual guidance to assist as appropriate. • Break complex tasks down into component parts, teach both parts and integrated whole. • Utilize bilateral transfer as appropriate. • Use blocked (repeated) practice of same task to improve performance. • Use variable practice (serial or random practice order) of related skills to increase depth of cognitive processing and retention; may decrease performance initially. • Use mental practice to improve performance and learning, reduce anxiety. Assess, modify arousal levels as appropriate. • High or low arousal impairs performance and learning. • Avoid stressors, mental fatigue. Structure environment. • Reduce extraneous environmental stimuli, distractors to ensure attention, concentration. • Emphasize closed skills initially gradually progressing to open skills.

Continued

Table 10.1 Characteristics of Motor Learning Stages and Training Strategies—cont'd

Associated Stage Characteristics	Training Strategies
The learner practices movements, refines motor program: spatial and temporal organization; decreases errors, extraneous movements Dependence on visual feedback decreases, increases for use of proprioceptive feedback; cognitive monitoring decreases *"How to do"* decision	Select appropriate feedback. • Continue to provide KP; intervene when errors become consistent. • Emphasize proprioceptive feedback, "feel of movement" to assist in establishing an internal reference of correctness. • Continue to provide KR; stress relevance of functional outcomes. • Assist learner to improve self-evaluation, decision making skills. • Facilitation techniques, guided movements may be counterproductive during this stage of learning. Organize feedback schedule. • Continue to provide feedback for continuing motivation; encourage patient to self-assess achievements. • Avoid excessive augmented feedback. • Focus on use of variable feedback (summed, fading, bandwidth) designs to improve retention. Organize practice. • Encourage consistency of performance. • Focus on variable practice order (serial or random) of related skills to improve retention. Structure environment. • Progress toward open, changing environment. • Prepare the learner for home, community, work environments.
Autonomous Stage Characteristics	**Training Strategies**
The learner practices movements, continues to refine motor responses, spatial and temporal highly organized, movements are largely error-free, minimal level of cognitive monitoring *"How to succeed"* decision	Assess need for conscious attention, automaticity of movements. Select appropriate feedback. • Learner demonstrates appropriate self-evaluation, decision making skills. • Provide occasional feedback (KP, KR) when errors evident. Organize practice. • Stress consistency of performance in variable environments, variations of tasks (open skills). • High levels of practice (massed practice) are appropriate. Structure environment. • Vary environments to challenge learner. • Ready the learner for home, community, work environments. Focus on competitive aspects of skills as appropriate, e.g., wheelchair sports.

Cognitive Stage

During the initial **cognitive stage** of motor learning, the major task at hand is to develop an overall understanding of the skill, termed the *cognitive map*. This decision making phase of *"what to do"* requires a high level of cognitive processing as the learner performs successive approximations of the task, discarding strategies that are not successful and retaining those that are. The resulting trial-and-error practice initially yields uneven performance with frequent errors. Processing of sensory cues and perceptual–motor organization eventually leads to the selection of a motor strategy that proves reasonably successful. Because the learner progresses from an initially disorganized and often clumsy pattern to more organized movements, improvements in performance can be readily observed during this acquisition phase. The learner relies heavily on vision to guide early learning and movement. A stable environment free from distractors optimizes learning during this initial stage.

Associative Stage

During the middle or **associative stage** of motor learning, refinement of the motor pattern is achieved through continued practice. Spatial and temporal aspects become organized as the movement develops into a coordinated pattern. As performance improves, there is greater consistency and fewer errors and extraneous movements. The learner is now concentrating on *"how to do"* the movement rather than on what to do. Proprioceptive cues become increasingly important, whereas dependence on visual cues decreases. The learning process takes varying lengths of time depending on

a number of factors. The nature of the task, prior experience and motivation of the learner, available feedback, and organization of practice can all influence acquisition of learning.

Autonomous Stage

The final or **autonomous stage** of learning is characterized by motor performance that after considerable practice is largely automatic. There is only a minimal level of attention, with motor programs so refined they can almost "run themselves." The spatial and temporal components of movement are becoming highly organized, and the learner is capable of coordinated motor patterns. The learner is now free to concentrate on other aspects, such as "how to succeed" at a personal goal or competitive sport. Movements are largely error-free with little interference from environmental distractions. Thus the learner can perform equally well in a stable, predictable environment (termed **closed skills**) or in a changing, unpredictable environment (termed **open skills**).

CONSTRAINTS ON MOTOR CONTROL AND LEARNING

Patients with neurological lesions may demonstrate impairments in voluntary movements (impaired motor planning or programming) or in the corrective actions (feedback adjustments) needed to initially relearn and coordinate movements. Movements can be uncoordinated with evidence of difficulty initiating or scaling the velocity of movements and controlling force, timing, or direction. Functionally linked synergies may be disorganized or fail to emerge and may show evidence of scaling issues. Reciprocal actions of agonists-antagonists, which normally are fine-tuned, become asynchronous. Disrupted synergistic patterns lead to impairments in body function. Instead of movements that are well matched to the intended movement and the environment, movements become highly stereotyped and limited. Abnormal obligatory or stereotypical synergies may emerge as is seen in the patient recovering from stroke, making it difficult to perform everyday functional tasks. Postural control and balance, a largely automatic function, becomes impaired with evidence of impaired activation of motor strategies, increased conscious control, and difficulty in maintaining balance. Overall, the efficiency and flexibility of motor patterns is significantly reduced.

Additional constraints are imposed by impairments in the musculoskeletal system (e.g., weakness, contracture, postural deformity). Impairments in muscle strength are common in patients with neurological dysfunction. Patients may exhibit complete loss (paralysis or plegia) or partial loss of muscle strength (paresis). Impairments can be localized to one side (hemiplegia), both lower extremities (paraplegia), or all four extremities (tetraplegia). Voluntary movements may become limited or absent with significant loss of the ability to perform common abilities. Fatigue, which can be directly due to a health condition (e.g., MS) or due to secondary factors such as prolonged immobility, often accompanies weakened muscles. Abnormal tone (spasticity or flaccidity) may also limit movement and alter posture. Spasticity and coactivation of agonist-antagonist muscles typically result in fixed, abnormal resting postures, and movements that are characteristically stiff and limited. Hyperactive stretch reflexes and inadequate recruitment of motor neurons present increased challenges for activating and controlling movements. Movements that might be possible at slow speeds become disordered or impossible at faster speeds. Overall, the number, range, and speed of movements are greatly reduced.

Constraints also emerge with impairments in sensory reception or perception, resulting in errors in stimulus identification or response selection. Motor learning is delayed, disorganized, or absent. Response programming may be impaired in the absence of accurate feedback to monitor and correct movement and posture. The central representation of the movement, termed *reference of correctness,* becomes inaccurate as a result of failed or inaccurate feedback. Impairments in cognitive processes (attention, planning, problem solving, emotional stability) may significantly affect learning and motor control. The patient with profound cognitive deficits (e.g., the patient with traumatic brain injury [TBI]) is unable to understand the idea of the movement. This inability to form a *cognitive map* creates severe limitations during the initial stage of learning and is particularly evident with complex or novel movements. Cognitive interference is also readily evident during complex movements such as dual tasking and performing in novel or open environments. Patients with cognitive deficits may also demonstrate a complete lack of awareness of their deficits. Impairments in the cardiovascular system (e.g., limited endurance) can significantly affect movement behavior and the ability to practice. The patient who exhibits profound deficits in motor control and learning can become poorly motivated. Every attempt at movement becomes a frustrating challenge, and activities previously done with ease become labored or impossible. The challenges of learning new motor behaviors can seem insurmountable. In addition to the individual system limitations and impairments discussed above, patients with CNS dysfunction may demonstrate failure of the whole system to function as an integrated whole. The design of a successful intervention needs to be based on careful examination of component parts, as well as the integrated whole.

MOTOR SKILLS

Motor development is the evolution of changes in motor behavior occurring as a result of growth, maturation, and experience.[1] Foundational skills are learned in infancy and childhood with the emergence of specific markers of developmental maturation.[13-15] These skills

are often referred to as *developmental motor skills* although they are best viewed as *functional motor skills* because they remain a permanent part of movement experience throughout life. Examples include movements such as rolling over and getting up out of bed. Motor skills can be categorized according to specific attributes or characteristics into four main groups:

- **Transitional mobility** refers to skills that allow movement from one posture to another (e.g., supine-to-sit, sit-to-stand).
- **Static postural control**, or ***stability,*** refers to the ability to maintain a posture with orientation of the center of mass (COM) over the base of support (BOS) and the body held steady (e.g., holding in sitting, kneeling, or standing).
- **Dynamic postural control (controlled mobility)** is the ability to maintain postural stability while parts of the body are in motion. Examples include weight shifting or maintaining a posture with the addition of progressively more challenging movements (e.g., sitting with upper trunk rotation and upper extremity [UE] reaching or standing with lower extremity [LE] stepping).
- **Skill** is the highest level of motor behavior and includes highly coordinated movement patterns such as grasp and manipulation and locomotion.

See Table 10.2 for a description of these categories of motor skills with examples of activities/postures and impairments.

Changes in motor skills are evident throughout the life span. During infancy (birth to 1 year) and childhood (1 to 10 years), changes are rapid and linked to cognitive/perceptual development and experience. During adolescence (11 to 19 years), motor skills become more complex and responsive to increasing cognitive/perceptual development and complex task and environmental demands. In adults, motor skills continue to be refined and are influenced by a number of factors, including age-related changes, overall health and nutrition, activity levels, and emerging pathology.[16-19] In middle adulthood (40 to 59 years), changes associated with aging are moderate in most systems. In older adults (60 years and older), changes are more apparent though there is marked heterogeneity in the aging process. Spirduso et al[19] have identified a continuum of physical function among older adults varying

Table 10.2 Categories of Motor Skills

Categories	Characteristics	Examples	Impairments
Transitional mobility	Ability to move from one posture to another; BOS and/or COM are changing	Rolling; supine-to-sit; sit-to-stand; transfers	Failure to initiate or sustain movements through the range; poorly controlled movements
Static postural control (stability, static equilibrium, or static balance)	Ability to maintain postural stability and orientation with the COM over the BOS with the body not in motion; BOS is fixed	Holding in antigravity postures: prone-on-elbows, quadruped, sitting, kneeling, half-kneeling, modified plantigrade, or standing	Failure to maintain a steady posture; excessive postural sway; wide BOS; high guard arm position or handhold; loss of balance (COM exceeds BOS)
Dynamic postural control (controlled mobility, dynamic equilibrium, or dynamic balance)	Ability to maintain postural stability and orientation with the COM over the BOS while parts of the body are in motion; BOS is fixed	Weight shifting; UE reaching in any of the above antigravity postures; LE stepping in modified plantigrade or standing	Failure to maintain or control posture during dynamic trunk or extremity movements; loss of balance
Skill	Ability to consistently perform coordinated UE and LE movement sequences for the purposes of investigation and interaction with the physical and social environment; during locomotion, COM is in motion and BOS is changing	UE skills: grasp and manipulation; LE skills: bipedal locomotion	Poorly coordinated movements; lack of precision, control, consistency, and economy of effort

UE = upper extremity; LE=lower extremity; COM = center of mass; BOS = base of support.

from the high ranges of the physically elite and physically fit to a middle range of physically independent to the lower ranges of physically frail, physically dependent and disabled. In the older adult, all stages of information processing are affected.[20] Sensory losses (decline in receptor sensitivity, recognition, and sensory encoding) affect stimulus identification. Response selection and programming are also affected by CNS changes with slowing of reaction time, especially for increasingly complex tasks. An age-related slowing of movement time is well documented.[21] Changes in motor units with a decrease in the overall number and increase in the size of motor units result in impaired coordination, especially for fine motor skills. There is a decreased ability to generate force and an increased tendency to coactivate agonist-antagonist muscles. This coactivation is most likely the result of attempts to modulate movement variability and maintain accuracy.[22] Older adults are also more sensitive to complexity of movement.[23] The principle of *speed–accuracy tradeoff* typically applies as adults age, that is, the accuracy of a movement is decreased as its speed is increased. To accommodate for this change, older adults typically move slower, especially when accuracy is required.[1] Overall movements become less efficient and more variable with age.

Secondary lifestyle factors (nutrition, body weight, exercise) have a significant impact on assisting individuals in maintaining health and in delaying the age of dependency. Decreasing levels of cardiovascular fitness, strength, and endurance and obesity commonly associated with a sedentary lifestyle adversely affect the performance of motor skills. In addition, older adults often experience multiple disease pathologies that affect their ability to move and learn. For example, an older adult may alter the method used to roll over and sit up secondary to an increase in body weight, a decrease in overall strength and fitness, and an emerging pathology such as Parkinson's disease (PD).

RECOVERY OF FUNCTION

Recovery of motor performance is defined as the reacquisition of motor patterns that were present before CNS injury. In complete recovery, performance of the reacquired skills is identical in every way to preinjury performance. It is far more likely that the individual with CNS insult will demonstrate recovery using preinjury skills that are modified in some way. Recovery can be further categorized into two main types:

1. **Spontaneous recovery:** the neuronal changes that result from the repair processes occurring within the CNS immediately after the insult, resulting in function being restored in neural tissue initially lost.
2. **Function-induced recovery:** the restoration of the ability to perform a movement in the same or similar manner as it was performed before the injury; occurring in response to changes in activity and the environment (e.g., increased use of involved body segments in behaviorally relevant tasks).

Compensation is defined as the appearance of new motor patterns resulting from the adaptation of remaining motor elements or substitution of alternative motor strategies and body segments. Thus the old movement is performed in a new manner. For example, the patient recovering from severe stroke learns to dress independently using the less affected UE; the patient with a complete T1-level spinal cord injury (SCI) learns to roll using UEs and momentum.[24]

Spontaneous Recovery

Immediately after a brain insult, a cascade of events occurs, producing transient depression of brain activity. Changes at a cellular level occur in the immediate area of damaged brain tissue. Disruption of the blood–brain barrier results in edema, with an accumulation of intracellular fluid and leakage of blood cells, proteins, and other toxic substances that disrupt nerve function. Release of neurotransmitters, glutamate, and calcium activates enzymes associated with neuron death and neuronal degeneration. Free radical damage from toxic particles of oxygen and iron also is associated with cell death. *Denervation supersensitivity,* defined as postsynaptic neuronal hypersensitivity, results in decreased synaptic efficiency. Changes also occur in areas remote from the injured brain. Blood flow changes suggestive of depressed neural activity have been found to exist on both sides of the brain and in both cortical and subcortical structures, areas that are remote from the injured site.[25-27]

Injury-related cortical reorganization is evidenced by a reduction in motor cortex excitability of the involved areas, a decrease in the cortical representation area of paretic muscles, and impairment of motor function. Initial spontaneous recovery that occurs over a relatively short time frame (typically within 3 to 4 weeks) is evidence of return to function of undamaged parts of the brain with the resolution of temporary blocking factors (i.e., shock, edema, decreased blood flow, decreased glucose utilization). This process has been termed *diaschisis.* For example, the patient with cerebral edema following stroke is likely to demonstrate early worsening of clinical signs as edema develops followed by spontaneous improvement within a few weeks as the edema and other factors resolve.[25]

Brain injury was for a long time thought to be permanent with little potential for brain repair. This is now viewed as incorrect and can represent a dangerous *self-fulfilling prophecy* when applied to the individual who suffers from such injuries. **Neuroplasticity** refers to "the ability of the brain to change and repair itself."[25, p. 134] Mechanisms of neuroplasticity include neuroanatomical, neurochemical, and neuroreceptive changes. Anatomical changes include nerve growth (*neural regeneration*) and activation of brain areas previously not active. Trophic molecules (*nerve growth factors*) have been shown to play a key role in growth and repair processes. Nerve

cells also change their interactions with each other, with physiological changes occurring at the level of the synapses. *Regenerative synaptogenesis* refers to *sprouting* of the injured axons to innervate (reclaim) previously innervated synapses. *Reactive synaptogenesis (collateral sprouting)* refers to the reclaiming of synaptic sites of the injured axon by dendritic fibers from neighboring axons. Neurotransmitter release and receptor sensitivity are improved *(synaptic plasticity).* Changes in synaptic strength, known as *long-term potentiation (LTP),* firm up neuronal connections and serve as a basis for all memory and learning.[26-30]

It is important to remember that the brain is organized with parallel and distributed circuits that provide multiple inputs to many areas with overlapping functions. Different and underutilized areas of the brain (e.g., cortical supplementary and association areas) can take over the functions of damaged tissue, a process known as *cortical remapping*. Another possibility is that the CNS has backup or fail-safe systems *(parallel cortical maps)* that become operational when the primary system breaks down. The unmasking of new, redundant neuron pathways permits cortical map reorganization and maintenance of function. Whole different areas of the brain are also capable of becoming reprogrammed, a process termed *substitution.* An example of substitution is the increased sensitivity of the hands as a sensory information system for the person who becomes blind. In this example, the changes in sensory strategy lead to structural reorganization within the brain. Newer techniques in brain mapping have led to better understanding of these processes. These include (1) positron emission tomography (PET) scanning used to measure regional cerebral blood flow (rCBF), (2) focal transcranial magnetic stimulation (TMS) used to measure responses in motor cortical regions to focal magnetic field stimulation, and (3) functional magnetic resonance imaging (fMRI) used to measure small changes in blood flow during brain activation.[28-31] In summary, recovery is a complex and dynamic process, involving multiple cellular, network, and biochemical processes. It is important to remember that these neuroplastic changes may be *adaptive,* resulting in improved function, or *maladaptive,* resulting in nonfunctional motor behaviors.

Function-Induced Recovery

Function-induced recovery *(use-dependent cortical reorganization)* refers to the ability of the nervous system to modify itself in response to changes in activity and the environment. Repetitive learning behaviors have been shown to prevent degradation and atrophy, enable growth of neurons, strengthen synaptic connections (LTP), alter cortical field representations, and expand topographical areas of motor activity; receptive fields are altered, processing time is improved, and evoked responses demonstrate increased strength and consistency with improved synchronicity. Improvements in functional outcomes are correlated with observed changes in neural adaptation. These can include improved fine and gross motor coordination, sensory discrimination, postural control and balance, procedural memory, adaptability, and so forth.[32-35] In rehabilitation, constraint-induced movement therapy and locomotor training using partial body weight support (BWS) and a treadmill are examples of targeted interventions to promote function-induced recovery. Changes occur at the level of body function (i.e., the patient moves the limb in a more normal pattern) and at the activity level (the patient reaches or walks with a more normal movement pattern). They differ from conventional or standard care in terms of the high levels of intensity and frequency that are required to improve neural plasticity and function.

There is an accumulating body of research on **constraint-induced movement therapy** (CIMT) in patients following stroke that has demonstrated significant improvements in UE function.[36-45] One important study is the EXCITE Randomized Clinical Trial, a large multisite trial. It consisted of a 2-week CIMT intervention program with training of the more affected UE up to 6 hr/day and use of the mitt on the less affected hand for up to 90% of waking hours. Participants were also encouraged to practice two to three tasks daily at home. Measurements were taken before and after intervention and at 4-, 8- and 12-months' follow-up. Patients in the intervention group showed greater improvement than the control group in all measures of hand function (the Wolf Motor Function Test Performance Time, the Motor Activity Log Amount of Use and Quality of Movement, self-perceived hand difficulty—Stroke Impact Scale).[36,37] Treatment-induced cortical reorganization has also been demonstrated with CIMT.[44,45] Box 10.1 Evidence Summary presents a summary of evidence from selected research in this area. Factors critical to the successful outcomes achieved in these studies include the following:

- A concentrated and repetitive task-specific practice using the more involved UE was utilized (Fig. 10.2). Training was intense, averaging 6 hr/day in CIMT studies. Page et al[41] demonstrated improved function with less intensive, longer duration modified CI therapy (mCIMT). All subjects started with some voluntary movement (wrist and finger extension) in their affected limb.
- Movement was constrained in the less affected UE through the use of a mitt worn up to 90% of waking hours.
- Behavioral techniques were used to enhance adherence and increased use of the affected UE in everyday life. Patients signed a behavioral contract indicating how often and with which activities patients will use their affected limb. Daily administration of the Motor Activity Log (MAL) also increased awareness of using the affected limb, assisting in overcoming

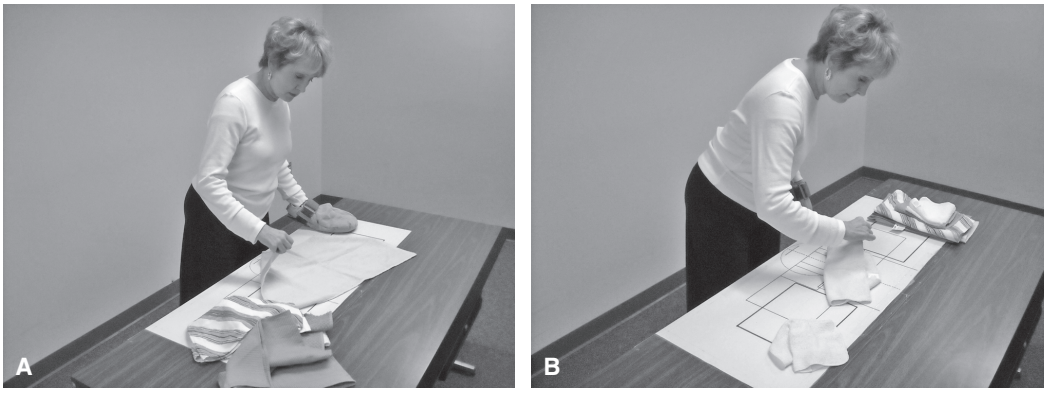

Figure 10.2 Patient is executing a task practice activity involving folding towels and stacking them during **(A)** early and **(B)** later stages of execution. *(From O'Sullivan and Schmitz,[92] with permission.)*

Box 10.1 Evidence Summary Constraint-Induced Movement Therapy (CIMT)

Reference	Subjects	Design Intervention	Duration	Results	Comments
Wolf et al[36] The EXCITE Randomized Clinical Trial, 2006	106 patients; 3 to 9 months after stroke compared to 116 controls	RCT; prospective, single-blind, RCTs, multisite clinical trial Testing at baseline, after CIMT treatment, and 4-, 8-, and 12-month follow-up	2-week intervention program of CIMT, up to 6 hr/day	CIMT produced statistically significant and clinically relevant improvements in UE motor function that persisted for at least 1 year Improved WMFT performance time; MAL (amount of use and quality of movement); decreased self-perceived hand function difficulty (SIS)	Supports CIMT as an effective treatment for improving UE function post-stroke. This study is important based on its design, sample size, and long-term follow-up.
Sirtori et al[38] Cochrane database, 2009	Systematic review of CIMT and mCIMT; identified19 studies involving 619 patients; CIMT and mCIMT Intervention included constraint to the normal limb together with exercise of the appropriate quality	Meta-analysis of multiple studies (RCTs, quasi-RCTs) assessing the efficacy of CIMT, mCIMT, or forced use of UE in management of subjects with hemiparesis	Variable	CIMT is associated with a moderate reduction in disability assessed at the end of the treatment period. Disability was measured some months after the end of treatment, there was no evidence of persisting benefit. Majority of studies were underpowered (median number of patients included = 15).	Supports CIMT as an effective treatment for improving UE function post-stroke. Meta-analysis of 19 studies revealed CIMT is a multifaceted intervention. Further RCTs with larger sample sizes and longer follow-up is recommended.

Box 10.1 Evidence Summary Constraint-Induced Movement Therapy (CIMT)—cont'd

Reference	Subjects	Design Intervention	Duration	Results	Comments
Hakkennes and Keating,[39] 2005	Systematic review of CIMT and mCIMT; identified 14 studies	Meta-analysis of multiple RCTs assessing the efficacy of CIMT compared to control (13 studies) and two CIMT protocols (1 study)	Variable	Significant results in support of CIMT improving UE function when compared to alternative or no treatment	Well-designed and adequately powered trials are required to evaluate the efficacy of different protocols on different stroke populations and to assess the impact on quality of life, cost, and patient/caregiver satisfaction.
Dahl et al,[40] 2008	30 patients with unilateral hand impairment after stroke, inpatient rehabilitation	Single RCT CIMT, restraining mitt used on unaffected hand Testing at baseline, post-treatment, and 6-month follow-up	6 hr/day for 10 consecutive weekdays	CIMT group had shorter performance time and greater functional ability than control group on WMFT. Non-significant trend toward greater hand use (MAL). No differences found on FIM. At 6 months, CIMT group maintained improvement; control group improved more.	Supports CIMT as an effective and feasible method to improve motor function post-stroke in the short term; no long-term effect was found.
Page et al,[41] 2004	17 patients, chronic stroke (> 1 year after stroke)	mCIMT, prospective, multiple-baseline, pre-post, single RCT Intervention: structured PT and OT sessions emphasizing affected UE use in patient-valued functional activities, mitt restraint on less affected hand 5 days/week for 5 hours	30-min sessions, 3×/week for 10 weeks	Improved scores on FMA and ARA for the mCIMT group; amount and quality of UE use as measured by MAL improved only in mCIMT group.	Supports mCIMT as an efficacious method of improving affected UE function and use in patients with chronic stroke. Intense task-specific practice is critical to reacquisition of function; practice schedule intensity is less critical.
Taub et al,[42] 2006	41 patients with chronic stroke (mean = 4.5 years after stroke)	Placebo-controlled trial of CIMT. Two groups: CIMT group: received intensive CIMT training and shaping; placebo group received program of physical fitness, cognitive and relaxation exercises	6 hr/day for 10 consecutive days; CIMT group had restraint of less affected UE for 6 hr/day	CI group showed large and significant improvements in functional use of more affected UE in daily activities (on WMFT, MAL).	Supports efficacy of CIMT for rehabilitating UE motor function in patients with chronic stroke.

Box 10.1 Evidence Summary Constraint-Induced Movement Therapy (CIMT)—cont'd

Reference	Subjects	Design Intervention	Duration	Results	Comments
		(same length of time; same amount of therapist interaction as CIMT group)			
Taub et al,[43] 1993	9 patients, post-stroke with moderate motor deficit (median post-stroke time = 4.1 years) Screening tools for inclusion: Cognitive tests IC: At least 1 year post-stroke; 20° voluntary wrist extension, 10° finger extension; no cognitive or balance problems	Single randomized clinical trial Treatment group: CIMT training of affected UE with restrictive splint/sling worn on nonaffected UE for 90% of waking hours Control group: Received training strategies to focus attention on using affected UE; traditional physical therapy and behavioral shaping techniques Pre- and post-treatment testing using WMFT and MAT	7 hr/day, 5 days/week for 2 weeks	Significant and large improvement in motor performance (performance time, quality of movement on WMFT) and use of UE (MAT). Gains maintained during 2-year follow-up.	Supports CIMT as an effective treatment for improving UE function post-stroke. Small N; long follow-up period. This is a classic, pioneering study .
Sawaki et al,[44] 2008	30 patients post-stroke in subacute phase (>3 and <9 months)	RCT: Two groups: CIMT treatment group and control group that received usual and customary care and CIMT after study period at 4 months; evaluated outcomes using TMS at baseline, 2 weeks, and at 4-month follow-up	CIMT given for 10 consecutive weekdays; wore padded mitt for at least 90% of waking hours over 2 weeks	Both CIMT and control group demonstrated improve hand function at 2 weeks. CIMT group showed significantly better grip force after intervention and at follow-up and an increase in size of the TMS motor map area compared to control.	Supports efficacy of CIMT for rehabilitating UE motor function for patients in the subacute phase post-stroke. This study is significant in demonstrating enlargement of TMS motor maps and CIMT-dependent plasticity.

ARA = Action Research Arm Test (includes 19 items of UE strength, dexterity, and coordination); BI = Barthel Index (measure of basic ADL and disability); CIMT = constraint-induced movement therapy (intensive, supervised task-specific practice of affected upper extremity [UE] with restriction of nonaffected UE); FMA = Fugl-Meyer Assessment Scale (stroke-specific instrument with UE motor section); mCIMT = modified constraint-induced movement therapy; MAL = Motor Activity Log (structured interview that identifies performance on 30 daily activities); N = number of subjects; NDT = neurodevelopmental treatment; NIHSS = National Institutes of Health Stroke Scale (stroke-specific instrument); OT = occupational therapy; PT = physical therapy; RCT= randomized controlled trial; RAP = Rehabilitation Activities Profile (based on ICIDH, semistructured interview that assesses disabilities and handicaps and consists of 21 items in 5 domains); Rehab = rehabilitation; SIS = Stroke Impact Scale; TMS = transcranial magnetic stimulation; WMFT = Wolf Motor Function Test (a UE functional test that includes 14 timed activities and 2 strength tests).

Table 10.3 Principles of Promoting Function-Induced Recovery

Focus on active practice of motor skills "Use it or lose it"	Engage the patient in active practice of specific goal-directed activities
Repetition is important	Focus on sufficient repetition to stimulate brain reorganization using high levels of practice both in-therapy and out-of-therapy and a carefully developed home exercise program (HEP)
Intensity is important	Focus on sufficient intensity of training to stimulate brain reorganization, carefully balancing the need for rest with activity
Focus on modifying motor skills "Use it and shape it to the patient's ability"	Continually challenge the patient's movement capability with acquisition of new skills to ensure continued learning; progressively modify skills to achieve functional outcomes
Enhance selection of behaviorally important stimuli	Reinforce behaviorally important stimuli to enhance skill learning; create the best possible environment for learning
Enhance attention and feedback	Actively engage the patient in evaluating goal-achievement and in making accurate adjustments of motor skills based on appropriate use of feedback
Target goal-directed skills	Select skills that are functionally relevant and important to the patient; focus on enhancing patient motivation and commitment; allow for success, select activities that are engaging and fun
Timing is important	Different forms of plasticity occur at different times during training. Very early training may be detrimental in some cases of neural injury (e.g., early intense training in acute after stroke or TBI is associated with exaggeration of cellular injury). Delayed or absent training limits recovery and results in neural degradation and "learned non-use"
Age	Plasticity and adaptive brain changes are strongest in the young; plasticity and brain changes in older adults may be slower and less demonstrable

Adapted from Kleim and Jones.[98]

learned nonuse. Shaping techniques (operant conditioning) and functional training were used to develop challenging intervention tasks. Tasks were selected and tailored to address the specific motor deficits of the patient and shaped to allow for improving movement control and appropriate rest intervals. Feedback, coaching, modeling, and encouragement were provided to set goals, provide motivation, and overcome learned nonuse. Patients were rewarded for improvement and correct movement patterns. Incorrect or poor performance was ignored in an attempt to break the cycle of learned nonuse.

Task-specific locomotor training using partial BWS, a treadmill, and manually assisted trunk and limb movements has also been shown to be effective in promoting function-induced recovery.[46-50] As in CIMT, practice is intense and task-specific. The limbs are loaded to tolerance and active postural control maximized. The treadmill allows control and progression of gait speed and provides rhythmic timing of the stepping movements. Training is progressed by decreasing the amount of loading (BWS) and manual assistance and moving toward overground and community ambulation. See discussion in Chapter 11, Locomotor Training, and Chapter 20, Traumatic Spinal Cord Injury, and the Evidence Summary Boxes in Chapter 15, Stroke, and Chapter 20.

Evidence from animal studies suggests beneficial effects from an enriched environment in promoting brain plasticity and development. Rats raised in enriched environments with opportunities for physical activity and social interaction with other rats demonstrated increased cortical depth, brain weight, dendritic branching, size of synaptic contact areas, and enzyme activity when compared to rats raised in impoverished environments. They also performed significantly better on motor tasks. When brain lesions were induced in rats, exposure to enriched environments and activity before surgical insult had a protective effect with greater sparing of function and improved recovery. Lesioned rats exposed post-surgery to enriched environments also demonstrated improved recovery and performance when compared to those in

impoverished surroundings. Finally, socialization influenced outcomes. Rats housed in social groups in enriched environments demonstrated superior recovery over isolated rats.[51-55]

In humans, an unfamiliar and unpredictable hospital or rehabilitation environment may contribute to depression, disorientation, and decline of function. This same environment may be overly structured and protective to the point that it contributes to learned helplessness and disuse. Carr and Shepherd[56] argue that poor recovery after stroke may be partially explained by the impoverished and non-challenging environments that many individuals recovering from stroke are exposed to. Although there are few environmental studies with humans, there is evidence that patients recovering from stroke who were treated on an acute stroke unit demonstrated better recovery and functional outcomes than patients who received a comparable amount of physical therapy while on a general medical unit.[57] This difference could also be due to the better coordination of care and expertise in specialized rehabilitation units. As Carr and Shepherd[58] point out, an important consideration is the amount of "down time" patients typically experience while in rehabilitation. As much as 30% to 40% of the day can be spent in passive pursuits while time in therapy is limited.[59] During non-therapy time, there is often little attention to self-directed practice, thereby further limiting the potential for optimal recovery of function.[60,61] In summary, a rehabilitation POC that focuses on promoting function-induced recovery will emphasize active, task-oriented practice based on the patient's unique needs, an enriched environment, and effective utilization of practice time both in-therapy and out-of-therapy. Principles of promoting function-induced recovery are summarized in Table 10.3.

INTERVENTIONS TO IMPROVE MOTOR FUNCTION

Neurorehabilitation interventions have evolved over time for the management of patients with disorders of motor function. Many treatment ideas emerged from empirical knowledge and clinical practice. Theory was applied to explain the success of these interventions and to organize them into a coherent treatment philosophy. Our understanding of motor function and its theoretical base has changed over the years. Emphasis on *evidence-based practice* has resulted in increased validation of therapeutic interventions through research.

The therapist's role is to accurately determine the patient's strengths and limitations and to develop a collaborative POC that includes goals and outcomes that match the patient's unique needs. See Box 10.2 for examples of general goals and outcomes for patients with disorders of motor function. The therapist must also determine an appropriate level of intensity, frequency, and duration of treatment. An important framework for

Box 10.2 Examples of General Goals and Outcomes for Patients with Disorders of Motor Function

Impact of pathology/pathophysiology is reduced.

- Risk of recurrence of condition is reduced.
- Risk of secondary impairment is reduced.
- Intensity of care is decreased.

Impact on impairments is reduced.

- Alertness, attention, and memory are improved.
- Joint integrity and mobility are improved
- Sensory awareness and discrimination are improved.
- Motor control is improved.
- Coordination is improved.
- Muscle performance (strength, power, and endurance) is improved.
- Postural control and balance are improved.
- Gait and locomotion are improved.
- Endurance is increased.

Ability to perform physical actions, tasks, or activities is improved.

- Functional independence in activities of daily living (ADL) and instrumental activities of daily living (IADL) is increased.
- Level of supervision for task performance is decreased.
- Tolerance of positions and activities is increased.
- Flexibility for varied tasks and environments is improved.
- Motor learning skills are improved.
- Decision making is improved.
- Safety of patient/client, family, and caregivers is improved.

Disability associated with acute or chronic illness is reduced.

- Ability to assume/resume self-care, home management, work (job/school/play), community, and leisure roles is improved.

Health status is improved.

- Sense of well-being is increased.
- Insight, self-confidence, and self-image are improved.
- Health, wellness, and fitness are improved.

Satisfaction, access, availability, and services are acceptable to patient/client.

Patient/client, family, and caregiver knowledge and awareness of the diagnosis, prognosis, anticipated goals/expected outcomes, and interventions are increased.

Adapted from *Guide to Physical Therapist Practice*.[100]

practice is based on current understanding that movement arises from the interaction of three basic elements: the task, the individual, and the environment (Fig. 10.3).[2] All three components must be considered in developing a successful POC.

Box 10.3 presents a framework of current neurorehabilitation interventions. The interventions are organized from top to bottom starting with *restorative interventions* that are designed to promote and restore optimal functional capacity. These include functional training, defined as activity-based, task-oriented intervention that uses normal patterns to accomplish the task and motor learning strategies. The next level includes impairment-specific and augmented interventions. Augmented interventions include hands-on assistance (guided or assisted movements) and neuromotor development training and are designed to "jumpstart" functional recovery for involved individuals with limited motor function and independent movements. Finally, some individuals will require *compensatory interventions* in the presence of severe impairment, poor prognosis, and multiple co-morbidities. These interventions are designed to promote optimal function using altered movement patterns and strategies using all body segments. A focus on *preventive intervention* is also important. Some activities designed to minimize impairments and disabilities also fall into this category. For example, the patient with stroke who presents with a flaccid and weak shoulder is given a protective sling to wear during transfer training to reduce the likelihood of shoulder pain and subluxation. Interventions may be used concurrently or in some cases sequentially. For example, the patient with weak hip and knee extensors and limited range of motion (ROM) in hip extension will not be successful in accomplishing sit-to-stand transitions until LE strength is increased and ROM is improved. The following section of the chapter presents an overview of motor learning strategies and therapeutic interventions.

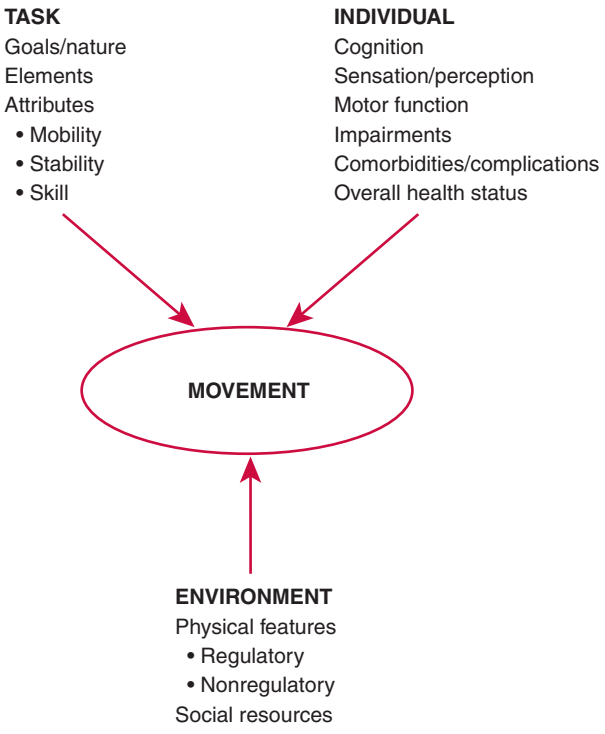

Figure 10.3 Movement emerges from interaction between the task, the individual, and the environment.

Box 10.3 Interventions to Improve Motor Function and Functional Independence

Therapeutic Outcome: Improved Motor Function and Functional Independence	
Restorative Interventions	
Functional Training	Motor Learning Strategies
Task-specific training:	Strategy development
• Functional mobility skills	Feedback
• Activities of daily living	Practice
Environmental context	Transference
Behavioral shaping	Active decision making
Safety awareness training	
Impairment-Specific and Augmented Interventions	
Impairment Interventions	Augmented Interventions
Strength, power, endurance	Neurodevelopmental treatment
Flexibility	Neuromuscular facilitation
Postural control and balance	Sensory stimulation
Coordination and agility	Biofeedback
Gait and locomotion	Neuromuscular electrical stimulation
Aerobic capacity/endurance	
Relaxation	
Compensatory Interventions	
Substitution training	Assistive/supportive devices

Motor Learning Strategies

Motor learning involves a significant amount of practice and feedback, with a high level of information processing related to control, error detection, and correction. Motor learning can be facilitated through the use of effective training strategies, summarized by stages in Table 10.1.

Strategy Development

The overall goal during the early cognitive stage of learning is to facilitate task understanding and organize early practice. The learner's knowledge of the skill and any existing problems must be ascertained. The therapist should highlight the purpose of the skill in a functionally relevant context. The task should seem important, desirable, and realistic to learn. The therapist should demonstrate the task *(modeling)* exactly as it should be done (i.e., coordinated action with smooth timing and ideal performance speed). This helps the learner develop an internal cognitive map or *reference of correctness.* Attention should be directed to the desired outcome and critical task elements. The therapist should point out similarities to other learned tasks so that schema that are part of other motor programs can be retrieved from memory. Features of the environment critical to performance should also be highlighted.

Highly skilled individuals who have been successfully discharged from rehabilitation can be expert models. Their success in returning to the "real world" will also have a positive effect in motivating patients new to rehabilitation. For example, it is very difficult for a therapist with full use of muscles to accurately demonstrate appropriate transfer skills to an individual with C6 complete tetraplegia. A successful former patient with a similar level injury can accurately demonstrate how the skill should be performed. Modeling has been shown to be effective in producing learning even with unskilled patient models. In this situation, the learner/patient benefits from the cognitive processing and problem solving used while watching the unskilled model attempt to correct errors and arrive at the desired movement.[61] Demonstrations can be live or videotaped. Developing a video library of demonstrations of skilled former patients is a useful strategy to ensure availability of effective models.

Guided movement involves physically assisting the learner through the task to be learned. It can have considerable positive effects during the early period of skill acquisition.[62-64] The therapist's hands can effectively substitute for missing elements, hold a part of the body stable while constraining unwanted movements, reduce errors, and guide the patient toward correct performance. It also allows the learner to preview the tactile and kinesthetic inputs inherent in the task, that is, to learn the *sensations of movement*. The supportive use of hands also allays fears and instills confidence while ensuring safety. Verbal guidance, "talking someone through the task," is also a form of guidance that can be used to improve performance. As discussed previously, improved performance does not represent true learning or retention of a skill. Without *active trial and error*, *discovery* learning, the changes in performance may be only temporary. The key to success in using guided movements is to limit guidance and intersperse practice with active movements as soon and as much as possible. Overuse of guided movements is likely to result in overdependence on the therapist for assistance, thus becoming a "crutch." The patient who tells you that he or she can only perform the skill if "my therapist" helps or the way "my therapist does it" is demonstrating an overreliance on guided movement. Guidance is most effective for slow postural responses (positioning tasks) and less effective during rapid or ballistic tasks.

During initial practice, the therapist should provide precise feedback, highlighting information critical for movement efficiency. The patient should not be overloaded with excessive feedback or wordy instructions. It is important to reinforce correct performance and intervene when movement errors become consistent or when safety is an issue. The therapist should *not* attempt to correct all the numerous errors that characterize this stage but rather allow for trial-and-error learning. Feedback, particularly visual feedback, is important during the early acquisition phase. The learner should be directed to watch the movements closely. The learner's initial performance trials can also be video recorded for later viewing. Cued or directed viewing of the task improves learning.

During the associated and autonomous phases of learning, the patient continues to refine movement strategies with high levels of practice. Random errors decrease. As consistent errors are identified, feedback may be given and solutions generated. The focus is on refinement of skills and movement consistency in varied environments. This will ensure an overall range of movement patterns that are adaptable and match the changing demands of open environments. The patient's attention should be now focused on proprioceptive feedback, the "feel of the movement." Thus, the patient is directed to attend to the sensations intrinsic to the movement itself and to associate those sensations with the motor actions. Guided movements are counterproductive at this stage because they limit active practice. During late-stage learning, the use of distracters such as ongoing conversation or dual task training (e.g., ball skills during standing and walking) can yield important evidence of a developing level of autonomous control. It is important to remember that many patients undergoing active rehabilitation do not reach this final stage of learning. For example, in patients with TBI, performance may reach consistent levels within structured environments, whereas safe, consistent performance in open, community environments is not possible.

Feedback

The vast body of motor learning literature affirms the critical role of feedback in promoting motor learning. Feedback can be *intrinsic (inherent),* occurring as a natural result of the movement, or *extrinsic (augmented),* incorporating sensory cues provided that are not normally received during the movement. Proprioceptive, visual, vestibular, and cutaneous signals are examples of

types of intrinsic feedback; visual, auditory, and tactile cues are forms of extrinsic feedback (e.g., verbal cues, manual cues, biofeedback devices such as the electromyogram [EMG], pressure-sensing devices [force plates, foot pad]). During therapy, both intrinsic and extrinsic feedback can be manipulated to enhance motor learning. The use of augmented feedback serves as an important source of information and helps the learner link associations between the movement parameters and resulting action.[1] *Concurrent feedback* is given during task performance, while *terminal feedback* is given at the end of task performance. Augmented feedback about the nature of the end result produced in relation to the goal is termed **knowledge of results (KR)**. Augmented feedback about the nature or quality of the movement pattern produced is termed **knowledge of performance (KP)**.[1] Although both are important, the relative usefulness of KP and KR can vary according to the skill being learned and the availability of feedback from intrinsic sources.[65-69] For example, tracking tasks are highly dependent on intrinsic visual and kinesthetic feedback (KP) whereas KR has less influence on the accuracy of the movements. In other tasks (e.g., transfers) KR provides the key information about how to shape the overall movements for the next attempt whereas KP may not be as useful. Performance cues (KP) should focus on key task elements that lead to a successful final outcome.

Therapists must consider the cognitive and physical resources of patients and the complexity of the tasks to be learned in determining the type of feedback possible. Clinical decisions about feedback include the following issues:

- What type of feedback should be employed (*mode*)?
- How much feedback should be used (*intensity*)?
- When should feedback be given (*scheduling*)?

Choices about type of feedback involve the selection of which intrinsic sensory systems to highlight, what type of augmented feedback to use, and how to pair extrinsic feedback to intrinsic feedback. The selection of sensory systems depends on specific examination findings of sensory integrity. The sensory systems selected must provide accurate and usable information. If an intrinsic sensory system is impaired and provides distorted or incomplete information (e.g., impaired proprioception with diabetic neuropathy), use of alternate sensory systems (vision) should be emphasized. Supplemental augmented feedback can be used to enhance learning. Decisions are also based on stage of learning. Early in learning, visual feedback is easily brought to conscious attention and therefore is important. Less consciously accessible sensory information such as proprioception should be emphasized during the middle and end stages of learning. Decisions about frequency and scheduling of feedback (when and how much) must be reached. Frequent augmented feedback (e.g., given after every trial) quickly guides the learner to the improved performance but slows retention and overall learning. Conversely, feedback that is varied (not given after every trial) slows initial performance of the skill while improving performance on a retention test.[70-74] This is most likely due to the increased depth of cognitive processing that accompanies the variable presentation of feedback. In contrast, the therapist who bombards the patient immediately after task completion with excessive augmented verbal feedback may preclude active information processing by the learner.[75,76] The patient's own decision making skills are minimized, while the therapist's verbal skills dominate. Winstein[77] points out that this may well explain why many studies on the effectiveness of therapeutic approaches cite minimal carryover and limited retention of newly acquired motor skills. Finally, the withdrawal of augmented feedback should be gradual and carefully paired with the patient's efforts to correctly utilize intrinsic feedback systems. Table 10.4 summarizes the types and uses of augmented feedback.

Practice

The second major influence on motor learning is practice. *General principles of practice* are (1) increased practice results in increased learning and (2) large and rapid improvements in performance are typically observed initially with smaller improvements noted over time. The therapist's role is to prepare the patient for practice and to ensure that the patient practices the desired movements. Practice of incorrect movement patterns can lead to a *negative learning* situation (interference) in which "faulty habits and postures" must be unlearned before the correct movements can be mastered. The organization of practice will depend on several factors, including the patient's motivation, attention span, concentration, and endurance, and the type of task. Making the task seem important and attainable improves motivation and commitment to practice. Patients who are involved in goal setting and recognize specific practice parameters (task purpose, schedule, limits) demonstrate improved commitment to practice. An additional factor that influences practice is the frequency of allowable therapy sessions, which is often dependent on hospital scheduling and availability of services and payment. Planning for effective use of out-of-therapy practice is important for all patients but especially so for patients with limited access to physical therapy. For outpatients, practice at home is highly dependent on motivation, family support, and suitable environment.

Therapists must consider the cognitive and physical resources of patients and the complexity of the tasks to be learned in determining the type of practice possible. Clinical decisions about practice include the following issues:

- How should practice periods and rest periods be spaced (*distribution of practice*)?

Table 10.4 Types of Augmented Feedback[1]

Concurrent feedback	Feedback is presented during the movement; KP information is provided; e.g., information about joint position; importance of forward weight shift to position the COM over the BOS during sit-to-stand training; or biofeedback; best used to highlight information not readily available from intrinsic feedback and if linked to active problem-solving
Terminal feedback	Feedback is given after the movement
Immediate feedback	Feedback is presented immediately after the movement
Delayed feedback	Feedback given after a brief time delay allows the learner a brief time for introspection and self-assessment; e.g., a 3-second delay Feedback given after long delays is contraindicated, especially if other movements not related to the task occur in between, degrading learning
Summary feedback	Feedback given after a set number of trials; e.g., after every 2nd trial or every 5th or every 20th trial
Faded feedback	Feedback given first after every trial, then less frequently on subsequent blocks of trials; e.g., after every 1st trial progressing to every 3rd trial, then to every 5th trial
Bandwidth-KR feedback	Feedback given only when performance deviates outside the boundaries of correct performance; error range is predetermined (e.g., top and bottom range of errors is determined)
Blocked feedback	One source of feedback is provided; KR is presented about the same segment on consecutive trials; learner processes a limited information about the task; e.g., during gait training, KR is presented about knee segment only on successive trials Blocked KR improves performance of the identified segment but may not improve performance and learning of the whole task (multiple segments); performance deteriorates once KR withdrawn
Variable (random) feedback	Multiple sources of feedback are provided; KR is presented about different segments on successive trials; e.g., during gait training, KR is presented about various different body segments (trunk, hips, knees) on successive trials Random KR is superior in improving both performance and learning of a task; encourages learner to process a wider range of information about the task

- What tasks and task variations should be practiced (*variability of practice*)?
- How should the tasks be sequenced (*practice order*)?
- How should the environment be structured (*closed vs. open*)?
- What tasks should be practiced in a parts-to-whole sequence?

Distribution: Massed Versus Distributed Practice

Massed practice refers to "a sequence of practice and rest times in which the rest time is much less than the practice time."[1, p. 497] Fatigue, decreased performance, and risk of injury are factors that must be considered when using massed practice. *Distributed practice* refers to "a sequence of practice and rest periods in which the practice time is often equal to or less than the time at rest."[1, p. 494] Although learning occurs with both, distributed practice results in the most learning per training time, although the total training time is increased. It is the preferred mode for many patients undergoing active rehabilitation who demonstrate limited performance capabilities and endurance. With adequate rest periods, performance can be improved without the interfering effects of fatigue or increasing safety issues. Distributed practice is of benefit if motivation is low or if the learner has a short attention span, poor concentration, or motor planning deficits (e.g., dyspraxia). Distributed practice should also be considered if the task itself is complex, is long, or has a high energy cost. Massed practice can be considered when motivation and skill levels are high and when the patient has adequate endurance, attention, and concentration. For example, the patient with SCI in the final stages of rehabilitation may spend long practice sessions acquiring the wheelchair skills needed for community access.

Blocked Versus Random Practice

Blocked practice refers to "a practice sequence in which all of the trials on one task are done together, uninterrupted by practice on any of the other tasks."[1, p. 493] *Random practice* refers to "a practice sequence in which

the tasks being practiced are ordered randomly across trials."[1, p. 498] Although both allow for motor skill acquisition, random practice has been shown to have superior long-term effects in terms of retention.[78-80] For example, a variety of different transfers (e.g., bed-to-wheelchair, wheelchair-to-toilet, wheelchair-to-bathtub transfer seat) can be practiced all within the same training session. Although skilled performance of individual tasks may be initially delayed, improved retention of transfer skills can be expected. The constant challenge of varying the task demands provides high *contextual interference* and increases the depth of cognitive processing through retrieval practice from memory stores. The acquired skills can then be applied more easily to other task variations or environments. Constant practice will result in superior initial performance because of low contextual interference and is required in certain situations (e.g., the patient with TBI and profound cognitive and behavioral deficits who requires a high degree of structure and consistency for learning; the patient with advanced PD).

Practice Order

Practice order refers to the sequence in which tasks are practiced. *Blocked order* refers to the repeated practice of a task or group of tasks in order (three trials of task 1, three trials of task 2, three trials of task 3: 111222333). *Serial order* refers to a predictable and repeating order (practice of multiple tasks in the following order: 123123123). *Random order* refers to a nonrepeating and nonpredictable order (123321312). Although skill acquisition can be achieved with all three, differences have been found. Blocked order produces improved early acquisition of skills (performance) whereas serial and random order produce better retention and generalizability of skills. This is again due to contextual interference and increased depth of cognitive processing.[81,82] The key element here is the degree to which the learner is actively involved in memory retrieval. For example, a treatment session can be organized to include practice of a number of different tasks (e.g., forward-, backward- and side-stepping and stair climbing). Random ordering of the tasks may initially delay acquisition of the desired stepping movements but over the long term will result in improved retention and generalizability.

Mental Practice

Mental practice is "a practice method in which performance on the task is imagined or visualized without overt physical practice."[1, p. 497] Beneficial effects result from the cognitive rehearsal of task elements. It is theorized that underlying motor programs for movement are activated but with subthreshold motor activity.[1] Brain mapping techniques have also revealed activation of similar brain areas during imagined movements as those activated during actual movement.[83-84] Mental practice has consistently been found to facilitate the acquisition of motor skills.[85-88] It should be considered for patients who fatigue easily and are unable to sustain physical practice. Mental practice is also effective in alleviating anxiety associated with initial practice by previewing the upcoming movement experience. Mental practice when combined with physical practice has been shown to increase the accuracy and efficiency of movements at significantly faster rates than physical practice alone.[89] When using mental practice, it is important to make sure the patient understands the task and is actively rehearsing the correct movement. Having the patient verbalize aloud the steps being rehearsed can ensure that this occurs. It is generally contraindicated in patients with profound cognitive, communication, and/or perceptual deficits.

Part–Whole Practice

Complex motor skills can be broken down into component parts for practice. The component parts are practiced before practice of the whole task is attempted. For example, during initial wheelchair transfer training the individual steps are practiced in isolation before practicing the whole transfer (e.g., locking the brakes, lifting the foot pedals, moving forward in the chair, standing up, pivoting, and sitting down). It is important to identify the key steps through accurate task analysis and to sequence them in the required order. It is also important to practice the integrated whole in conjunction with the parts practice so that the learner develops the whole idea for the required task (i.e., cognitive mapping). Delaying practice of the integrated whole can interfere with transfer effects and learning.[1] Part–whole practice is most effective with discrete or serial motor tasks that have highly independent parts. Part–whole practice is not as effective for continuous movement tasks (e.g., walking) or for complex tasks with highly integrated parts. Both require a high degree of coordination with spatial and temporal sequencing of elements. For these tasks, practice of the integrated whole will result in superior learning.

Transfer Training

Transfer of learning refers to the gain (or loss) in the capability of task performance as a result of practice or experience on some other task. Learning can be promoted through practice using contralateral extremities, termed *bilateral transfer*. For example, a patient with stroke first practices the desired movement pattern using the less affected extremity. This initial practice enhances formation or recall of the necessary motor program, which can then be applied to the opposite, involved extremity. This method cannot, however, substitute for lack of movement potential of the affected extremities (e.g., a flaccid limb on the hemiplegic side). Transfer effects are optimal with similarity of the tasks (e.g., identical components and actions) and environments.[90] For example, optimal transfer can be expected with practice of a UE flexion pattern first on one side, then with an identical pattern on the other side.

Practice of **lead-up tasks** is commonly used in physical therapy. Lead-ups are tasks or activities presented to prepare learners for a more important or complex task or activity.[1, p. 496] The subtasks are practiced, typically in easier postures with significantly reduced degrees of freedom. Anxiety is also reduced and safety is ensured. Thus initial upright postural control can be practiced with activities in kneeling, half-kneeling, or plantigrade before standing. The patient develops the required trunk and hip extension/abduction stabilization control required for upright stance but without the demands of the full standing position or fear of falling. The more closely the lead-ups (subskills) resemble the final task, the better the transfer. For example, bridging, which involves hip extension to neutral in a supine hook-lying position, can be a lead-up to successful sit-to-stand transitions. Table 10.5 summarizes the types of practice and practice parameters.

Promoting Active Patient Decision Making and Autonomy

Fundamental psychological needs of the patient include autonomy, competence, and social-relatedness. For effective planning, the therapist needs to have a clear understanding of the patient's values (beliefs and attitudes), self-perceptions, preferences, outcomes expectation, and sense of *self-efficacy* (a belief that the patient can accomplish the task successfully). Focus on the development of decision making skills is critical in ensuring perceived confidence, continued learning, and problem-solving success in the patient's real world environment. The therapist also needs to communicate effectively, develop rapport, and support the patient in collaborative planning. Having the patient actively involved in self-monitoring, analysis, and self-correction of movements encourages self-determined behavior. Trial-and-error learning can only be successful if the patient is challenged to think about the movement, to consider the information feedback received about the movement's performance, and to evaluate the movement outcome.[91] Key questions to promote active decision making and autonomy are presented in Box 10.4.

The therapist should allow adequate time for reflection and confirm the accuracy of the patient's responses. For example, if the patient's efforts do not achieve the

Table 10.5 Types of Practice and Practice Parameters[1]

	Types of Practice
Massed practice	A sequence of practice and rest times in which the rest time is much less than the practice time
Distributed practice	Spaced practice intervals in which the practice time is equal to or less than the rest time
	Practice Sequence
Blocked practice	A practice sequence organized around one task performed repeatedly, uninterrupted by practice of any other task
Random practice	A practice sequence in which a variety of tasks are ordered randomly across trials
	Practice Order
Blocked order	The repeated practice of a task or group of tasks in order; three trials of task 1, three trials of task 2, three trials of task 3 (e.g., 111222333)
Serial order	A predictable and repeating order; practice of multiple tasks in the following order (e.g., 123123123)
Random order	A nonrepeating and nonpredictable order of multiple tasks (e.g., 123321312)
	Practice Strategies
Mental practice	A practice strategy in which performance of the motor task is imagined or visualized without overt physical practice
Part/whole practice	Component parts of a task are practiced before practice of the whole task
Transfer training	The gain (or loss) in the capability of task performance as a result of practice or experience on some other task • Acquisition of motor skills in one training experience enhances acquisition of similar or related skills (*positive learning*) • Acquisition of motor skills in one training experience interferes with acquisition of other skills (*negative learning*)
Practice of lead-up activities	Simpler task versions of the required complex task are practiced

Box 10.4 Key Questions to Promote Active Patient Decision Making and Autonomy

- What is the goal of the intended movement?
- Did you accomplish the goal? If no, does the goal need to be modified?
- Did you move as planned? If no, what problems were encountered during the movement?
- What do you need to do to correct the problems in order to achieve movement success?
- For complex movements, what are the component parts or steps of the task? How should the component parts be sequenced?
- What aspects of the environment led to the success (or failure) of reaching the goal of the intended movement?
- What motivates you to keep trying?
- How confident are you in your abilities to move on your own? To be safe in your home environment?

expected outcome, the patient can be challenged to consider why. The patient who consistently falls to the right while standing can be challenged with questions such as, "In what direction did you fall?" and "What do you need to do to correct this problem?" The therapist has an important role as a motivational coach ("We can do this together as a team"). This includes emphasizing the patient's capabilities rather than failures and pointing out successes in improving function and obstacles that have been overcome on a regular basis. Beginning and ending the therapy session with a positive and successful movement experience is also a useful strategy to improve self-efficacy.

Functional Training

Functional, task-specific training is based on careful examination of motor function and activity performance (see Chapter 8, Examination of Function). Tasks targeted during early rehabilitation include basic activities of daily living (BADL) (e.g., feeding, dressing, hygiene, and so forth) and functional mobility skills (FMS) (e.g., bed mobility, transfers, locomotion). Later in rehabilitation instrumental activities of daily living (IADL) (e.g., home chores, shopping), community mobility, and work activities are targeted, depending on the patient's level of recovery and discharge placement. Task analysis yields an understanding of task, the essential elements within the task, and the context or environment in which the task occurs (see Chapter 5, Examination of Motor Function: Motor Control and Learning, Box 5.1). The therapist then selects activities and modifies task demands based on this analysis to determine an appropriate POC.

As previously discussed, extensive practice and appropriate feedback are essential in order to reacquire skills and enhance recovery. Involved segments are targeted for training. For example, training the patient with stroke focuses on use of the more involved extremities during daily tasks whereas use of the less involved extremities is minimized (e.g., CIMT). Initial tasks are selected to ensure patient success and motivation (e.g., grasp and release of a cup for feeding, forward reach for UE dressing). Tasks are modified to permit early practice. For example, training using partial BWS and a motorized treadmill provides a means of early locomotor training for patients with stroke or incomplete spinal cord injury. Tasks are continually modified to increase the level of difficulty, promote adaptation of skills, and promote independence. For example, sit-to-stand training begins with standing up from a raised seat. Progressively lowering the seat height during training increases the difficulty of the task until the patient is able to stand up from a normal seat height. During early training assistive devices may be used to assist function (e.g., for transfer training, gait and locomotion, dressing). The goal is to transition the patient away from using such devices toward independent function as soon as the patient is able. Continued use of and dependence on assistive devices falls under the category of compensatory training (e.g., wheelchair training for the patient with complete paraplegia).

Functional training represents a shift away from some conventional rehabilitation approaches that utilize an extensive hands-on approach to promote recovery and/or substitution. Although initial movements can be assisted in functional training, active movements are the overall goal. The therapist's role is one of training coach, structuring practice and providing appropriate challenge and feedback while encouraging the patient. Task-oriented training effectively counteracts the effects of immobility and the development of indirect impairments such as muscle weakness or loss of flexibility. It also prevents *learned nonuse* of the involved segments while stimulating CNS recovery.

Achieving control in various different functional activities and postures is a primary focus of intervention during rehabilitation. Careful attention to the demands of the postures can effectively address the degrees of freedom problem in controlling body segments and influence the selection of lead-up skills. For example, the prone-on-elbows posture focuses on development of shoulder, upper trunk, and head control while eliminating all demands for movement control in the lower body; because the COM is low and the BOS is wide, the posture is inherently safe. The kneeling posture can be used to improve trunk and hip control without the demands for control of the knee and ankle. As with the prone-on-elbows posture, the low COM and wide BOS reduce the likelihood of falls and injury. See Table 10.6 for a summary of postures and potential treatment benefits. Refer to O'Sullivan and Schmitz's *Improving Functional Outcomes in Physical Rehabilitation*[92] for a more in-depth discussion.

Table 10.6 Functional Postures and Potential Treatment Benefits

Posture	Treatment Benefits
Prone-on-elbows	• Improve upper trunk, UE, and neck/head control • Weight-bearing through shoulders, elbows flexed • Increase extensor ROM at hip extensors • Improve head/neck and shoulder stabilizers strength • Wide BOS, low COM; inherently safe • Limits degrees of freedom: control of lower trunk and LEs not required
Quadruped	• Improve upper trunk, lower trunk, LE hips, UE (shoulders, elbows), and neck/head control • Weight-bearing through hips and shoulders and extended UEs • Improve hip, shoulder, and elbow stabilizers strength • Decrease extensor tone at knees by prolonged weight-bearing • Decrease flexor tone at elbows, wrists, and hands by prolonged weight-bearing • Increase extensor ROM at elbows, wrists and fingers • Wide BOS, low COM • Limits degrees of freedom: control of LE knees and feet, UE hands not required; allows UEs to share postural loading and support with LEs
Bridging	• Improve lower trunk and LE control • Increase hip stabilizers strength • Weight-bearing through feet and ankles • Lead-up activity for bed mobility, sit-to-stand • Wide BOS, low height of COM • Limits degrees of freedom: control of upper trunk, head/neck, and UE not required
Sitting	• Improve upper trunk, lower trunk, LE, and head/neck control • Weight-bearing in upright, antigravity position; can include weight-bearing through extended UEs • Functional posture, important for reaching and ADL skills • Improve balance reactions • Medium BOS, medium height of COM • Limits degrees of freedom: control of LEs not required
Kneeling and half-kneeling	• Improve head/neck, upper trunk, lower trunk, and LE control • Weight-bearing through hips in upright, antigravity position • Decrease extensor tone at knees by prolonged weight-bearing • Increase hip and trunk stabilizers strength • Improve balance reactions • Weight-bearing through ankle in half-kneeling • Narrow BOS, intermediate height of COM (kneeling) • Wide BOS, intermediate height of COM (half-kneeling) • Limits degrees of freedom: control of LE knees, feet/ankles not required in kneeling
Modified plantigrade	• Improve head/neck, upper trunk, lower trunk, and UE and LE control • Weight-bearing through extended UEs and LEs, upright antigravity position • Improve balance reactions • Functional posture, lead-up for standing, stepping and reaching • Decrease tone in elbow, wrist, and finger flexors by prolonged weight-bearing • Increase extensor ROM at wrists and fingers • Wide BOS, high COM • Requires control of multiple degrees of freedom of head/neck, trunk, UEs and LEs: allows UEs to share postural loading and support with LEs
Standing	• Improve head/neck, upper trunk, lower trunk, and LE control • Weight-bearing through extended LEs, full upright, antigravity position • Improve balance reactions • Functional posture, important for ADL skills; lead-up for gait • Narrow BOS, high COM • Requires maximum control of multiple degrees of freedom of head/neck, trunk, LEs

ADL = activities of daily living; BOS = base of support; COM = center of mass; LE = lower extremity; ROM = range of motion; UE = upper extremity.

Intense task-oriented training may not be appropriate for every patient. Its selection is dependent on the degree of recovery and severity of motor deficits. Research findings suggest that early overemphasis on use-dependent training may actually increase the vulnerability of the brain to additional damage in animals[93,94] and in humans.[95-98] Patients who are not able to participate in task-oriented training include those who lack voluntary control or cognitive function. For example, a patient with TBI who is in the early recovery stages has limited potential to participate with this type of intensive training. Similarly, patients with stroke who experience profound UE paralysis and perceptual deficits would not be candidates for CIMT UE training. One of the consistent exclusion criteria for CIMT has been inability to perform voluntary wrist and finger extension of the more involved hand. Thus, threshold abilities to perform the basic components of the task need to be identified. Careful analysis of underlying impairments with a focus on intervention (e.g., improved strength, ROM) complements task-oriented training. For example, during locomotor training using BWS and a treadmill system, stepping and pelvic motions are guided into an efficient motor pattern. To participate in this type of training, essential prerequisites include basic head stability during upright positioning.

Environmental Context

Altering the environmental context is an important consideration in structuring practice sessions. During early learning many patients benefit from practice in a stable, or predictable, *closed environment.* As learning progresses the environment should be varied and incorporate more variable features consistent with real world, *open environments.* Practicing walking only within the physical therapy clinic might lead to successful performance in that setting (*context-specific learning*) but does little to prepare the patient for ambulation at home or in the community. The therapist should begin to gradually modify the environment as soon as performance becomes consistent. Consideration must be given to practice in a safe environment where the patient can learn without the risk of injury or outright failure. Simulated environments (e.g., Easy Street Environments) are found in many rehabilitation centers. They can serve as an intermediate practice environment before the patient moves to the home or community setting. It is important to remember that some patients (e.g., a patient with TBI and limited cognitive recovery) may never be able to function in anything but a highly structured environment.

Behavioral Shaping

Behavioral shaping refers to the use of techniques designed to systematically progress the level of difficulty of the tasks practiced. The therapist provides immediate and explicit feedback to shape and improve performance. Attention is directed toward the successful aspects of performance. Thus the therapist serves to direct and motivate the patient toward optimal performance. The tasks chosen should be within the capabilities of the patient. Excessive effort, which can degrade performance and motivation, is avoided. The patient is kept focused on the training activity, fully informed of progress, and continually challenged.[99]

Safety Awareness Training

An important element of functional training is injury prevention or reduction. First and foremost is safety awareness training during self-care activities, postural control and balance activities, and functional mobility. For example, during postural awareness training, the patient learns to define limits of stability (LOS) during weight shifts. During anticipated or reactive perturbations, the patient learns how to react to these destabilizing forces with appropriate adjustments that maintain posture and balance. Identifying fall risk and developing strategies to reduce fall risk are important elements of functional mobility training. Instruction in the use of assistive devices and equipment is also accompanied by safety awareness training. For example, the patient with SCI learns to safely transfer into and out of the tub during bathing and to avoid risk of injury by testing water temperature before emersion. Finally, *secondary prevention* (efforts to decrease the severity of disability and sequelae through early diagnosis and prompt intervention) is an important component of rehabilitation. For example, prevention and management of UE overuse injury is an important component in the rehabilitation of patients with SCI who are wheelchair users.

Box 10.5 presents a summary of task-oriented training strategies to promote function-induced recovery.

Impairment Interventions

Task analysis reveals if the patient is able to perform the functional activity and its basic components. Additional examination and evaluation can reveal if a specific impairment or group of impairments is linked to the functional/task limitation. The therapist then needs to focus on specific interventions to improve performance. For example, a patient with multiple sclerosis (MS) demonstrates inability to stand up or transfer without moderate assistance of one. Lower extremity weakness in hip and knee extension is identified. Strength training of these muscles needs to be a targeted intervention. It is important to remember that resolution of the impairment may still not yield the desired functional performance. It is entirely possible that other impairments, previously masked by an inability to perform the task, were also contributing to the patient's inability to stand up independently (e.g., balance impairments). Without attention to correcting impairments, continued functional training has the potential of delaying recovery and creating a host of faulty movement patterns that

Box 10.5 Functional, Task-Oriented Training Strategies

Emphasize early training.

- To promote use-dependent cortical plasticity and overcome learned nonuse.

Define the goal of task practice.

- Involve the patient in goal setting and decision making, thereby enhancing motivation and promoting active commitment to recovery.

Determine the activities to be practiced.

- Consider the patient's past history, health status, age, interests, and experience.
- Consider the patient's abilities/strengths, level of recovery, learning style, impairments, and activity limitations.
- Determine a set of activities to be practiced for each training goal.
- Select activities that are interesting, stimulating, and important to the patient.
- Choose activities with the greatest potential for patient success and intersperse more difficult tasks with easier tasks.
- Target active movements involving the affected extremities.
- Constrain or limit use of unaffected extremities; set parameters, time limits for use of constraints.
- Prevent or limit compensatory strategies.

Determine the parameters of practice.

- Manage fatigue, determine rest and practice times.
- Model ideal performance; establish a *reference of correctness*.
- Establish requirements for intensity, minimal number of repetitions.
- Establish practice schedule of tasks (blocked or variable); shift to variable practice as soon as possible to enhance retention.
- Determine the practice order of tasks (constant, serial, random); shift to random order as soon as possible to enhance retention.
- Control use of instructions and augmented feedback to promote learning.
- Control use of assisted or guided movements to promote initial learning; ensure that the patient successfully transitions to active movements as soon as possible.

Utilize behavioral shaping techniques.

- Gradually modify the task to increase the challenge and make it progressively more difficult as patient performance improves.
- Provide immediate and explicit feedback; recognize and acknowledge small improvements in task performance.
- Emphasize positive aspects of performance.
- Avoid excessive effort because it degrades performance and dampens motivation.

Promote problem-solving.

- Have the patient evaluate performance, identify obstacles, generate potential solutions, choose a solution, and evaluate outcome.
- Relate successes to overall goals.

Structure the environment.

- Promote initial practice in a supportive environment, free of distractors (closed environment).
- Progress to variable practice in real-world environments (open environments).

Establish parameters for practice outside of therapy.

- Identify specific goals and strategies for unsupervised practice; maximize opportunities.
- Utilize a written behavioral contract, and have the patient agree to targeted behaviors to be carried out during the day.
- Provide home exercise program with adequate training for patient/family/caregivers.
- Have patient document unsupervised practice using an activity log or home exercise diary.

Maintain focus on active learning.

- Minimize hands-on therapy.
- Maximize role as *training coach*.

Monitor recovery closely and document progress.

- Use sensitive, valid, and reliable functional outcome measures.

Be cautious about timetables and predictions, because recovery may take longer than expected.

later may prove difficult to unlearn. For example, early gait training in the parallel bars in which the patient with stroke requires maximal assistance of the therapist to drag the involved and splinted leg forward does very little if anything to promote active locomotor control of that limb. It is also important to remember that impairment-specific interventions must be linked to functional training. The patient needs to practice the functional activity concurrently to resolve or diminish disability. The activity can be modified to ensure patient safety and make it easier. The following section provides an overview of impairment-specific interventions.

Interventions to Improve Strength, Power, and Endurance

Muscle performance is defined as "the capacity of a muscle or group of muscles to generate forces."[100, p. 688] **Muscle strength** is the "muscle force exerted by a muscle or a group of muscles to overcome a resistance under a specific set of circumstances."[100, p. 688] **Muscle power** is "the work produced per unit of time or the product of strength and speed."[100, p. 688] **Muscle endurance** is "the ability to sustain forces repeatedly or to generate forces over a period of time."[100, p. 688] Muscle performance is regulated by a number of factors. Neural factors include motor unit recruitment (number, type), motor neuron firing patterns, and efficiency of cooperative synergistic patterns. Muscle and biomechanical factors include initial muscle length and tension, muscle fiber composition, fuel storage and delivery, speed and type of contraction, and movement arm. Techniques that optimize these factors while addressing the specific demands of the task and environment will yield maximum functional outcomes.

Patients undergoing neurorehabilitation commonly present with disruption of motor neurons from central pathways and reductions in muscle force production, a direct result of a UMN lesion. Weakness or paralysis can affect one side of the body (hemiparesis, hemiplegia), both lower limbs (paraparesis, paraplegia), all four limbs (tetraparesis, tetraplegia), or a single limb or segments of a limb. Patients with hemispheric stroke from an ipsilateral lesion can also demonstrate bilateral weakness with the less involved side showing mild weakness.[101] As recovery progresses, the status of muscle strength and performance may change (e.g., the patient recovering from incomplete SCI regains muscles under voluntary control and functional performance improves). In addition, prolonged periods of disuse and immobility result in diminished neural activity, atrophy, and weakness. Older adults typically demonstrate a preferential loss of type II fibers. It is important to recognize that the patient may have been inactive before the insult or injury, resulting in preexisting deconditioning. Physical size (total body weight) and the demands of the task (e.g., stair climbing vs. walking on level surfaces) also influence the amount of strength required.

Strength Training

The benefits of strength training for patients with disorders of motor function include the following:

- An increase in the production of maximal force due to changes in neural drive (increased motor unit recruitment, increased rate, and synchronization of firing pattern of motor units, improved reaction time).
- Changes in muscle (hypertrophy of muscle fibers, improved metabolic/enzymatic adaptations, increased size and number of myofibrils, muscle fiber type adaptation).
- Increases in connective tissue tensile strength and bone mineral density.
- Improved body composition relative to body mass ratio of fat to lean.
- Improved functional performance and activity levels.
- Improved sense of well-being and self-confidence.

Basic principles of strengthening exercise include overload, specificity, cross training, and reversibility. The loads placed on muscle must be greater than those normally incurred *(overload principle).* Training effects are specific to the mode of exercise stress imposed on the exercising muscles *(specificity principle).* Thus, the training effects from an isometric protocol are specific to the exercising muscle and the point in the range that the muscle is holding. Effects do not carry over to improved dynamic performance (concentric or eccentric contractions). Nor will exercise training of the UEs transfer to improved LE performance. *Cross training* refers to a training program that includes a variety of training elements (e.g., isometric, concentric, eccentric, and endurance exercise). Cross training is used to place broadest possible demands on the neuromuscular system and overcome the effects of specificity. *Reversibility principle* refers to the failure to sustain the benefits of strength training if muscles are not regularly used in a maintenance program of resistance or functional exercises. Detraining effects include a reduction in muscle performance, decreased neural recruitment, and muscle fiber atrophy. The effectiveness of strength training is dependent on achieving an adequate training stimulus. Exercise guidelines for strength training are presented in Table 10.7.[102-105]

Patients with impaired motor function may demonstrate deficits in muscle activation. Early training should focus on isometric and eccentric contractions because muscle tension is better maintained than with concentric contractions. With isometric contractions, there is improved peripheral reflex support of contraction as opposed to the spindle unloading that occurs as the muscle moves into the shortened range of a concentric contraction. Eccentric contractions also produce greater muscle force with lower rates of motor unit discharge than concentric contractions. During training, the patient is initially asked to actively hold at midrange where the greatest tension can be generated. The patient is then

Table 10.7 Exercise Guidelines for Strength Training

Determine	Parameters of Exercise
Type of muscle contraction	Isometric, eccentric, concentric exercise
Mode of exercise training	Open chain (isolating one segment): isotonic and isokinetic exercises Closed chain: kinetic chain weight-bearing exercises (e.g., step-ups, modified squats) Circuit training: combination of varied methods Aquatic exercise Synergistic patterns: may be more efficient for improved function (based on specificity principle); e.g., PNF patterns with manual resistance
Type of resistance/equipment	Free weights, pulleys, elastic bands, mechanical resistance machine, isokinetic resistance (dynamometry), manual resistance, body weight, water resistance (aquatics)
Intensity: exercise load that best challenges the patient (based on overload principle)	Use submaximal loads • With weights, load is typically 60%–80% 1-RM with a goal • Very weak individuals can start at 50% 1-RM and fewer than 10 repetitions (reps) Exercise progression: increase reps, number of sets, or load as tolerated; adjust the exercise load on the basis of exercise responses, strength measures, perceived exertion, and fatigue threshold.
Number of repetitions and sets; number of exercises per set	Initial frequency is typically 3 sets of 10–15 reps or as tolerated
Duration	Total time of resistance training: typically 15–30 minutes per session or as tolerated
Frequency	Typically 2-3 days/week, depending on intensity and level of impairment/disease
Warm-up and cool-down periods	Include 5–10 min of warm-ups (calisthenics, stretching, ROM exercises) and 5–10 min of cool-down (muscle relaxation, stretching)
Additional considerations	Movements should be slow and controlled. Progression should occur in small increments. Reduce intensity with sudden onset of fatigue and exhaustion. Reduce intensity with prolonged and severe delayed onset muscle soreness. Regular breathing pattern should be maintained, while avoiding straining/Valsalva. Consider the interactions of exercise and medications. Exercise is contraindicated in some patients (e.g., with severe atrophic polio and recent weakness or ALS with muscle grades less than 3/5).
Outcomes	Relate strength training to functional tasks. Focus the patient on improvements in functional performance in terms that are understandable and meaningful.

ALS = amyotrophic lateral sclerosis; PNF = proprioceptive neuromuscular facilitation; RM = repetition max.

asked to slowly lower the limb (an eccentric contraction) and hold (an isometric contraction). Once control is achieved in both of these types of contractions, concentric contractions can be attempted. For isotonic contractions, prestretching the muscle by starting the contraction in the lengthened range optimizes tension development through increased use of viscoelastic forces *(length–tension relationship)* and peripheral reflex support (e.g., PNF patterns; see later definition and discussion). Weak muscles can be initially lightly resisted to facilitate contraction through *proprioceptive loading* (recruitment) of the muscle spindle. Control of velocity is also important to ensure efficiency of initial movement attempts. During concentric contractions, total tension decreases as velocity increases. Thus, patients may be able to generate a contraction at slow speeds but not at high speeds. For example, the patient with stroke who demonstrates limited control should be instructed to begin with slow and controlled movements. As movements become more efficient, they can be progressed to faster speeds.

Patients with UMN lesions typically exhibit spasticity. Early neurorehabilitation approaches (e.g., *Bobath*) viewed spasticity as a primary contributor to neuromuscular impairment. Strength training and high resistance were contraindicated because they were viewed as likely

to increase spasticity (reflex hyperactivity), co-contraction, and abnormal movement patterns.[105] These views are no longer supported by scientific literature as investigators have shown that it is possible to increase strength without additional detrimental effects on tone and movement control.[106-112]

Open-chain exercises involve an isolated segment of the limb moving in space without simultaneous motions at adjacent joints. Muscle activation occurs predominantly in the prime mover(s) crossing the moving joint. Resistance is applied to the distal moving segment, typically in non–weight-bearing positions. *Closed-chain exercises* involve motions in which the distal part is fixed (foot or hand) while proximal segments are moving (e.g., weight shifting in standing, bilateral short-arc squats). They are performed in weight-bearing postures and involve simultaneous actions of synergistic muscles at multiple joints. The added joint approximation and stimulation of joint and muscle proprioceptors enhances neuromuscular control and joint stabilization (co-contraction). A limitation of closed-chain exercise is the substitution of other agonist muscles for specific muscle weakness. In comparison, open-chain exercises can be used to isolate contraction of a muscle or muscle group. However, the muscles trained and movements used are not well matched to normal functional movements that utilize complex movements and multisegment linkage.[105]

Gains in strength can be obtained through progressive resistive exercises (PRE) using free weights or fixed mechanical resistance machines. A major disadvantage of PRE is that the weight selected is determined by the amount that can be lifted by the muscle at the weakest point of the range. Isokinetic training devices offer the advantage of providing accommodating resistance throughout the range. Muscle performance is therefore not limited to the weakest part of the range. The amount of force generated is recorded, providing an important objective measure of performance. Different isokinetic protocols using concentric and eccentric contractions have been developed. The speed of movement can be predetermined. This is an important consideration for training the patient who demonstrates neuromuscular impairments in timing and velocity control. For example, the patient recovering from stroke may be unable to generate the acceleration and deceleration forces needed during the different phases of gait. This results in delayed sequencing of muscle components and a general slowing of gait. Isokinetic training that focuses on the timing of these various components can improve gait function.

Proprioceptive neuromuscular facilitation (PNF) utilizes manually resisted patterns (PNF patterns) and offers the advantage of functionally based, synergistic movements. Patterns of motion are spiral and diagonal in nature as opposed to straight planes of motion and are linked to normal functional patterns. The therapist can accommodate to the patient's specific level of weakness by providing repetitive graded resistance throughout the range and by adding additional facilitation as needed to improve or maintain performance. Effective verbal commands improve the magnitude of muscle contraction. Stretch is applied in the lengthened range to assist in the initiation of contraction and throughout the range as needed to sustain contraction. Approximation is applied to assist extensor patterns, and traction is applied to assist flexor patterns. Specific PNF techniques (e.g., dynamic reversals, repeated contractions, and so forth) are useful in improving strength. Elastic resistance bands or pulley weights can also be used to provide resistance in synergistic PNF patterns.[113,114]

Strength gains can be achieved through functional training that uses task-related practice. Resistance is provided by gravity and body weight and is applied simultaneously to multiple moving segments. It can be supplemented with manual resistance of the therapist, weights, elastic resistance bands, or resistance of water during pool therapy. Activities are selected that initially focus on specific body segments and progress to involve increasingly larger segments of the body. This serves to increase the level of difficulty and the degrees of freedom that must be controlled during the movement. Benefits of functional training include improved coordination of muscles, improved postural control and balance, and improved muscle extensibility and flexibility. Functional training helps the patient develop control of synergistic muscle groups acting in multiple axes and planes of movements. It also fosters the control of varying types and combinations of muscle contractions (concentric, eccentric, isometric) that are used interchangeably during normal movement. This is a very different focus from the straight planes of motion and isolated movements commonly employed during PRE and isokinetic training. Intrinsic sensory input (somatosensory, vestibular, visual) is maximized during functional training.

Combining strength training protocols with task-specific practice is an important strategy to maximize transfer gains to functional skills. For example, strengthening of weak lower limb extensor muscles can be first achieved using an isokinetic machine that targets both eccentric and concentric contractions of the quadriceps. This training can effectively be combined with repetitive practice of functional activities also demanding similar extensor control (e.g., partial squats, sit-to-stand transfers, and stair climbing). The important consideration here is to match the strength training protocol to the requirements of the functional task in terms of ROM achieved and type, magnitude, and speed of contraction. Use of varied strength training activities and conditions also promotes development of flexibility of performance, an important goal for independence in daily life.

Muscular Endurance and Fatigue

Patients with deficits in motor function may demonstrate poor muscular endurance and fatigue. **Fatigue** is

defined as the inability to contract muscle repeatedly over time. Thus, exercise cannot be sustained and exercise tolerance is reduced. The onset of fatigue is variable from patient to patient. Although many different factors may play a role, among the most important are the type and intensity of exercise. With the onset of fatigue, patients will demonstrate a decrement in force production progressing to total *exhaustion* (a ceiling effect). Fatigue can arise from neuromuscular disease affecting three primary sites: (1) the CNS (central fatigue), (2) the peripheral nerves or neuromuscular junction, or (3) the muscle itself. Examples of CNS conditions that can produce debilitating fatigue include MS, Guillain-Barré syndrome (GBS), chronic fatigue syndrome, and post-polio syndrome (PPS). The real danger of exercise training with these patients is the risk of *acute exercise overdose* producing exhaustion and possibly injury. *Overtraining*, defined as chronic overdose of exercise, is associated with both psychological and physiological decompensation, as well as musculoskeletal injury.[104] *Overuse weakness* is manifested as aching on exertion and a prolonged decrease in absolute strength and endurance as a result of excessive activity. This is often seen in patients with PPS. For example, following an exercise session the patient with PPS demonstrates prolonged weakness and fatigue that does not recover with rest. If exercise is exhaustive, the patient may be unable to get out of bed the next day or perform normal activities of daily living (ADL). Even a simple conditioning program should be carefully monitored and progressed slowly to avoid overexertion and injury.

Aerobic Training

The benefits of aerobic training for patients with disorders of motor function include the following:

- Improved cardiovascular and peripheral (muscular) endurance
- Decreased anxiety and depression
- Enhanced physical function
- Enhanced sense of well-being

A cardiovascular training program is determined based on the patient's level of deconditioning and specific symptoms. Aerobic exercises can include ergometry (two-limb or four-limb), recumbent stepper, therapeutic aquatics, and conventional weight-bearing activities such as walking. In general, moderate intensities of exercises are appropriate for most patients undergoing active rehabilitation (e.g., 40% to 70% of maximal oxygen consumption) whereas high intensities are contraindicated. For many patients, a frequency of 3 to 5 days per week with 20- to 30-minute sessions is often recommended (e.g., the patient with stroke or TBI). Alternatively, multiple 10-minute sessions can be used. Most patients will require a discontinuous protocol that carefully balances exercise with rest.[104] Clinical practice guidelines including exercise recommendations are available to assist the therapist in treating patients with chronic disabilities.[115-120] *ACSM's Exercise Management for Persons with Chronic Diseases and Disabilities* is particularly helpful for the rehabilitation therapist as it discusses exercise guidelines for a number of different disabilities (e.g., stroke, TBI, SCI, MS, PD, and so forth).[104]

Effective management of patients with low endurance and fatigue includes the use of energy conservation techniques, activity pacing, lifestyle changes, regular rest periods during the day, and improved sleep through the use of relaxation techniques and medications. An activity log can be used to help the patient identify activities that are particularly exhausting and to document the effectiveness of rest. Unnecessary energy-consuming activities should be discontinued and essential activities restructured and paced to include regular rest periods throughout the day. Patients can monitor their level of general fatigue using the Borg Rating of Perceived Exertion (RPE) scale[121] and should aim to keep their activities at an RPE level of "somewhat hard" (14 or lower using the 6–20 RPE scale). Ergonomic changes (e.g., seating and workstations) should be implemented to reduce energy cost of activities. Finally, stress management should be included in the educational program.[118]

Interventions to Improve Flexibility

Joint ROM and muscle flexibility must be adequate to allow for normal functional excursions of muscle and biomechanical alignment. Prolonged periods of disuse and immobility and motor dysfunction associated with neurological insult can lead to changes in muscle and joint function, postural alignment, and a host of indirect impairments. These include muscle tightness, atrophy, fibrosis, contracture, joint ankylosis, and postural deformity. Older adults demonstrate age-related changes affecting joint flexibility. These include increased viscosity of synovial fluid, stiffening of the joint capsule and ligaments, and calcification of articular cartilage.[122] Proactive intervention following neurological insult (e.g., stroke, TBI, SCI) is an important component of intervention. Patients with chronic and irreversible diseases (e.g., PD, MS, amyotrophic lateral sclerosis [ALS]) also need targeted intervention (tertiary prevention) to limit sequelae and degree of disability. Benefits include maintaining joint flexibility, tissue extensibility, physical ability, and function. Additional benefits include improved circulation and tissue nutrition to the limbs and pain inhibition.

Techniques include ROM exercises, passive stretching, and joint mobilization. The use of a preliminary therapeutic heat modality (e.g., hot pack) increases muscle temperature and elasticity and collagen extensibility. A warm-up period of exercise can also be used. For example, calisthenics or low-resistance cycling will gradually increase tissue temperatures and elasticity, thereby enhancing the safety of stretching. Cold modalities can

be used to cool muscles and decrease muscle spasm and physiological splinting.

ROM Exercises

Range of motion is "the arc through which movement occurs at a joint or a series of joints."[100, p. 690] ROM can be *active (AROM),* performed and controlled entirely by the voluntary muscular efforts of the patient, *active-assisted* (*AAROM),* requiring some degree of external assistance for voluntary efforts, or *passive (PROM),* performed solely by therapist or caregiver. The *Guide to Physical Therapist Practice* classifies the first two as therapeutic exercise whereas PROM is classified as manual therapy.[100] PROM is typically used when active movement is not possible (e.g., due to pain, paralysis, or unresponsiveness). AROM and AAROM have additional benefits of improving circulation, decreasing atrophy, and improving motor function. Progression should be to AROM exercises whenever possible because they are an important component of the home exercise program (HEP). ROM exercises are performed through the patient's full available range. The limb should be well supported with stable positioning of the patient to prevent joint trauma. The movements should be slow and within the patient's tolerance. Excess force and pain are contraindicated. This is especially important when working with the patient at risk for osteoporosis and heterotopic ossifications.

ROM exercises can be administered in anatomical planes of motion or in diagonal patterns of motion (PNF patterns). The latter may be more efficient because ROM can be administered throughout a limb, combining motions at more than one joint. ROM can also be achieved during functional training activities (e.g., shoulder ROM is achieved during weight shifting in quadruped or plantigrade positions). An added benefit may be the patient's lack of attention to joint motion during the activity with less protective splinting.

Passive Stretching

Stretching involves the application of manual or mechanical force to elongate (lengthen) structures that have adaptively shortened and are hypomobile.[100] The term *static stretching* refers to a method of stretching in which the muscle is slowly elongated to tolerance. The end position (greatest tolerated length) is held at least 20 to 30 seconds and the stretch is repeated four to five times, depending on the patient's tolerance. The use of slow, prolonged stretch alters neural activity by minimizing muscle spindle activation and reflex contraction of the muscle being stretched. Maintaining the position at maximal end range results in the firing of the Golgi tendon organs (GTOs) with resulting inhibition of the muscle being stretched through mechanisms of autogenic inhibition. The combined effects result in improved muscle elongation. Passive stretching also affects the muscle directly, resulting in viscoelastic changes affecting muscle extensibility. Low-load stretching results in less danger of soft tissue tearing, less muscle soreness, and decreased energy requirements.[122-124] Frequency of stretching (number of sessions per day or per week) varies according to underlying cause, the chronicity and severity of contracture, the patient's age and level of tissue integrity and healing, and medical management (e.g., use of corticosteroids).[105] Optimally, stretching is daily and balanced with adequate rest in between to minimize tissue soreness. The results of stretching (i.e., newly gained range) should be combined with active exercise. The adage "use it or lose it" holds true for maintaining the benefits of both ROM and stretching exercises. Patients and/or their families/caregivers should be taught stretching exercises (i.e., self-stretching) as part of the HEP to maintain carryover outside of the clinic setting.

Ballistic stretching, defined as the use of a high-load, short-duration, intermittent stretch, is generally contraindicated for the elderly, the chronically ill, or patients undergoing active rehabilitation with neuromuscular impairments.[125] The high-velocity, high-intensity movements are not easily controlled. In addition, activation of muscle stretch receptors (muscle spindle Ia endings) results in reflex contraction and limits muscle elongation. Also, in chronic contractures, connective tissue is more brittle and tears easily. Thus, it is associated with high rates of microtrauma and injury.[105]

Low-load prolonged stretch (LLPS) (15 to 30 minutes) can be applied using mechanical pulleys and weights or specialized orthotic devices. Prolonged positioning on a tilt table with wedges and straps can be used effectively to improve LE range (e.g., hamstrings, gastroc-soleus muscles).[126,127] Prolonged stretch can also be applied to prevent or reduce contractures using serial casting (discussed later in this chapter).

Facilitated Stretching

Facilitated stretching refers to the use of neuromuscular inhibition techniques to relax (inhibit) and elongate muscles when used in conjunction with stretching. *PNF-facilitated stretching techniques* include *hold-relax (HR)* and *contract-relax (CR).* The limb is actively moved to the end of PROM (range-limited position). The patient is then instructed to perform a maximal isometric contraction of the restricted, shortened muscles (antagonist pattern). The contraction should be maintained for at least 5 to 8 seconds. This pre-stretch contraction results in muscle inhibition from activation of the GTO (autogenic inhibition). This is followed by voluntary relaxation. In HR, the therapist then passively moves the limb into the new limit of range. In CR, the patient actively moves the limb to the new limit of range in the pattern against resistance. The resisted isotonic contractions of the agonist muscles focuses on all muscles in the pattern with an emphasis on rotators and provides additional reciprocal inhibition effects (i.e., agonist

contraction further inhibits the tight muscle via muscle spindle activity). These techniques were originally applied while using PNF patterns though some clinicians have adopted these techniques in patterns using anatomical planes of motion.[113,114] Research has demonstrated the effectiveness and superiority of facilitated stretching techniques over static stretching techniques, particularly when active contractions are used.[128-130] An additional benefit is that patients frequently report less discomfort with the application of facilitated stretching techniques as compared to other stretching methods. Because the inhibitory mechanisms affect primarily muscle and depend on voluntary contraction, these techniques are not effective with very weak or paralyzed muscles or range limitation associated with substantial connective tissue changes (chronic contracture).

Stretching and Positioning for the Patient with Spasticity

The patient with UMN syndrome typically exhibits spasticity (velocity-dependent hypertonia) and hyperactive deep tendon reflexes (DTRs). Functionally the patient demonstrates poor volitional control of movements and limitations in functional skills. The limbs are typically held in fixed, abnormal postures with antigravity muscles primarily affected. For example, the UE typically assumes an abnormal flexor posture whereas the LE assumes an abnormal extensor posture. If left untreated, spasticity can lead to the development of secondary impairments such as contracture, postural asymmetries, and deformity.

Stretching and positioning are important components of management of the patient with spasticity. Patient tolerance needs to be carefully assessed. Precise handling of a spastic limb is important. The therapist should use constant, firm manual contacts positioned over bony or nonspastic areas and avoid direct pressure on spastic muscles. The limb is moved out of the shortened spastic position into the lengthened range using slow, repeated rotations of the limb. The patient's limb can then be positioned and maintained in the newly gained range to provide prolonged stretching. For example, during treatment of the patient with stroke and a spastic UE, the therapist grasps the hand over the thumb and slowly moves the elbow out into full extension with the hand open. The hand is then placed palm down on the mat to the side of the patient in weight-bearing with the elbow extended, hand open, and wrist and fingers extended. Weight shifting forward/backward during sitting can then be used to maintain inhibition and range. Although time to maintain the stretch in order to reduce spasticity is unknown, one group of researchers found 10 minutes to be optimal.[131]

Serial Casts

Serial casts are recommended for patients who have or are at risk for contractures as a result of decreased PROM and/or spasticity. They have been shown to improve ROM, reduce contracture, and prevent deformity.[132-137] The therapist first positions the limb into its fully lengthened end-range. A layer of thin foam and white cotton wrap is applied first, followed by the cast material (e.g., Softcast™, reinforced Softcast, or bivalved fiberglass). Casts are typically changed every 7 to 10 days (serial application) and are used for 1 to 6 weeks. Poor casting techniques include lack of end-range positioning of the limb, loose-fitting cast, or insufficient padding. Faulty technique may result in a lack of improvement or even increased tone, skin breakdown (especially on bony prominences), decreased circulation, and peripheral edema. Highly agitated patients (e.g., the patient with TBI) may potentially injure themselves and demonstrate increased risk of skin breakdown and cast breakage. Patients with cognitive or communication impairments should be monitored closely because they will be unable to indicate pain or discomfort and potential skin breakdown (e.g., the patient with stroke and aphasia). Casting is contraindicated in patients with severe heterotropic ossification; skin surface not intact, such as open wounds, blisters, or abrasions; impaired circulation and marked edema; uncontrolled hypertension; autonomic storming (marked increase in sympathetic nervous system activity); unstable intracranial pressure; pathological inflammatory conditions, such as arthritis or gout; or in individuals at risk for compartment syndrome or nerve impingement. Application to individuals with long-standing contractures (longer than 6 to 12 months) is also contraindicated.[138]

Adjustable orthoses have also been used to provide passive, prolonged stretch with the added benefits of easy removal for hygiene and observation. These devices use a rotating adjustable dial attached to metal rods and a flexible acrylic thermoplastic base.[139] The required adjustments are easier and less time consuming than fabricating an entirely new serial cast. Dynamic orthoses, primarily used on elbow or knee flexion contractures, use a spring-loaded or hydraulic mechanism to provide nearly constant pressure.

ROM for the Patient with Hypotonia

The patient with lower motor neuron (LMN) syndrome typically exhibits hypotonia (low tone) with weak or paralyzed muscles, joint instability, and deformity. Following neurological insult, tone varies relative to recovery stage. For example, the patient with a new or recent stroke or SCI will present with initial flaccidity during the stage of cerebral or spinal shock whereas the same patient later on demonstrates emerging spasticity. In using PROM exercises for the patient with hypotonia, the therapist needs to be cognizant of end-range joint instability and the risk of hyperextension injury. Supportive and protective devices may be necessary to prevent injury to limbs and postural asymmetry during functional training.

Interventions to Improve Postural Control and Balance

Postural control is the ability to control the body's position in space for stability and orientation. **Postural orientation** is the ability to maintain normal alignment relationships between the various body segments and between the body and environment. *Static postural control* (static balance control, stability) is the ability to maintain stability and orientation with the COM over the BOS with the body at rest. *Dynamic postural control* (dynamic balance control, controlled mobility) is the ability to maintain stability and orientation with the COM over the BOS while parts of the body are in motion (see Table 10.2).[2] An intervention program to improve postural control must be based on an accurate evaluation of data obtained during examination of deficits (see Chapter 5, Examination of Motor Function: Motor Control and Motor Learning).

Training activities can be used to improve the following:

- Postural alignment, body mechanics, and static postural control
- Dynamic postural control, including musculoskeletal responses necessary for control of movement and posture
- Adaptation of balance skills for varying task and environmental conditions
- Use of sensory monitoring for postural control
- Safety awareness and compensatory strategies for effective fall prevention

Increased understanding of the range and variability of postural strategies for balance negates any simplistic view of balance based on a developmental perspective of reflex control (i.e., righting and equilibrium reactions). Overall, the organization of postural control strategies must be viewed as flexible, not rigid, involving multiple body segments and postural strategies.[140-142] In that context, patterns will vary according to a number of different factors, including initial conditions, balance requirements and challenges, perturbation characteristics, learning, and intention.[143] The patient needs to practice steady state, anticipatory, and reactive balance control using activities that focus on both static and dynamic postural control. Functional activities selected should be based on an accurate evaluation of the patient's abilities and needs. The activities selected should include those required for ADL, as well as those required for social participation, recreation, and work, if appropriate. Sensory selection and organization should also be a part of a balance training program. Repetition and practice are essential factors in assisting CNS adaptation.

It is important to remember that some balance training activities may cause the patient distress initially. The patient will feel threatened when placed in situations where he or she is in jeopardy of falling. The therapist should ensure patient confidence by providing a clear explanation of the nature of the task, what the challenges to balance are, and the steps the therapist will take to prevent falls in terms that are easy to understand. The patient with instability can wear a gait belt or practice standing activities wearing an overhead safety harness. The therapist needs to stand close enough to the patient to guard safely but not so close as to interfere with the activity. For the very unstable patient, two spotters may be necessary. The environment can be used to assist in keeping the patient from falling. For example, standing exercises can be performed in the parallel bars, between two tables, near a wall or two walls (corner standing), or in a pool with the patient standing in waist-high or chest-high water. Support given early in training should be withdrawn as soon as possible to allow focus on active control.

An understanding of the foundational requirements of upright postures will direct the therapist in improving postural alignment and body mechanics. Sitting is a relatively stable posture with a moderately high COM and a moderate BOS that includes contact of the buttocks, thighs, and feet with the support surface. During normal sitting, weight is equally distributed over both buttocks with the pelvis in neutral position or tilted slightly anterior. The head and trunk are vertical, maintained in midline orientation. The line of gravity passes close to the joint axes of the spine. Muscles of the cervical, thoracic, and lumbar spine are active in maintaining upright postural control and core stability. BOS can be increased by using one or both hands for additional support.

Deficits in sitting can be broadly grouped into those involving alignment, weight-bearing, and extensor muscle weakness. Changes in normal alignment result in corresponding changes in other body segments. For example, a slumped sitting posture (dorsal kyphosis and forward head) is typically the result of sacral sitting with the pelvis tilted posteriorly. The therapist should instruct the patient in the correct sitting posture and demonstrate the position to provide an accurate *reference of correctness*. It is important to focus the patient's attention on key task elements and improve overall sensory awareness of the correct sitting posture and position in space.

Standing is a less stable posture with a high COM and a small BOS that includes contact of the feet with the support surface. During normal quiet standing, there is minimal body sway with ankle muscle activity (dorsiflexors/plantarflexors, invertors/evertors) activated to counteract body sway. Weight is equally distributed over both feet. The line of gravity falls close to most joint axes: slightly anterior to the ankle and knee joints; slightly posterior to the hip joint; posterior to the cervical and lumbar vertebrae; and anterior to the thoracic vertebrae and atlanto-occipital joint. Natural spinal curves are present but somewhat

flattened in upright stance depending on the level of postural tone (e.g., lumbar and cervical lordosis, thoracic kyphosis). The pelvis is in neutral position, with no anterior or posterior tilt. Normal alignment minimizes the need for muscle activity during erect stance.

Impairments in standing can also be broadly grouped into those involving alignment, weight-bearing, and specific muscle weakness. Faulty postures such as forward head and kyphosis or lordosis, excessive hip and knee flexion, or pelvic asymmetries can result in decreased postural stability. Inaccurate kinesthetic awareness of true vertical and pain can affect postural position and significantly impair balance. Patients are typically unable to self-correct faulty postures. Physical therapy interventions should focus first on improving specific musculoskeletal impairments (e.g., limited ROM, weakness). For example, active exercises to improve standing can include standing heel-cord stretches, heel-rises, toe-offs, partial wall squats, chair-rises, side-kicks, back-kicks, and marching in place using touch-down support of the hands as needed. These are sometimes referred to as the "kitchen sink exercises." Postural reeducation begins with demonstration of the correct posture. Verbal cues should focus on control of essential postural elements, that is, stable (neutral) pelvis, axial extension (e.g., "stand tall"), and normal alignment (e.g., head erect, shoulders back, weight evenly distributed under both feet). Patients can benefit from tactile cues during initial practice (manual or surface related). For example, patients can stand with the back positioned against a wall or patients with a lateral lean (e.g., patients with pusher syndrome following a stroke) can sit with their side positioned against the seated therapist or a wall. Corner standing or standing between two treatment tables can be effective for patients with significant COM distortion. Mirrors can provide important visual cues regarding vertical position. For example, the patient wears a shirt with a taped vertical line on it and is asked to match it to a taped vertical line on a mirror.[2] The taped lines provide useful visual feedback for achieving vertical. Mirrors are generally contraindicated for the patient with visuospatial perceptual deficits. Application of correct postures to real-life functional situations is important to ensure carryover and lasting change. Instruction in proper body mechanics should include a discussion of the activities of standing up, lifting, reaching, carrying, and arising from the floor.

Interventions to Improve Static Postural Control

Patients who demonstrate impairments in static postural control (stability) are unable to maintain or hold a steady position for a number of reasons, including decreased strength, tonal imbalances (hypotonia, spasticity, dystonia), impaired voluntary control and hypermobility (ataxia, athetosis), sensory hypersensitivity (tactile-avoidance reactions), or increased anxiety or arousal (high sympathetic "fight or flight" state). Instability is associated with excessive postural sway, wide BOS, low- or high-guard hand position, holding onto an object in the environment (handhold), and loss of balance (falls).

The therapist can select any of a number of weight-bearing (antigravity) postures to develop stability control. Typical training postures include sitting and standing (in modified plantigrade and full standing). Postures are selected on the basis of (1) patient safety and level of control and (2) importance in terms of functional tasks. The therapist varies the level of activities, selecting activities that both allow success and provide an appropriate challenge for the patient.

The therapist should focus on obtaining symmetrical, balanced weight-bearing. Patients may present with specific directional instabilities, such as weight-bearing more on one side than the other. For example, after a stroke the patient typically keeps weight centered toward the less affected side. Practice should focus on redirecting the patient into a centered position by moving toward the more affected side, both in sitting and standing positions. The patient is instructed to "hold steady" while sitting or standing tall and maintaining a visual focus on a forward target. Progression is to holding for longer and longer durations. Techniques that can be used to enhance stabilizing muscle contractions include quick stretch, tapping, resistance, approximation, manual contacts, and verbal cues. For the patient unable to actively stabilize the body, the therapist can begin with resisted isometric contractions of antagonist postural muscle groups (e.g., PNF technique of rhythmic stabilization). For example, the patient with severe instability following TBI who is unable to sit independently may need to begin practice holding a neutral trunk position first in a supported sitting position. The therapist can then progress the patient to active sitting and to postures that demand increasing amounts of upright (antigravity) postural control (standing). If an imbalance exists, the stabilizing activity can be coupled with a strengthening activity for the weak muscles. As the trunk becomes more stable, the patient is expected to assume active control in stabilizing in the posture. For a patient with hyperkinetic disorders (e.g., ataxia, athetosis), the PNF technique of stabilizing reversals is appropriate. Alternating isotonic contractions are used, allowing only very small-range movements. Progression is toward decreasing range (*decrements of range*) until finally the patient is asked to stabilize and hold steady against resistance in the posture.

Additional strategies to improve stability include the use of elastic resistance bands to enhance *proprioceptive loading* and contraction of stabilizing muscles. For example, in the prone-on-elbows position or supported sitting with elbows weight-bearing on a table, a band can be placed around both forearms. The patient is instructed to push out against the band and maintain the forearms apart against the resistance. This selectively

loads and facilitates contraction of the shoulder stabilizers (abductors and rotator cuff muscles). In kneeling or standing, elastic resistance bands can be placed around the lower thighs. The patient is instructed to maintain the thighs apart against the resistance of the bands. This selectively loads and facilitates contraction of the hip stabilizers (abductors, extensors), improving stability control at the hips.

As static postural control improves, the therapist can progress the patient to stabilizing on a moveable surface (e.g., sitting on a therapy ball). Gentle bouncing on the therapy ball provides joint approximation through the vertebral joints, facilitating extensors and an upright posture. For patients requiring an additional challenge, sitting control can be practiced on other compliant surfaces (e.g., foam, wobble board, or Dynadisc™) placed on a platform mat. The therapist can also increase task difficulty by reducing the BOS (feet apart to feet together to sitting with single foot support [legs crossed]).

Aquatic therapy can also be used to enhance proprioceptive loading. The water provides a degree of unweighting and resistance to movement. This can be quite effective in reducing hyperkinetic movements and enhancing postural stability. For example, a patient recovering from TBI who demonstrates significant ataxia may be able to sit or stand in the pool with minimal assistance whereas these same activities outside the pool are not possible.

To improve standing control, the patient is directed to practice neuromuscular *fixed-support strategies* that occur at the ankle and hip joints.[142] Feedback is provided to assist the patient in recruiting the correct pattern. To recruit *ankle strategies,* the patient practices small-range, slow-velocity shifts progressing to holding steady. Attention is directed to the action of ankle muscles to maintain the body (COM) over the fixed feet (BOS). Standing on a wobble board (moveable surface) or foam roller with the flat side down progressing to flat side up are effective activities to increase the challenge in recruiting ankle strategies. The patient is also directed to practice tasks that normally recruit *hip strategies.* These are recruited with larger shifts in the COM that approach the LOS and/or faster body sway motions that are characterized by early activation of proximal hip and trunk muscles. Hip flexion and extension responses are generated during anterior–posterior displacements. Lateral hip motions are generated during lateral displacements. Patients can be instructed to move their upper body forward and backward while standing on a foam roller progressing to steady holding. More challenging activities include standing with feet together, tandem standing, and single-limb stance. Tandem standing on a foam roller is an effect way to recruit lateral hip strategies.[97]

Anticipatory postural adjustments should also be practiced, because predictive control must be operational for functional balance. The patient is provided with advance information about the upcoming demands of the task. For example, "I want you to catch this 5-pound weighted ball while maintaining your sitting (or standing) position." The prior knowledge serves as an important source of information in initiating the correct postural pattern. To promote generalizability, practice should occur in a variety of environments. For example, training can progress from a closed or fixed environment (e.g., quiet room) to a more variable environment (e.g., busy physical therapy gym). Training must ultimately be context specific to real-life settings of home or community to ensure functional carryover (e.g., standing at the bathroom sink or kitchen counter).

Interventions to Improve Dynamic Postural Control

Patients who demonstrate impairments in dynamic, anticipatory postural control are unable to control postural stability and orientation while moving segments of the body. A number of impairments may be contributing factors, including tonal imbalances (spasticity, rigidity, hypotonia), ROM restrictions, impaired voluntary control and hypermobility (ataxia, athetosis), impaired reciprocal actions of the antagonists (cerebellar dysfunction), or impaired proximal stabilization. Clinically, the patient demonstrates difficulty weight shifting from side-to-side, forward-backward, or diagonally. Difficulties are also apparent in moving one or more limbs while maintaining a posture (sometimes referred to as *static-dynamic control*). For example, one limb is moving (UE reaching or LE stepping) while the patient maintains the sitting or standing posture. In the quadruped position, the patient lifts one arm or leg or opposite arm and leg. These added movements increase the demand for stabilization control because the overall BOS is reduced and the COM must shift over the remaining support segments before the dynamic limb movement can be successful (e.g., stepping).

The therapist can select any of a number of weight-bearing (antigravity) postures to develop dynamic postural control (see Table 10.7). Postures typically selected include sitting and standing. Practice begins with movements emphasizing smooth directional changes that engage antagonist actions (e.g., weight shifts). *Limits of stability* should be explored. For example, in sitting or standing, the patient is instructed to slowly sway in all directions (forward-backward, side-to-side) as far as possible while still maintaining the position. The outer point at which the COM is still maintained within the BOS is termed the LOS. Loss of balance occurs when the LOS has been exceeded, for example, when the COM extends beyond the BOS. Practice of volitional body sway is important to assist the patient in developing accurate perceptual awareness of stability limits, an important component of an overall CNS internal model of postural control. Because LOS changes with different tasks, a variety of functional activities should

be practiced in different environmental settings. As control improves, the movements are gradually expanded through an increasing range (*increments of range*). For the patient who has difficulty initiating or controlling movements, the movements can be facilitated using quick stretch, tapping, light tracking resistance, manual contacts, and dynamic verbal commands. Although active movement is the goal, guided assistance may be required for some patients during initial movement attempts.

Specific task-oriented training incorporates both reaching and stepping activities. Functionally important and motivating activities should be selected. For example, the patient practices reaching for a cup (requiring shoulder stabilization with elbow extension and wrist stabilization) while maintaining a stable sitting position. Or a bilateral UE task (e.g., folding and stacking towels) can be used while maintaining a stable standing position.

PNF extremity patterns can be used to introduce a dynamic challenge to postural stability and promote movement in synergistic patterns. For example, in sitting the patient is asked to move the UEs using a chop/reverse chop pattern in sitting. In addition to the extremity movement, the pattern incorporates diagonal and rotational movement of the trunk along with a weight shift. The patient's full attention is focused on performing the pattern and not on the stabilizing postural components. This ability to redirect cognitive attention is an important measure of developing postural control because intact postural control functions largely on an automatic and unconscious level. Movements can be active or resisted (e.g., PNF techniques of dynamic reversals [slow reversals]).[97]

Therapy ball activities are effective in developing dynamic stability control in sitting. For example, the patient sits on a ball and gently moves the ball side-to-side, forward-backward, or in a combination (pelvic clock motions). Or the patient sits on the ball while performing voluntary movements of the arms or legs (e.g., alternate leg or arm raises). Progression is from unilateral to bilateral and finally to reciprocal limb movements (e.g., Mexican hat dance). Voluntary trunk motions can be practiced while sitting on the ball (e.g., head and trunk rotation with arms held out to the side). Resistance can be introduced by using elastic resistance bands, a weighted ball, or weight cuffs on the ankles or wrists. Difficulty can be increased by adding a second task (*dual task training*) such as catching and throwing a ball, batting a balloon, or kicking a ball. A secondary cognitive task can also be introduced (e.g., spelling forward or backward, remembering a list, counting backward by 3's).[2]

To improve standing control, the patient is directed to practice neuromuscular *stepping strategies.*[142] Stepping strategies can be evoked with perturbations that provide the COM displacement. Stepping movements are accompanied by early activation of hip abductors and ankle co-contraction for medial-lateral stability during static single-limb support.[144] Maki and McIlroy[145] investigated the role of limb movements in maintaining upright stance, specifically compensatory stepping and grasping movements of the upper limbs, which they termed *change-in-support strategies* (as opposed to the fixed-support strategies at the ankle and hip). These investigators found that both stepping and arm movements were common reactions to loss of balance. Moreover, they were initiated well before the COM reached the LOS, contradicting the traditional view that they are strategies of last resort. They also found that stepping may actually be a preferred strategy to using a hip strategy. The direction and magnitude of change-in-support strategies were found to vary according to the magnitude and direction of the perturbation. For example, stepping may occur forward or backward in response to anterior or posterior displacements. Lateral displacements typically resulted in cross-stepping pattern, seen in 87% of lateral stepping responses, as opposed to straight side-stepping. Lateral destabilization with its increased demands for lateral weight transfer is particularly problematic for a large portion of older adults who experience falls. Arm reactions in response to whole-body instability were also found to be prevalent with activation of shoulder muscles occurring in 85% of destabilizing trials.

Training in standing should include practice of a variety of voluntary stepping movements (e.g., marching in place; anterior, posterior, lateral, or crossed side steps). Steps can start out small and gradually increase to mini-lunges or full lunges. Stepping can also be progressed from tandem stepping (e.g., forward tandem to backward tandem steps) to crossed stepping (e.g., stepping forward and across to backward and across). Upper trunk rotation and arm swing can be combined with these cross-stepping movements. Elastic resistance bands positioned around the pelvis can be used to improve the strength of stepping responses.[97] Research evidence demonstrates the effectiveness of training in improving balance control.[146-152]

Interventions to Improve Reactive Balance Control

Patients with deficits in motor function and balance are also typically unable to respond effectively to external perturbations. The therapist can utilize gentle manual pulls or pushes applied to the shoulders or hips, or moving platforms, to provide perturbations. Small perturbations can be used to activate strategies designed to maintain position (e.g., ankle or hip strategies) whereas larger perturbations can be used activate stepping strategies. The therapist should vary inputs so as to not be predicable in terms of the response activated (i.e., direction, type, and speed of response). An elastic band around the hips can also be used to promote stepping strategies. The therapist maintains resistance of band

against the hips and then suddenly releases the resistance, requiring the patient to take a step. Patient safety and protection against falls should be maintained during all perturbation training. Research evidence demonstrates the effectiveness of training in improving reactive balance control.[149,152] Tai Chi training has also been shown to improve balance control and stepping strategies.[153-155]

Interventions to Improve Sensory Selection and Utilization for Balance

An important focus of balance training is utilization and integration of appropriate sensory systems. Normally three sources of inputs are utilized to maintain balance: somatosensory inputs (proprioceptive and tactile inputs from the feet and ankles), visual inputs, and vestibular inputs. Careful examination can identify the patient's use of inputs to maintain balance (e.g., *Clinical Test for Sensory Interaction and Balance* [CTSIB]; see Chapter 5, Examination of Motor Function: Motor Control and Motor Learning, for a discussion of this test). Training is directed to using varying sensory conditions to challenge the patient. For example, patients who demonstrate a high degree of dependence on vision can practice balance tasks with absent visual cues (e.g., eyes closed or blindfolded), with reduced visual cues (e.g., low light), or with inaccurate vision (e.g., petroleum-coated lenses on a pair of eyeglasses). Altering the visual inputs allows the patient to shift focus and reliance to other sensory inputs, in this case to intact somatosensory and vestibular inputs. Patients can practice varying somatosensory inputs by standing and walking on different surfaces, from flat surfaces (floor) to compliant surfaces (low to high carpet pile), to dense foam. A patient who is barefoot or wearing thin-soled shoes is better able to attend to sensation from the feet than if wearing thick-soled shoes. Challenges to the vestibular system can be introduced by reducing both visual and somatosensory inputs through sensory conflict situations. For example, the patient practices standing on dense foam with the eyes closed. The patient can also be directed to walk on foam with eyes closed, a condition that requires maximum use of vestibular inputs. Patients should also practice varying environmental influences such as walking outside, progressing from relatively smooth terrain (sidewalks) to uneven terrain to moving surfaces (escalator, elevator). Practice can also include standing or walking in bright or full lighting to reduced lighting. Research evidence demonstrates the effectiveness of altering sensory contexts in improving sensory selection and organization for balance.[156-160]

Patients with significant sensory loss will require assistance in shifting toward the intact systems to monitor and adjust balance using *compensatory training strategies.* For example, the patient with LE proprioceptive losses (e.g., diabetic neuropathy) will need to learn to shift focus to the visual system for functional mobility and balance. The patient with bilateral amputations learns to rely heavily on visual inputs for control in standing and walking. If deficits exist in more than one of the major sensory systems, compensatory shifts are generally inadequate and balance deficits will be pronounced. Thus, the patient with diabetic neuropathy and retinopathy will be at high risk for loss of balance and falls. Compensatory training with an assistive device is indicated. Other patients must be encouraged to ignore distorted information (e.g., impaired proprioception accompanying stroke) in favor of more accurate sensory information (e.g., vision). Patients with low vision should practice balance activities while wearing their eyeglasses. The exception to this is when patients wear bifocal glasses, which should not be worn during balance training. The lower lens (designed for reading) can distort vision when looking down and interfere with depth perception (e.g., stair climbing).

Interventions Using Augmented Feedback

Augmented feedback can be used to during balance training (e.g., biofeedback cane with auditory signals, limb load monitor, posturography). Force-platform devices are used to measure forces and provide *center of pressure (COP) biofeedback* (posturography feedback). COP displacement is associated with movement of the COM or postural sway. Although COP excursion always exceeds COM sway, this relationship is close during ankle motions (ankle strategies) when the body moves like a pendulum over the feet. However, when a hip strategy is used (upper body motion focused at the hips), the COP:COM relationship becomes distorted and does not accurately reflect sway.[161] A computer analyzes the data and provides relevant biofeedback concerning sway path and COP position on a visual monitor. Some units also provide auditory feedback.

Posturography training can be used to shape sway movements to enhance symmetry and steadiness. The patient can be instructed to increase or decrease sway movements or move the COP cursor on the computer screen to achieve a designated range or to match a designated target. It is an effective training mode for patients who demonstrate problems in force generation. For example, the patient with decreased force generation (hypometria) as typically demonstrated by individuals with PD is directed toward achieving larger and faster sway movements during posturography training. The patient with too much force (hypermetria), as typically demonstrated by the individual with cerebellar ataxia, is directed toward decreasing sway movements progressing to holding a stable, centered posture.[162] Research evidence demonstrates the effectiveness of platform training in improving symmetrical weight distribution.[163-166]

It is important to remember that although balance retraining using posturography biofeedback does improve symmetrical standing, it does not automatically

transfer to balance skills during functional skills such as gait. Winstein et al[163] found that a reduction in standing balance asymmetry did not result in a concomitant reduction in asymmetrical limb movement patterns associated with hemiparetic locomotion. Given the specificity of training principle, this is not a surprising finding that platform training did not transfer to improved locomotion. Finally, a set of bathroom scales or limb load monitors can provide a low-tech, low-cost form of biofeedback weight information to assist patients in achieving symmetrical weight-bearing.

Strategies to Improve Safety and Reduce Fall Risk

Prevention of falls in the elderly and for the patient with balance deficiency is an important goal of therapy. Patient education and lifestyle counseling can help the patient recognize potentially dangerous situations and reduce the likelihood of falls. For example, high-risk activities likely to result in falls include turning, sit-to-stand transfers, reaching and bending over, and stair climbing. Patients should also be discouraged from clearly hazardous activities such as climbing on step stools, ladders, and chairs, or walking on slippery or icy surfaces. The education plan should stress the harmful effects of a sedentary lifestyle. Patients should be encouraged to maintain an active lifestyle, including a program of regular exercise and walking. Medications should be reviewed and those medications linked to increased risk of falls (e.g., medications that result in postural hypotension) should be addressed. A consultation with the physician for medication review may be indicated.

Compensatory training strategies can be utilized to prevent falls if normal strategies are lacking. The patient should be instructed in how to maintain an adequate BOS at all times. For example, the patient should widen BOS when turning or sitting down. If a force is expected, the patient should be instructed to widen the BOS in the direction of the expected force (e.g., leaning into the wind). If greater stability is needed, instruction should be provided in how to lower the COM (e.g., crouching down to reduce the likelihood of a fall). Greater stability can also be achieved if friction is increased between the body and the support surface. The patient should therefore be instructed to wear shoes with flat rubber soles for better gripping (e.g., athletic shoes). Assistive devices should be used improve balance when necessary. Consideration should always be given to using the least restrictive device while at the same time ensuring safety. Light touch-down support using a vertical or slant cane (used by individuals who are blind) has been shown to improve balance.[167] A fall prevention program must also address environmental factors that contribute to falls. Recommendations for reducing falls in the home environment are presented in Box 10.6.

Box 10.6 Fall Prevention Strategies: Modifying the Home Environment

- Adequate lighting is essential. Both low light and glare can be hazardous, particularly for the elderly. Glare can be reduced with translucent shades or curtains.
- Light switches should be positioned at the entrance to a room and fully accessible. Timers can ensure that lights come on routinely at dusk. Clapper devices can be used to enable the patient to turn on lights from across the room. Night-lights typically used in bathrooms or hallways do not provide enough light to ensure adequate balance.
- Carpets with loose edges should be tacked down. Scatter or throw rugs should be removed.
- Furniture that obstructs walkways should be removed or repositioned.
- Chairs should be of adequate height and firmness to assist in sit-to-stand transfers. Chairs with armrests and elevated seat heights may be required. Motorized chairs that elevate the patient into standing may be hazardous for (1) some patients who are unable to initiate active balance responses in a timely manner during initial standing and (2) those with impaired LE strength unable to maintain firm foot contact with the floor as the chair rises.
- Stairs are the site of many falls. Ensure adequate lighting. Contrast tape using bright, warm colors (red, orange, or yellow) can be used to highlight steps. Handrails are important for safety on stairs and, if not present, may need to be installed.
- Grab bars or rails reduce the incidence of falls in the bathroom. Nonskid mats or strips in the bathtub along with a tub or shower seat can also improve safety. Toilet seats can be elevated to facilitate independent use.

Interventions to Improve Coordination and Agility

Coordination is the ability to execute smooth, accurate, and controlled movements. **Agility** is the ability to perform coordinated movements combined with upright standing balance. **Ataxia** is defined as uncoordinated movement that manifests when voluntary movements are attempted, influencing gait, posture, and patterns of movement. The principal causes of ataxia are cerebellar disease or lesions (e.g., cerebellar atrophy, tumor, MS, TBI, stroke, Friedreich's ataxia, chronic alcoholism). Patients with ataxia typically demonstrate impaired synergistic actions with decomposition of movement (dyssynergia), impaired ability to judge the distance or range of movement (dysmetria), and impaired ability to perform rapid alternating movements (dysdiadochokinesia), along with intention tremor and

disturbances of posture and gait. Typical standing postural abnormalities include an exaggerated lumbar lordosis, anterior pelvic tilt, flexion at the hips, hyperextension at the knees, and weight placed more on the heels. Patients with ataxia also typically demonstrate mild decreases in strength (asthenia) and tone (hypotonia) and hypermobility. Postural instability in the patient with ataxia is associated with excessive postural sway, wide BOS, high guard hand position, handhold, and frequent loss of balance (falls). Motor learning is also typically slowed, given the inability of the cerebellum to timely and correctly utilize feedback to modulate movement. The reader is referred to Chapter 6, Examination of Coordination and Balance, for additional information.

Training activities can be used to accomplish the following:

- Improve postural stability and balance
- Improve accuracy of limb movements
- Improve function
- Improve safety awareness and compensatory strategies for effective movement control and fall prevention

Interventions to improve postural stability and balance have been previously discussed. Patients with ataxia generally benefit from the use of light resistance to slow limb and trunk movements, temporarily reducing dysmetria and tremor. This can include use of weight cuffs (ankle, wrist), elastic bands, weighted trunk vest, weighted walkers and canes, and water resistance (pool activities). PNF patterns are an appropriate focus of treatment because of the required synergistic actions of muscles. PNF resistive techniques of rhythmic stabilization, dynamic reversals or dynamic-reversal-hold, and resisted progression are the techniques of choice. The key issue for the therapist is to provide enough resistance to enhance proprioceptive loading and movement without producing debilitating fatigue. During training, movements should be kept slow and controlled; fast movements are considerably more problematic in terms of learning and performance. Complex *gross motor skills* that engage and move large segments of the body (e.g., sit-to-stand, transfers, locomotion) are particularly difficult for patients with ataxia. *Fine motor skills* that engage the small muscles of the hand (e.g., feeding, writing, ADL) are also difficult and can lead to functional dependence (e.g., inability to feed or dress). Augmented feedback in the form of biofeedback, rhythmic auditory stimulation (metronome, music), can be used to help modulate speed and focus attention. Devices that promote reciprocal movements and timing (e.g., cycle ergonometer, motorized treadmill with an overhead harness) can also be effective. To enhance motor learning, the patient should practice in a low-stimuli environment. Variable practice should only be attempted as skill development becomes apparent and at a much more gradual rate of progression. A distributed practice schedule is important because patients with ataxia can demonstrate low endurance and increased fatigue. For the patient with significant ataxia and postural instability, hands-on support and guidance may be necessary. Aids for mobility (assistive devices) may be necessary to ensure safety and prevent falls. There is limited research evidence demonstrating the effectiveness of physical therapy in improving ataxia.[168-171]

Interventions to Improve Gait and Locomotion

Most patients with impaired motor function exhibit deficits in gait and locomotion, which is a complex, higher-level motor skill. Substantial rehabilitation efforts are directed toward improving gait and locomotion to restore or improve a patient's functional mobility and independence. Walking is frequently the number one goal of patients who "want to walk" above all other considerations. Ability to ambulate or use a wheelchair independently is often a significant factor in determining discharge placements (e.g., return to home or extended care facility). To establish a realistic POC, the physical therapist must accurately analyze the patient's gait and locomotor ability. Comprehensive gait analysis is discussed in Chapter 7, Examination of Gait. The functional demands of the patient's home, community, or work environment must be considered in planning successful interventions and in predicting a patient's future status. Chapter 11, Locomotor Training, provides a comprehensive discussion of training. Wheelchair training is discussed in Chapter 20, Traumatic Spinal Cord Injury.

Relaxation Training

Patients with impaired motor function typically experience a great deal of stress resulting from loss of motor control, pain, inability to perform functional tasks previously performed with ease, and loss of control in life decisions. Sympathetic nervous system responses (fight or flight) are typically heightened. (See Chapter 5, Examination of Motor Function: Motor Control and Motor Learning, for a discussion of sympathetic and parasympathetic responses.) A goal of therapy is to promote stress reduction and relaxation. A *relaxation response* is associated with engagement of parasympathetic responses along with an increase in alpha brain waves. Positive benefits of relaxation training include the following:

- Muscle relaxation
- Lowered blood pressure
- Reduced ischemic pain
- Enhanced awareness of emotional state and memory
- Increased energy level
- Increased sense of control

Two elements are the important components in producing the relaxation response as described by

Benson:[172] quiet deep breathing and attention on a single focus (thought, word, or object). The patient initially practices while lying down and later can shift to practicing while sitting or standing comfortably. The patient is directed to breathe deeply with the diaphragm moving downward as air is drawn into the lungs. The patient inhales slowly, holds the breath for a few seconds, and then slowly exhales. The patient is also directed to concentrate on a specific focus, while disengaging from all other thoughts and distractions. Relaxation training can be used throughout the day as needed (e.g., 4- to 5-minute sessions) and can be performed individually or in small groups (e.g., before a group exercise class). Use of imagery is another technique that can redirect the patient's focus from the frustrating aspects of performance or pain. With eyes closed, the patient is asked imagine a place or experience that is deeply relaxing (e.g., a sunset at the beach) and to maintain focus on that special experience. The environment should be relaxing and quiet, with softened lights.[173] Jacobson[174] originally described progressive relaxation exercises to promote relaxation. While resting comfortably, the patient is directed to alternately clench and release various different muscle groups, moving progressively throughout the body. This technique may not be the technique of choice for patients who experience high levels of muscle tension or muscle weakness.

Augmented Interventions

Augmented interventions are appropriate for patients who demonstrate insufficient recovery and lack voluntary movement control (e.g., inability to initiate or sustain movement). An intensive hands-on approach (e.g., neurodevelopmental treatment) and neuromuscular/sensory stimulation can be used to "jumpstart" recovery and promote early movement. Biofeedback and electrical stimulation are also important adjuncts. Augmented interventions are contraindicated in patients with sufficient active movement control. The focus of rehabilitation for these patients should be active exercise and task-oriented training (see Tables 10.8 and 10.9).

Key decisions regarding the use of augmented interventions include the following:

- What movements might benefit from augmented intervention?
- What type of stimulation or modality should be used and how much?
- When should the stimulation/modality be withdrawn?
- How can it used to enhance active, task-oriented practice?

Continued use of augmented interventions long after they are needed can result in the patient becoming dependent. For example, a therapist who continually manually assists a patient's movements hears the patient remark to an aide that he or she is not helping correctly. It has to be done the way "my therapist" does it (i.e., "my therapist" syndrome). This patient is demonstrating an overreliance on the therapist for movement assistance. Augmented interventions can help the patient bridge the gap between absent or severely disordered movements and active movements. Once the patient develops independent voluntary control of movement, these treatment approaches are counterproductive.

Neurodevelopmental Treatment

Neurodevelopmental treatment (NDT) is an approach developed in the late 1940s through 1960s by Dr. Karel Bobath, an English physician, and Berta Bobath, a physiotherapist.[175,176] Their work focused on patients with neurological dysfunction (cerebral palsy and stroke). The essential problems of these patient groups were identified as a release of abnormal tone (spasticity) and abnormal postural reflexes (primitive spinal cord and brainstem reflexes) from higher-center CNS control with resulting loss of the normal postural reflex mechanism (righting, equilibrium, protective extension reactions) and normal movements. The therapist's primary focus in treatment was on specialized handling so that spastic and reflex patterns were inhibited and normal movements promoted. The rationale for this approach (hierarchical theory with top-down control) has been largely refuted by more recent studies on the nervous system.[177,178] Current NDT has realigned itself with newer theories of motor control (systems theory and a distributed model of CNS control). Many different factors are recognized as contributing to loss of motor function in patients with neurological dysfunction, including the full spectrum of sensory and motor deficits (weakness, limited ROM, impaired tone and coordination). Emphasis is on the use of both feedback and feedforward mechanisms to support postural control. Postural control is viewed as the foundation for all skill learning. Normal development in children and normal movement patterns in all patients are stressed. The patient learns to control posture and movement through a sequence of progressively more challenging postures and activities. NDT uses physical *handling techniques* and *key points of control* (e.g., shoulders, pelvis, hands, and feet) directed at supporting body segments and assisting the patient in achieving active control. Sensory stimulation (facilitation and inhibition via primarily proprioceptive and tactile inputs) is used as needed during treatment. Postural alignment and stability are facilitated while excessive tone and abnormal movements are inhibited. For example, in the patient with stroke, abnormal obligatory synergy movements are restricted while out-of-synergy movements are facilitated. Activities are selected that are functionally relevant and varied in terms of difficulty and environmental context. Compensatory training strategies (use of the less involved segments) are avoided. Carryover is promoted through a strong emphasis on patient, family, and caregiver education. NDT is taught today in recognized training courses.[179] Recent literature on the effectiveness of the

Bobath approach to stroke rehabilitation has not revealed any superiority of this approach over other approaches. However, serious methodological shortcomings of the studies reviewed exist, emphasizing the need for further high-quality trials.[180-182]

Neuromuscular Facilitation

The term *neuromuscular facilitation* refers to the facilitation, activation, or inhibition of muscle contraction and motor responses The term *facilitation* refers to the enhanced capacity to initiate a movement response through increased neuronal activity and altered synaptic potential. An applied stimulus may lower the synaptic threshold of the alpha motor neuron but may not be sufficient to produce an observable movement response. *Activation,* on the other hand, refers to the actual production of a movement response and implies reaching a critical threshold level for neuronal firing. *Inhibition* refers to the decreased capacity to initiate a movement response through altered synaptic potential. The synaptic threshold is raised, making it more difficult for the neuron to fire and produce movement. The combination of spinal and supraspinal inputs acting on the alpha motor neuron (final common pathway) will determine whether a muscle response is facilitated, activated, or inhibited. Table 10.8 lists commonly used neuromuscular facilitation techniques.

Table 10.8 Neuromuscular Facilitation Techniques

Stimulus	Response	Comments
Resistance: applied manually, using body position/gravity, or mechanically	Facilitates both intrafusal and extrafusal muscle contraction; hypertrophies extrafusal muscle fibers; enhances kinesthetic awareness (muscle spindle)	With very weak muscles, use light resistance; isometric and eccentric contractions before concentric. Maximal resistance can produce overflow from strong to weak muscles within the same synergistic pattern or to contralateral extremities.
Quick stretch to agonist	Facilitates both intrafusal and extrafusal agonist muscle contraction (*stretch reflex*)	Optimally applied in the lengthened range. A low-threshold response, relatively short-lived; can add resistance to maintain contraction.
Tapping/repeated quick stretch over tendon or muscle belly	Facilitates both intrafusal and extrafusal agonist muscle contraction (*stretch reflex*)	Tapping over muscle belly produces a weaker response than over the tendon. Tapping over a muscle is used to enhance holding in a weight-bearing position.
Prolonged stretch: slow, maintained stretch, applied at maximum available lengthened range	Inhibits or dampens muscle contraction and tone due to peripheral reflex effects (*stretch-protection reflex*)	Positioning; inhibitory splinting, casting; mechanical low-load weights using traction
Joint approximation: compression of joint surfaces, using manual pressure or position/gravity; weighted vest or belt	Facilitates postural extensors and stabilizing responses (co-contraction); enhances joint awareness (joint receptors)	Approximation applied to top of shoulders or pelvis in upright weight-bearing positions facilities postural extensors and stability (e.g., sitting, kneeling, or standing). Used in PNF extensor extremity patterns, pushing actions.
Joint traction: manual distraction of joints; wrist and ankle cuffs	Facilitates joint motion; enhances joint awareness (joint receptors)	Joint mobilization uses slow, sustained traction to improve mobility, relieve muscle spasm, and reduce pain. Used in PNF flexor extremity patterns, pulling actions.

Several general guidelines are important to consider. First, facilitative techniques can be *additive*. For example, several inputs applied simultaneously, such as quick stretch, resistance, and verbal cues, are commonly combined during practice of a PNF pattern. These stimuli collectively can produce the desired motor response, whereas use of a single stimulus may not. This demonstrates the property of *spatial summation* within the CNS. *Repeated stimulation* (e.g., tapping) may also produce the desired motor response owing to *temporal summation* within the CNS, whereas a single stimulus does not. Thus, repeated stretch is used to ensure that the patient with a weak muscle is able to move from the lengthened to the shortened range. Sensory receptors vary in their adaptation over time. Generally, they can be divided into two categories, slow- and fast-adapting receptors. In treatment, fast-adapting, phasic receptors such as touch receptors and phasic Ia muscle spindle endings are generally effective in initiating and shaping dynamic movements, whereas slow-adapting, tonic receptors such as joint receptors, GTOs, and static II muscle spindle endings are effective in monitoring and regulating postural responses. The response to stimulation or inhibition is unique to each patient and dependent on a number of different factors, including level of intactness of the CNS, arousal, and the specific level of activity of the motor neurons in question. For example, a patient who is depressed and hypoactive may require a larger amount of stimulation to achieve the desired response. Stimulation is generally contraindicated for the patient with hyperactivity and high arousal. For this patient, inhibition/relaxation techniques are indicated. The intensity, duration, and frequency of simulation need to be adjusted to meet individual patient needs. Unpredicted responses can result from inappropriate application of techniques. For example, stretch applied to a spastic muscle may increase spasticity and negatively affect voluntary movement. Facilitation techniques are *not* appropriate for patients who demonstrate adequate voluntary control. They should be viewed primarily as a temporary bridge to voluntary movement control.

Sensory Stimulation Techniques

The term *sensory stimulation* refers to the structured presentation of stimuli to (1) improve attention and arousal levels and (2) enhance sensory selection and discrimination. Effects are immediate and specific to the current state of the nervous system. Activity practice using inherent or naturally occurring sensory inputs is necessary for meaningful and lasting functional change to occur. Patients with deficits in sensory function exhibit variable sensory and perceptual impairments. For example, decreased sensitivity may be evident in some older adults and in some patients with neurological conditions such as stroke or TBI. Table 10.9 lists commonly used sensory stimulation techniques.

Several general guidelines are important in using sensory stimulation. Use of appropriate intensities is important to ensure that desired responses are obtained. Excess stimulation can produce unwanted responses, including generalized arousal and sympathetic fight or flight reactions. Sensory receptors adapt over time. Certain body segments such as the face, palms of the hands, and soles of the feet demonstrate both high concentrations of tactile receptors and increased representation in the sensory cortex. These areas are highly responsive to stimulation and are closely linked to both protective and exploratory functions.

Alterations in tactile, proprioceptive, visual, or vestibular systems can affect a patient's ability to move and learn new activities. Deafferentation in animals and in humans is associated with nonuse of a limb, although gross movements are possible under forced situations. Motor learning of new movements is impaired. The therapist should maintain focus on forced training of sensory-deficient limbs even though the patient may have little interest in moving the limb. The movements obtained should not be expected to be normal because significant deficits have been noted in fine motor control in deafferentated limbs.

Sensory stimulation and retraining have been used to improve sensory function in patients with stroke-related impairments.[183-186] Interventions include sensory reeducation, tactile kinesthetic guiding, repetitive sensory practice, and desensitization. The patient is repeatedly exposed to sensory experiences and practices sensory identification tasks (e.g., numbers, letters drawn on the hand or arm), discrimination tasks (e.g., detecting size, weight, and texture of objects placed in the hand), or passive-assisted drawing using a pencil. Intermittent pneumatic compression with an automatic intermittent pattern and electrical stimulation has also been used. The tasks were alternated between the more affected and less affected hands. Outcome measures included testing of sensory modalities (e.g., light touch temperature, two-point discrimination, sustained pressure, stereognosis, kinesthesia, and so forth) and upper limb functional tests (e.g., Motor Assessment Scale, Motor Activity Log, Frenchay Activities Index). In a systematic review of the literature, Doyle et al[185] found insufficient evidence to reach conclusions on the effectiveness of any intervention for sensory impairment of the UE. Limited preliminary evidence was found in support of using mirror therapy for improving detection of light touch, pressure, and temperature pain; thermal stimulation

Table 10.9 Sensory Stimulation Techniques

Stimulus	Response	Comments
Maintained pressure: firm manual pressure to midline back, abdomen; mechanical pressure via cones, pads	Calming effect, generalized inhibition, decreased fight or flight responses; desensitizes skin	Useful with patients with agitation and high arousal (e.g., the patient with TBI). Can be combined with other relaxation techniques (deep breathing, imagery, quiet environment). Also useful for patients with hypersensitivity (e.g., the patient with tactile defensiveness).
Slow, repetitive stroking: applied to midline back	Calming effect, generalized inhibition, decreased fight or flight responses	Performed while patient is prone or in supported sitting (head and arms resting on table top). Can use massage lubricant; stroke on either side of the spine; applied for 3–5 min. May be contraindicated with very hairy surface.
Light touch: brisk, quick stroking	Facilitates muscle; can elicit protection/flexor withdrawal response	Low threshold response, accommodates rapidly. Can be used to initially mobilize patients with low response levels (e.g., the patient with TBI who is minimally responsive).
Neutral warmth: retention of body heat through body wraps (Ace wraps, towel wraps, snug-fitting clothing gloves, socks, tights); air splints; tepid bath	Calming effect, generalized inhibition, decreased fight or flight responses	Useful for patients with high arousal or increased sympathetic activity. Overheating should be avoided, may produce rebound effects.
Prolonged cooling: immersion in cold water; ice wraps, ice massage; cooling suit	Decreases neural and muscle spindle firing Provides inhibition of muscles and painful muscle spasm Decreases metabolic rate of tissues	Monitor effects carefully: can produce sympathetic arousal, withdrawal or fight-or-flight responses. *Contraindicated* in patients with sensory deficits, generalized arousal, autonomic instability, and vascular problems.
Slow vestibular stimulation: constant, repetitive rocking; manually assisted in side-lying or sitting; mechanical (rocking chair); therapy ball; hammock	Calming effect, generalized inhibition, decreased fight or flight responses	Useful with patients who are hypertonic, hyperactive, or who demonstrate high arousal or tactile defensiveness (e.g., the patient with TBI who is agitated).
Rapid vestibular stimulation: rapid movements, fast spinning in a chair, mesh net	Heightens postural responses, movements	Useful for patients with hypotonia (e.g., an individual with Down syndrome); patients with sensory integrative dysfunction (e.g., a child with hyperactivity); patients with bradykinesia (e.g., a patient with PD) Can activate sympathetic arousal responses.

for improving rate of recovery of sensation; and intermittent pneumatic compression intervention for improving tactile and kinesthetic sensations.[185] Schabrun and Hillier[186] also found some evidence to suggest that electrical stimulation can improve sensory hand function and dexterity. While some techniques show promise, more quality research is needed. Continued practice with functionally relevant tasks is necessary to maintain the positive effects of any sensory retraining program.

Biofeedback

For patients with severe motor weakness, electromyographic biofeedback (EMG-BFB) can be used to assist the patient in regaining neuromuscular control. With careful electrode placement, it provides an accurate indication of electrical activity associated with muscular effort. It does not, however, provide an accurate indication of force of contraction. Surface electromyography (SEMG) electrodes are commonly used for recording. The signal is amplified and converted in audio and/or visual form, providing useful information about muscular performance to the patient. Patients who exhibit weak (trace, poor, or fair) muscle grades or deficient sensory feedback systems will benefit the most. Biofeedback has been used to increase the contraction of a muscle, train voluntary inhibition of muscle spasm and decrease muscle guarding.[187]

Woodford et al. in a Cochrane Database Systematic Review of the effects of EMG-BFB for motor function recovery following stroke found evidence from a small number of individual studies to suggest that EMG-BFB plus standard physiotherapy produced improvements in motor power, functional recovery and gait quality when compared to standard physiotherapy alone.[188] The researchers concluded that the results are limited because the trials were small, generally poorly designed, and utilized varying outcome measures. Additional research and meta-analysis can be found by reviewing the work of Amagan et all[189,] Basmjian[190], Gantz et al[191], Hiraoka[192], Moreland et al[193] and Schleenbaker and Mainous[194], EMG-BFB has also been shown to improve motor function following incomplete SCI.[195] The therapist must carefully structure the use of biofeedback with practice of desired functional movement patterns. External feedback must be gradually reduced in order to foster use of intrinsic feedback mechanisms and active movements as recovery progresses.

Neuromuscular Electrical Stimulation

Neuromuscular electrical stimulation (NMES) is an effective modality to stimulate contraction in very weak muscles and improve motor function. Electrodes are placed directly over the muscle to be stimulated. Contraction is elicited by depolarizing motor neurons, with larger motor units and a greater number of Type II fibers firing first. The motor units will continue to fire until the stimulus stops. NMES can be used to reeducate muscle, improve ROM, decrease edema, and treat disuse atrophy. It is effective in reducing spasticity with stimulation of the weak antagonist. Applications to the tibialis anterior muscle or to the common peroneal nerve have been shown to reduce spasticity in the plantarflexor muscles and improve dorsiflexor function.[196] Electrical stimulation in patients with stroke has been shown to reduce flexor tone and posturing of the hand and improve functional grasp,[197-200] and reduce shoulder subluxation.[201]

Functional electrical stimulation (FES) uses a microprocessor to recruit muscles in a programmed synergistic sequence for the purposes of improving functional movements.[187] Following stroke, FES of the peroneal nerve has been shown to be effective in assisting dorsiflexion (drop foot) and improving walking.[202-205] It has been effectively combined with BWS and a treadmill.[206,207] Patients with incomplete SCI have been stimulated to exercise on bicycle ergometers (FES ergometry) and walk.[208,209]

Compensatory Interventions

Compensatory training strategies allow the patient to perform a task using alternate limbs and/or alternate movement patterns. Thus, the patient is able to perform an old task in a new manner. For example, the patient with hemiplegia dresses using the less-affected UE and increased trunk movement; the patient with paraplegia regains functional rolling, transfers, and wheelchair locomotion using the UEs. *Adaptive compensation* is the result of alternative or new movement patterns. *Substitutive compensation* is the result of using different parts of the body, effectors, to accomplish the task.[210] During training, the patient is made aware of movement deficiencies (cognitive awareness is developed). Changes are then made in the patient's overall approach to functional tasks. Alternate ways to accomplish the task are suggested, simplified, and adopted. The patient practices and relearns the task using the new pattern. The patient then practices the new pattern in the environment in which the function is expected to occur. Energy conservation techniques are incorporated into practice to ensure that the patient can successfully complete all daily tasks. Adaptation of the environment is also used to facilitate relearning of skills, ease of movement, and optimal performance. For example, the patient with unilateral neglect is assisted in dressing by color-coding the shoes (red tape on the left shoe, yellow tape on the right shoe). The wheelchair brake toggle is extended and color-coded to allow easy identification by the patient.

One of the major criticisms of this approach is that the focus on less-involved segments may suppress recovery for certain patients and contribute to *learned nonuse* of impaired segments. For example, the patient with stroke fails to learn to use the more involved extremities. Compensatory training should not become the focus of treatment in patients with potential for recovery. It is important to remember that given appropriate training, motor improvements can continue well into the chronic stages (e.g., patients with stroke). Compensatory training can also lead to development of *splinter skills,* which are skills acquired in a manner inconsistent with skills the individual already possesses. Splinter skills cannot be easily generalized to other task variations or to other environments.

A compensatory training approach may be the only realistic approach possible when recovery is limited or the patient presents with significant impairments and functional limitations with little or no expectation for

additional recovery. Examples include the patient with complete SCI or the patient recovering from stroke with severe sensorimotor deficits and extensive co-morbidities (e.g., severe cardiac and respiratory compromise or memory deficits associated with Alzheimer's disease). The patient in the latter example is severely limited in the ability to actively participate in rehabilitation and to relearn motor skills.

Patient/Client-Related Instruction

Patient/client-related instruction is an important component of any rehabilitation plan of care. Components include instruction and training of patients/clients about the following:

- Current condition (pathology/pathophysiology, impairments, activity limitations, and participation restrictions)
- Accommodations to deficits in communication, cognitive, behavioral, or emotional impairments
- Anticipated goals and expected outcomes
- Strategies and preferred interventions to enhance performance and function
- Risk factors for pathology/pathophysiology and prevention of additional impairments, functional limitations, and participation restrictions
- Strategies and preferred interventions to enhance health, wellness, and fitness

Patients with deficits in motor function need to recognize the importance of repetitive practice both in-therapy and out-of-therapy to bring about meaningful recovery. Relevant tools to ensure high levels of practice include a behavioral contract, a caregiver contract, a daily schedule, an activity log or home diary, and a home skill assignment. These tools serve to focus the patient on the POC and ensure full, active participation in reaching successful outcomes. Patient skills in self-evaluation, problem solving, and decision making are promoted to foster independence. This empowerment serves to improve quality of life and prepare the patient for the life-long adjustments needed when living with a disability. If patient independence is not possible because of the complexity of deficits and limitations in recovery, education of family, friends, and caregivers assumes paramount importance.

SUMMARY

This chapter has outlined a conceptual framework for rehabilitation of the patient with deficits in motor function based on an understanding of the normal processes of motor control, motor learning, and recovery. Clinical decision making is based on a thorough examination of the patient's deficits in terms of impairments, activity limitations, and participation restrictions. The unique problems of each patient require that the therapist also recognize a number of interrelated factors, including individual needs and changing status, motivation, goals, concerns, and potential for independent function. The diversity of problems experienced by patients with disordered motor function negates the idea that any one intervention or group of interventions could be successful for all patients. Broad categories of interventions have been presented, with a major emphasis on training functional skills and promoting motor learning. Interventions also need to promote adaptability of skills for function in real-world environments. In selecting interventions, the therapist must consider those that have the greatest chance of success. The choice of interventions must also take into consideration other factors, including ability to deliver care, cost-effectiveness in terms of length of stay and number of allotted physical therapy visits, age of the patient, co-morbidities, social support, and potential discharge placement. Carefully planned and structured education empowers the patient and ensures skills for life-long learning and adjustment.

Questions for Review

1. Differentiate between the terms *motor control* and *motor learning*. How can impairments in motor control be distinguished from those of motor learning?
2. Differentiate between the three stages of motor learning. How do training strategies differ during each stage?
3. Define *neuroplasticity*. What are some of the mechanisms of neuroplasticity (changes in brain function) seen during recovery of function?
4. Discuss feedback strategies designed to improve retention and generalizability. How do they differ from strategies that optimize initial learning and performance?
5. Define *function-induced recovery*. Give an example of an intervention that could be used to promote function-induced recovery for the patient with incomplete paraplegia.

6. Identify three augmented interventions that can be used to calm the patient with traumatic brain injury who is demonstrating high arousal and agitated behavior.
7. Define *compensatory training*. Identify two compensatory training strategies for the patient with left hemiplegia and severe unilateral neglect.

CASE STUDY

HISTORY

The patient is a 36-year-old man who sustained a traumatic brain injury following a motorcycle accident. On admission to a local hospital, the patient was found to have a left frontal laceration with an underlying linear skull fracture. Computed tomography scan revealed edema, a right basal ganglia contusion, and a left frontal contusion. The patient was comatose on admission. His acute hospital course was complicated by increased intracranial pressure and severe spasticity. A gastric tube was inserted.

The patient's neurological status did not substantially improve at the acute hospital. He was transferred to a rehabilitation hospital 4 weeks after injury for intensive rehabilitation. He had a brief readmission to the acute hospital during his sixth week after injury for stabilization of acute hypothermia and hypothyroidism. He was then returned to the rehabilitation facility for continued intensive rehabilitation. His medications consisted of Tegretol (200 mg po qid), multivitamins, and Colace.

PART I: PHYSICAL THERAPY EXAMINATION FINDINGS (INITIAL ADMISSION TO REHAB, 4 WEEKS AFTER INJURY)

Behavior/cognition: He is functioning at Rancho Levels of Cognitive Functioning (RLOCF) Level V Confused-Inappropriate. The patient is able to respond to simple commands fairly consistently. With increased complexity of commands or lack of any external structure, responses are nonpurposeful, random, or fragmented. Highly distractible and lacks ability to focus on a specific task. Memory is severely impaired; often shows inappropriate use of objects. May perform previously learned tasks with structure but is unable to learn new information. Easily frustrated and responds with disinhibited behaviors (name calling and swearing).

Language–communication: Unable to examine.

Social: Married with no children. Wife is a registered nurse and very supportive of her husband.

Vital signs: Heart rate 60 beats per minute; blood pressure 122/70 mm Hg; respiratory rate 14 breaths per minute; O_2 saturation level is 92.

Sensation: Localizes to pinprick with withdrawal.

Passive range of motion:

- Right upper extremity (RUE) is limited in elbow ROM (0° to 70°); left upper extremity (LUE) elbow ROM is 10° to 100°.
- Both lower extremities (BLEs) are within normal limits except for ankle dorsiflexion 0° to 5° on R and 0° to 10° on L.

Motor Function

Tone (Modified Ashworth Scale grades [M-AS]): Severe flexor tone and spasms of the trunk that result in the patient moving in bed from a supine to a left-side-lying, curled-up (fetal) position, M-AS = 4.

- RUE extensor tone, M-AS = 3
- Right lower extremity (RLE) extensor tone, M-AS = 3
- LUE flexor tone, M-AS = 3
- Left lower extremity (LLE) extensor tone, M-AS = 2

Reflexes:

- Frequent asymmetrical tonic neck reflex posturing with head rotated to the right
- Flexor withdrawal reflexes bilaterally in response to pain (delayed on the left with decreased intensity of response)
- Positive support reflex on the left
- Hyperactive deep tendon reflexes throughout
- At times, the lower extremities scissor (extend and adduct), especially when upper body flexor tone increases

Voluntary movements:

- The patient is agitated with restless movements and is frequently diaphoretic.
- Limited head or trunk control, dependent sitting.
- Movement of RUE is spontaneous, purposeful at times, and out-of-synergy.

- Movement of the RLE is spontaneous, nonpurposeful, and out-of-synergy.
- LUE: no active movement.
- LLE movement: demonstrates abnormal obligatory extensor synergy pattern.

Coordination: Unable to assess.

Balance—sitting:

Static: Poor; requires handhold support and moderate assistance; demonstrates sacral sitting with posterior tilt of the pelvis

Dynamic: Poor; unable to accept challenge or move without loss of balance

Balance—standing:

Static: Poor; requires maximal assist of two persons to stand in the parallel bars with splint on LLE

Dynamic: Unable to weight shift or step

- **Gait and locomotion** (wheelchair [w/c]): Unable

Skin: Multiple healed lacerations on the knees and calves and pressure sores bilaterally on the lateral malleoli and calcanei from bivalve positioning splints.

Bladder and bowel: Incontinent of bowel and bladder, and has external catheter in place.

Functional activities: Max assistance in all ADL, FIM level 2.

PART I (QUESTIONS 1–3)

1. Identify and prioritize the problems in motor function presented in this case in terms of impairments and activity limitations based on initial admission data (4 weeks after injury).
2. Identify the goals of physical therapy intervention for this patient at this point in his recovery (initial admission).
3. Identify the motor learning strategies and two treatment interventions appropriate for this patient at this point in his recovery (initial admission).

PART II: REEXAMINATION 12 WEEKS AFTER INJURY

Behavior/cognition: He is functioning at Rancho Levels of Cognitive Functioning (RLOCF) Level VII Automatic-Appropriate. He appears appropriate and oriented within the hospital setting; goes through daily routine automatically, but frequently robot-like. Shows minimal to no confusion and has shallow recall of activities. Shows carryover for new learning but at a decreased rate. With structure is able to initiate social and recreational activities. Judgment remains impaired.

Language–communication: The patient is dysarthric; speech is usually intelligible but difficult to understand and delayed in onset. Auditory comprehension is good.

Vital signs: Within normal limits (WNL).

Skin: Lacerations are healed.

Sensation:

- **Vision and hearing** are WNL.
- **LUE:** Absent sensation.
- **LLE:** Impaired sensation, decreased proprioception.
- **RUE and RLE:** Intact

Range of motion:

- **RUE:** elbow ROM 0° to 90°; LUE: elbow ROM 5° to 110°
- **BLEs:** WNL except for ankle dorsiflexion bilaterally of 0° to 15°

Motor function

Tone (modified Ashworth Scale grades, M-AS):

Trunk: Tone in the trunk is WNL except for occasional flexor spasms

- **RUE and RLE:** Extensor tone, M-AS = 1
- **LUE:** Flexor tone, M-AS = 2
- **LLE:** Extensor tone, M-AS = 1

Reflexes:

- Exhibits strong associated reactions in the LUE and increased flexor posturing with stressful activities.

Voluntary movements:

- **RUE and RLE:** Demonstrates purposeful, full, isolated motions through available ROM against gravity. Strength is grossly F+ in the RUE and RLE.
- **LUE:** Limited voluntary movement; extensor synergy predominates.
- **LLE:** Movement is purposeful; strength is grossly F.
- **Head and trunk:** Movement is functional and strength is grossly F.

Coordination:
Exhibits moderate ataxia in trunk.
Demonstrates moderate impairment in finger-to-nose and toe-tapping test in RUE; LUE not tested.
Balance—sitting:
Static: Good, able to maintain balance without handhold support, limited postural sway
Dynamic: Good, able to accept moderate challenge and move without loss of balance
Balance—standing:
Static: Fair, requires handhold support to stand in the parallel bars, occasional minimal assistance
Dynamic: Fair, accepts minimal challenge; able to balance while turning head/trunk
Functional Activities:
- **Bed mobility:** Rolls to right and left with supervision (S)
- **Supine-to-sit and sit-to-stand:** Moderate assistance × 1, FIM level 3
- **Transfers:** Moderate assistance × 1 in stand-pivot transfers, FIM level 3
- **Wheelchair locomotion:** Maneuvers manual wheelchair with close S for safety, FIM level 5
- **Gait:** Walks in parallel bars 10 ft with moderate assistance × 1, FIM level 3
- **Dressing and grooming:** Minimal assistance × 1, FIM level 4

PART II (QUESTIONS 4–6)

4. Identify and prioritize this patient's motor function problems in terms of impairments and activity limitations (12 weeks after injury).
5. Identify the goals and outcomes of physical therapy intervention for this patient at this point in his recovery.
6. Identify the motor learning strategies and two treatment interventions appropriate for this patient at this point in his recovery.

Chapter 11

Locomotor Training

George D. Fulk, PT, PhD
Thomas J. Schmitz, PT, PhD

LEARNING OBJECTIVES

1. Discuss the major elements of physical therapy intervention for patients with locomotor limitations.
2. Describe the locomotor training principles that guide selection of interventions.
3. Differentiate between advantages and limitations of using parallel bars for locomotor training.
4. Explain the rationale for each component of indoor overground locomotor training.
5. Identify strategies to vary locomotor task demands.
6. Discuss the rationale for locomotor training using body weight support and a treadmill.
7. Compare and contrast locomotor training using body weight support and a treadmill with other locomotor training strategies.
8. Describe strategies for varying task and environmental demands during locomotor training.
9. Describe training activities used for locomotion overground in the community.
10. Using the case study example, apply clinical decision making skills within the context of locomotor training.

EMERGING INTERVENTION STRATEGIES *457*

CLINICAL DECISION MAKING *457*

SUMMARY *458*

The recovery or improvement of walking ability is a primary goal for people with many different health conditions who seek the services of a physical therapist.[1-3] Initially, approximately two-thirds of people who experience a stroke cannot ambulate or require assistance to walk.[4] Three months later, one-third of those with a stroke still require some level of assistance to walk.[4] Approximately 70% of people with a spinal cord injury (SCI) cannot walk 1 year after their injury.[5] People with Parkinson's disease (PD) often have impaired postural control and limited walking ability.[6] Individuals with low back pain, lower extremity (LE) amputations, multiple sclerosis (MS), and a host of other health conditions all may present with impaired locomotion. The *Guide to Physical Therapist Practice* includes elements of gait and locomotor training (LT) as an intervention category within each of the four preferred practice patterns.[7]

The recovery of walking ability is such an important goal because people who can walk independently are more likely to be able to participate in expected social roles and desired recreational activities, have a higher quality of life, and have improved health status.[2,3,6,8,9]

The major requirements for successful walking include the following:

- Support of body mass by the LEs
- Production of locomotor rhythm

- Dynamic postural control of the moving body
- Propulsion of the body in the intended direction
- Adaptability of the locomotor response to changing environmental and task demands

These requirements should be performed in an energy-efficient manner so as to minimize stress on the individual.

Recent advances in basic science research using animal models of different neurological health conditions provide a strong foundation for physical therapy interventions designed to improve locomotor capability in different patient populations. Research using an SCI cat model has found that spinalized cats trained by suspension in a harness over a treadmill (TM) and provided with manual assistance to step can learn to walk/step on the TM without supraspinal input.[10-12] Studies incorporating an animal model of stroke indicate that skilled, repetitive, task-oriented training can lead to beneficial neural plastic changes that are associated with improved mobility and reaching.[13-17] Exercise in animal models of PD have also demonstrated beneficial effects.[18-20]

Taken together these findings from basic science research provide important insight and guidance for physical therapists. Clinical researchers have used these findings to develop physical therapy interventions designed to improve locomotor ability in a variety of patient populations. Locomotor training using a body weight support (BWS) and a TM system,[21-24] task-oriented circuit training,[24,28-33] TM training and task-specific strengthening exercises[24,30,31] are some of the interventions developed based on translating findings from basic science research to clinical practice. Although the specific interventions strategies vary, they share common principles.[75] These LT principles guide selection of interventions that are:

- Task oriented to the specific task of walking.
- Goal directed and meaningful to the patient.
- Shaped and progressed to maximally challenge the patient's capabilities.
- Performed multiple times (high number of repetitions).

The application of these principles to the specific LT interventions will vary depending on a variety of factors, including patient health condition, prognosis, patient goals, body structure/function impairments, and weight-bearing status. Evaluation of gait analysis data (see Chapter 7, Examination of Gait) can assist the therapist in developing an appropriate, task-oriented, goal-directed plan of care (POC) to address the limitations in walking ability. The LT interventions and principles can be implemented in and progressed through different environments: parallel bars, BWS and TM system, overground with and without a BWS system, and in the community. Interventions that target improved strength, transferring from sitting to/from standing, and standing balance are complementary activities often performed in conjunction with LT because these activities are functionally related to the task of walking.

Box 11.1 provides an overview of complementary interventions to LT and specific LT strategies. It should be noted that the interventions in their entirety are

Box 11.1 Overview of Complementary Interventions and Specific Locomotor Training Strategies

I. Interventions Complementary to Locomotor Training

Complementary activities focus on improved:
- Strength
- Sit to/from stand transfers
- Standing balance

II. Locomotor Training

A. Parallel Bars

Instruction and training in:
- Sit-to-stand and reverse with and/or without assistive device
- Static and dynamic standing balance with and/or without assistive device
- Use of appropriate gait pattern with and/or without assistive device while progressing forward and turning (because of limited space, it may not be possible to use an assistive device in standard parallel bars)
- Stepping forward, backward, sideward, and turning

B. Overground Indoors

Instruction and training in:
- Appropriate gait pattern and assistive device use
- Stepping forward, backward, and sideward

Continued

Box 11.1 Overview of Complementary Interventions and Specific Locomotor Training Strategies—cont'd

- Cross-stepping and braiding
- Walking over and around objects (i.e., obstacle course)
- Crossing thresholds and entering/exiting through doorways
- Variations in locomotor task demands (e.g., altering speed, scanning for objects, dual-task activity)
- Stairs
- Falling and transitioning from the floor to standing
- Running

C. Overground Community

Instruction and training in:

- Curb climbing, negotiating ramps, stairs, and sloped surfaces
- Walking over even and uneven terrain
- Walking within imposed timing requirements (e.g., crossing at a stoplight, on/off elevators, escalators)
- Walking for long distances
- Walking at varying speeds, walk using a rhythmic timing device (e.g. metronome)
- Walking while scanning for objects in the environment
- Dual-task training while walking (cognitive and/or motor dual tasks)
- Walking in open environment with distracters
- Entering/exiting transportation vehicles
- Running

D. Body Weight Support/Treadmill

Instruction and training in:

- Stepping on treadmill using body weight support (BWS) with maximally tolerated lower extremity load bearing progressing to no BWS
- Reciprocal stepping pattern with manual assistance at lower extremities and/or trunk with normal or near normal lower extremity and trunk/pelvis kinematics progressing to no manual assistance
- Production of rhythmic stepping pattern with arm swing and minimal to no weight-bearing through the upper extremities
- Progress stepping speeds to normative values based on age
- Walk forward, sideward, and backward
- Strategies to minimize abnormal/compensatory movement patterns
- Strategies to improve aerobic capacity

E. Body Weight Support/Overground

Instruction and training in:

- Walking overground with maximally tolerated lower extremity load bearing progressing to no BWS
- Use of assistive device (if indicated) for walking on level surfaces
- Reciprocal stepping pattern with manual assistance at pelvis with normal or near normal lower extremity and trunk/pelvis kinematics progressing to no manual assistance
- Production of rhythmical, coordinated stepping pattern with arm swing and minimal weight-bearing through the upper extremities
- Strategies to minimize abnormal/compensatory movement patterns
- Strategies to maintain/regain balance when perturbed

F. Assistive Devices (see Appendix 11.A)

Instruction and training in:

- Function and purpose of assistive device
- Sit-to-stand and reverse with assistive device
- Static and dynamic standing balance with assistive device
- Gait pattern
- Use of assistive device and appropriate gait pattern indoor overground and overground in community

likely not indicated for each patient. Depending on individual patient need, multiple interventions may be accomplished concurrently, a more rapid progression may be used, or portions may be completely omitted. While performing LT within the different environments (e.g., parallel bars, indoor, community), principles of motor learning (see Chapter 10, Strategies to Improve Motor Function), strength training, and aerobic conditioning should be incorporated to facilitate learning and maximize walking ability.

LOCOMOTOR TRAINING COMPLEMENTARY INTERVENTIONS

The selection of interventions complementary to LT is based on examination findings (e.g., identified impairments and activity limitations) and typically includes strategies to improve the following:

- Strength
- Sit to/from stand transfers
- Standing balance

Strength

A key strategy for improving strength is to combine strength training with task-specific practice. This requires repetitive practice of tasks that are *specific to the outcome* (i.e., locomotion) and *meaningful to the patient* in terms of function. Although muscle-specific strengthening (e.g., progressive resistance, isokinetic equipment) may also be indicated and complementary to LT, using task-specific practice provides optimum transfer of strength gains to functional skills.

Inherent to task-specific strength training is resistance provided by body weight or limb segment weight; this weight may be augmented by the addition of external resistance (e.g., resistive bands, pool activities, cuff weights). Task selection is based on elements of the whole task, including the body segments involved; the required type, speed, and magnitude of contractions; and the degrees of freedom needed for the desired outcome. The goal is progression to whole task training. Activities typically begin with individual joints or body segments with progression to whole body movements.

For example, strengthening of LE extensor muscles is often a complementary activity to LT for some patient groups (e.g., stroke, Parkinson's disease). Task-specific functional activities that focus on extensor control might include partial wall squats, step-ups and step-downs, sit-to-stand transfers, and first bilateral, then single-limb heel rises to strengthen ankle plantarflexors. Another example is strengthening of hip abductors and adductors using side-stepping, cross-stepping, and braiding (manual contact or resistive bands can be used for resistance). Task-specific strengthening is important because it requires interplay of contraction types similar to the demands of walking.

Sit to/From Stand Transfers

Practice to improve transfers focuses initially on sitting with symmetrical weight-bearing, an erect posture on anterior portion of chair with neutral or slight anterior tilt of pelvis, and feet behind knees (allows dorsiflexors to assist forward rotation of legs over feet); emphasis is also placed on coordinated muscle responses and on appropriate timing. The reader is referred to the work of Fulk[25] for a thorough discussion of interventions to improve transfers.

To accomplish a sit-to-stand transfer, the patient must first actively flex the trunk and hips and may use momentum to shift the body mass forward. The patient's arms may be folded across chest, held forward with hands clasped, or hands placed on the chair armrests. (*Note*: Using the hands on a support surface should not be substituted for effective forward translation of body weight.) A higher, firm, seating surface (e.g., high-low treatment table) may be used initially for patients with weakness, and the height gradually reduced. Asking the patient to focus on a visual target can promote upper trunk extension during forward weight shift and enhance postural alignment and vertical orientation. As the patient moves toward the extension phase of the transfer, greater demands are placed on the hip and knee extensors to come to vertical. Tactile and proprioceptive cues can be used to promote contraction of extensor muscles.

To return to the seated position from standing, the motion is similar to that used for sit-to-stand transitions, but executed in reverse order. However, the timing and types of contractions are different. The focus of practice is on eccentric control as the body mass moves downward and backward. Eccentric contractions of the LE extensor muscles control lowering as the hips, knees, and ankles flex.

Initially, transfers may be performed slowly. With repetitive practice, focus can be placed on increasing speed of movement and performance of sit-to-stand and reverse without pausing. Practice should also include a variety of seating surfaces and heights, performance in open environments, and a gradual reduction in verbal cues.

Standing Balance

Adequate standing balance and control are integral components of locomotion. As continuous postural adjustments are needed during locomotion, intervention strategies to improve balance should be selected that impose similar demands. Locomotion requires static postural control (stability) to maintain standing and dynamic postural control (controlled mobility) to control movements within standing (e.g., weight shifting,

LE stepping). Examples of interventions to improve balance follow; balance interventions are also discussed in Chapter 10, Strategies to Improve Motor Function, and in the work of O'Sullivan.[26]

Initial standing activities may require touch-down support of the hands and can be performed in the parallel bars, between two treatment tables, or next to a wall or corner of a room (corner standing). The patient is first directed to stand tall and hold steady in the posture. Techniques such as quick stretch or approximation can be used to enhance postural stabilizing muscle contractions. Enhanced postural awareness can be achieved with limits of stability (LOS) training during weight shifting and in response to anticipated and reactive perturbations. Active exercise to improve standing may include heel-rises, toe-offs, back-kicks and sidekicks, hip and knee flexion, hip flexion with knee extension, partial wall squats, and marching in place. These exercises can also be performed in a pool. Adding ankle cuff weights, altering the base of support (BOS) (feet apart, together, tandem stance), upper extremity (UE) position (e.g., arms overhead, reaching), and support surface (e.g., inflated disc, wobble board) can all impose greater challenge.

Engagement of ankle and hip strategies can be promoted using incremental shifts in center of mass (COM) alignment and postural sway movements. Challenges can be enhanced using a foam cushion (eyes open to closed), split foam rollers (flat side down to flat side up), and wobble boards. Large COM shifts in all directions beyond the LOS will promote stepping strategies. Balance control can be further enhanced using manual perturbations, resistive band around pelvis during stepping (forward, backward, sideward), and using mobile and compliant surfaces with alterations in BOS (feet together, tandem standing, and single-limb stance).

LOCOMOTOR TRAINING ENVIRONMENTS

The discussion of locomotion training strategies is divided into the following environments in which LT can be performed: (1) parallel bars, (2) overground indoors, (3) overground community, (4) BWS and TM, (5) BWS overground, and (6) other.

The following section addresses the parallel bar progression. Parallel bars have a time-honored tradition in conventional LT. They provide a reasonably safe and stable environment to become acclimated to upright standing, and they allow early walking practice on a relatively normal indoor floor surface for short distances. They also permit the UEs to assist in maintaining an erect posture and static/dynamic balance control, and to partially or fully unweight an LE. Because a high level of stability is provided by UE support, there is less demand imposed for balance control and the highly coordinated movements required of normal locomotor rhythm. However, prolonged parallel bar training promotes compensatory practice and learning of skills that often transfer poorly to independent overground walking and use of an assistive device. Owing to the increased weight borne by the UEs, a forward head and flexed trunk posture (limiting hip extension range of motion [ROM] and loading) is imposed and practiced. Locomotor speed, symmetry, and rhythm (timing) are typically diminished and appropriate dynamic balance mechanisms cannot be effectively promoted. In addition, the amount of body weight relief cannot be easily monitored.

In recent years, the availability of partial BWS training devices has diminished the routine use of parallel bars in many facilities. Training using a BWS system can be used in conjunction with a TM or used on overground surfaces and involves the patient donning a harness attached to an overhead frame that supports him or her in an upright vertical posture. Treadmill training using BWS is addressed later in this chapter.

Parallel Bars

Before standing, two important preliminary activities are fitting the patient with a guarding belt and adjusting the parallel bars. The initial adjustment of the parallel bars is an estimate based on the patient's height. Ideally the bars should be adjusted to allow 20 to 30 degrees of elbow flexion and come to about the level of the greater trochanter. Considering individual variations in body proportions and arm length, the elbow measurement is usually most accurate. Once the patient is standing, the height of the bars can be checked. If adjustments are required, the patient should be returned to a sitting position.

Before beginning LT in the parallel bars, wheelchair positioning and use of a guarding belt are important considerations. The patient's wheelchair should be positioned at the end of the parallel bars. The brakes should be locked, the footrests placed in an upright position, and the patient's feet on the floor well under the seating surface (COM over the BOS). The guarding belt should be fastened securely around the patient's waist. Guarding belts provide several critical functions. They increase the therapist's effectiveness in controlling or preventing potential loss of balance; they improve patient safety; they facilitate the therapist's use of proper body mechanics in untoward circumstances; and they are an important consideration regarding issues of liability. The safety implications of the guarding belt should be explained to the patient carefully.

Locomotor training in the parallel bars is initiated with patient instruction and demonstration. First, the entire progression should be presented before breaking it into sequential component parts. This will include instruction and demonstration in how to assume a standing position in the parallel bars, guarding techniques to be used by the therapist, the components of initial standing balance activities, gait pattern to be used, how to turn in the parallel bars, and how to return to a sitting position. Demonstrating these activities by assuming

the role of the patient during verbal explanations will facilitate learning. Each component of the parallel bar progression should then be reviewed before the patient's actual performance of the activity. A sequence of activities for use in the parallel bars follows.

Assuming the Standing Position

To prepare for standing, the patient should be instructed to move forward in the chair. The therapist is positioned directly in front of the patient. A method of guarding should be selected that does not interfere with the patient's use of the UEs while moving to standing. Having moved forward in the chair with the supporting foot or feet on the floor well under the seating surface, the patient should be instructed to come to a standing position by leaning or rocking forward and pushing down on the armrests of the wheelchair with verbal cueing from the therapist (*"rock your shoulders forward, continue rocking and on the count of three push down on the armrests, and come to standing, one, two, three"*). The patient should not be allowed to stand by pulling up on the parallel bars because this approach has little functional carryover. As the patient nears an erect posture, the hands should be released from the armrests one at a time and placed on the parallel bars. The patient's COM should be guided over the BOS to promote a stable standing posture.

Standing Activities

During initial parallel bar activities, the therapist typically stands inside the bars facing the patient or outside the bars on the patient's weaker side. In guarding the patient from inside the bars, one hand should grasp the guarding belt anteriorly, and the opposite hand should be in front of, but not touching, the patient's shoulder. (*Note:* An underhand grip is always used when grasping a guarding belt.) From outside the bars one hand should grasp the belt posteriorly with the opposite hand in front of, but not touching, the patient's shoulder. This method of guarding provides effective hand placement for an immediate response should the patient lose his or her balance. It also eliminates the patient's feeling of being "held back" or "pushed forward," which may occur with manual contacts at the shoulders. The following initial activities in the parallel bars can be modified relative to the patient's weight-bearing status and specific requirements (e.g., use of a prosthesis or orthosis). The therapist maintains guarding techniques during these activities.

1. Standing, holding, acclimation to upright position; feet in symmetrical stance position, equal weight on both LEs; hands supported on parallel bars.
2. Limits of stability training (weight shifts with feet in stance position; alteration in hand placement on parallel bars).
   a. Lateral weight shift from side-to-side without altering the BOS; hand placement on the parallel bars is not altered.
   b. Anterior–posterior weight shifting forward and backward without altering the BOS; hand placement on the parallel bars is not altered.
   c. Anterior–posterior hand placement and weight shift; patient lifts and moves hands forward on bars and shifts weight anteriorly; alternated with posterior hand placement, and weight is shifted backward.
   d. Single-hand support; patient balances with support from only one hand on the parallel bars; hands are alternated. A progression of this activity involves gradual changes in position of the freed hand and UE. For example, move the freed hand several inches above the bar and gradually progress to alternate positions such as shoulder flexion, abduction, crossing the midline, and so forth. A progression can be made to balancing with both hands freed from the bars.
3. Stepping forward and backward. Patient steps forward with one LE, anterior weight shift, and then returns foot to starting position (normal BOS); alternated with stepping backward with one LE, posterior weight shift, with return of foot to starting position.
4. Side-stepping and cross-stepping. Patient turns 90° from a forward-facing position and places both hands on one parallel bar; weight is then shifted over support limb and dynamic limb abducts and side-steps. Progression made to cross-stepping; weight shifted over support limb and dynamic limb moves up and over the stance limb.
5. Forward progression. Ambulation in the parallel bars using selected gait pattern and appropriate weight-bearing (e.g., partial, full).

Clinical Note: The patient should be instructed to push down rather than to pull on the parallel bars while ambulating, inasmuch as this is the motion that eventually will be required with an assistive device. This will be easier if the patient is instructed to use a loose or open grip on the bars rather than a tight grip; the loose or open grip facilitates correct use of the parallel bars and, ultimately, the assistive device.

6. Turning. Once the desired distance in the parallel bars has been reached, the patient should be instructed to turn toward the stronger side. For example, with a non–weight-bearing left LE, the turn should be toward the right. The patient should be instructed to turn by stepping in a small circle and not to pivot on a single extremity. This technique will carry over to ambulation outside the bars, when pivoting will always be discouraged because of the potential loss of balance by movement on a small BOS. Guarding can be accomplished two ways. The therapist can remain in front of the

patient, maintain the same hand positions, and turn with the patient. This will keep the therapist positioned in front of the patient. A second method is not to turn with the patient but, rather, to guard from behind on the return trip. In this method hand placements will change during the turn. Hand placement is changed gradually by first placing both hands on the guarding belt as the patient initiates the turn. One hand then remains on the posterior aspect of the belt and the freed hand is placed anterior to, but not touching, the shoulder on the patient's weaker side for the return trip toward the chair. Although both techniques are acceptable, the latter is probably more practical, considering the limited space available in the parallel bars.

7. Return to seated position. When reaching the chair the patient should again turn as described above. Once completely turned, patients are typically instructed to continue backing up until they feel the seat of the chair on the back of their legs (this will require substitution with visual or auditory clues for patients with impaired sensation). At this point the patient releases the stronger hand from the parallel bar and reaches back for the wheelchair armrest. Once this hand has securely grasped the armrest, the patient should be instructed to bend forward slightly, release the opposite hand from the parallel bar, and place it on the other armrest. Keeping the head and trunk forward, the patient gently returns to a seated position.

Clinical Note: Owing to limited space, use of the parallel bars may not be possible with an assistive device. However, when adjustable-width bars are available, they provide added security for preliminary use of the assistive device. An alternative approach would be to begin use of the device outside and next to standard parallel bars or oval-shaped bars.

Overground Indoors

Activities for the indoor overground progression typically include walking forward and backward, resisted progression, side-stepping and cross-stepping, and stair climbing. Manual contacts can be used to guide and assist control of pelvic movement if necessary. Verbal cueing can be used to promote normal timing and locomotor rhythm. Upper extremity support may initially be required (e.g., hands resting lightly on therapist's shoulders; or therapist may be positioned in front of patient with elbows flexed and forearms supinated and patient uses therapist's hands for touch-down support as needed). Manual contacts, verbal cueing, and UE support are progressively decreased and then eliminated.

1. Walking forward and backward. This activity can begin with standing; stepping in place with emphasis on diagonal weight shifts forward and backward onto stance limb; and pelvic rotation in combination with advancing the swing limb.
2. Resistance with forward and backward walking is applied using a resistive band around the pelvis and held from behind as the patient moves forward or held in front facing the patient as he or she moves backward. In standing, wooden dowels held horizontally by both the patient and therapist can be used to promote reciprocal UE movements and trunk rotation moving both forward and backward.
3. Side-stepping and cross-stepping. Side-stepping involves abduction of the leading dynamic limb with foot placement followed by movement of the remaining limb to a parallel position with the first (symmetrical stance). Emphasis should be placed on keeping the pelvis level. Cross-stepping involves side-stepping and then crossing the remaining limb up and over the other limb.
4. Braiding. This activity involves a cross-step and side-step progression with one limb advancing alternately anteriorly and posteriorly across the other while the second limb side-steps. It incorporates lower trunk rotation, as well as crossing the midline. This is a challenging activity and may require support from the therapist standing in front of the patient (forearms supinated, patient's hands lightly touching therapist's hands) or by use of a modified plantigrade position with UEs lightly supported on the treatment table.
5. Step-ups. To practice stepping up, a portable step can be placed directly in front of the patient. The patient weight shifts laterally toward the support limb and places the dynamic limb on the step. The limb is then returned to the original stance position. Verbal cues and manual guidance are provided as needed. The height of the step can be varied to increase or decrease the difficulty of the activity. For example, a 4-in (10-cm) step can be used initially with a gradual progression to a standard 7-in (17.5-cm) step. A progression is made to a step-over-step pattern on stairs. Early activities may require support from a railing. An erect trunk posture should be maintained and "pulling" on the railing should be avoided.

Indoor overground practice activities should also include strategies to vary locomotor task demands such as the following:

- Walking with head turns on verbal command such as *look right, look left, look up,* or *look down.*
- Increasing speed and rhythm of gait by using pacing cues to vary speed such as *walk slow* and *walk fast.*
- Use of a metronome or personal listening device (e.g., marching music) to increase speed and improve rhythm.
- Progress to longer distances with decreased number of rest intervals to improve walking endurance.

- Practice dual-task walking (e.g., walk and talk; walk and catch/throw a ball; tapping a balloon back and forth; bouncing a ball; carrying a tray that holds a glass of water, walk and perform a cognitive task).
- Practice walking on varied indoor surfaces such as tile, wood flooring, and carpeting.
- Practice walking through doorways including opening and closing door.
- Progress from a closed to an open environment.

Box 11.2 presents an overview of strategies for varying locomotor task demands. It provides suggested practice activities for enhancing specific (missing) components of gait that can be incorporated into the indoor overground progression.[27]

Circuit Training

These (see Box 11.2) and other activities can be incorporated into a task-oriented circuit-training program. Circuit training generally consists of different stations at which patients participate in different specific, task-oriented activities designed to improve walking ability.[24,28-33] For example, there may be six to eight stations at which patients participate in the activity for 5 to 10 minutes. Specific training stations may have activities such as standing and reaching, standing on different surfaces, walking through an obstacle course, transitioning from supine to sitting to standing, walking and carrying objects, walking and picking up objects from the floor, stepping up and down, walking at varying speeds and over varying

Box 11.2 Strategies for Varying Locomotor Task Demands

Upright Postural Alignment

- Practice walking upright; assist patient in vertical trunk posture using manual and verbal cues (*"Look up and stand tall"*)
- Trekking poles or body weight support harness can be used to promote upright alignment and reduce upper extremity support, forward head, and flexed trunk position (common with use of an assistive device such as a walker)
- Progress upper extremity support provided by assistive device to light touch-down support, then to use of a trekking pole or wall for support as needed, and finally to no support

Foot Placement/Toe Clearance

- Practice heel-toe initial contact; tactile cues can be provided to dorsal foot by tapping over pretibial muscles
- Practice high step marching in place and then high step walking accompanied by marching music
- Practice walking with even steps using foot prints attached to floor
- Practice increasing step length and/or step width using floor grids
- Practice walking with altered base of support; progressing from wide base (8–12 inches apart [20.32-30.48 cm]) to narrow base (2 inches [5 cm] apart) to tandem (heel-to-toe)
- Practice step-to walking (i.e., taking a long step with one limb; then bring opposite limb even with the first on next step)
- Practice walking on a 3-inch (7.6 cm) line taped to floor; half-foam roller; low balance beam

Single- and Double-Limb Support

- Practice controlled lateral and diagonal weight shifts
- Combine diagonal weight shifts with pelvic rotation movements and stepping forward and backward

Forward Progression and Push-off

- Practice push-ups (toe rises) in stance; progress to toe-walking
- Practice heel-rises in stance; progress to heel-walking
- Practice forceful push-off on cue during walking
- Practice alternating between heel-walking and toe-walking (i.e., walk a certain number of steps on heels, then same number on toes)

Walking Against Resistance

- Practice walking against manual resistance using resisted progression
- Walking against resistance from resistive band around pelvis
- Pool walking (ideal initial supportive environment for patients with ataxia)

Trunk Counterrotation and Arm Swing

- Practice walking with exaggerated arm swings
- Practice walking with wooden dowels; therapist is behind and holds one end of dowels; patient is in front and holds other end of dowels

Continued

Box 11.2 Strategies for Varying Locomotor Task Demands—cont'd

Walking Sideward

- Practice walking using lateral side-steps; resisted progression (manual and elastic resistive bands)
- Practice walking using cross-steps
- Practice walking using braiding

Walking Backward

- Walking backward (retro-walking)
- Practice appropriate knee flexion in combination with hip extension

Step-Ups/Step-Downs

- Practice stepping-up and stepping-down; vary step height progressing from low (4 in [4 cm]) to high (8 in [20 cm])
- Practice lateral step-ups
- Practice forward step-ups
- Practice stepping onto and off varied surfaces (e.g., foam pad, half foam roller, inflatable disc, BOSU® Balance Trainer)

Stopping, Starting, and Turning on Cue

- Practice abrupt stops and starts on verbal cue
- Practice turns on verbal cue, progressing from a quarter turn to half turn to full turn; progress from wide base turns with progression to narrow base
- Practice figure-8 turns

Visual Input

- Practice walking alternating between eyes open and eyes closed; three steps with eyes open and then three steps with eyes closed

Head Movements

- Practice walking alternating head movements; alternate between taking three steps with head to right and then three steps with head to left
- Practice walking with head movements on verbal cue (*"look right, look left, look down, look up"*)

Practice Timed Walking, Increasing Speed and Locomotor Rhythm

- Begin walking at comfortable speed, gradually increase velocity
- Use pacing cues to vary speed, (e.g., *"walk slow, walk fast"*)
- Use metronome or brisk marching music to increase speed, improve locomotor rhythm
- Practice imposing short bursts of fast walking (on verbal cue) with walking at a comfortable speed

Improve Duration of Walking

- Progress to longer distances with decreased number of rest intervals

Practice Dual-Task Walking

- Walk and talk
- Walk and count by threes
- Walk and bounce or toss a ball, carry a tray

Improving Compensatory Responses to Unexpected Perturbations

- Change speed of treadmill or stop and start treadmill while patient is walking on it
- Practice resisted forward progression using an elastic resistive band with unexpected release of resistance
- Practice walking while recovering from small external perturbations given manually

Adapted from Schmitz,[27, pp. 206-207] with permission.

surfaces, and standing and kicking a ball. As patients' performance improves, the specific tasks are progressed by increasing the complexity and difficulty. For example, to progress a patient in an obstacle course the patient can be required to do it more quickly, carry an object while walking through it, or step over higher objects. A dual cognitive task can be added to the activity to increase the difficulty as well. Progressive resistive strength training targeting key muscles can also be incorporated.[31] Box 11.3 Evidence Summary presents research examining the effectiveness of circuit training for improving locomotor ability.[24,28-32]

Box 11.3 Evidence Summary Selected Studies of Circuit Class Training for Patients with Stroke

Reference	Subjects	Methods/Procedure	Results	Comments
Fritz et al[24] (2011)	A case series of four participants with chronic neurological diagnoses	Each participant completed 10 sessions of Intense Mobility Training (IMT): 3 hr/day with 1 hour each of body weight supported locomotor training, balance training, and coordination/strength training. Emphasis was on task-specific training that was massed in schedule.	Despite the wide range of diagnoses, all tolerated the IMT well and each showed improvement in at least one measure for each target area of gait, balance, and mobility.	Study informs us about general feasibility only; a randomized trial of IMT with a more homogenous population is needed.
van de Port et al[28] (2012)	250 subjects with stroke recruited from multiple outpatient centers; randomly allocated to circuit training or usual physical therapy	12 weeks of graded task-oriented circuit training (2×/wk for 90 min) intended to improve walking competency (n = 126) versus 12 weeks of usual outpatient physical therapy (n = 124).	Small but significantly higher scores in comfortable walking speed, distance, and modified stairs test for circuit training group at 12 weeks; no differences in primary outcome (mobility index of Stroke Impact Scale [SIS]) or secondary measures (except gait speed) at 24-week follow-up.	Circuit training appears safe and effective as usual therapy; differences in gait speed and distance were not clinically meaningful; insufficient detail of "usual therapy" to effectively compare groups on intervention content and dose.
Rose et al[29] (2011)	180 clients with stroke (average 10 days post-stroke) participating in a traditional, acute care rehabilitation program	Study compared standard physical therapy (SPT) 1.5 hr/day, 5 days/wk of 1:1 therapy for mobility, gait, balance, and UE function to circuit training physical therapy (CTPT) 1.5 hr/day, 5 days/wk; 60 min/session devoted to circuit training of four task-specific stations. CTPT consisted of four levels of circuit training based on client's stroke severity.	The CTPT group had significantly higher intensity of task repetition than the SPT group. Significantly greater changes in gait speed for CTPT versus SPT. No other significant differences for measures of LE function, balance, or overall mobility. No group differences noted on follow-up (90 days post-stroke).	Nonblinded, nonrandomized controlled trial. The primary finding of this feasibility study is that individuals only 10 days post-stroke tolerated an intervention mode that provided intense, whole-body task practice focused on repetition and progression.

Box 11.3 Evidence Summary Selected Studies of Circuit Class Training for Patients with Stroke—cont'd

Reference	Subjects	Methods/Procedure	Results	Comments
Combs et al[30] (2010)	A case series of 12 participants with chronic stroke	4-hour sessions daily for 2 weeks included progressive resistance training, locomotor training (BWS with TM and overground), task-specific skills training, education, and home exercise program.	Most clients showed improvement from baseline to follow-up and retention for the activity-based outcome measures (balance, walking ability, UE function) but the effect sizes were all small. Self-perceived improvements on participation-based measures (SIS and Canadian Occupational Performance Measure) were significant and had large effect sizes at follow-up and were maintained.	This protocol is a good representation of how a patient-centered, task-specific, and whole-body program for persons with stroke can be both standardized and feasible, as well as effective.
Wing et al[31] (2008)	Retrospective review of 35 adults with chronic stroke receiving comprehensive, outpatient therapy	Clients received intensive, whole-body rehabilitation 3–6 hr/day, 4 days/wk for a minimum of 2 weeks. Sessions included BWS with TM, overground gait training, progressive resistance training, balance and transfers training, and task-specific UE training.	Clients demonstrated improved walking speed and UE function; small improvements in balance were also noted.	Another good example of how a whole-body rehabilitation program can be applied to this population. No correlations were found between injury chronicity or amount of therapy and outcomes measured.
English and Hillier[32] (2010)	Systematic literature review through 2009; randomized or quasi-randomized studies of adults with stroke were reviewed	Six trials including 292 participants were selected for final analysis.	Positive findings from four studies favored circuit training compared to control intervention for walking capacity and speed. Two studies showed superiority of circuit training for measures of balance and hospital length of stay.	The authors conclude that circuit training classes are effective for improving mobility and reducing rehabilitation length of stay for persons with moderate stroke.

Evidence Summary Box prepared by Coby D. Nirider, PT, DPT, Director of Therapy Services, Touchstone Neurorecovery Center, Conroe, TX 77308.
BWS = body weight support; LE = lower extremity; SIS = stroke impact scale; TM = treadmill; UE = upper extremity.

Body Weight Support/Treadmill

Locomotor training using a BWS and TM system involves suspending a patient over a TM and using the BWS system to partially unweight the patient. The ability to partially unweight the patient allows patients with LE or trunk weakness to stand and take steps in a more symmetrical, natural manner without the need for excessive UE weight-bearing or compensatory movement patterns. Using this system also allows physical therapists and other rehabilitation professionals to manually assist the patient while stepping on the TM (see Fig. 20.37 in Chapter 20, Traumatic Spinal Cord Injury).

Locomotor training using a BWS and treadmill system was first used in patients with SCI. The rationale for its use is supported by animal studies of cats with thoracic spinal cord lesions that regained hind limb stepping patterns when supported by a harness over a moving treadmill.[10-12] These findings suggest that the spinal cord is capable of reciprocal locomotor patterns produced by central pattern generators (CPGs) at the spinal cord level in the absence of supraspinal input. Central pattern generators are also influenced by sensory input, allowing motor output modification based on environmental demands.

Behrman et al[21] and Behrman and Harkema[34] have proposed the following guiding principles for LT:

- Maximally load the LEs for weight-bearing, while minimizing weight-bearing on the UEs (e.g., the BWS system sustains sufficient body weight so that the patient can stand and step with minimal or no UE support).
- Provide sensory cues that are consistent with normal walking (e.g., manual facilitation to the extensors and flexors during stance and swing, respectively).
- Promote trunk, limb, and pelvic kinematics associated with normal walking.
- Promote balance and upright control consistent with normal walking.
- Maximize the recovery and use of normal movement patterns and minimize compensatory movement patterns.

The overarching principle is to *train like you walk*. A key element of LT using BWS and a TM is facilitation of automatic walking movements within the context of intensive, task-specific training (whole-task practice). With body weight supported, the TM speed provides a rhythmic input. Manually guided movements are used to enhance the rhythmicity of the gait pattern. The BWS and TM system provides an environment in which these LT strategies can be accomplished.

Sensory input such as appropriately timed manually assisted limb movements can promote function-induced recovery.[28,31] Within a task-specific and safe patient environment, LT using BWS and a TM allows the therapist access to trunk, pelvis, and LEs to manually assist, guide, or adjust locomotor rhythm, limb placement, weight shifts, and stepping symmetry. Movements are coordinated to simulate normal gait; upright posture and balance are maintained, and speed of walking is controlled. Kosak and Reding[35] emphasize the role of sensory input during LT using BWS and a TM by stating, "Stride and cadence vary with treadmill speed, indicating local sensory feedback to a lumbosacral gait pattern-generator. The intensity and timing of sensory feedback from pressure receptors in the sole of the foot and joint proprioceptors from the ankle, knee, and hip are thought to provide facilitory and inhibitory effects on flexor-extensor motor neuron pools in the spinal cord at appropriate time during the gait cycle."[35, p. 14]

Some of the advantages of LT using BWS and a TM include the following:[34]

- Interlimb and intralimb timing can be practiced before limbs are capable of fully supporting body weight.
- Gait training can be initiated earlier within an episode of care.
- Specific elements of the gait cycle (e.g., midstance limb loading; swing phase unweighting and stepping) can be promoted within a dynamic task-specific strategy.
- Limb loading can be varied based on ability to support weight.
- Owing to forced stepping movements, "learned nonuse" may be prevented by focusing attention on both involved and uninvolved limbs.
- Opportunity to practice walking is provided without undue fear of falling.
- Dynamic balance can be enhanced by decreasing BWS and increasing TM speed.
- Compensatory strategies (e.g., UE support) to compensate for LE impairment are reduced.
- Constant speed of the TM provides rhythmic input that may reinforce a coordinated reciprocal gait pattern.
- Hip extension is facilitated.

Locomotor training using a BWS and TM system can be progressed by increasing TM speed, decreasing the amount of BWS and manual guidance, and increasing the time of stepping on the TM. For example, training may be initiated at very low speeds (e.g., 0.3 m/sec) with limited LE weight-bearing (30% to 40% of BWS), constant manual guidance at both LEs and the trunk/pelvis, and a stepping session of only 1 to 3 minutes. With continued training and patient improvement, this can be progressed to normal, age-appropriate walking speeds of 1.2 to 1.4 m/sec (4 to 4.5 ft/sec), full weight-bearing through the LEs, no manual guidance for stepping, and a stepping session of 30 minutes without rest.

Locomotor training using a BWS and TM system has also been successfully combined with robotic interventions; a robotic device instead of a physical therapist moves the LEs.[36-39] Although the effectiveness of LT using a BWS and TM system has been examined in a variety of patient populations, including those with spinal cord injury[39-43] (see Evidence Summary Box 20.8), stroke[35,44,45] (see Evidence Summary Box 15.9), Parkinson's disease,[46-48] and multiple sclerosis,[49,50] it is not clear that it is more effective than other intervention approaches and what specific patients it is best suited for.

Overground Community

Locomotor training overground in the community is integral to returning the patient to a former environment and lifestyle. Overground community training

activities must be specifically examined to determine their appropriateness for an individual patient.

1. Curbs. A useful lead-up activity to curb climbing is provided by training using a series of interlocking portable steps arranged in increments of height. For additional security they can be placed next to a treatment table, wall, or other support surface. A progression can be made from a 3- or 4-in (7.62- or 10.16-cm) increment to a 7-in (17.78-cm) curb height.
2. Ramps and slopes. Ramps and other sloping surfaces can be negotiated in several ways. If the incline is very gradual, it may be sufficient simply to instruct the patient to use smaller steps. For steeper inclines the patient should be instructed to use smaller steps and to traverse the ramp (use a diagonal, zigzag pattern) for both ascending and descending. Practice should include inclines of varying height. Walking up an inclined surface is associated with decreased speed, cadence, and step length.
3. Terrain variations. Community walking presents a variety of terrains that require adaptation of locomotor skills. Practice should include uneven surfaces such as sidewalks, grassy surfaces, parking lots, and so forth.
4. Timing requirements. Several community settings impose precise time restrictions (coincident timing) on movement. Walking should be practiced within these time constraints and can include crossing at a stoplight, stepping on and off a moving walkway or escalator, walking onto an elevator, and walking through a revolving door.
5. Open environment. Walking should be practiced in a variable open community environment such as a shopping mall, community center, grocery store, or other patient-specific location. Because learning is task and environment specific, walking should be practiced in all environments normally used by the patient.

Additional overground community practice activities include the following:

- Exit and entrance through outside doors and thresholds (both residential and commercial structures)
- Outdoor stair climbing (e.g., cement stairs)
- Entering and exiting public or private transportation
- Variations in visual conditions (e.g., full to reduced lighting)
- Scanning the environment

Nordic Walking

Nordic walking (trekking poles) has gained considerable presence in overground LT programs with varied patient populations.[51-58] It is also used in health promotion and fitness programs.[55,59] The International Nordic Walking Federation (INWA) defines Nordic walking as "a form of physical activity, where to regular natural walking there has been added the active use of a pair of specially designed Nordic Walking poles. However, the characteristics of natural, biomechanically correct walking and appropriate posture are maintained in all aspects."[60]

Nordic walking engages muscles of the UE and trunk and is effective in improving gait and aerobic conditioning.[60] Ample evidence supports the use of Nordic walking in overground LT. It has been shown to be a safe and effective training method for patients with chronic obstructive pulmonary disease (COPD)[51] and coronary artery disease.[57] Improvements in postural stability, stride length, gait pattern, and gait variability were found in patients with Parkinson's disease.[52] Nordic walking has also been found to be an effective intervention for low back pain,[53] fibromyalgia,[55,56] intermittent claudication,[58] and overweight individuals with type 2 diabetes.[54]

General goals of Nordic walking include the following:[60,61]

- Increase cardiorespiratory endurance
- Promote correct upright alignment and posture
- Improve balance, agility, and coordination
- Improve gait characteristics and walking speed
- Promote active engagement of multiple muscle groups
- Increase ROM and strength

Nordic walking may progress from overground indoors to overground in the community (see previous section). Other organizations promoting Nordic walking include the American Nordic Walking Association (http://anwa.us/html/index.php) and the International Nordic Fitness Sports Organization (www.nordicfitness.net/).

Body Weight Support/Overground

The task-oriented approach to LT using a BWS system can also be performed overground. Some systems are equipped with casters (Fig 11.1). Moving the BWS system away from the treadmill creates a mobile, safe, and efficient environment for continuing the controlled reduction in BWS to overground surfaces. Although a BWS system can be used overground, very few studies have examined its effectiveness in improving walking ability.[62]

During initial overground training, verbal cueing and manual guidance are provided as needed. Gait speeds may be slower on overground surfaces as compared to over the TM with elimination of the rhythmic steady-state input provided by the TM. Ambulatory assistive devices such as a cane or a walker can be incorporated into overground training (see Appendix 11.A, Ambulatory Assistive Devices: Types, Gait Patterns, and Locomotor Training). The BWS device is manually moved to keep pace with the patient's forward progression. For use without an assistive device, the patient can move and steer the unit with the UEs (Fig. 11.2) before progressing to an assistive device or hands-free reciprocal arm movements.

Figure 11.1 Body weight support overground locomotor training using a walker. *(Courtesy of Mobility Research, Tempe, AZ 85281.)*

Figure 11.2 Body weight support overground locomotor training without an assistive device. Hand placements allow the patient to move and steer the unit during forward progression. *(Courtesy of Mobility Research, Tempe, AZ 85281.)*

EMERGING INTERVENTION STRATEGIES

Other intervention strategies that can be used to improve locomotor capability include virtual reality–based interventions[63-66] and mental practice with motor imagery.[67-69] Virtual reality–based locomotor interventions are typically paired with a TM or robotic device to move the LEs (Fig. 11.3). A computer-generated virtual environment provides a stimulating, task-oriented environment that engages the patient. Visual, proprioceptive, and auditory feedback through interaction in the virtual environment can be used to enhance motor learning.

Motor imagery is the imagining of a motor task without actually performing it, and mental practice is the repetitive imagining of the motor task with the goal of improving physical performance.[69] Similar areas of the brain are activated when people imagine walking and actually walk. The medial primary sensorimotor cortices and the supplementary motor area (SMA) are activated during actual and imagined walking.[69] Optimally, mental practice of gait-related movement should be paired with physical practice.

CLINICAL DECISION MAKING

As discussed above, a variety of different intervention strategies can be used to improve locomotor capability. Although these different rehabilitation interventions have been shown to be effective, research has not shown one particular strategy to be superior to another, what the most effective dosage is, or when in the recovery

Figure 11.3 CAREN (Computer Assisted Rehabilitation Environment) Extended System is comprised of a treadmill mounted on a motion base (tilting platform), a 12-camera real-time motion capture system, 120- to 180-degree cylindrical screen projection system, and a surround sound system. Standing on the treadmill and safeguarded by a harness, the curved screen engages the patient in the activity of a virtual environment. The system is used for balance as well as all gait applications. *(Courtesy of Motek Medical, Keienbergweg 77 1101 GE Amsterdam, The Netherlands.)*

process a particular intervention strategy should be employed.[32,70-73] This challenges intervention selection when developing a specific POC.

A variety of factors should be considered when deciding on what intervention to select. Current theories of motor control and motor learning advocate for a task-oriented, repetitive approach to interventions.[74] Two basic treatment strategies are a ***compensatory*** and a ***restorative*** (recovery) approach. The compensatory approach seeks to improve functional skills by compensating for the lost ability. A simple example of this is the use of an assistive device such as a cane to provide postural support while walking. A restorative approach seeks to restore the "normal" movement while walking. Locomotor training using a BWS and TM system can be viewed as a restorative approach as the guiding principles emphasize normal movement strategies and minimizing compensatory movement patterns. In many cases interventions will require a balance between both compensatory and restorative approaches. Below are some factors to consider when selecting specific intervention strategies:

- Injury severity (i.e., degree of sensorimotor impairments, weight-bearing restrictions)
- Chronicity of injury
- Secondary complications
- Co-morbid health conditions
- Cognitive, communication, or behavioral barriers
- Motor learning capability
- Psychosocial and financial support
- Discharge destination

When determining dosage of the intervention, principles of neuroplasticity[75] (see Chapter 19, Traumatic Brain Injury), strength training, and endurance training should be incorporated.[76]

SUMMARY

Recovery of independent locomotion is an extremely important goal for many patients seen in rehabilitation settings. It is a functional skill that directly affects performance of expected roles within the patient's social, cultural, and physical environment. A framework of LT strategies has been presented that can be modified to meet the needs of an individual patient. Through a process of careful examination and communication with the patient, family, and/or caregivers, specific training strategies can be identified and implemented.

Questions for Review

1. Describe the LT principles that guide selection of interventions.
2. As a complementary activity to LT, what is the benefit of approaching strength training using task-specific practice (as compared to muscle-specific strengthening)? How is task selection determined for task-specific practice?
3. Describe the approach for instructing and guiding a patient to assume a standing position in the parallel bars.
4. What activities are typically included in overground indoor LT?
5. Describe strategies for varying task demands for overground indoor LT.
6. Describe the guiding principles for LT using BWS and a TM.
7. What advantages does LT using BWS and a TM provide?
8. Identify the parameters used for progressing LT using a BWS and TM system.
9. Describe practice activities required for locomotion training overground in the community.
10. At times, LT requires a balance between both compensatory and restorative approaches. What factors are considered when selecting specific intervention strategies?

CASE STUDY

HISTORY

Patient is a 74-year-old male, right-handed, admitted for acute care with progressive right-sided weakness over several hours before admission.

Admission computed tomography (CT) scan was unremarkable; carotid Dopplers were unremarkable without significant stenosis or plaque. Electrocardiogram (ECG) was within normal limits. Chest x-ray showed no active disease. Complete blood count (CBC) was within normal limits.

PHYSICAL EXAMINATION

- Blood pressure (BP): 130/76
- Heart rate (HR): 80
- Respirations (regular): 20
- Temperature: 97.9
- Head, ears, eyes, nose, and throat (HEENT) examination unremarkable
- Chest clear to percussion and auscultation
- Neck supple without carotid bruits
- Abdominal examination: obese without tenderness or organomegaly
- Peripheral pulses intact
- Extremities without deformities

INITIAL NEUROLOGICAL EXAMINATION

Patient is alert and cooperative with mild dysarthria. Speech is fully intelligible. He is able to follow complex commands. There is no neglect or apraxia. Visual fields are full to confrontation. Extraocular movements are full without nystagmus. Pupils are equal and reactive. There is a mild right central facial droop. Sensation is intact over the face. His palate and tongue are midline. Motor examination revealed a spastic right hemiparesis, with right UE (RUE) 3+/5 deltoid, trace triceps, 2+/5 biceps, and 2+/5 finger flexors; on the right LE (RLE) 2/5 iliopsoas, 3/5 quadriceps, 4-/5 gastrocnemius. There is no voluntary dorsiflexion of the foot. Deep tendon reflexes are slightly hyperactive on the right with a right + Babinski. The left side is strong in all muscle groups. Sensation is intact to all modalities.

DIAGNOSIS

Lacunar left cerebrovascular accident (L CVA)
