and spasms can cause involuntary muscle contractions or a muscle to appear stronger than it really is. Orthoses and spinal precautions may preclude the patient from assuming a recommended test position or forcefully contract certain muscles. The use of alternate (nonstandard) test positions should be documented.

Pain

Pain should be examined continually. A *visual analog scale* can be used to identify the intensity of pain. The patient rates pain on a scale from 0 to 10, where 0 is no pain and 10 is severe, disabling pain. There are also self-report measures of pain designed specifically for people with SCI. The *International Spinal Cord Injury Basic Pain Data Set* items have been modified for self-report use.[186] This self-report measure poses a series of questions related to impact of pain on various aspects of daily activities and life satisfaction, location of pain, intensity of pain, and duration of pain. The *Wheelchair User's Shoulder Pain Index* measures the impact of shoulder pain on transfers, self-care, wheelchair mobility, and general activities.[187,188] Wheelchair users rate the amount of pain they experience while performing different activities on a scale from 0 to 10. Total score ranges from 0 to 150, with higher scores indicating a greater impact of pain.

Self-Care and Home Management

One of the main goals of rehabilitation is to promote independence in functional mobility skills and self-care. In addition to wheelchair propulsion skills and possibly gait (discussed above), it is important to carefully examine the patient's ability to perform other mobility skills such as transfers, bed mobility, and ability to perform pressure relief. The amount of physical assistance, method of performing the task, verbal cues required, use of adaptive/assistive devices, environment, and degree of safety should all be carefully documented. In order to be truly independent with a task the patient must be able to complete the task safely, in a timely manner, without undue effort, in an open environment, in different environments, and consistently. It may be tempting to provide a small amount of assistance such as stabilizing the wheelchair while the patient transfers (to prevent sliding) and still document that the patient was independent with the bed-to-wheelchair transfer. However, in this case the patient was not truly independent with the task. The patient should be able to complete the task without the physical therapist present. However, the physical therapist must actually observe the patient performing the task because patients may overestimate their own ability.

The amount of assistance required to complete a task is commonly documented using definitions from the *Functional Independence Measure (FIM).*[189-191] The amount of assistance is scored on an 8-point ordinal scale where 1 = total assistance (patient performs less than 25% of the effort), 2 = maximal assistance (patient performs 25% to 49% of the effort), 3 = moderate assistance (patient performs 50% to 74% of the effort), 4 = minimal assistance (patient performs greater than 75% of the effort), 5 = supervision (patient requires verbal cues, setup, or stand by), 6 = modified independent (patient requires assistive or adaptive device), and 7 = independent. More information on the FIM is provided in Chapter 8, Examination of Function.

Several other SCI-specific outcome measures are available to examine self-care and home management. The *Spinal Cord Injury Independence Measure (SCIM)* was specifically created to assess function in people with SCI (Fig. 20.20). It is made up of 19 items divided into 3 subcategories: self-care, respiration and sphincter management, and mobility. Total scores range from 0 to 100, where higher scores indicate greater independence. The SCIM is valid, is reliable, and may be more responsive than the FIM.[192-194]

The *Quadriplegia Index of Function (QIF)* was developed to measure small but significant improvement in function in people with tetraplegia that are missed by other measures.[195] The QIF consists of 10 ADL items (transfers, grooming, bathing, feeding, dressing, wheelchair mobility, bed activities, bladder program, bowel program, and personal care). The last item, personal care, is a series of questions that examines knowledge of personal care areas such as skin, medication, and AD. The QIF is reliable, valid, and responsive to change.[194-196]

The *Capabilities of Upper Extremity Instrument (CUE)* is a questionnaire that assesses the ability to grasp, release, and lift, and wrist and finger actions, unilaterally and bilaterally.[197] Each item is scored on a 7-point ordinal scale where 1 is totally limited, cannot do at all and 7 is not at all limited. Total scores range from 32 to 224, where higher scores indicate better UE function. The CUE is reliable, valid, and responsive.[197,198]

Work, Community, and Leisure Integration or Reintegration

The ultimate goal of rehabilitation is to allow the individual to return to his or her normal roles and fully participate in society. Measures of participation provide insight into how the individual is functioning in the home and community. Some commonly used outcome measures are the *Craig Handicap Assessment and Reporting Technique*,[199] *Assessment of Life Habits*,[200,201] and *Reintegration to Normal Living Index*.[202]

Neuromuscular Recovery Scale

The *Neuromuscular Recovery Scale (NRS)* is an outcome measure used to assess the ability to perform a functional goal in the manner used by the intact neuromuscular system before injury and without compensation.[148,153] In comparison, the FIM assesses whether a functional task can be accomplished and how much assistance is required

SCIM–SPINAL CORD INDEPENDENCE MEASURE — Version III, Sept 14, 2002

Self-Care — DATE — Exam 1 2 3 4 5 6

1. Feeding (cutting, opening containers, pouring, bringing food to mouth, holding cup with fluid)
- 0. Needs parenteral, gastrostomy, or fully assisted oral feeding
- 1. Needs partial assistance for eating and/or drinking, or for wearing adaptive devices
- 2. Eats independently; needs adaptive devices or assistance only for cutting food and/or pouring and/or opening containers
- 3. Eats and drinks independently; does not require assistance or adaptive devices

2. Bathing (soaping, washing, drying body and head, manipulating water tap.) **A–upper body; B–lower body**

A.
- 0. Requires total assistance
- 1. Requires partial assistance
- 2. Washes independently with adaptive devices or in a specific setting (e.g., bars, chair)
- 3. Washes independently; does not require **a**daptive **d**evices or **s**pecific **s**etting (not customary for healthy people) (adss)

B.
- 0. Requires total assistance
- 1. Requires partial assistance
- 2. Washes independently with **a**daptive **d**evices or in a **s**pecific **s**etting (adss)
- 3. Washes independently; does not require **a**daptive **d**evices (adss) or **s**pecific **s**etting

3. Dressing (clothes, shoes, permanent orthoses: dressing, wearing, undressing). **A–upper body; B–lower body**

A.
- 0. Requires total assistance
- 1. Requires partial assistance with **c**lothes **w**ithout **b**uttons, **z**ippers or **l**aces (cwobzl)
- 2. Independent with cwobzl; requires **a**daptive **d**evices or in a **s**pecific **s**etting (adss)
- 3. Independent with cwobzl; does not require adss; needs assistance or adss only for bzl
- 4. Desses (any cloth) independently; does not require adaptive devices or specific setting

B.
- 0. Requires total assistance
- 1. Requires partial assistance with **c**lothes **w**ithout **b**uttons, **z**ippers or **l**aces (cwobzl)
- 2. Independent with cwobzl; requires **a**daptive **d**evices or in a **s**pecific **s**etting (adss)
- 3. Independent with cwobzl; does not require adss; needs assistance or adss only for bzl
- 4. Desses (any cloth) independently; does not require adaptive devices or specific setting

4. Grooming (washing hands and face, brushing teeth, combing hair, shaving, applying makeup)
- 0. Requires total assistance
- 1. Requires partial assistance
- 2. Grooms independently with adaptive devices
- 3. Grooms independently without adaptive devices

SUBTOTAL (0–20)

Respiration and Sphincter Management

5. Respiration
- 0. Requires tracheal tube (IT) and permanent or intermittent assisted ventilation (IAV)
- 2. Breathes indpendently with TT; requires oxygen, much assistance in coughing or TT management
- 4. Breathes independently with TT; requires little assistance in coughing or TT management
- 6. Breathes independently without TT; requires oxygen, much assistance in coughing, a mask (e.g., peep) or IAV (bipap)
- 8. Breathes independently without TT; requires little assistance or stimulation for coughing
- 10. Breathes independently without assistance or device

6. Sphincter Management—Bladder
- 0. Indwelling catheter
- 3. Residual urine volume (RUV) >100cc; no regular catheterization or assisted intermittent catheterization
- 6. RUV <100cc or intermittent self-catheterization; needs assistance for applying drainage instrument
- 9. Intermittent self-catheterization; uses external drainage instrument; does not need assistance for applying
- 11. Intermittent self-catheterization; continent between catheterizations; does not use external drainage instrument
- 13. RUV <100cc; needs only external urine drainage; no assistance is reqeuired for drainage
- 15. RUV <100cc; continent; does not use external drainage instrument

7. Sphincter Management—Bowel
- 0. Irregular timing or very low frequency (less than once on 3 days) of bowel movements
- 5. Regular timing, but requires assistance (e.g., for applying suppository); rare accidents (less than twice a month)
- 8. Regular bowel movements, without assistance; rare accidents (less than twice a month)
- 10. Regular bowel movements, without assistance; no accidents

8. Use of Toilet (perineal hygiene, adjustment of clothes before/after, use of napkins or diapers).
- 0. Requires total assistance
- 1. Requires partial assistance; does not clean self
- 2. Requires partial assistance; cleans self independently
- 4. Uses toilet independently in all tasks but needs adaptive devices or special setting (e.g., bars)
- 5. Uses toilet independently; does not require adaptive devices or special setting

SUBTOTAL (0–40)

Figure 20.20 Spinal Cord Injury Independence Measure,[192-194] with permission. *(From Topics in Spinal Cord Injury Rehabilitation 4(1):20, 1998. Thomas Land Publishers. Available at www.thomasland.com.)*

Mobility (room and toilet) DATE Exam 1 2 3 4 5 6

9. Mobility in Bed and Action to Prevent Pressure Sores
- 0. Needs assistance in all activities: turning upper body in bed, turning lower body in bed, sitting up in bed, doing push-ups in wheelchair, with or without adaptive devices, but not with electric aids
- 2. Performs one of the activities without assistance
- 4. Performs two or three of the activities without assistance
- 6. Performs all the bed mobility and pressure release activities independently

10. Transfers: bed-wheelchair (locking wheelchair, lifting footrests, removing and adjusting arm rests, transferring, lifting feet).
- 0. Requires total assistance
- 1. Needs partial assistance and/or supervision, and/or adaptive devices (e.g., sliding board)
- 2. Independent (or does not require wheelchair)

11. Transfers: wheelchair-toilet-tub (if uses toilet wheelchair: transfers to and from; if uses regular wheelchair: locking wheelchair, lifting footrests, removing and adjusting armrests, transferring, lifting feet)
- 0. Requires total assistance
- 1. Needs partial assistance and/or supervision, and/or adaptive devices (e.g., grab-bars)
- 2. Independent (or does not require wheelchair)

Mobility (indoors and outdoors, on even surface)

12. Mobility indoors
- 0. Requires total assistance
- 1. Needs electric wheelchair or partial assistance to operate manual wheelchair
- 2. Moves independently in manual wheelchair
- 3. Requires supervision while walking (with or without devices)
- 4. Walks with a walking frame or crutches (swing)
- 5. Walks with crutches or two canes (reciprocal walking)
- 6. Walks with one cane
- 7. Needs leg orthosis only
- 8. Walks without walking aids

13. Mobility for Moderate Distances (10–100 meters)
- 0. Requires total assistance
- 1. Needs electric wheelchair or partial assistance to operate manual wheelchair
- 2. Moves independently in manual wheelchair
- 3. Requires supervision while walking (with or without devices)
- 4. Walks with a walking frame or crutches (swing)
- 5. Walks with crutches or two canes (reciprocal walking)
- 6. Walks with one cane
- 7. Needs leg orthosis only
- 8. Walks without walking aids

14. Mobility Outdoors (more than 100 meters)
- 0. Requires total assistance
- 1. Needs electric wheelchair or partial assistance to operate manual wheelchair
- 2. Moves independently in manual wheelchair
- 3. Requires supervision while walking (with or without devices)
- 4. Walks with a walking frame or crutches (swing)
- 5. Walks with crutches or two canes (reciprocal walking)
- 6. Walks with one cane
- 7. Needs leg orthosis only
- 8. Walks without walking aids

15. Stair Management
- 0. Unable to ascend or descend stairs
- 1. Ascends and descends at least 3 steps with support or supervision of another person
- 2. Ascends and descends at least 3 steps with support of handrail and/or crutch or cane
- 3. Ascends and descends at least 3 steps without any support or supervision

16. Transfers: wheelchair-car (approaching car, locking wheelchair, removing arm and footrests, transferring to and from car, bringing wheelchair into and out of car)
- 0. Requires total assistance
- 1. Needs partial assistance and/or supervision and/or adaptive devices
- 2. Transfers independent; does not require adaptive devices (or does not require wheelchair)

17. Transfers: ground-wheelchair
- 0. Requires assistance
- 1. Transfers independent with or without adaptive devices (or does not require wheelchair)

(i.e., burden of care). Other measures are used to examine the time to perform a task (e.g., 10-Meter Walk Test for walking speed). The FIM and 10-Meter Walk Test allow compensation as a movement strategy and only address whether a goal is achieved, but not how it is accomplished. Compensation may include the use of one's own body in an alternative manner, an assistive device or brace, or physical assistance to achieve a goal. The NRS uniquely examines how a goal is attempted (or achieved) and does not allow the use of compensation strategies during task performance. Thus, the gold standard for recovery is not whether a goal is achieved, but whether it is accomplished in the manner (i.e., behavioral pattern) used before injury. This scale is particularly important because therapeutic interventions for rehabilitation after SCI are now targeting recovery to preinjury status as opposed to compensation for injury-related impairments.

The need to examine recovery is further supported by the introduction of combinatorial approaches targeting restoration of function below the level of the lesion. Such approaches may combine a surgical, stem cell, or pharmacological intervention with a behavioral intervention to enhance the potential for neural plasticity. For instance, in a recent case study, an epidural stimulator was surgically implanted on the spinal cord and paired with locomotor training to activate the neuromuscular system below the lesion.[154] Neuromuscular recovery was the goal and thus could aptly be examined using the NRS.

The NRS (version 2011) is comprised of 14 motor tasks: 4 items are tested on the treadmill (TM) and 10 items are tested overground. The TM-based items include stand retraining, stand adaptability, step retraining, and step adaptability. These items are tested with the use of partial body weight support (BWS) and TM to afford an environment in which the capacity of the neuromuscular system to stand and generate steps can be determined in a safe environment. The capacity of the neuromuscular system is examined by noting the amount of BWS, TM speed, and manual facilitation required to achieve optimal standing and stepping (stand and step retraining) and independence from manual facilitation (stand and step adaptability).

Items tested overground include sit, reverse sit-up, sit-up, forward reach and grasp, overhead press, door pull and open, trunk extension in sitting, sit to stand, stand, and walking. Each item is evaluated along a continuum of performance from an inability to perform the task to full recovery by executing the task in the manner performed before injury. Each item is individually scored and a phase of recovery identified. An overall composite score of recovery is calculated based on several individual scores at the lower end of the continuum. Phase 1 is the earliest stage of recovery with the patient requiring use of a wheelchair and dependent on others for assistance. Phase 2 is the mid-stage of recovery with initiation of independent standing. Phase 3 is a later stage, and independent standing is observed and walking achieved, though with compensation. Phase 4 is the final stage of recovery in which the patient demonstrates increasing endurance, speed, and adaptability to environmental challenges during walking while returning to preinjury activities without compensation. Therapists may use the NRS to identify specific goals for rehabilitation based on the patient's current phase of recovery for each task. The lagging items, the items least recovered (lowest on the continuum), may serve as a focal point for rehabilitation efforts.

Using "sit" as an example from the NRS, the goal is to assess the level of recovery of this specific functional task. Sitting entails no UE support and good posture of the head, shoulders, trunk, and pelvis. The continuum of recovery is from the inability to achieve good sitting posture without UE support to reaching greater than 10 in (25 cm) in forward and lateral directions with appropriate sitting posture and trunk/pelvis kinematics. Interim phases of recovery between the lowest and highest levels of recovery assess the ability to maintain sitting, sit with inappropriate posture, attain sitting, sustain sitting with appropriate kinematics, sit appropriately for at least 1 minute, sit appropriately indefinitely, sit appropriately while maintaining the arms at 90 degrees of flexion, sitting with forward and lateral reach less than 5 in (12.7 cm), sitting with forward and lateral reach 5 to 10 in (12.7 to 25 cm), and sitting with forward and lateral reach greater than 10 in (25 cm). Thus, with the NRS the therapist rates recovery of sitting via incremental advances in task difficulty with full recovery being the aim.

Prognosis and Goals

Functional outcome after SCI is dependent on many factors; primary among these, especially for individuals with complete injuries, is level of motor function. With complete lower-level lesions (i.e., more musculature intact), there is greater potential for independence in mobility tasks and ADL. With incomplete lesions (ASIA B, C, or D) there is greater functional potential as compared to ASIA A injuries; ASIA D injuries represent greater functional independence than that of ASIA B or C injuries. See Box 20.4 for other factors that can affect functional outcomes.[12,203-206] Table 20.5 provides a guide to expected functional outcomes for people with complete SCI based on level of injury. The physical therapist,

Box 20.4 Factors That Affect Functional Outcomes

- Motor level
- Age
- Concomitant injury
- Preexisting health conditions
- Secondary complications
- Body type
- Psychosocial support

		Driving	Independent with car with adaptive controls
L1, L2, L3			
Gracilis Iliopsoas Quadratus lumborum Rectus femoris Sartorius	Hip flexion Hip adduction Knee extension	Ambulation	Independent short distances in home and possibly community Many choose to use wheelchair in the community due to high energy demands of community ambulation Assistive devices (e.g., forearm crutches) Orthoses: HKAFO, KAFO, AFO (depending on which muscles are innervated)
L4, L5, SI			
Quadriceps (L4) Anterior tibialis (L5) Hamstrings (L5–S1) Gastrocnemius (S1) Gluteus medius and maximus (L5–S1) Extensor digitorum, posterior tibialis, peroneals, flexor digitorum (L5, S1)	Strong hip flexion Strong knee extension Knee flexion Ankle dorsiflexion Ankle plantarflexion Ankle eversion Toe extension	Ambulation	Independent ambulation in home and community (L4-level injury may elect to use wheelchair for long distances) Assistive devices (e.g., forearm crutches, canes) Orthoses: AFO Less supportive assistive device and orthoses the more caudal the SCI

*This table presents general functional expectations at various lesion levels. Each progressively lower motor includes the muscles from the previous levels. Although the key muscles listed frequently receive innervation from several spinal levels, they are listed here at the key neurological levels where they add to functional outcomes. Although intact musculature plays a main role in determining functional capability, many other factors influence function, including concomitant injuries, premorbid health status, age, body type, and psychosocial factors. Individuals with an incomplete injury will likely have greater functional abilities.

rehabilitation team, and patient can use these expected outcomes to establish goals and outcomes. However, as mentioned above, factors other than motor level may affect functional recovery.

Goals should reflect what is important and meaningful to the patient. This will increase motivation, promote achievement of goals, and enhance patient autonomy. Early after injury patients are not likely to fully understand the consequences of a SCI and are still in the process of adjusting to the injury. It is important to educate patients on the impact of SCI and review the findings of the initial examination and all reexaminations. Potential functional goals should be discussed and the patient encouraged to suggest his or her own goals as well. Long-term goals should focus on activity and social participation, not body structure and function impairments. Goals should be specific in what the patient will achieve. The level of assistance, the environment/conditions, and the length of time to achieve the goal should all be documented.

Examples of general goals and outcomes for patients with SCI (Practice Pattern 5H) as adapted from the *Guide to Physical Therapist Practice*[207] are presented in Box 20.5.

For patients with high cervical SCI who may not be able to physically perform certain functional mobility tasks, goals should be directed toward the patient being able to independently direct an attendant caregiver to perform the task appropriately.

Recovery of Walking Ability

Recovery of walking ability is one of the most common goals expressed by people with SCI.[208] Individuals with complete (ASIA A) UMN injuries are not likely to regain the functional LE strength required to become independent ambulators.[209] In patients with iSCI (ASIA B, C, and D) the prognosis for recovery of walking ability is more complex. For individuals with ASIA B (sensory incomplete) the preservation of pinprick sensation is an important prognostic indicator of the recovery of

Box 20.5 Examples of General Goals and Outcomes for Patients With SCI

- Airway clearance is improved.
- Aerobic capacity is increased.
- Integumentary integrity is improved.
- Muscle performance is increased.
- Risk of secondary impairments is reduced.
- Tolerates upright sitting posture.
- Independence in ADL.
- Independence transfers.
- Independence in wheelchair propulsion.
- Independence in self-directing care.
- Independence with pressure relief.

walking ability.[94,210] Most patients with ASIA D and C SCI will regain some ability to walk.[211,212] Lower extremity ASIA motor score, quadriceps strength in particular, can be a useful predictor of functional walking ability in people with motor incomplete injuries.[213,214]

In 2011 the *European Multicenter Study on Human Spinal Cord Injury* published a clinical prediction rule for predicting ambulation after SCI.[215] In a cohort of almost 500 patients, findings indicated that age, motor scores of quadriceps and gastrocnemius, and light touch sensory scores at L3 and S1 were able to accurately distinguish between independent home ambulators (as scored on the SCIM) and those who require assistance or cannot ambulate. The clinical prediction rule was 96% accurate.[215]

As with any clinical prediction guide it is important to keep in mind that these factors should only be used as a *guide* to assist in the development of goals and the POC. Other factors such as psychosocial support, insurance coverage, and patient psychological status and motivation can affect outcomes. Additionally, new therapies may be developed that improve neurological recovery.

Physical Therapy Interventions

Improvements in body structure/function impairments, the ability to perform activities that are important to the individual, and a return to participating in normal, desired social roles can be achieved through interventions that are based on compensatory strategies, restorative strategies, or a combination of the two. In people with SCI the intervention strategy selected is largely based on the amount of preserved motor function. Independence in functional skills in patients with complete motor SCI (ASIA A and B) is largely achieved through compensatory mechanisms and interventions are developed accordingly. For example, a person with a C6 ASIA A injury is taught to transfer from bed-to-wheelchair using a sit pivot method. Patients with ASIA C or D SCI, depending on the degree of motor return, may relearn how to perform functional tasks using more normal movement strategies. For example, a person with an ASIA D SCI may relearn how to walk through locomotor training using a BWS and TM system, an intervention that promotes normal movement patterns during gait training. This restorative approach attempts to minimize compensatory movement strategies and promote normal movement patterns to drive beneficial neuroplastic changes within the central nervous system.[216]

There are some common principles and precautions that can be applied to many interventions. Because SCI affects many different body systems, certain precautions must be considered when performing interventions (Box 20.6). Common principles used across compensatory intervention strategies to promote functional independence in mobility tasks are momentum, head–hips relationship, and muscle substitution. These strategies allow performance of functional mobility tasks through compensatory mechanisms that the patient may not be able to otherwise perform owing to loss of motor function and muscle strength below the lesion level. For example, a patient with a T1 ASIA A SCI will use momentum by swinging the arms across the body multiple times to roll from supine to sidelying to compensate for lost trunk or LE muscles that would normally assist in performing the task.

Motor learning concepts should be incorporated into the POC. In the early stages of motor learning, when the patient is not skillful and cannot perform the task independently, extrinsic feedback regarding task performance may be useful. For example, the physical therapist may provide tactile and verbal cues on correct hand placement on the hand rim when the patient is practicing and learning how to perform wheelies. Extrinsic feedback provided on a faded schedule promotes motor learning. In later stages of motor learning it is beneficial to have the patient use intrinsic feedback and rely less on extrinsic feedback. The practice schedule and environment can also be set up to promote motor learning. A random practice schedule is more beneficial to learning than a blocked practice schedule. The environment should be varied as the patient develops more skill in performing the task. For example, the patient should practice transferring to and from a

Box 20.6 Common Precautions to Take Into Account When Performing Interventions With People With Spinal Cord Injury

- Overuse/stress

variety of different surfaces (e.g., wheelchair to/from mat, bed, chair, car, sofa, and so forth) once basic competence in the skill has been achieved. See Chapter 10, Strategies to Improve Motor Function, for a discussion of motor learning strategies.

For certain mobility tasks it may be beneficial to break down the task into component parts and practice parts of the task along with the integrated whole. For example, when learning how to move from supine to long sitting, practice can first focus on a component part such as transitioning to supine on elbows. The task can also be modified so that it is easier to perform initially. When first learning to roll from supine to prone, pillows can be placed along the patient's back so the starting position is already halfway toward side-lying. As the patient's ability improves the pillows can be removed. Assistive and adaptive equipment can be used to promote independence in functional tasks as well. A patient with a C5 ASIA A injury may be able to rise to long sitting using a trapeze or loop system suspended from the ceiling or foot of the bed.

Strengthening

As described above, strengthening innervated musculature is an important component of the physical therapy POC. Key UE muscles to strengthen include serratus anterior, latissimus dorsi, pectoralis major, rotator cuff muscles, and triceps brachii.[217-219] These muscles are important for independent transfers. Strengthening exercises should be performed 2 to 4 times a week, performing 2 to 3 sets of 8 to 12 repetitions at 60% to 80% of one repetition max.[220] Initially, strengthening exercises may be done daily during early rehabilitation. A variety of methods can be used to implement strengthening exercises: pulley systems, free weights, elastic bands, and weight cuffs. With very weak muscles (grade ≤2) strengthening can be performed in gravity-reduced positions on a powder board or with active assistive ROM. Strengthening can be done in functional postures as well. For example, push-ups can be performed in prone-on-elbows and supine-on-elbows.

Cardiovascular/Endurance Training

As with able-bodied people, cardiovascular training has important health benefits for people with SCI. A number of research studies have shown that endurance training can improve aerobic fitness.[221-224] Upper extremity–based exercises such as arm ergometry, wheelchair propulsion, and swimming are the most common method of aerobic training. In people with iSCI with sufficient walking capacity locomotor training on a TM with or without BWS is another method of endurance training.[225,226] The American College of Sports Medicine (ACSM) recommends endurance training 3 to 5 days a week, with a total duration per day of 20 to 60 minutes at 50% to 80% of peak heart rate.[220] The duration and intensity of the training should be gradually increased for those not able to initially tolerate these training levels. Surface Functional Electrical Stimulation (FES)–induced cycling or walking is also an effective means of improving cardiovascular fitness.[227-229] Surface electrodes are attached bilaterally to the hamstrings, quadriceps, and gluteal muscles; a computer controls the intensity of the muscle stimulation and cadence based on the position of the pedals (Fig. 20.21).[42]

Bed Mobility Skills

Bed mobility skills are necessary to promote independence in functional mobility. Bed mobility skills include rolling, transitioning supine to/from sitting on the edge of the bed, and LE management. Independence in these skills is also necessary for dressing, positioning in bed, and skin inspection. The degree to which these skills can be performed independently varies depending on the individual's level of injury and other factors (see Box 20.3). The exact method of performing the task will vary with the individual. The skills and intervention techniques described below provide a general guide; however, these may need to be adapted depending on the unique presentation of the patient. Also, as mentioned above, certain precautions need to be observed when teaching patients these techniques. For example, excessive friction on the elbows while weight shifting in prone-on-elbows may result in skin breakdown. Patients may begin training wearing protective elbow pads.

Figure 20.21 Functional Electrical Stimulation powered lower extremity ergometer. *(Courtesy of Restorative Therapies, Baltimore, MD 21224.)*

At first bed mobility skills are learned and practiced on an exercise mat, which is firmer and larger than a typical bed. However, as skill improves they should be practiced on a bed similar to that used at home. A patient may be independent performing these skills on a mat, but still require more practice to become independent performing the same task on a bed due to the softer and smaller surface.

Individuals with complete SCI will need to use compensatory movement strategies (e.g., momentum, muscle substitution, and head-hips principle) to move the entire body. For example, a patient with a T1 ASIA A injury will use momentum by swinging the arms up and across the body to generate momentum that will cause the trunk and legs to roll to the side-lying position from supine. A patient with a T10 ASIA A injury will use muscle substitution by using the UEs to lift the legs up onto the mat from a short sitting position when transitioning to supine from sitting. Individuals with iSCI may be able to use more normal movement strategies to perform these tasks. This will depend on the extent of motor recovery. Regardless of whether the injury is complete or incomplete, the recovery of normal movement patterns should be attempted and assessed (e.g., Neuromuscular Recovery Scale).

Rolling

Rolling is a frequent starting point of mat programs, and it is also a prerequisite skill for other bed mobility tasks and provides an early lesson in developing functional patterns of movement. It requires the patient to learn to use the head, neck, and UEs, as well as momentum, to move the trunk and/or LEs. It is usually easiest to begin rolling activities from the supine position, working toward the prone position. If asymmetric involvement exists, rolling should be initiated with movement toward the weaker side.

To develop maximum independence adaptive devices such as bed rails, ropes, canvas "ladders," or overhead devices such as trapezes should be avoided, if possible. However, if these adaptive devices allow more efficient or independent task performance or when the task cannot be otherwise accomplished, they should be incorporated into the overall POC. In addition, the patient should work toward achieving independent rolling when covered by sheets and blankets. To begin training and facilitate rolling, several strategies can be used:

- Flexion of the head and neck with rotation may be used to assist movement from supine to prone positions.
- Extension of the head and neck with rotation may be used to assist movement from prone to supine positions.
- Bilateral, symmetrical UE rocking with outstretched arms produces a pendular motion when moving from supine to prone positions. The patient rhythmically rocks the outstretched arms and head from side-to-side and then forcefully "tosses" them to the side to which the patient is rolling. The trunk and hips will follow (Fig. 20.22). The head and arms should be synchronized. Use of wrist cuff weights (2 to 3 lb) may be used initially to increase kinesthetic awareness and momentum. The number of rocking motions necessary will depend on the patient's skill, level of SCI, and body type.
- Crossing the ankles will also facilitate rolling initially (see Fig. 20.22). The therapist crosses the patient's ankles so that the upper limb is toward the direction of the roll (e.g., the right ankle would be crossed over the left when rolling toward the left). When first learning, flexing the hip and knee of the top LE and placing it over the opposite limb (e.g., the hip and knee of the right LE would be flexed and placed over the left when rolling toward the left) can assist.
- In moving from the supine position to the prone position, pillows may be placed under one side of the pelvis (or scapula, if needed) to create initial rotation

Figure 20.22 Rolling from supine to prone using UE momentum and crossing the ankles.

in the direction of the roll. The activity can be started with two pillows, progress to one, and then to rolling without the use of pillows. If difficulty is encountered in initiating the roll, the activity can be started from a side-lying position. To facilitate movement from prone to supine positions, pillows may be placed under one side of the chest and/or pelvis. Again, the number and height of pillows should be reduced gradually and eventually eliminated.

- Several *Proprioceptive Neuromuscular Facilitation* (PNF) patterns are useful during early rolling activities. The UE patterns of D1 flexion, D2 extension, and reverse chop will facilitate rolling toward the prone position. The UE lift pattern will facilitate rolling toward the supine position from side-lying.

Transitioning Supine to/from Sitting

The ability to transition from supine in bed to sitting on the edge of the bed is a critical skill necessary for independent mobility. Before a person can transfer out of bed to a wheelchair, the ability to sit up on the edge of the bed must be first achieved. There are two basic methods (with variations) to transition from supine to sitting: (1) "walking" onto elbows from prone or side-lying and (2) coming straight up from supine. Both of these methods transition the patient from supine to long sitting. The patient then must learn to manage the LEs to move into short sitting on the edge of the bed. In addition to rolling, two important prerequisite skills/postures that are necessary to come to long sitting from supine are the ability to assume and move within prone-on-elbows and supine-on-elbows.

Prone on Elbows

Prone-on-elbows can be assumed from either prone or side-lying. In prone, the shoulders can be either abducted (elbows out away from the body) or adducted (elbows at the side of the trunk) and the patient weight shifts from side to side while moving the unweighted arm to eventually position both elbows directly underneath the shoulder joints (Fig. 20.23A and B). From side-lying the patient pushes the elbow that is on the mat down into the mat by extending the shoulder, then swings the top arm forward while rolling to prone so the elbow comes onto mat in the prone-on-elbows position.

Transitioning into prone-on-elbows is a challenging skill, particularly for individuals without functioning triceps. The patient can be assisted into the position and practice stability and controlled mobility interventions initially.

- Weight-bearing in the prone-on-elbows position will improve strength stability at the upper trunk, neck, and shoulders.
- The PNF technique of rhythmic stabilization may be used to increase stability and strength at the head, neck, shoulders, and scapula.

Figure 20.23 Transitioning from prone **(A)** to prone on elbows **(B)** with shoulders initially abducted and weight shifting.

- Weight shifting assists with development of controlled mobility and is usually easiest in a lateral direction with a progression to anterior or posterior movements.
- Unilateral weight-bearing on one elbow can be achieved in the prone-on-elbows position by having the patient lift one arm. This further facilitates co-contraction in the weight-bearing limb.

- Movement within this posture can be achieved by walking on elbows to both sides, up toward the head of the mat, and backward toward the foot of the mat.
- Strengthening of the serratus anterior and other scapular muscles can be achieved with prone-on-elbows push-ups. This is accomplished by having the patient push the elbows down into the mat and tuck in the chin while lifting and rounding out the shoulders and upper thorax (Fig. 20.24). This is similar to the "cat/camel" maneuver used in the quadruped position. The patient lowers the upper chest to the mat again by allowing the scapula to adduct.

Supine-on-Elbows

There are several approaches to assuming the supine-on-elbows position. If control of abdominal muscles is present, the patient may have sufficient strength to achieve the position by pushing the elbows into the mat and lifting into the position. A common technique is for the patient to "wedge" the hands under the hips or to hook the thumbs into pants pockets or belt loops. By contracting the biceps and/or wrist extensors, the patient can pull up partially into the posture. By shifting weight from side-to-side, the elbows can then be positioned under the shoulders (Fig. 20.25A, B, and C).

Some patients may find it easiest to assume this position from side-lying. The lower elbow is first positioned and pushed into the mat. The patient then rolls toward the supine position and quickly extends the upper arm, landing on the elbow as close to the shoulder as possible. By weight shifting, placement of the elbows can then be adjusted.

Much of the inherent benefit of this activity is achieved in learning to assume the posture and then move into long sitting. In addition to its direct functional significance, this activity is also an important strengthening exercise for shoulder extensors and scapular adductors.

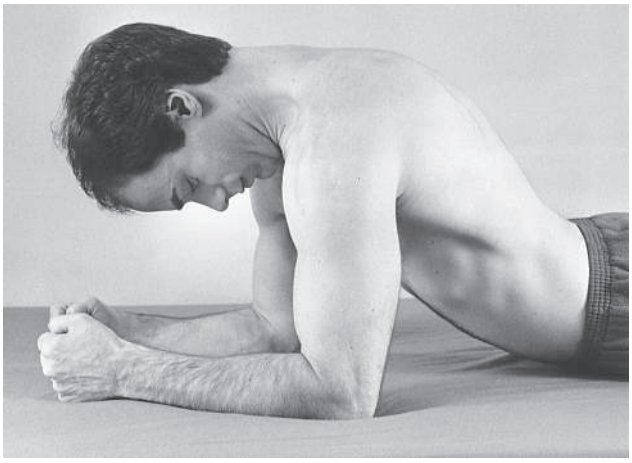

Figure 20.24 The prone-on-elbows position can be used to strengthen the serratus anterior and other scapular muscles.

- Rhythmic stabilization may be used to increase stability and strength at the head, neck, shoulder, and scapula.
- Lateral weight shifting can be practiced in this position.
- Side-to-side movement in this posture will enhance the patient's ability to align the trunk with the LEs when in bed or in preparation for positional changes.
- Precautions should be taken with this posture because it may cause increased shoulder pain due to the pressure exerted on the anterior shoulder joint capsule.

Walking on Elbows to Assume Long Sitting

From prone the patient walks on elbows toward one side into a "C" position. The patient then unweights the elbow closest to the legs and hooks it around the knees and pulls the trunk toward the legs. At a certain point the patient can then shift weight off the weight-bearing elbow to the palm and push with one arm while pulling with the other up to a long sitting position (Fig. 20.26A, B, C, and D).

This method of coming to long sitting does not require as much ROM in the shoulders as coming to sitting straight up from supine (see below). Practicing parts of the entire task, for example, walking on elbows or pulling up with one arm once in the "C" position, is a way to learn to the skill.

Coming Straight to Long Sitting From Supine

To come to long sitting from supine requires a more than normal amount of shoulder extension and strong elbow flexors. From supine the hands are placed under the hips or in pants pockets. By flexing the elbows from this position, the upper trunk is lifted off the mat. The shoulders are extended and the elbows placed in weight-bearing so that the patient is then in supine on elbows. From this position the patient unweights one elbow by shifting onto the opposite elbow. For the patient with a midlevel cervical SCI, the unweighted UE is thrown back into hyperextension and external rotation with the elbow extended so that the palm is on the mat. The patient then rotates the upper trunk onto the UE that was just thrown back in order to unweight the other UE. The unweighted UE upper extremity is now thrown back in a similar manner so that the patient is now weight-bearing on both hands, then weight shifts side-to-side and walks the hands up to assume a long sitting position (Fig. 20.27A, B, and C). Again, it is useful to practice parts of the task to assist in learning how to perform the entire skill.

Patients without sufficient strength or ROM, or due to other factors, may use adaptive equipment such as bed rails, loop ladder, suspended trapeze, or suspended loops to assist in coming to long sitting.

Figure 20.25 Patient transitioning from supine **(A)** to supine-on-elbows **(B)** by stabilizing hands under pelvis, forcefully pulling up by contracting the biceps, weight shifting side to side, and placing elbows further underneath the shoulder joints **(C)**.

Figure 20.26 Patient transitioning from prone-on-elbows **(A)** to long sitting **(B)**; walks into a "C" position **(C)**, pulls trunk up to long sitting position **(D)**.

Figure 20.27 Patient transitioning to long sitting from supine-on-elbows **(A)**. Bears weight on one elbow while the other UE is thrown back into shoulder extension with the elbow extended to bear weight on the other UE **(B)**, then weight shifts onto the other UE and throws other UE back into shoulder extension with elbow extended to come into long sitting **(C)**.

Once in long sitting, patients must learn to move the LEs off the edge of the bed to come to short sitting, back onto the bed when moving from short sitting to supine, and to position themselves in bed using their UEs. Patients who do not have full finger and hand musculature innervation can slide the wrist under a leg so that the palm of the hand is facing the mat and extend the wrist to help move the legs. Alternatively, leg loops can be placed around the thighs to slide the hand in and extend the wrist to lift the leg.

Sitting Balance

Independent sitting balance, both in short sitting and long sitting, is an important skill for many different functional tasks such as transfers, dressing, and wheelchair mobility. Sitting posture will vary considerably with lesion level. Patients with low thoracic lesions can be expected to sit with a relatively erect trunk. Individuals with low cervical and high thoracic lesions maintain sitting balance by forward head displacement and trunk flexion (Figs. 20.28 and 20.29).

Due to the varying degrees of sensory and motor impairment patients need to relearn their center of balance, the limits of stability, and how to maintain postural control. The following are some suggestions that can be incorporated to improve sitting balance, both in long and short sitting.

- Sitting balance training is initially done by assisting the patient into a balanced short or long sitting position. In short sitting the patient should initially be positioned with the feet firmly supported on the floor and the hips and knees flexed to 90 degrees. In long sitting patients should have approximately 90 to 100 degrees of straight leg raise ROM to avoid overstretching the low back muscles. Initially, it is easier to maintain balance in long sitting due to the larger BOS. The LEs can be placed with the hips in external rotation and slight abduction to allow knee flexion to avoid overstretching the low back muscles.

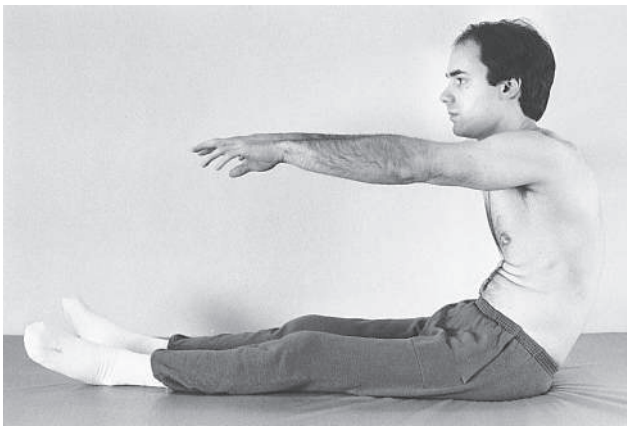

Figure 20.28 Individual with a T4 ASIA A injury in long sitting.

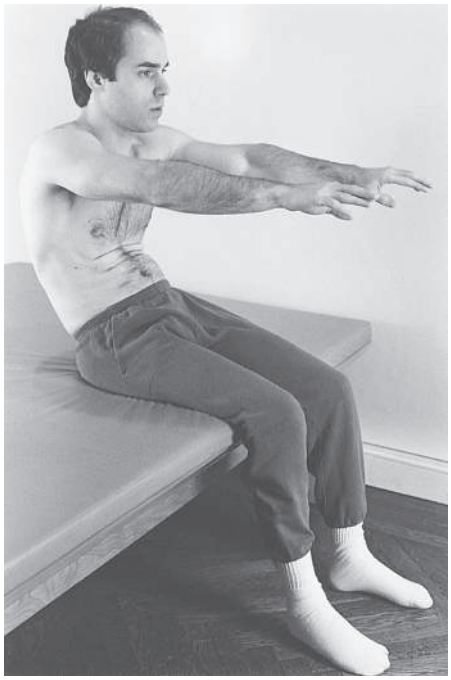

Figure 20.29 Individual with a T4 ASIA A injury in short sitting.

- Patients may initially need to bear weight through the UEs to maintain the sitting position. For patients with cervical level lesions who utilize a tenodesis grasp to hold and manipulate objects, the fingers should be flexed at the proximal and distal interphalangeal joints when the wrist is in full extension to prevent overstretching the finger flexor tendons. Patients who do not have triceps innervation need to learn to keep the elbows extended through muscle substitution. The patient throws back the shoulder into full shoulder extension while externally rotating the shoulder and supinating the forearm. When the UE is weight-bearing in this position the patient can contract the anterior deltoids to flex the shoulder in a closed chain, which will extend the elbow.
- Stability in sitting can be enhanced by providing manual resistance to the upper trunk using PNF techniques of alternating isometrics and rhythmic stabilization.
- Sitting practice should include altering UE support (bilateral, unilateral, with progression to no support). Reaching for objects with one and both UEs can improve anticipatory balance reactions. Patients should also practice maintaining postural control while manipulating objects and performing ADL in sitting.
- Patients should safely learn their new limits of stability. This can be accomplished by weight shifting until the point is reached where balance can no longer be maintained; close supervision/assistance is warranted.
- Providing unexpected perturbations in a safe manner can be used to practice reactive postural control.

- Balance interventions should be practiced on a variety of surfaces: firm mat, bed, dense foam, sofa cushion, and so forth. Balance interventions should also be practiced while sitting in the patient's wheelchair.

Transfers

There are three components to the sit-pivot transfer (e.g., bed to/from wheelchair in a seated position): preparatory phase, lift phase, and descent phase.[230] During the *preparatory phase,* the trunk flexes forward, leans laterally, and rotates toward the trailing arm (Fig. 20.30A). The *lift phase* starts when the buttocks lift off the sitting surface and continues while the trunk is lifted halfway between the two surfaces (Fig. 20.30B). The *descent phase* denotes the period when the trunk is lowered to the other seated surface, from the halfway point until the buttocks are on the other surface (Fig. 20.30C).

The following are key components and intervention strategies to improve transfer ability:

- Provide support and assistance so the patient feels safe and comfortable while learning transfers.
- Confidence and skill in maintaining sitting balance is critical (see above strategies).
- The head–hips relationship is important. Moving the head and upper trunk in one direction causes the lower trunk and buttocks to move in the opposite direction. For example, if the patient wants to transfer from bed to the wheelchair, which is positioned to the patient's right, the patient rocks the head and upper trunk forward/downward and to the left. In combination with protracting the scapulae to lift the buttocks, this will cause the lower trunk and buttocks to lift upward and swing to the right into the wheelchair.
- For patients without innervated triceps the strategies described above can be used to place and maintain the elbows in extension. For patients without full finger function, overstretching the finger flexors as described above should be avoided.
- Hand position is important. The hands should be positioned forward of the hips to form a tripod with the buttocks. Greater force is generated in the trailing UE[230,231] (UE furthest from the surface transferring to); if one UE is weaker or more painful it should be the lead UE. The lead UE should be further from the trunk/buttocks and the trailing UE closer to the trunk/buttocks.
- Using the head–hips relationship described above (leaning head and upper trunk forward and down), protracting the scapulae should be practiced to lift the buttocks off the sitting surface. The physical therapist can assist by placing his or her hands under the patient's hips and assisting the lift or by placing one hand on the front of the chest and the other between the scapulae to guide and assist the forward/downward lean and lift. Push-up blocks or wrist cuffs can be used initially to provide assistance to achieve a greater lift.
- Again using the head–hips relationship, practice should include lifting the buttocks and shifting laterally to the left and right. The patient should lean the head/upper trunk forward and downward, then twist to left or right to lift and shift the hips in the opposite direction. Patients may initially lift the hips and then twist the upper trunk to shift the lower trunk and buttocks in the opposite direction

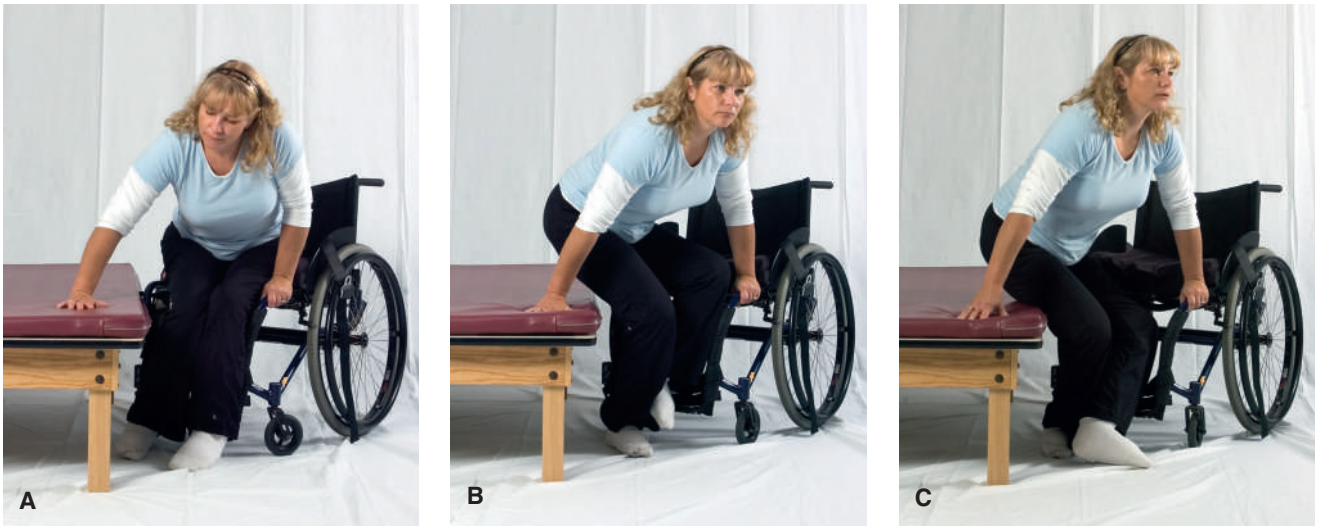

Figure 20.30 **(A)** Preparatory phase of the transfer; trunk is flexed forward and laterally away from surface transferring to. **(B)** Lift phase; buttocks are lifted off the seating surface as the trunk rotates. **(C)** End of the descent phase when the buttocks are on the other sitting surface. *(From O'Sullivan, S, and Schmitz, T: Improving Functional Outcomes in Physical Rehabilitation. FA Davis, Philadelphia, 2010, with permission.)*

in two motions. As the patient improves, these two movements should be performed as a single motion.
- Lower extremities should be positioned with the feet supported and the hips and knees at approximately 90 degrees of flexion or slightly more at the hips. The legs should be midway between the two surfaces so they do not block the movement of the trunk and body toward the transfer surface.
- Emphasis should be placed on lifting and shifting laterally instead of sliding/scooting to the side to avoid shearing of the skin. Control of movement should be promoted during the descent phase to avoid trauma to the skin. A transfer board may be used initially until the patient gains more skill with the task. Some patients with mid-cervical SCI may always require a transfer board.
- Transfer training should include a variety of surfaces from the wheelchair (bed, sofa, toilet, car, and so forth) and to varying heights (higher and lower than the wheelchair surface).

There are important complementary skills that patients need to perform to be fully independent with transfers (Box 20.7).

Floor-to-Wheelchair Transfers

There are three basic floor-to-wheelchair techniques: backward approach, forward approach, and sideways approach (Figs. 20.31A-C, 20.32A-D, and 20.33A-C). *Improving Functional Outcomes in Physical Rehabilitation*[232] and *Spinal Cord Injury: Functional Rehabilitation*[113] provide more detail on how to perform these transfers and other interventions to improve transfer ability.

Locomotor Training

Regaining the ability to walk is a common goal for most individuals following SCI. A number of factors will influence the success or failure in attaining this goal. Patients must possess adequate muscle strength, postural alignment, ROM, and sufficient cardiovascular endurance to become functional ambulators. Becoming a functional ambulator following a complete SCI is very difficult. Walking with orthoses and assistive devices is slower and requires considerably more energy than walking before the injury. Many individuals with motor complete SCI who learn to walk with these devices may not continue walking once they stop rehabilitation. Patients with motor iSCI (ASIA C and D) are more likely to regain functional ambulation skills than those with complete or sensory incomplete injuries.[209,211,212]

This section on locomotor training is divided into two sections. The first deals with gait retraining using a compensatory-based approach for people with motor complete SCI. The second section highlights a recovery and activity-based approach for people with motor iSCI.

Locomotor Training for Individuals with Motor Complete SCI

When initiating a locomotor training (LT) program for complete SCI, therapists should be realistic and provide a clear picture of the costs and potential benefits. Patients who wish to relearn to ambulate following SCI should be given this option even if their potential for functional ambulation is limited. Although some patients may not become functional ambulators, standing alone may provide other important benefits such as improved circulation, skin integrity, bowel and bladder function, sleep, and a sense of well-being.[233]

Individuals with complete SCI rely on orthotic and assistive devices, adequate ROM, and maximizing strengthen of neurologically intact musculature for standing and walking. Full ROM in hip extension is essential in attaining balance in the upright position. The patient learns to lean into the anterior ligaments of the hip to stabilize the trunk and pelvis. The absence of knee flexion and plantarflexion contractures is also important in attaining upright standing balance.

Adequate cardiovascular endurance also is a criterion for functional ambulation. Because the energy cost of ambulation for a patient with complete paraplegia is higher than it is for people without SCI, endurance becomes an important factor in determining success or failure and continued ambulation once rehabilitation is complete.

Other factors that may restrict ambulation include severe spasticity, loss of proprioception (particularly at the hips and knees), pain, obesity, and the presence of secondary complications such as decubitus ulcers, heterotopic bone formation at the hips, or deformity. In addition, the patient's motivation plays a key role in determining success or failure in ambulation. A highly motivated patient can learn to walk using KAFOs and assistive devices. However, these patients may eventually find that the energy cost of ambulation is too great.

Follow-up studies of long-term continuation of ambulation have not been extensive. Mikelberg and Reid[234] surveyed 60 individuals with SCI for whom orthotics had been prescribed. From this group, 60% used

Box 20.7 Complementary Skills Necessary for Independence With Transfers

- Position wheelchair

their wheelchairs as the primary means of mobility. Thirty-one percent completely discarded their orthoses. Those who did use their orthoses reserved them primarily for standing and exercise activities.

For patients with complete SCI, training emphasis is on strengthening available musculature; using assistive devices and orthoses to support weak or denervated muscles; and learning new, compensatory methods of walking.

Orthotic Prescription

The orthotic prescription varies according to the lesion level. Ankle and/or knee control bracing is often necessary. Patients with complete thoracic lesions will require

Figure 20.33 **(A-C)** Floor to wheelchair transfer using a sideways approach. *(From O'Sullivan, S, and Schmitz, T: Improving Functional Outcomes in Physical Rehabilitation. FA Davis, Philadelphia, 2010, with permission.)*

KAFOs. Conventional KAFOs include bilateral metal uprights, posterior thigh and calf bands, an anterior knee flexion pad, drop-ring or bail locks, adjustable locked ankle joints, a heavy-duty stirrup, and a cushion heel. The ankle joints are usually locked in 5 to 10 degrees of dorsiflexion to assist hip extension at heel strike. Orthotic hip control is not necessary, because the braces allow the patient to balance weight over the feet with the hips hyperextended. The center of gravity is kept posterior to the hip joints but anterior to the ankles.

The Scott–Craig orthosis is another type of KAFO that may be used by patients with paraplegia. These orthoses consist of standard double uprights, an offset knee joint providing improved biomechanical alignment, bail locks, a posterior thigh band, an anterior tibial band, adjustable ankle joint, and a sole plate that extends beyond the metatarsal heads. The orthosis may also include a plastic solid ankle section in place of the metal ankle joint and sole plate. This change decreases overall weight of the orthosis, improves cosmesis, and eliminates the need for custom-made shoes.

Another type of orthotic device available to patients with SCI is the reciprocating gait orthosis (RGO). The RGO is composed of two plastic KAFOs that are joined by a molded pelvic band with thoracic extensions. The RGO has a dual-cable system that runs posteriorly and attaches at the hip joints. These cable attachments transmit forces between LEs and provide reciprocal movement. Movement at the hip in one direction facilitates movement in the opposite direction on the contralateral hip. For example, as weight is shifted onto the left LE the right is moved forward. The dual-cable system allows control of both flexion and extension. These cables function to "coordinate" action between the two extremities during ambulation. As the advancing leg is unloaded, it is assisted into flexion while the stance leg is simultaneously pushed into extension. Thus, the orthosis allows for unilateral leg advancement and a reciprocating gait pattern. With this orthosis, a two- or four-point gait pattern can be used in combination with crutches or a reciprocating walker. Movement to a seated position is accomplished by unlocking the drop lock at the knee joint.

Ankle-foot orthoses (AFOs) are often appropriate for patients with lower-level lesions (e.g., L3 and below). Either a conventional metal-upright or plastic AFO may be indicated. Chapter 30, Orthotics, provides a detailed discussion of these different types of orthoses.

Locomotor Training Strategies

Swing-through (Fig. 20.34) and 4-point gait patterns are two common walking patterns learned by patients with complete SCI using KAFOs. Initial standing balance and gait training should be done in the parallel bars and then progressed to the appropriate assistive device when the patient is ready. Relevant training activities include those described below.

- *Putting on and removing orthoses.* The patient is first taught the correct way to don and doff the orthoses. The entire procedure is usually done in the supine or sitting position. The patient must be cautioned to continuously monitor skin for pressure areas, particularly after brace removal.
- *Assistive device*. Forearm crutches are most often selected for patients with paraplegia. These crutches provide several advantages. They are lightweight; they allow use of the hand without the crutch becoming disengaged; they fit more easily into an automobile; and, most important, they improve function in ambulation and stair climbing by allowing full hip extension and unrestricted movement at the shoulders.
- *Sit-to-stand activities*. These activities should be practiced in the parallel bars using a wheelchair, then progressed to using the forearm crutches. The patient must learn to slide to the edge of the chair and unlock and lock the orthoses. Initially the patient is taught to pull to standing, using the parallel bars (a progression is made to using the wheelchair armrests to push to standing). Once in an upright position, the patient pushes down on the hands and tilts

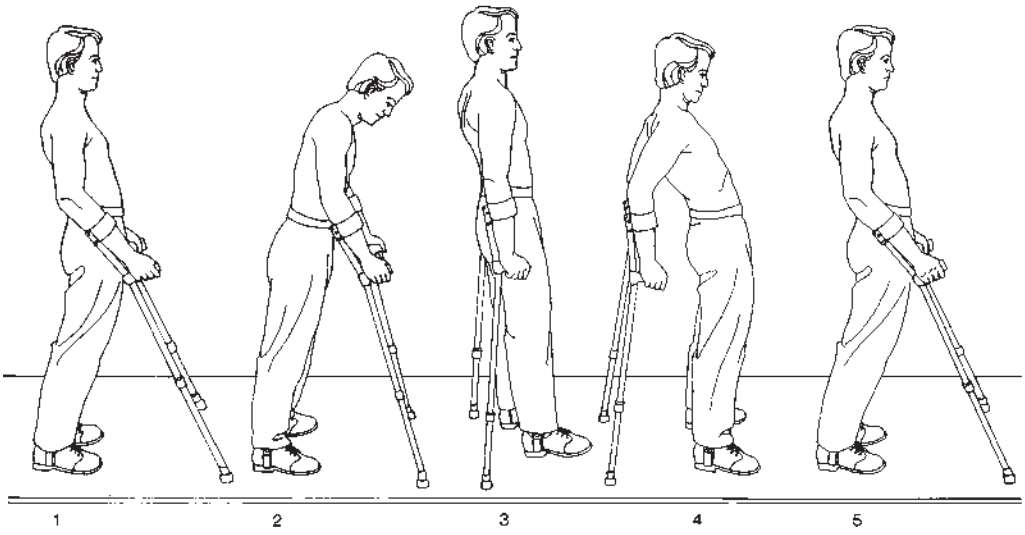

Figure 20.34 Swing-through gait pattern.

the pelvis forward in front of the shoulders. Return to sitting is a reversal of this procedure. To begin this activity with crutches the patient first places the crutches behind the chair, leaning against the push handle(s). To assume a standing position with crutches, the patient moves forward in the chair, locks both knee joints, crosses one leg over the other, and then rotates the trunk and pelvis (Fig. 20.35). Hand placements on the armrest are reversed and the patient pushes to standing by pivoting around to face the chair. The reverse of this technique is used to return to the chair.

- *Static standing balance.* The patient learns to balance in standing with the hips in hyperextension and the upper trunk, head, feet, and arms behind the pelvis. The feet are 3 to 5 in (7.6 to 12.7 cm) apart.

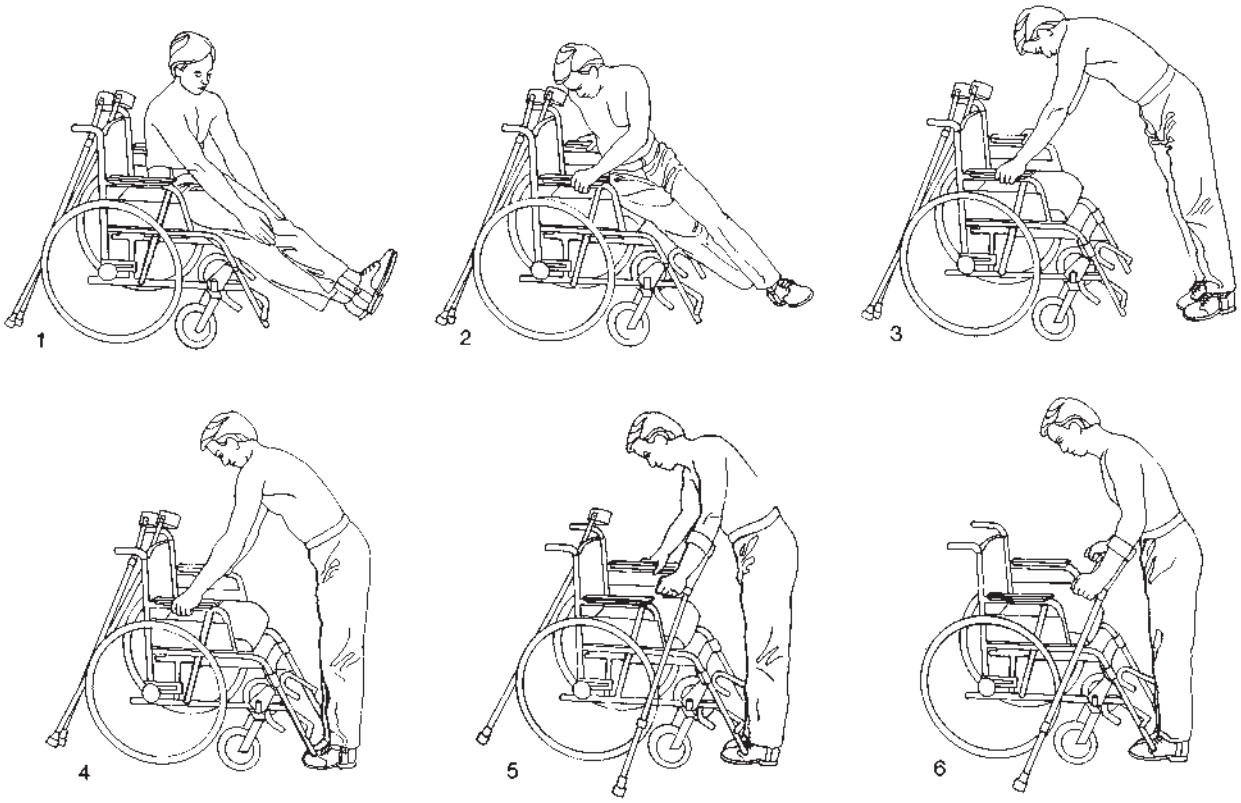

Figure 20.35 Standing from wheelchair using forearm crutches and KAFOs. The reverse sequences is used to return to sitting in the wheelchair.

The patient should first practice maintaining this position with both hands on the parallel bars, then progress to balancing with one hand off the parallel bars, and finally with both hands off the bars. The greater the amount of dorsiflexion at the ankle, the more anterior the pelvis can be.

- *Weight shifting in standing.* This entails controlling the pelvic position using UE support and positioning the head and shoulders forward ahead of the pelvis. The head hips relationship applied in transfers also applies in standing. The patient must be taught recovery to overcome and/or to prevent jackknifing from happening during ambulation. Jackknifing occurs when the patient's center of mass (COM) falls anterior to the hips causing the patient to flex forward suddenly.
- *Push-ups*. This includes lifting the body off the floor using elbow extension and scapulae depression and protraction, tucking the head to gain added height, and controlled lowering of the body.
- *Swing-through pattern.* From a balanced standing position with the hands posterior to the pelvis, the patient moves the hands forward causing the trunk to flex. Then the patient lifts up by extending the elbows and protracting/depressing the scapula and tucking the head. Gravity will cause the trunk and legs to swing forward. When the heels strike the ground the patient quickly extends the upper trunk and head, and pushes the pelvis forward to come back to the starting position (Fig. 20.34).
- *Four-point pattern.* This gait pattern is slower but safer than a swing-through pattern; three points are always in contact with the ground, as opposed to a swing-through pattern, in which there are times when only two points are in contact with the ground. From a standing position with the pelvis forward, both feet on the ground, and hands posterior to the pelvis, one hand/crutch is lifted up and placed forward. Weight is shifted away from the contralateral LE so it can swing forward as the hip is hiked and the head is moved down and away from the swing leg. This unweighting and hip hiking allows gravity to assist the forward swing. This process is repeated on the opposite side.

Spinal Cord Injury: Functional Rehabilitation[113] provides more detail on these and other gait training activities for people with complete SCI.

Locomotor Training for Individuals with Incomplete Spinal Cord Injury

Locomotor training (LT) for patients with iSCI using partial BWS, a TM, and manual assistance by trainers is an important therapeutic intervention to retrain walking after iSCI. Terms to describe this training include *body weight supported treadmill training*, *partial body weight supported treadmill training*, or *weight supported treadmill training*. These terms emphasize the exercise or training equipment that is currently advocated for retraining walking by medical equipment manufacturers and by some clinicians and researchers; however, the terms fail to describe the critical elements of the training[235] and the specific rehabilitation goal. What does a therapist actually do with a patient to retrain walking using this equipment? This section provides (1) a global perspective on LT and how it differs from LT for persons with complete SCI; (2) the clinical guidelines for selection and use of LT strategies; and (3) evidence regarding use of LT following SCI.

Locomotor training is a product of *translational research* or *bridge research*. Knowledge gained by basic science researchers concerning the neurobiological control of walking laid the foundation for developing a therapeutic intervention with application to human, clinical populations. Basic scientists seeking to understand the role and contribution of the spinal cord to the control of walking used an animal model of complete SCI for their inquiries. They discovered that when mid-thoracic spinalized cats (i.e., cats that had a complete transaction of the spinal cord) were placed on a TM, suspended by a sling, and repetitively trained for hind-limb stepping with assistance of trainers for loading and limb placement, the animals learned to hind-limb step (on the TM) independent of supraspinal input. With continued training the cats were ultimately able to step on the TM independent of manual assistance.[236,237] Furthermore, this intense training was task-specific in that the spinalized cats could be trained to stand, or to step, but that training to perform one task did not transfer to performance of the other task.[238] Seminal research in this arena provided the impetus for Hugues Barbeau, a neuroscientist and physical therapist, to attempt the same strategy for retraining walking in humans after traumatic SCI: translational research.

Barbeau and co-workers published the first studies in which humans were partially suspended with a BWS apparatus over a TM to examine its impact on gait[239,240] and then provided training similar to that experienced by the cats for persons with SCI.[241] Though a suspension system and TM appear to be strong common denominators of the training, the equipment is likely not the dominant, critical component. The equipment provides an effective and controlled environment for consistent and intense practice of walking that can closely approximate the sensory experience of walking. The successes of the spinalized cats and improvements in walking by humans after iSCI were attributed to activity-dependent plasticity of the neural axis.[242] Activity-dependent plasticity, or the responsiveness of the neural circuitry of the spinal cord to task-specific practice and its capacity to learn, was a new concept and revolutionary for the rehabilitation of persons after SCI.[243] The spinal cord and neural axis were responsive to the ensemble of sensory information specific to walking and generated a motor response for stepping below the level of the lesion. Many researchers and clinicians, including Barbeau, continue

to translate knowledge from basic science into developing a rehabilitation intervention to retrain walking after neurologic injury or disease.[154,244-247] In parallel, other researchers have focused on testing the efficacy of this intervention and effectiveness for the recovery of walking after SCI.[155,248-252]

Historically, rehabilitation for ambulation after SCI has been built on the premise that the spinal cord is neither "plastic" (adaptable), nor can it can learn or repair itself. After SCI, clinicians thus set goals to maximize use and strength of the musculature remaining under voluntary control and to substitute for weak or paralyzed muscles with braces and/or assistive devices. Thus, therapists taught alternative strategies for ambulation that incorporated braces and assistive devices and compensatory gait patterns. Locomotor training is a means of intensely practicing the distinct and specific task of walking (providing the sensory experience of walking) with the aim of tapping into the intrinsic neural pathways responsible for generating steps. This strategy may be viewed as a relative "bottom-up" approach, emphasizing the sensory experience of walking to drive the motor response of walking. In contrast, teaching new strategies to walk, such as "brace-walking," is a relative "top-down" approach requiring the development of a new skill with which to be upright and to ambulate. Certainly, sensory and cognitive processing is required for learning both strategies; however, the relative emphasis on recovery of preinjury movement patterns versus the introduction of alternative compensatory behaviors to achieve mobility differs.

Locomotor training occurs across three environments: (1) on the TM with use of BWS and manual facilitation; (2) assessment of the patient's ability to apply new skills, and control occurs overground (e.g., use of NRS); and (3) community integration. Retraining the neuromuscular system occurs most effectively in the TM environment with ease in control of BWS, speed, and manual facilitation by the trainers to optimize afferent input. Transfer of skills learned in the TM environment is assessed off the TM (overground) and limitations to independence assessed here and in community integration (home and community-based activities).

The focus of LT is to "*train like you walk.*" The task of walking, its kinematics, kinetics, spatial-temporal pattern, posture, balance, and adaptability as accomplished before injury, is the aim and reference point for progress. Retraining neuromuscular control for the task of walking involves (1) reciprocal stepping, (2) balance during propulsion, and (3) the ability to adapt the locomotor pattern to behavioral goals (e.g., carry a grocery bag) and environmental conditions (e.g., walk on carpet). Locomotor training is conducted in environments to experience the specific task of walking during intense practice, with progression toward independence in walking for home and community mobility.

Figure 20.36 contains a series of photos of a person walking with a rolling walker and a right AFO at a walking speed of 0.13 m/sec (0.43 ft/sec) using a traditional approach to gait retraining after SCI. Is this individual effectively practicing the task of walking? What elements are consistent with the task of walking and what elements are inconsistent with the task of walking? For instance, moving from point A to point B while upright is consistent with the aim of achieving walking. However, a forward-flexed trunk and head aimed at the ground, weight-bearing through the arms, hip extension only to neutral, uneven step lengths, hiking the right hip, vaulting on the left toe, no knee flexion on the right, and the slow walking speed are not consistent with the task of walking and its known typical pattern. Moving from point A to B while using a walker is certainly a form of mobility. However, the walker has become an inherent component to a new task of mobility and is not aligned with the known critical elements (e.g., kinematics, muscle activation) that define "walking."

Train like you walk translates into the following practical LT guidelines:

- The LEs are maximally loaded for weight-bearing, minimizing or eliminating loading of the arms.
- Sensory cues provided are consistent with the task of walking (e.g., TM speed, manual cues to facilitate flexor or extensor muscle activation).

Figure 20.36 Gait pattern of a person with an incomplete spinal cord injury using a rolling walker and a right ankle-foot orthosis. *(From Behrman et al,[216] with permission.)*

- The posture, trunk, pelvis, and limb kinematics are coordinated and specific to the task of walking.
- Compensatory strategies for movement (i.e., hip hiking) are minimized or eliminated with recovery of preinjury movement patterns as the goal.[153,253]

These principles were derived from scientific evidence with animal models of SCI and from humans with and without SCI demonstrating the role of sensory input in generating a motor output.[153,243] As with learning any skill, practice and repetition are important and carryover beyond the clinic is critical. Persons with iSCI may exhibit compromised balance; weakness in the trunk, UEs, and LEs; increased or decreased muscle activity in flexors or extensors; symmetrical or asymmetrical impairments; and, in some, an inability to stand without lower or upper limb support.[254] To practice the specific task of walking for this population, a training environment must afford safety, support, task-specific repetition of walking, and a means to challenge and progress abilities.

An appropriate BWS system and TM provide such an opportunity within a controlled and safe environment. The patient wearing a trunk/pelvis harness is supported by an overhead and adjustable suspension system over a TM. Trainers require access to the trunk/pelvis and lower limbs to facilitate upright posture, weight shift, and limb movements. This environment allows control of the amount of lower limb loading, assists in upright posture and balance, and allows control of the speed of walking (Fig. 20.37).[216] With 35% BWS, manual assistance at the trunk and pelvis to promote upright posture and minimize hip hiking, and lower limb trainers promoting step symmetry, hip extension, and hip/knee flexion on the right, the individual is able to walk at a speed of 0.8 to 1.0 m/sec. The therapist must determine what elements of practice are consistent with the task of walking and what elements are inconsistent with the task of walking. If the aim is task-specific training, then this is perhaps a good starting point for training. Each of these parameters then becomes a means of progression[216] by adjusting load, TM speed, and amount of manual assistance. As with any training protocol, intensity is required; thus, achieving 20 to 30 minutes of total stepping time is recommended, with increasing duration of each training bout. Frequency of training will depend somewhat on the setting; patients in inpatient rehabilitation may be able to train daily, whereas those in an outpatient setting may train 3 to 5 days a week. Goals must also be set to address adaptability for negotiating the environment and for meeting the behavioral demands of the individual for walking.[254]

The same training principles should be applied outside of the BWS-TM system overground in the clinic, home, and community. Adaptations can be made for advancing skills for walking when off the TM and should be consistent with LT principles. In the

Figure 20.37 Locomotor training for a person with an incomplete spinal cord injury using body weight support, treadmill, and manual assistance by trainers. *(From Behrman et al,[216] with permission.)*

example from Fig. 20.36, the rolling walker may permit a faster walking speed; however, this individual's posture and inability to flex the right knee preclude any faster speed. The lack of upright posture also limits hip extension range and loading, likely necessary precursors to initiating swing. Several suggestions for treatment are to have this individual practice upright standing with his back to a wall using the walker to load his legs as opposed to his arms (Fig. 20.38), to have him stand weight-bearing solely on the left LE and with the right leg flexed on a stool or chair (Fig. 20.39A and B), and to elevate the height of the walker to encourage upright posture.[216] A posterior walker may also encourage a more upright posture. Certainly, use of the BWS system and TM has advantages and may be the optimal environment for consistent practice and retraining the neuromuscular system, but the transition and application to community ambulation is critical (Fig. 20.40).

Locomotor training principles can thus be applied both while on the TM with a BWS system and continued overground for community ambulation (see Fig. 20.40). Transferring skills acquired in one environment to another is an important element for learning and can be reinforced by a daily examination of the walking abilities overground and on the TM with BWS.[216] Modifying the parameters of training in both environments will challenge the use of new skills,

Figure 20.38 Locomotor training principles applied to the task of standing with upright posture for a person with an incomplete spinal cord injury. *(From Behrman et al,[216] with permission.)*

Figure 20.39 Locomotor training principles applied to standing upright while practicing loading and extension on the left lower limb while the right lower limb is unloaded and flexed on the treadmill with body weight support **(A)** and overground with a walker **(B)**. *(From Behrman et al,[216] with permission.)*

Figure 20.40 Translation of skills acquired on the treadmill to walking overground and community ambulation. *(From Behrman et al,[216] with permission.)*

reinforce new patterns and independence, and inform goal setting across environments.

Engaging the client in each aspect of goal setting and understanding of the LT principles empowers the client to extend "training" beyond the time in the clinic to the rest of the day. The choices that the therapist and client make on a daily basis may significantly affect the rate and magnitude of the client's recovery and achievement of goals. For instance, a client's choice to walk using a grocery cart instead of shopping from a wheelchair reinforces the principle of maximizing weight-bearing through the LE. If the individual walks with an upright posture, the goal is further enhanced with increased load-bearing on the LE versus the arms and achievement of hip extension during loading. This simple choice will advance the individual's recovery. Many more choices can be made by the client to support recovery regardless of where one is on a continuum of recovery.

Clinical guidelines for LT and for safe and effective use of therapeutic equipment are essential to the practice of evidence-based physical therapy for rehabilitation following SCI. As research findings are published, clinicians should seek information to guide their decision making and practice. Such information may identify the following:

- Who will benefit from LT with the aim of improving the ability to walk? Persons classified according to ASIA A, B, C, or D impairments or persons classified according to the NRS; persons who already walk, but not well; persons who have a particular clinical motor or sensory presentation; or persons at a particular neurological level of injury (i.e., severity of injury)?[254]
- When is the best time after injury to provide an intervention for optimal recovery of walking? In the acute stage of rehabilitation, after discharge from rehabilitation, or at some other point after SCI (and if so, what is the appropriate time after injury)?
- What is the optimal dose of therapy (i.e., intensity, frequency, and duration of the training)?
- How to train and progress a patient, how to use the BWS system and TM equipment, how to examine new training equipment as it reaches the market (e.g., suspension systems, robotic devices, and so forth), and how to monitor the trainers' body ergonomics during training?
- Any medical precautions and safety issues for persons with SCI and their effect on LT locomotor training (e.g., AD, skin, bowel and bladder, falling, osteoporosis, spasticity, cardiovascular health, and so forth).
- What therapies may augment LT or what combined therapies enhance the recovery of walking (e.g., strengthening, FES)?[155,255,256]
- The cost–benefit ratio (i.e., cost to provide this intervention in the clinic, including equipment and personnel; reimbursement policies; and outcomes and value to the patient and community).

Currently, the literature (case studies, small *n,* efficacy studies, clinical evaluation, and clinical trials) indicates that LT that incorporated use of a BWS system and TM in subacute and postacute rehabilitation with persons with iSCI (ASIA Impairment Scale classification C and D) improved balance, gait speed, endurance, stair-climbing, and independence[155,248,249,253,257] (Box 20.8 Evidence Summary).[155,251,257-263]

The Christopher and Dana Reeve Foundation *NeuroRecovery Network* (NRN) utilizes a standardized protocol

Field-Fote and Tepavac (2002)[258]	Ss	Total N = 14 iSCI (5 women and 9 men) and 3 healthy controls	**Design**	Pre-post design	Mean OG and TM speed improved (84% and 158%, respectively). The interlimb coordination also improved after intervention. Note: Testing speeds differed for pre and post training conditions.
	Level of injury and AIS	At or above T10 neurological level and C	**Intervention**	BWSTT with electrical stimulation: 36 sessions (3 times/wk for 12 wk). ES set at 500–750 msec train, 50–80 pulses per second, 1.0 to 1.5 msec pulse duration and 60 to 150 V. The treadmill speed and BWS was adjusted to participants' capacity to optimally walk.	
	Time after injury	70 months			
Dobkin et al (2006)[251]	Ss	Total N = 146 (BWSTT, n = 75 with 57 UMN and 18 LMN) along with OG step training (CONT; n = 71 with 54 UMN and 17 LMN)	**Design**	Single-blinded multicenter randomized clinical trial	No difference in primary outcome (walking speed) between BWSTT and control group; however, both groups exceeded expectations by achievement of near-normal walking speed, 1.1 m/sec. AIS C group showed better prognosis irrespective of the treatment they received. Individuals with ASIA B score at 8 weeks after SCI had a low probability of achieving functional walking with FIM-L score ≥4 when treated with BWSTT or CONT. Note: First study to demonstrate feasibility and safety to provide LT within the period of acute, inpatient rehabilitation and to patients wearing external stabilization devices (e.g., halo). Control group received an additional hour of therapy per day to be consistent with the experimental group.
	Level of injury and AIS	C5–L3 and B, C, D	**Intervention**	12 wk, 5 times/wk of either (1) BWSTT and OG step training or (2) control received only OG usual care stand/walking training (CONT). BWSTT = 1 hr/day of step and stand training (20–30 min BWSTT) and 10–20 min translation to OG walking. Treadmill speed > 0.72 m/sec with target training speed = 1.07 m/sec. BWS set to allow treadmill speed > 0/72 m/sec. CONT = Standing accomplished via braces or standing frame. Walking practiced with braces and assistive devices overground.	
	Time after injury	8 weeks

Reference	Participants		Methods/Procedure		Results and Comments
Jayaraman et al (2008)[259]	Ss	5 participants (male = 4 and female = 1)	**Design**	Longitudinal prospective case series	Plantar flexors muscle cross-section area increased by 6.8% to 21.8%, but no meaningful change in knee extensor cross-section area was observed except in 1 participant. Improvement in voluntary activation and in ability to generate both peak torque about the knee and ankle joints. Though LT had limited impact on changes in muscle size, increases in voluntary activation occurred. Note: Specific muscle resistance training may have greater impact on change in muscle size and torque generation.
	Level of injury and AIS	C4–T12 with C and D	**Intervention**	45 sessions, 5 times/wk, 30 min of step training over treadmill with manual assistance at near-normal walking speed (2.0–2.8 mph). BWS set at 30%–40% progressing to 5%–15%.	
	Time after injury	8–20 months			
Musselman et al (2009)[260]	Ss	4	**Design**	Single-blind A–B crossover design with BWSTT and OG skill training.	Modified Emory functional ambulation profile, 10-MWT, 6-MWT, BBS, ABC scales were used to measure clinically meaningful improvement in walking performance. Walking speed endurance, obstacle clearance, and stair climbing ability improved following OG skill training intervention when compared to BWSTT. 3 out of 4 participants retained their gains at follow-up.
	Level of injury and AIS	C5–L1 and C	**Intervention**	Training 1 hr/day, 5 times/wk for 3 months of either (1) BWSTT with manual assistance or (2) OG skill training, then crossover to the other intervention. BWS was the lowest amount possible to prevent knee and hips collapsing into flexion during stance at a speed selected for at least 3 min. Braces were worn for both interventions. Side rails were allowed, but positioned at chest height to minimize weight-bearing through the arms. Maximum treadmill speed was 1.0 m/sec. OG skill training included walking balance; skilled walking tasks (e.g., obstacle avoidance, negotiating different environmental challenges, walking with secondary task, endurance and speed increases). Borg scale was used to monitor exertion during training.	
	Time after injury	Mean time since injury = 2.7 years			

Box 20.8 Evidence Summary Selected Studies Examining the Use of Locomotor Training—cont'd

Reference	Participants		Methods/Procedure		Results and Comments
Field-Forte and Roach (2011)[155]	Ss	Total N =74 treadmill-based training with manual assistance (TM, n = 19), treadmill-based training with stimulation (TS, n = 22), overground training with electrical stimulation (OG, n = 18), treadmill-based training with robotic assistance (LR, n = 15).	**Design**	Single-blinded, randomized controlled clinical trial	Primary outcomes measures (10-MWT and distance covered in 2 min) were collected before, immediately after, and 6 months after the intervention with subjects using assistive and/or orthotic devices. Secondary outcome measure was LEMS. OG training showed the greatest improvement in the walking distance. The effect size was greater for speed and distance covered for OG than observed for any of the treadmill-based training. However, the TS group had more severely impaired subjects and the OG group had the least impaired subjects. The greater voluntary effort needed to walk during OG training was speculated as increasing the supraspinal drive for overground locomotion. The other possible factor identified was the difference in the motor strategy used for treadmill walking and OG walking. In the 6 months follow-up the amount of improvement in walking seen at immediate post time point declined but was still higher than the pre-training stage. Note: The amount of increase in walking speed post-intervention (0.04–0.05 m/sec) may be within measurement error and/or not clinically significant. The difference in the testing environment (overground) and the training environments (treadmill-based) may have contributed to differences in outcomes. Transfer of locomotor skills acquired on the treadmill to overground may be a necessary step.
	Level of injury and AIS	At or above T 10, C and D			
	Time after injury	≥ 1 year	**Intervention**	5 times/wk for 12 wk using 4 types of locomotor training approaches all with BWS: (1) TM, (2) TS, (3) OG, (4) LR. The BWS was set to maintain upright posture and minimize knee flexion and progressing to ≤ 30%. In the OG condition greater BWS was used to accommodate for the increased effort needed for forward progression.	
	Age	25–58 years

Box 20.8 Evidence Summary Selected Studies Examining the Use of Locomotor Training—cont'd

Reference	Participants		Methods/Procedure		Results and Comments
Harkema et al (2012)[257]	Ss	n = 196	**Design**	Prospective observational cohort	The outcome measures (BBS, 6-MWT, 10-MWT) were assessed at baseline, after every 20 sessions, and after intervention. The intensive activity-based therapy produced functional improvements in individuals with chronic iSCI. 86% of the patients had less than 45 score in BBS at enrollment out of which 27% improved their scores to beyond the value reflecting minimal risk of fall. At baseline, 69 patients were unable to complete the 6-MWT and 10-MWT, out of which 41% were able to complete the tests by the intervention end. The 6-MWT and 10-MWT speed improved by an average of 63 m and 0.20 m/sec. Significant improvement occurred in balance and walking measures for patients with AIS grades C and D. The magnitude of improvement, however, differed based on AIS grades. The chronicity of the injury was not significantly associated with the outcome measures at enrollment, but was inversely related to the level of improvement. 12% (n = 24) of the total patients failed to respond to LT.
	Level of injury and AIS	Above T11 and AIS C and D			
	Time after injury	Months to > 2 decades	**Intervention**	Median of 47 treatment sessions (minimum of 20 and maximum of 251) with 1 hour of step training with BWS and manual facilitation on treadmill followed by 30 minutes of OG assessment and community integration. TM speed was set from 0.5–10 mph. BWS was set to optimize kinematics and progressively reduced.

Studies in Children					
Prosser (2007)[261]	Ss	1	**Design**	Case study	After intervention the child ambulated independently in the community with a forward rolling walker and articulated ankle-foot orthosis. Significant improvement in strength (LEMS), ambulatory capacity (WeeFIM II scores, WISCI II scores), and participation in community occurred.
	Level of injury and AIS	C4 and C	**Intervention**	LT with BWS and manual assistance for 20–30 min/day, 3–4 times/wk for 6 months at near-normal walking speed. Ankle orthotics were used during training on the treadmill. OG training was initiated at 10 wk when independent stepping was initiated with the right leg. Least amount of BWS was used, which was enough to achieve knee extension independently starting with 80% BWS and gradually reducing to 10% by training end.	
	Time after injury	4–5 months			
	Age	5 years and 10 months			
Behrman et al (2008)[262]	Ss	1	**Design**	Case report	The child progressed from nonambulatory to first, nonexternally (sensory)-cued step at session 29 of LT. At session 33, the child took 7 consecutive, independent steps overground. The next session, he initiated 24 to 35 steps without cueing. From 51 session onward, he used a reverse rolling walker independently. After session 76, he was a community ambulator with a self-selected speed of 0.29 m/sec, fastest speed of 0.48 m/sec, and averaged 2,488 steps/day.
	Level of injury and AIS	C 6 on the left and C 8 on the right and AIS C	**Intervention**	76 sessions, 5 times/wk. Locomotor training with BWST with manual assistance for 20–30 min of step training interspaced every 5 min with stand training. This was followed by 10–20 min of overground training. Treadmill speed was set at 0.8–1.2 m/sec with emphasis on normal trunk and limb kinematics during stepping. BWS was set initially at 30%–40% and reduced to 15%–20% by training completion.	
	Time after injury	16 months			
	Age	4.5 years

Fox, E, et al, 2010[263]	Ss 1	**Design**	This study was a 2-year follow-up to the Behrman et al (2008) case study. The age of the child was 6.5 years and the time since injury was 3 years, 6 months.	Follow-up tests were conducted at 1 month (baseline), 1 year after LT, and 2 years after LT. No change occurred in the WISCI scores as the child continued to use reverse rolling walker for ambulation. The child's fastest walking speed increased from 0.45 m/sec to 0.67 m/sec in 2 years. The number of home and community-based stepping bouts increased from 31 at baseline to 88/day at 2 years. Trunk compensation and frequency of leg crossing midline while walking decreased. The number of steps per day increased from 1,600 to 3,000 at 1 year and remained at 2 years. He showed normal musculoskeletal growth (90th–95th percentile of age and normal body weight) with no reports of secondary complications (e.g., scoliosis or hip dysplasia).

ABC = Activity Balance Confidence measure; AIS = ASIA Impairment Scale; ASIA = American Spinal Injury Association; BBS = Berg Balance Scale; BWS = body weight support; BWSTT = body weight supported treadmill training; ES = electrical stimulation; FIM = Functional Independence Measure; LT = locomotor training; LEMS = lower extremity motor score; OG = overground; Ss = subject characteristics; 10-MWT = 10-Meter Walk Test; 6-MWT: 6-Minute Walk Test; WISCI II = Walking Index for Spinal Cord Injury II; WeeFIM II = Functional Independence Measure for pediatrics.

of LT with standardized outcomes across seven outpatient clinical sites in the United States to persons with ASIA C and D injuries.[264] The NRN currently has the largest database (over 350 persons) who have received a minimum of 20 sessions of LT and is being used to evaluate the LT program and inform practice. Inclusion of persons with ASIA A and B injuries will further advance our understanding of the clinical impact of LT.

Safety and feasibility for providing LT to persons with iSCI during acute rehabilitation have also been established.[265] Clinical adaptations were required to safely train persons having a halo, a catheter and drainage bag or bladder/bowel impairments, sensory impairment, and susceptibility to orthostatic hypotension or AD. The question of whether providing LT has benefit during the acute rehabilitation phase warrants further investigation.

LT also has been provided to persons with motor complete SCI (ASIA A and B) in both research and clinical settings. Although independent walking has not been achieved, other potential benefits may be considered valuable and important to a person's quality of life after SCI.[266,267]

Another important area for research is the benefits of LT to a person's health after SCI, whether an incomplete or a complete injury. Additional questions that need to be answered include the following: Does LT decrease the risk of pressure sores or bladder infections; reduce bone loss or muscle atrophy? Do benefits for health warrant increased access to LT? Can robotic devices provide an avenue to cost-effectively provide this service? What is the impact of LT outcomes on the quality of life of the person with SCI and the impact on the family or caregiver(s)?

The advent of LT represents a new era in spinal cord rehabilitation. This era, brought forth by partnership among basic scientists, rehabilitation scientists, physicians, and clinicians, encompasses knowledge of the neurobiological control of walking and the physiological promise of activity-dependent plasticity as bases for developing new interventions and advancing the potential for recovery after SCI. Whereas LT alone may provide a means for recovery of preinjury abilities and fostering neuromuscular activity below the level of the lesion, the next generation of physical rehabilitation may employ combinatorial approaches. Such approaches may include advancing technology, epidural stimulation, stem cell transplants, and pharmacological approaches to bolster the neuroplasticity of the neural environment. Locomotor training in combination with these approaches or others may be an essential component and catalyst to achieve an effective therapeutic outcome.[154,158,268]

Activity-Based Upper Extremity Training

For people with a cervical SCI the recovery of UE function is a primary goal.[269] Interventions aimed at improving functional use of the UE have primarily been compensatory in nature. For example, patients with active wrist extension are taught how to manipulate and pick up objects using a tenodesis grasp, use the hand as a hook, and use different types of orthoses to feed themselves. More recently, researchers have begun to explore the use of massed practice interventions to promote functional recovery and corticomotor and spinal reorganization.[270,271]

Based on massed practice principles used in constraint-induced movement therapy[272] (see Chapter 10, Evidence Summary Box 10-1, and discussion in Chapter 15, Stroke), Field-Fote and colleagues[270,271,273] applied similar training techniques by having patients practice unimanual[270,271,273] or bimanual[271] UE activities 2 hour per day 5 days a week for 3 weeks. Patients did not have a UE constrained. Applying sensory electrical stimulation to the volar surface of the wrist over the median nerve while the patients performed the different tasks augmented the massed practice. Patients with cervical iSCI practiced four main types of unimanual or bimanual UE activities: finger isolation, grasp, grasps with rotation, pinch, and pinch with rotation. Finger isolation activities included activities such as typing on a keyboard, dialing phone numbers, and playing piano notes. Grasp activities included squeezing a spray bottle, cutting paper with scissors, and building with Legos. Grasp with rotation activities included pouring liquid from one container to another and opening containers. Pinch activities included picking up objects, threading a large needle, and writing. Pinch with rotation activities included screwing nuts on bolts, locking and unlocking a lock with a key, and turning a doorknob. The researchers found significant improvements in hand and arm function after the intervention.[270,271,273]

Health and Wellness

Just as with people without SCI, regular exercise is an important part of a healthy lifestyle. Patients should be provided a comprehensive home exercise program (HEP) that incorporates stretching, balance, aerobic, and strengthening exercises. Aerobic exercises such as UE ergometer should be done 3 to 5 days a week for a total of 20 to 60 minutes per session at an intensity of 50% to 80% of maximum heart rate. Strengthening exercises should be done 2 to 4 days a week at an intensity of 8 to 10 repetitions at 60% to 80% of one repetition maximum.[220] When developing the exercise program, attention should be paid to the unique precautions associated with people with SCI such as the possibility of overuse injuries (particularly in the shoulders), AD, thermal dysregulation, and exaggerated heart rate response to exercise.[42]

Patient/Client-Related Education

Because SCI can affect many different body systems and drastically change an individual's life, ongoing education about the consequences of SCI is critical. Education should begin early after injury and continue throughout rehabilitation and cover the extensive impact of SCI discussed above (e.g., skin care, AD, self-directing care, wheelchair mobility and maintenance, sexuality, and so forth). Without education patients will not be able to make informed decisions regarding their care or informed choices regarding community reintegration.

Peer mentoring with others who have experienced an SCI and are living in the community can be an effective method of providing education, support, and assistance with the rehabilitation process.[274] For example, a person with an ASIA A T2 SCI will be able to realistically demonstrate how to transfer from the bed to a wheelchair to a person recently injured who is undergoing rehabilitation. This person may also be able to discuss the impact of SCI on everyday life in a way a physical therapist could not.

An important aspect of rehabilitation involves planning for discharge and community reintegration. Consideration must be given to multiple issues, including accessible housing, nutrition, transportation, finances, maintaining functional skills and level of physical fitness, employment or further education, and methods for involvement in desired social or recreational activities. Each of these issues must be addressed early and continued throughout the course of rehabilitation in consultation with the patient, family, and appropriate team members. Educating the patient will allow him or her to make informed decisions regarding medical care and

lifestyle choices throughout the life span. A plethora of resources are available on the Internet. Patients should be encouraged to contact and to explore the available resources. Appendix 20.A lists some of the many resources available for patients, families, and clinicians.

PRESCRIPTIVE WHEELCHAIR AND WHEELCHAIR SKILLS TRAINING

Many people with SCI will use a wheelchair as their primary means of mobility. A wheelchair both acts as a mobility base and serves to provide postural support. Because patients with SCI will have varying degrees of trunk, hip, and shoulder girdle paralysis, the wheelchair and accompanying seating system provides postural support to keep the pelvis, spine, and extremities in optimal alignment. Postural alignment affects a variety of areas, including respiration, bowel and bladder function, skin integrity, and mobility. Poor posture in the wheelchair can negatively affect all of these areas. Because most patients will be using a wheelchair exclusively, it should be custom-ordered (prescribed) for each individual. When prescribing a wheelchair consideration should be given to the patient's goals and characteristics, as well as the activities and environment in which it will be used.

The first choice is between a power and manual wheelchair. Generally, individuals with intact triceps function are able to independently propel a manual wheelchair. Individuals with a C6- or C5-level injury may also be able to independently propel a manual wheelchair, but may not have the endurance or strength for community wheelchair mobility. The selection of a manual or power wheelchair in these cases should be done on an individual basis. Individuals with higher cervical injuries generally rely on a power wheelchair for their mobility needs (see Table 20.5). Before prescribing a wheelchair a series of trials with different types of chairs with different components will assist with making an informed decision on what specific type of wheelchair to obtain.

There are two basic frames for manual wheelchairs, a *folding* or a *rigid* frame, and three weights, standard, lightweight, and ultralight. Folding chairs are an important consideration for patients who plan to transfer into a car because they can be folded compactly for storage without having to remove as many parts. Folding frames typically incorporate a below-seat crossbar and generally provide a smoother ride on uneven surfaces. Potential drawbacks include heavier and more moveable parts causing it to be less energy efficient during propulsion than rigid frames.

A rigid frame is generally lighter, is more energy efficient, and often has an adjustable seat-to-back angle. This type of frame may be more difficult to store in a car. Both wheels must be removed for storage. A rigid frame is often more durable than a folding frame.

A variety of different components and options can be selected for a manual wheelchair. There are benefits and drawbacks to the different options. For example, the wheel locks can be mounted high or low on some wheelchair frames. High-mounted wheel locks are easier to access, but can be an obstacle to transfers. Conversely, low-mounted wheel locks are more difficult to access but are not in the way of transfers or during propulsion.

Advances in rehabilitation technologies have created a new class of wheelchairs that fall between manual and power wheelchairs, *pushrim-activated power-assist wheelchairs* (PAPAWs). A PAPAW is a manual wheelchair to which power-assist wheels have been added. When the user applies force to the pushrims the motor is activated, which provides assist to the wheels. Propelling a PAPAW requires less energy, lower stroke frequency, and less shoulder ROM than a manual wheelchair.[275-277] A PAPAW may be beneficial for individuals with mid to lower level cervical injuries (C5–C6) who may not have the endurance or strength to use a manual wheelchair full time.[278]

Power wheelchairs are indicated for all patients with C4 lesions and above. Patients with C5-level lesions may also elect to use power wheelchairs, particularly for community mobility. A tilt-in-space or reclining seating system provides improved postural control and allows the user to independently perform pressure relief. There are various types of controls. They range from a hand-operated joystick to a sip-and-puff control.

A wheelchair prescription will vary according to the level and extent of injury. Some general considerations follow:

- Seat depth should be approximately 1 to 2 in (2.5 to 5.1 cm) back from the popliteal space to allow an even weight distribution on the thighs and to prevent excessive pressure on the ischial tuberosities.
- Floor-to-seat height is important. The type and dimensions of the cushion or custom-made seat must be known so that seat height can be measured accurately, allowing adequate (2 in [5.1 cm]) clearance from the floor to the foot pedals and provide slightly greater than a 90° angle at the hips.
- Back height is important. If the patient will not be pushing the wheelchair, a high back may be desired for added comfort and stability. A patient with tetraplegia who will be pushing the wheelchair requires a back height that is below the inferior angle of the scapula so that the axilla is free of the handles during functional activities. Most patients with paraplegia prefer a lower back height, especially if they have intact abdominal muscles.
- Seat width and depth are variable and should be fitted to the anthropometric characteristics of the

patient. The patient should be fitted in the narrowest chair possible, but have adequate space between the lateral edges of the thighs and wheelchair armrests or wheels to avoid skin irritation. The patient's previous weight should be considered, especially if there has been a significant loss since the initial injury, and potential exists to regain the weight. If orthoses or thick clothing in cold climates are worn, they must also be included in the consideration of width.

- Removable armrests and detachable swing-away leg rests are important components of wheelchairs used by many patients with SCI. On some chairs, the leg rests do not detach and the armrests are of a "flip-up" design. The suitability of these features must be considered with respect to the transfer capabilities and techniques used by the individual patient.
- Additional wheelchair accessories may be required to meet specific patient needs. Several features that warrant consideration include enlarged release mechanisms on the leg rests, a friction surface on the hand rims, brake extensions, anti-tipping devices, and grade aids (which decrease backward movement of the chair while ascending inclined surfaces).

Configuring the wheelchair to provide optimal postural support is an important consideration when selecting a wheelchair, seating system, and different components.[279] The wheelchair can assist in providing postural support to keep the pelvis and spine in alignment with trunk and pelvic muscle paralysis or paresis. Optimal postural support allows the patient to effectively use UEs to perform ADL and to propel the wheelchair. Configuring the wheelchair so that the seat slope is higher in the front than the rear (i.e., seat to floor height at the front of the cushion approximately 2 in. higher than at the back of the cushion) with the backrest perpendicular to the floor and relatively low may help keep the pelvis in a neutral alignment and maintain the natural curves of the spine (as opposed to a sitting posture of a posterior pelvic tilt with a C curve throughout the lumbar and thoracic spine).[280]

Some patients may require more than one wheelchair. Many lightweight "everyday" chairs are not suitable for sport and recreational activities. Depending on the interests of the patient, a second chair specifically designed for a particular sport such as tennis or racing may be desired.

The customized seating system includes a wheelchair cushion to assist in preventing skin breakdown and providing postural support. Selection of a cushion should be individualized. Patients should try different types of cushions to determine their impact on postural support, comfort, and pressure distribution. Pressure mapping can be done during the evaluation process with different types of cushions to select the cushion that provides the optimal pressure redistribution. A large variety of cushion styles are commercially available. Cushions generally are designed to redistribute pressure across the entire surface or take pressure off high-risk, bony areas. Cushions are made of different types of materials, including elastomer gel, open cell foam, closed cell foam, and air. These materials are often used in combination to provide reduced or redistributed pressure.

Chapter 32, The Prescriptive Wheelchair, provides more detail on the wheelchair and seating evaluation, drawbacks, and benefits of different wheelchair components, cushion types, and a variety of other issues associated with selecting a wheelchair. "Seating and Wheelchair Prescription" by Hastings and Betz is another excellent resource on this topic.[281]

Wheelchair Skills

For individuals who use a manual wheelchair, the ability to propel and maneuver over and around various obstacles and terrains in their home and community is essential for functional independence. In order to propel a manual wheelchair independently in the home and community environments, patients need to be able to perform certain basic wheelchair mobility skills: forward and backward propulsion, turning, ascend and descend inclines, assume and maintain a wheelie, and propulsion on uneven terrain.

Propulsion on Even Surfaces

To propel the wheelchair forward, the patient reaches back and grasps the wheelchair hand rims (Fig. 20.41) then pushes forward, releasing the hand rims after the hands have passed in front of the hips. Patients should practice reaching far back on the hand rims to initiate the stroke and pushing far forward before releasing the hand rims. A longer pushing stroke is more efficient. Patients who do not have the ability to grasp the hand rims propel the wheelchair by pressing their palms against the lateral aspect of the hand rims and then pushing forward. These patients will often use hand rim projections or have plastic-coated hand rims.

The technique used to turn depends on how quickly the patient needs to turn, as well as the size of the turning radius. To make a large radius or slow turn, the patient just pushes harder with one arm (e.g., if turning to the right the patient pushes harder with the left arm). To make a tight and/or quick turn, the patient pushes forward with one hand while pulling back with the other (e.g., if turning to the right quickly, the patient pushes forward with the left arm while pulling back with the right arm).

Inclines

There are a variety of surfaces with inclines that wheelchair users need to negotiate to be independent in their home and community. These include ramps, curb

Figure 20.41 Propelling wheelchair forward. *(From O'Sullivan, S, and Schmitz, T: Improving Functional Outcomes in Physical Rehabilitation. FA Davis, Philadelphia, 2010, with permission.)*

Figure 20.42 Performing a wheelie. *(From O'Sullivan, S, and Schmitz, T: Improving Functional Outcomes in Physical Rehabilitation. FA Davis, Philadelphia, 2010, with permission.)*

cutouts, slopes, and hills. The basic techniques used to ascend and descend these inclines are the same. To ascend an incline the patient takes shorter and quicker strokes and pushes on the hand rims more forcefully. If possible, the patient should lean forward with the head and trunk while pushing forward to prevent the chair from tipping backward.

Gripping the hand rim and slowly releasing the grip in a controlled manner to slow the descent of the wheelchair controls the speed of descent. Patients without full hand function control the descent of the wheelchair by applying pressure to the hand rims with the palms of the hands and slowly release the pressure to control the descent of the wheelchair.

Wheelies

The ability to perform a wheelie (Fig. 20.42) is an essential skill in order to negotiate curbs, steep declines, uneven terrain, and other areas of the community. To attain a wheelie, the patient reaches back on the hand rim and forcefully pushes forward to lift the front casters off the ground (as if attempting to tip the wheelchair over backward). When first learning any skill that involves a wheelie or there is a risk of the wheelchair tipping over, the patient should always be closely supervised and guarded. To ensure safety while practicing wheelies, a gait belt is looped through the frame of the wheelchair. The therapist is positioned behind the wheelchair, holding the gait belt in one hand with the other hand placed on the patient's shoulder or push handle of the wheelchair (Fig. 20.43).

The type of wheelchair and its configuration have an impact on how easy or difficult it is to attain a wheelie. Achieving a wheelie in a heavier wheelchair and one with the axle plate that is posterior is more difficult. An axle that is more forward, so that the user's COM is behind the axle, causes the wheelchair to be less stable and more "tippy." This makes it easier to assume a wheelie.

The ability to maintain a wheelie should be learned in conjunction with attaining a wheelie. Both of these skills are important lead-up activities to more advanced wheelie skills such as ascending and descending curbs and propulsion on uneven terrain. The therapist should assist the patient into the *balance point* in which the front casters are off the ground with the wheelchair in equilibrium. The patient's hands should lightly grip the hand rim in a position near the hips. Pushing forward on the hand rims causes the chair to tip backward and pulling backward causes the wheelchair to tip forward onto the casters back into a stable position. The patient should practice lightly pushing and pulling on the hand rim to learn the balance point; the hand rim should slide through the patient's grip as he or she does this. The patient should not keep the hand firmly grasped at the same point on the hand rim.

Figure 20.43 Technique to safely spot a patient while she practices performing wheelies. *(From O'Sullivan, S, and Schmitz, T: Improving Functional Outcomes in Physical Rehabilitation. FA Davis, Philadelphia, 2010, with permission.)*

When propelling a wheelchair on uneven surfaces (e.g., gravel, grass) there is a possibility of the front casters catching, causing the wheelchair to tip over in a forward direction. Being able to propel the wheelchair forward while maintaining a wheelie can minimize this risk and allow the patient to propel the wheelchair independently over a variety of terrains. When learning to propel the wheelchair forward and backward and while turning in a wheelie position, the patient should be instructed again not to use a firm grip but to allow the hand rims to slide within his or her grip.

On some uneven surfaces it may be easier to "pop up" into a wheelie for only a brief time (not maintain the wheelie) and push forward. The patient then crosses the surface in a series of short wheelies while pushing forward.

Wheelies are also used to ascend and descend curbs. To ascend a curb while moving, the patient pops a wheelie while moving forward just before reaching the curb. This lifts the front casters so they are up on top of the curb. As the wheels make contact with the curb, the patient pushes forward on the hand rims and leans his or her head and trunk forward (Fig. 20.44A-C). To descend a curb the patient pushes the wheelchair forward and just as the casters approach the edge of the curb the patient pops a wheelie. The wheelie is maintained as momentum carries the back wheels off the curb. The patient maintains the wheelie so the back wheels land first, then the casters land (Fig. 20.45A-C).

Other wheelchair skills that patients should learn include falling from a wheelchair, picking up objects off the floor, opening and closing doors, and negotiating obstacles. Patients should also learn how to manage the parts of the wheelchair: putting wheel locks on and off, removing and returning leg rests, folding the wheelchair, removing the cushion, moving arm rests, and removing and putting the wheels back on.

In addition to developing the Wheelchair Skills Test described earlier, Kirby and colleagues also developed the *Wheelchair Skills Training Program*. Based on the skills of the Wheelchair Skills Test and principles of motor learning, the Wheelchair Skills Training Program was designed to improve manual wheelchair user performance and safety. Research studies have shown it to be a safe and effective training method for new wheelchair users,[282] community-based wheelchair users,[283] occupational therapy students,[284] and caregivers.[285] Detailed information on both the Wheelchair Skills Test and Wheelchair Skills Training Program can be obtained on the Internet at www.wheelchairskillsprogram.ca/. *Spinal*

NEUROTECHNOLOGIES

People with SCI also benefit from recent advances in neurotechnologies designed to improve function and quality of life. Neurotechnologies can fall into four main areas: neuromodulation (use of electrical stimulation to improve control of an intact portion of the nervous system), neural prosthesis (use of electrical stimulation to replace or improve function of a paralyzed or weak limb), neurorehabilitation (applying technologies to promote normal recovery of impaired body functions), and neurosensing and diagnostics (technologies to monitor the nervous system or diagnose a condition).

Electrical stimulation can be used in a variety of ways. One of the most common is to use FES to cause the contraction of paralyzed or weak muscles below the level of the lesion for exercise, walking, and functional use of the UEs. As discussed above, surface FES can be used with an LE ergometer as a method of cardiovascular training.[227,228] Surface FES can also be applied to LEs to allow standing and walking in people with SCI.[286] Surface electromyography (EMG) has been paired with FES to provide patients with a method of triggering the FES to produce a more normal walking pattern than FES alone.[287] Implanted FES systems allow people with SCI to stand and walk,[288] as well as those with high cervical SCI to use their hand to grasp and manipulate objects.[289] Implanted FES systems can also be used for phrenic nerve stimulation to allow patients with high cervical SCI to breathe without a ventilator[290] and to provide patients with bladder control.[291,292]

Brain-computer interface devices (BCIs) acquire brain signals (electroencephalogram [EEG]) and translate them into commands that are relayed to output devices that perform an action such as control a mouse on the computer screen.[293] People with high cervical SCI with little motor function are able to use BCIs to use a computer, play video games, potentially drive a power wheelchair, and control a robot.[294-297]

Robotic devices can be used during LT to move the LEs in a stepping pattern to promote recovery of walking ability.[155,298] Exoskeleton robots are being developed that will allow people with complete SCI to walk with assistance from the robot.[299]

Harkema and colleagues[154] combined epidural spinal electrical stimulation with LT on a TM with BWS and stand training in an individual with a chronic ASIA B C7 injury. After training, the individual was able to stand with full weight-bearing on the LEs and assistance only for balance when the stimulator was on. The individual was also able to voluntarily activate some LE muscles when the stimulator was on. The authors speculate that this combination therapy (epidural electrical stimulation with task-specific locomotor and stand training) may be a viable method to improve function after SCI.

These examples offer existing ways of how technology is being used and glimpses of the future of rehabilitation that provide exciting opportunities to increase activity levels, improve social participation, and enhance the quality of life for people with SCI.

SUMMARY

Spinal cord injury has a profound impact on many different body systems, which can greatly affect a person's ability to move, perform everyday tasks, and participate in expected social roles. This chapter has reviewed the impact of SCI on different body systems, common impairments that result from SCI, classification of different types of SCI, and secondary complications associated with SCI. Physical therapists play a role across the continuum of care from the acute care hospital through rehabilitation to community reintegration. Physical therapists should use standardized outcome measures as part of their examination and evaluation process. The POC should be individually tailored to the patient's presentation, concerns, and goals. Rehabilitation interventions may be compensatory or recovery based depending on the presentation of the patient. Education is a critical component, and patients who can no longer perform certain activities should be able to self-direct their care. Rehabilitation is an important cornerstone of recovery. People with SCI, no matter at what level, can lead a productive, healthy, and high-quality life.

Questions for Review

1. Identify the clinical features of Brown-Sequard, anterior, central, and posterior cord syndromes.
2. Define *spinal shock.*
3. Describe complications associated with spinal cord injury.
4. What is autonomic dysreflexia? Describe the initiating stimuli and symptoms of this syndrome. What action would you take if a patient experienced an onset of symptoms during a physical therapy treatment?
5. Identify two primary factors affecting prognosis following spinal cord injury.
6. What is included in a physical therapy examination during the acute phase of recovery? How might some of the standard examination techniques need to be modified?
7. What is meant by the term *selective stretching*?
8. Describe potential goals and interventions to improve respiratory function during the acute phase of management.
9. Identify tests and measures and outcome measures used during the active rehabilitation phase of management.
10. List factors that will have an impact on the prognosis for recovery of walking ability.
11. Outline interventions to improve transfers for a patient with C6 and ASIA A tetraplegia. Describe the specific activities you would include. What type of progressive strengthening and endurance training activities would you suggest for each patient as an adjunct to the mat program?
12. Describe how you would modify training parameters when performing LT using a BWS and TM system for an individual with an incomplete SCI.

CASE STUDY

HISTORY

The patient is a 21-year-old white man who was transferred to a rehabilitation hospital yesterday. He suffered a traumatic cervical spinal cord injury 8 days ago. He was given methylprednisolone in the emergency department. He had surgery to stabilize the fracture site, internal fixation, and decompression using a right iliac bone graft. He was discharged to your facility yesterday and is currently wearing a Philadelphia collar. He is able to extend his elbows but cannot flex his fingers in either hand. He is a senior at college, computer science major. Lives in on-campus apartment, not wheelchair accessible. His parents live in the next state.

MEDICATIONS

Lovenox, midodrine, amitriptyline, OxyContin, and Dulcolax.

PHYSICAL THERAPY EXAMINATION

Cardiopulmonary

HR: 75

BP: supine: 110/72; sitting: 100/66 (only able to tolerate sitting for about 10 minutes, then blood pressure drops due to orthostatic hypotension)

Forced vital capacity: 2.2 liters

Weak functional cough

Communication/Cognition

Alert, oriented ×3, able to follow multistep commands; MMSE: 30/30

Muscle Performance

Bilateral: biceps: 5/5, wrist extensors: 5/5, triceps: 4/5, no active contraction below C7

Sensory Integrity

Intact pinprick and light touch bilaterally C2–T4, absent below T4

Intact anal sensation

Functional Mobility

Bed mobility: moderate assistance to roll to the left and right

Supine ↔ short sit: maximal assistance

Supine ↔ long sit: maximal assistance

Transfer wheelchair ↔ bed: FIM score 2 (requires maximal assistance with transfer board)

Transfer wheelchair ↔ toilet: FIM score 2 (requires maximal assistance with transfer board)

Locomotion

Unable to ambulate.

Able to propel wheelchair 150 ft on level surface with minimal assistance.

Wheelchair Skills

Requires assistance with locking wheel locks, removing footrests and armrests, and to perform pressure relief. Wheelchair Skills Test score: 4%.

Currently uses a lightweight, folding wheelchair with hand rim projections.

Gel cushion.

Tolerates sitting in wheelchair for 20 to 30 minutes.

Balance

Long sitting: able to maintain balance on mat for 1 minute with UEs in weight-bearing position with supervision.

Short sitting: able to maintain balance on edge of mat for 1 minute with UEs in weight-bearing position with minimal assistance, 0 inches for modified functional reach.

Motor Function

Increased spasticity in bilateral hip flexors, 1+ on modified Ashworth Scale.

Passive ROM

WNL except bilateral ankle dorsiflexion is 5° from neutral.

Skin Integrity

Stage 1 wound on right heel.

Self-Care

Dressing upper body: FIM score 2 (requires maximal assistance)

Dressing lower body: FIM score 1 (dependent)

Bathing: FIM score 1 (dependent using shower chair)

Feeding: FIM score 3 (moderate assistance with adapted utensils)

Grooming: FIM score 3 (moderate assistance with adapted utensils)

Toileting: FIM score 2 (maximal assistance)

Bowel and Bladder

Bladder: FIM score 1 (just began intermittent catheterization program and requires total assist to manage)

Bowel: FIM score 1 (just began bowel training program with nursing, has been incontinent of bowel during the past day)

CASE STUDY GUIDING QUESTIONS

1. What is the patient's neurological level of injury, motor level of injury, and sensory level of injury? What is the patient's ASIA impairment classification?
2. Identify/categorize this patient's problems in terms of
   a. Body structure/function impairments
   b. Activity limitations
   c. Restrictions in social participation
3. Identify three anticipated goals and three expected outcomes for this patient.
4. Formulate three interventions with one progression that could be used during the first 3 weeks of therapy to improve bed mobility skills.

DavisPlus | For additional resources, including answers to the questions for review and case study guiding questions, please visit **http://davisplus.fadavis.com**

The reader is referred to the following video case studies for additional review and study:

- **Case Study 4: Patient with Spinal Cord Injury, T12/L1 Complete**
- **Case Study 5: Patient with Spinal Cord Injury, C5/6 Incomplete**

The full written case study, including all tables, figures, charts, and three video segments (examination, intervention, and outcome), appears online at DavisPlus. The case studies pose questions for the reader's consideration with suggested answers to the case study questions, also posted online at DavisPlus.

Vestibular Disorders

Michael C. Schubert, PT, PhD

Chapter 21

LEARNING OBJECTIVES

1. Differentiate vestibular symptom pathology from other manifestations of vertigo, dizziness, and dysequilibrium.
2. Identify the examination procedures used to evaluate patients with vestibular dysfunction to establish a diagnosis, prognosis, and plan of care.
3. When presented with a clinical case study, analyze and interpret examination data and determine appropriate interventions for the clinical problems presented.
4. Determine appropriate elements of the rehabilitation program for patients with vestibular dysfunction.

CHAPTER OUTLINE

ANATOMY *966*
- Peripheral Vestibular System *966*
- Central Vestibular System *967*

PHYSIOLOGY AND MOTOR CONTROL *967*
- Tonic Firing Rate *967*
- Vestibulo-Ocular Reflex *968*
- Push–Pull Mechanism *969*
- Inhibitory Cutoff *969*
- Velocity Storage System *969*

- Cervicogenic Dizziness *993*

CONTRAINDICATIONS TO VESTIBULAR REHABILITATION *993*

SUMMARY *994*

Physical therapists are likely to encounter patients with vestibular disorders in a variety of clinical settings. At an incidence of 5.5%, dizziness in the United States affects more than 15 million people each year.[1] The reported prevalence of dizziness as a medical symptom in community-dwelling adults varies based on subjects' age, gender, and definition of the complaint (1% to 35%).[2-6] Dizziness is one of the most common complaints adults report to their physicians and prevalence increases with age.[7,8] A cross-sectional study of emergency department visits for dizziness found that otologic/vestibular pathology was the number one cause (32%).[9] Patients who experience dizziness report a significant disability that reduces their quality of life.[10-12] Furthermore, it has been reported that greater than 70% of patients with initial complaints of dizziness will not have a resolution of symptoms at a 2-week follow-up. Of patients with persistent dizziness, 63% reported recurrent symptoms continuing beyond 3 months.[13]

Cawthorne[14] and Cooksey[15] were the first clinicians to advocate exercises for persons suffering from dizziness and vertigo. It has only been within the last two decades, however, that our knowledge of vestibular function and related disorders has profoundly changed rehabilitation approaches. Once an accurate diagnosis involving the vestibular pathways has been made, activity limitations are minimized and progression toward disability can be prevented. Evidence suggests that an individualized approach to vestibular rehabilitation is important for a better outcome.

The peripheral vestibular system serves as the primary focus of this chapter because it is the most common origin for patient signs and symptoms. The physical therapist, however, must recognize patterns of signs and symptoms from a central pathology as well. With an appreciation of the complexity of the vestibular system coupled with an understanding of tests to measure its function, the reader will be able to discern anomalies of the system and begin to formulate effective rehabilitation strategies.

ANATOMY

Peripheral Vestibular System

The three primary functions of the peripheral vestibular system are (1) stabilizing visual images on the fovea of the retina during head movement to allow clear vision; (2) maintaining postural stability, especially during movement of the head; and (3) providing information used for spatial orientation.

Semicircular Canals

Within the petrous portion of each temporal bone (base of the skull between the sphenoid and occipital bones) lies the membranous vestibular labyrinth. Each labyrinth contains five neural structures that detect head acceleration: three *semicircular canals* and two *otolith* organs (Fig. 21.1). The three semicircular canals (SCCs) (*horizontal*, *posterior* [inferior], and *anterior* [superior]) respond to angular acceleration and are orthogonal (at right angles) with respect to one another. Alignment of the SCCs in the temporal bone is such that each canal has a contralateral coplanar mate. The horizontal canals form a coplanar pair while the posterior and contralateral anterior SCCs form coplanar pairs. The anterior aspect of the horizontal SCC is inclined 30° upward from a plane connecting the external auditory canal to the lateral canthus. The posterior and anterior SCCs are inclined about 92° and 90°, respectively, from the plane of the horizontal SCC.[16] Angular head rotation stimulates each canal to varying degrees.[17]

The SCCs are filled with *endolymph* (fluid) that has a density slightly greater than water.[18] Endolymph moves freely within each canal in response to the direction of the angular head rotation. The SCCs enlarge at one end to form the *ampulla*. Within the ampulla lies the *cupula*, a gelatinous barrier that contains the sensory hair cells (Fig. 21.2). The *kinocilia* (mechanosensing cilia involved in the sense of movement) and *stereocilia* (mechanosensing organelles) of the hair cells are seated in the *crista ampullaris* (sensory organ of angular rotation). Deflection of the stereocilia caused by motion of the endolymph results in an opening (or closing) of the transduction channels of hair cells, which results in changes in the membrane potential of the hair cells. Deflection of the stereocilia toward the kinocilia in each hair cell leads to excitation (*depolarization*) and deflection of the stereocilia away from the kinocilia leads to inhibition (*hyperpolarization*).

Each of the SCCs responds best to motion in its own plane with coplanar pairs exhibiting a *push–pull dynamic*. For example, as the head is turned to the right, the hair cells in the right horizontal SCC are excited, while hair cells in the left horizontal SCC are inhibited. The brain detects the direction of head movement by comparing input from the coplanar labyrinthine mates.

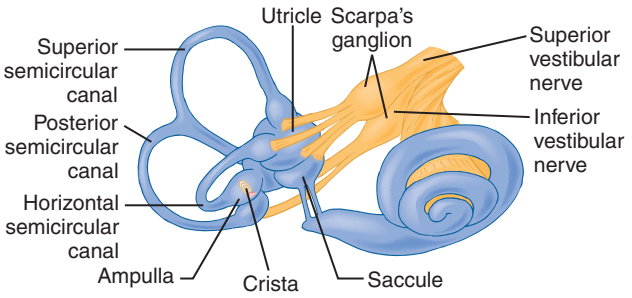

Figure 21.1 Anatomy of the vestibular labyrinth. Structures include the utricle, sacculus, superior semicircular canal, posterior semicircular canal, and the horizontal semicircular canal. The three semicircular canals (SCCs) are orthogonal with each other. Note the superior vestibular nerve innervating the superior (anterior) and horizontal semicircular canals as well as the utricle. The inferior vestibular nerve innervates the posterior semicircular canal and the saccule. The cell bodies of the vestibular nerves are located in Scarpa's ganglion (Gangl. Scarpae). Also note that the semicircular canals enlarge at one end to form the ampulla.

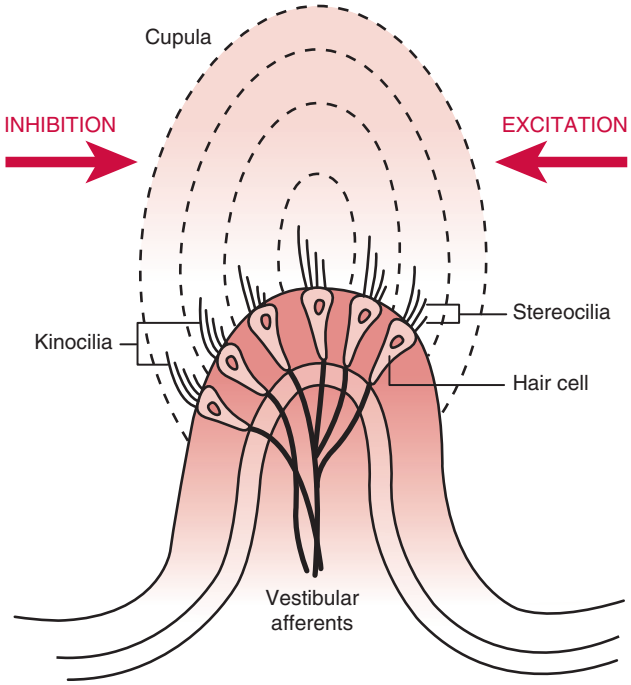

Figure 21.2 The cupula of the ampulla is a flexible, gelatinous barrier that partitions the canal. The crista ampullaris contains the kinocilia and stereocilia sensory hair cells. The hair cells generate action potentials in response to cupular deflection. Deflection of the stereocilia toward the kinocilia causes excitation; deflection in the opposite direction causes inhibition.

Otolith Organs

The saccule and utricle make up the otolith organs of the membranous labyrinth and respond to linear acceleration and static head tilt. Sensory hair cells project into a gelatinous material that has calcium carbonate crystalline-structure material (otoconia) embedded in it, which provides the otolith organs with an inertial mass (Fig. 21.3). Similar to the SCCs, motion toward the kinocilia causes excitation, while motion away leads to inhibition. Utricular excitation occurs during horizontal linear acceleration and/or static head tilt and saccular excitation occurs during vertical linear acceleration.

Central Vestibular System

Brainstem processes provide primary control of many vestibular reflexes. Tracing techniques, used to follow axonal projections from their source to point of termination, have identified extensive connections between the vestibular nuclei and the reticular formation, thalamus, and cerebellum[19-21] (Fig. 21.4). In addition, vestibular pathways appear to terminate in a unique cortical area. Primate studies have identified the junction of the parietal and insular lobes as the location for a vestibular cortex.[22-24] Recent evidence in human studies using functional magnetic resonance imaging (fMRI) appears to confirm the parietal and insular regions as the cortical location for processing vestibular information.[25] Connections with the vestibular cortex, thalamus, and reticular formation enable the vestibular system to contribute to the integration of arousal and conscious awareness of the body, as well as to discriminate between movement of self and the environment.[26,27] The cerebellar connections help maintain calibration of the vestibulo-ocular reflex (VOR), which stabilizes images on the retina during head movements, contributes to posture during static and dynamic activities, and influences the coordination of limb movements.

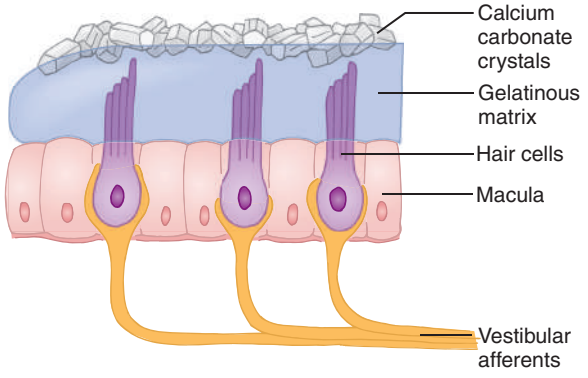

Figure 21.3 Otoconia are calcium carbonate crystals that are embedded in a gelatinous matrix which provides an inertial mass. Linear acceleration shifts the gelatinous matrix and excites or inhibits the vestibular afferents depending on the direction in which the stereocilia are deflected.

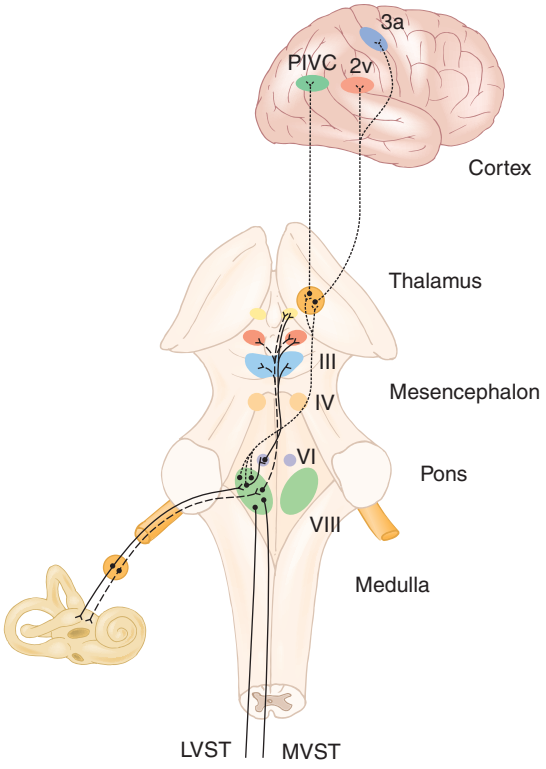

Figure 21.4 The semicircular canal (angular) and otolith (linear) input is sent to the vestibular nuclei. From the vestibular nuclei, the input travels to the ocular motor nuclei (III, IV, VI) for mediation of the vestibulo-ocular reflex. For arousal and conscious awareness of the head and body in space, information proceeds further to the thalamus and cortex. For maintenance of postural control, the peripheral vestibular input is sent distally as the medial and lateral vestibulo-spinal tracts (MVST, LVST). PIVC = Parieto-insular vestibular cortex.

PHYSIOLOGY AND MOTOR CONTROL

Foundational knowledge of vestibular neurophysiology is important for understanding the signs and symptoms of vestibular dysfunction. Important principles of the vestibular system include the *tonic-firing rate, VOR, push–pull mechanism, inhibitory cutoff*, and *velocity storage system.*

Tonic Firing Rate

In primates, primary vestibular afferents of the healthy vestibular system have a resting firing rate that is typically 70 to 100 spikes/sec.[28,29] The presence of the high tonic firing rate means each vestibular system can detect head motion through excitation or inhibition. During angular head rotations, ipsilateral vestibular afferents and ipsilateral central vestibular neurons are

excited.[28] Such head movements also result in inhibition of peripheral afferents and of many central vestibular neurons receiving innervation from the contralateral labyrinth.

Vestibulo-Ocular Reflex

The VOR is responsible for maintaining stability of an image on the fovea of the retina during rapid head movements. To do this, the VOR must generate rapid compensatory eye movements in the direction opposite the head rotation. The VOR achieves this with relatively simple patterns of connectivity in the central vestibular pathways. In its most basic form, the pathways controlling the VOR can be described as a three-neuron arc.

- Primary vestibular afferents from the anterior SCC synapse in the ipsilateral vestibular nuclei.
- Secondary ipsilateral vestibular neurons receiving innervation from the ipsilateral labyrinth decussate and synapse in the contralateral oculomotor nucleus.
- Motor neurons from the contralateral oculomotor nucleus then synapse at the neuromuscular junction of the ipsilateral superior rectus and the contralateral inferior oblique muscles, respectively (Fig. 21.5).

Similar patterns of connectivity exist for each SCC and the eye muscles that receive innervations from them (Table 21.1). See Figure 21.6 for insertions of the ocular muscles.

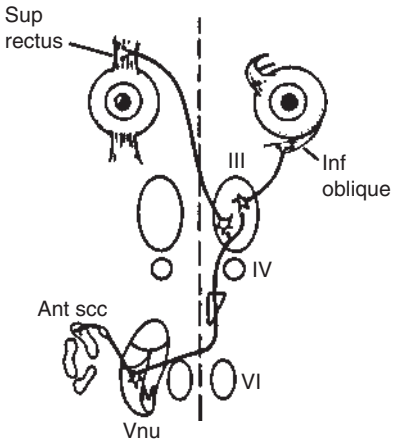

Figure 21.5 From the anterior semicircular canal (Ant Scc), afferent input travels to the vestibular nuclei (Vnu). The signal continues to the contralateral oculomotor nuclei (III). From there, motoneurons synapse with the superior rectus muscle that moves the eye upward, and the inferior oblique muscle that moves the eye upward and torsionally. Also shown are the oculomotor nuclei IV, and VI. *Adapted from Baloh and Honrubia,[30, p. 52] with permission.*

VOR Gain and Phase

Normally, as the head moves in one direction, the eyes move in the opposite direction with equal velocity. This relationship of eye velocity to head velocity is expressed as the gain (*VOR gain*) of the vestibular system (eye velocity/head velocity = –1). For example, when the head is moved down, the anterior SCCs are stimulated. Excitation of the anterior SCC afferents rotates both eyes in the direction opposite the angular head movement, or up (see Fig. 21.5). *VOR phase* is a second useful measure of the vestibular system and represents the amplitude relationship between the eye and head. VOR phase should represent an equal but opposite head and eye position relationship. Therefore, if the head moves 10 degrees to the right, the eyes should be positioned 10 degrees to the left. When the head and eyes are equally positioned but oppositely directed, this is described as a zero phase shift. *Note*: VOR phase is not equivalent with VOR gain, which examines the difference between head and eye velocity.

In individuals with healthy oculomotor function, for head velocities below 60°/sec *gaze stability* can be maintained fairly well using *smooth pursuit* (the ability to move the eyes with smooth, continuous motions in order to follow the movement of a target of interest and maintain the moving image on the fovea).[30] In situations where head velocity is greater than 60°/sec the vestibular system is primarily responsible for generating eye movement (in the direction opposite the head movement) to

Table 21.1 Innervation Pattern of Excitatory Input from the Semicircular Canals

Primary Afferent	Secondary Neuron[a]	Extraocular Motor Neuron	Muscle
Horizontal (left)	Medial vestibular nucleus	Left oculomotor nucleus[b] →	Left medial rectus
		Right abducens nucleus →	Right lateral rectus
Posterior (left)	Medial vestibular nucleus	Right trochlear nucleus →	Left superior oblique
		Right oculomotor nucleus →	Right inferior rectus
Anterior/Superior (left)	Lateral vestibular nucleus	Right oculomotor nucleus →	Left superior rectus
		↘	Right inferior oblique

[a]Ascending secondary neurons travel in the medial longitudinal fasciculus.
[b]In the horizontal semicircular canal, secondary neurons also travel in the ascending tract of Dieters.

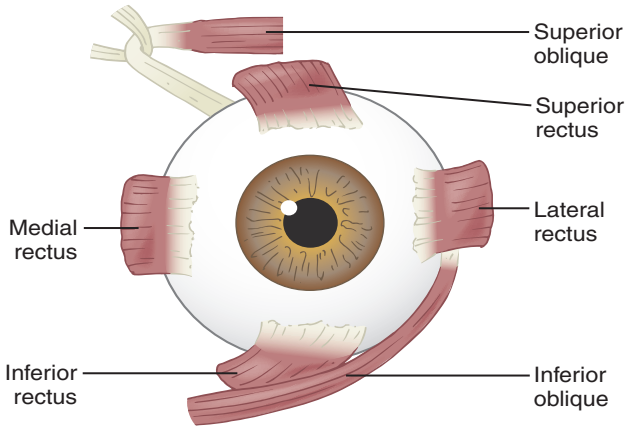

Figure 21.6 Muscle insertions of the left eye. Six extraocular muscles insert into the sclera and can be considered as complementary pairs. The medial and lateral rectus muscles rotate the eyes horizontally, the superior and inferior rectus muscles rotate the eyes vertically, and the superior and inferior oblique muscles rotate the eyes torsionally with some vertical component. By convention, the torsional rotation is noted as it relates to the superior poles of the eyes. The superior oblique muscle rotates the eye downward and toward the nose, whereas the inferior oblique muscle rotates the eye upward and away from the nose. The superior oblique muscle travels through the fibrous trochlea, which attaches to the anteromedial superior wall of the orbit.

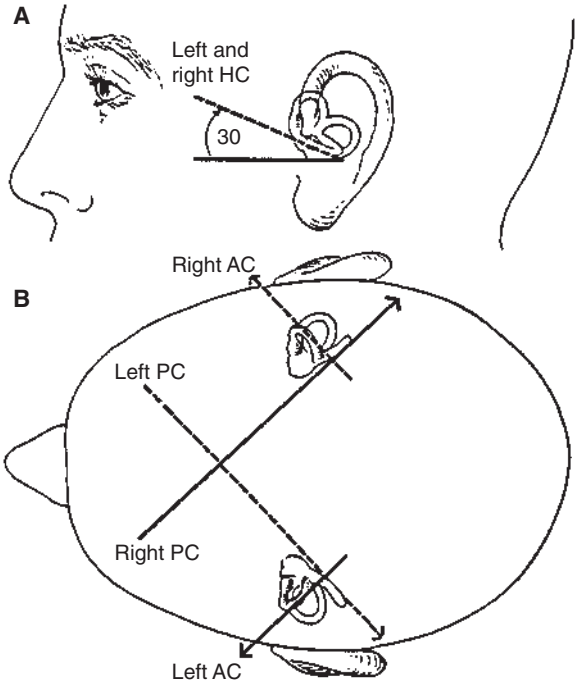

Figure 21.7 **(A)** Orientation of the horizontal semicircular canals (HC) in situ, with the head neutrally aligned. **(B)** The semicircular canals (ipsilateral anterior and contralateral posterior, and each horizontal) work in pairs. The arrows indicate the angular pitch direction of individual SCC stimulation. The dashed and continuous lines illustrate each SCC has an equally opposing SCC, sensitive to the opposite angular pitch direction of the head, for example, the left anterior canal (left AC) is paired with the right posterior canal (right PC) an collectively recognized as the left anterior right posterior (LARP) plane. *Adapted from Baloh and Honrubia,[30, p. 52] with permission.*

maintain *gaze* on the target.[31] The VOR operates at head velocities as great as 350 to 400°/sec.[32]

Push–Pull Mechanism

The brain detects head movement and direction through comparison of inputs between the two vestibular systems. The SCCs each work in coplanar fashion as mentioned earlier; as the head is turned to the right, the right horizontal SCC will have an increased firing rate while the left horizontal SCC has a decreased firing rate. This is called the *push–pull mechanism* (Fig. 21.7). The brain is then responsible for recognizing the difference and interpreting movement. A faulty interpretation will lead to difficulties with gaze stabilization, postural stability, and motion perception.

Inhibitory Cutoff

Recall that during angular head rotations (rotations about an axis) ipsilateral vestibular afferents can be excited up to 400 spikes/sec.[32] A simultaneous hyperpolarization (spontaneous firing rate reduction) of the opposite labyrinth also occurs. However, the inhibition of the hair cells in the opposite labyrinth can only reduce the firing rate to zero, at which point the inhibition is cut off (*inhibitory cutoff*). Thus, for ipsilateral rapid head rotations, the contralateral vestibular afferents cannot detect head rotation when the head velocity is greater than the inhibitory cutoff of those contralateral afferents. The response to head movements that hyperpolarize the hair cells is therefore limited to a velocity range up to 70 to 100°/sec. For example, if the tonic firing rates of the vestibular afferents are 80 spikes/sec, with a rotation to the right of 120°/sec the vestibular afferents increase their firing rate from 80 to 200 spikes/sec (tonic firing rate + rotational velocity). In contrast, the left ear will decrease from 80 to 0 (zero), not to negative 40 (–40), which limits the afferents from the left ear from adequately detecting the head velocity. (It is generally accepted that a 1:1 ratio exists between head velocity and spikes per second neuronal firing rate.) Because the resting discharge rate of these afferents and central vestibular neurons averages 70 to 100 spikes/sec, inhibitory cutoff is more likely to occur than is excitation saturation.

Velocity Storage System

The signal generated by movement of the cupula is brief, lasting only as long as the cupula is deflected.[33] The response is sustained, however, by a circuit of neurons

in the medial vestibular nucleus and lasts longer than 10 seconds in people with normal vestibular function. It is generally believed that the purpose of sustaining vestibular input is to assist the brain in detecting low-frequency head rotation.

PHYSICAL THERAPY EXAMINATION

History and Systems Review

Physical therapists examining people who report dizziness and imbalance have the difficult task of sorting through potential causes. Capturing a thorough history and performing a systems review are critical components of the process. Key elements of taking the history are identification of symptoms, as well as their duration and the circumstances under which the symptoms occur.

Identification of Symptoms

Many patients and clinicians use the imprecise term "dizziness" to describe a vague sensation of lightheadedness or a feeling that they have a tendency to fall. The imprecision of the term can entangle clinical management decisions. It is essential to determine what the patient is experiencing when the term **dizziness** is used. Most complaints of being "dizzy" can be categorized as vertigo, lightheadedness, dysequilibrium, or oscillopsia (targets in visual field appear to move during head motion). Generally, dizziness is vaguely defined as the sensation of whirling or feeling a tendency to fall. Ideally, patients should be directed away from using the word and to use more precise terms that will help the clinician develop more direct treatment approaches.

Vertigo is defined as an illusion of movement. Many patients use the term "vertigo" incorrectly and thus the clinician must be certain to inform patients of the true definition, as well as identify their unique experience. Patients may describe that they sense their environment is moving or that they see the environment moving (spinning). Vertigo tends to be episodic and to indicate pathology at one or more locations along the vestibular pathways. It is most common during the acute stage of unilateral vestibular hypofunction (UVH), but may also manifest itself via displaced otoconia (benign paroxysmal positional vertigo), or an acute unilateral brainstem lesion affecting the root entry zone of the peripheral vestibular neurons or the vestibular nuclei.

Lightheadedness is often defined as a feeling that fainting is about to occur and can be caused by nonvestibular factors such as hypotension, hypoglycemia, or anxiety.[34] Lightheadedness is vague and less localizing than vertigo.

Dysequilibrium is defined as the sensation of being off balance. Typically, acute and chronic vestibular lesions will produce dysequilibrium. Often, however, this symptom is associated with nonvestibular problems such as decreased somatosensation or weakness in the lower extremities (LEs) (Table 21.2).

Table 21.2 Symptoms and Possible Causes

Symptom	Possible Cause
Vertigo	BPPV, UVH, unilateral central lesion affecting the vestibular nuclei
Lightheadedness	Orthostatic hypotension, hypoglycemia, anxiety, panic disorder
Dysequilibrium	BVH, chronic unilateral vestibular hypofunction, lower extremity somatosensation loss, upper brainstem/vestibular cortex lesion, cerebellar and motor pathway lesions

BPPV = benign paroxysmal positional vertigo; BVH = bilateral vestibular hypofunction; UVH = unilateral vestibular hypofunction.

Oscillopsia is the subjective experience of motion of objects in the visual environment that are known to be stationary. Oscillopsia can occur with head movements in patients with vestibular hypofunction since the vestibular system is not generating an adequate compensatory eye velocity during the head motion. Such a deficit in the VOR results in motion of images on the fovea and in a decline in visual acuity. The severity of gaze instability, however, varies across individuals with vestibular hypofunction.[35-38]

Duration and Circumstances of Symptoms

The physical therapist must determine how recently the patient has had an acute attack of vertigo, lightheadedness, dysequilibruim, or oscillopsia and whether the symptom is constant or episodic. If the symptom is episodic, the clinician must attempt to determine the average duration of the episodes in seconds, minutes, or hours. For example, vertigo lasting seconds to minutes commonly suggests benign paroxysmal positional vertigo. In contrast, vertigo lasting minutes to hours suggest Ménière's disease, and vertigo lasting for days implies vestibular neuronitis or migraine-associated dizziness.

The physical therapist must also determine under what circumstances the patient experiences symptoms. It is important to discern whether the patient experiences symptoms with particular movements, positions, or at rest. For example, is the patient sensitive to motion as the passenger in a moving car? Or does the patient experience a vigorous vertigo when the head is moved into certain positions?

Tests and Measures

Visual Analogue Scale

Use of a *visual analogue scale (VAS)* is an effective technique to obtain subjective intensity ratings of vertigo, lightheadedness, dysequilibrium, and oscillopsia.[39,40] The patient is asked to answer a question (e.g., *How intense are your symptoms?*) and mark on a 10-cm line (on a

continuum from "none" to "worst possible intensity") where the symptoms exist at that moment. The clinician then measures the line and obtains a quantified value.

Dizziness Handicap Inventory

The *Dizziness Handicap Inventory (DHI)* is a popular tool used to measure a patient's self-perceived handicap as a result of vestibular disorders (Table 21.3).[41] The DHI has excellent test–retest reliability (r = 0.97) and good internal consistency reliability (r = 0.89). Patients respond to 25 questions, subgrouped into functional, emotional, and physical components. The DHI provides quantification of the patient's perception of dysequilibrium and its impact on daily activities. It is useful to establish subjective improvement. Measures of subjective impairment and physiological improvement are often not correlated;[42,43] therefore, it is likely that factors other than organic recovery of vestibular function are responsible for subjective impairment.

Functional Disability Scale

The Vestibular Rehabilitation Benefit Questionnaire (VRBQ) was developed to specify the benefit from vestibular physical therapy and includes questions that address avoidance behavior, which is often absent in similar measures.[44] The VRBQ is a 22-item questionnaire that uses seven unique choices (word descriptors) to answer questions from one of four subscales: Dizziness, Anxiety, Motion-Provoked Dizziness, and Quality of Life. The VRBQ has excellent test–retest reliability (r = 0.92) and is moderately correlated with the DHI (0.59).

Table 21.3 Sample of the Types of Questions Included in the Dizziness Handicap Inventory, Based on the Three Sub-Components

Physical Domain
Does looking up increase your problem?
Does walking down the aisle of a supermarket increase your problem?
Does performing more ambitious activities like sports, dancing, or household chores (such as sweeping or putting dishes away) increase your problem?
Does bending over increase your problem?
Emotional Domain
Because of your problem, do you feel frustrated?
Because of your problem, are you afraid to leave your home without having someone accompany you?
Has your problem placed stress on your relationships with members of your family or friends?
Because of your problem, are you afraid to stay home alone?
Functional Domain
Because of your problem, do you restrict your travel for business or recreation?
Because of your problem, do you have difficulty getting into or out of bed?
Does your problem significantly restrict your participation in social activities such as going out to dinner, going to the movies, dancing, or to parties?
Because of your problem, is it difficult for you to walk around the house in the dark?

The patient instructions are as follows: The purpose of these questions is to identify difficulties that you may be experiencing because of your dizziness. Please answer "yes", "no", or "sometimes" to each question. Answer each question as it pertains to your dizziness or balance problem only.

Motion Sensitivity Quotient

The *Motion Sensitivity Quotient (MSQ)* was developed to provide a subjective score of an individual's sensitivity to motion.[45] The test involves placing patients into positions incorporating head or entire body motion to determine whether the movement reproduces dizziness (Fig. 21.8). If the patient reports an increased symptom intensity moving into a provoking position, the intensity is assigned a point, graded by the patient between 1 (mild) and 5 (severe). The duration of symptoms is also assigned points from 0 to 3 (0 to 4 seconds = 0; 5 to 10 seconds = 1; 11 to 30 seconds = 2; greater than 30 seconds = 3). The symptom intensity and duration values are then added together for a score. The MSQ is calculated by multiplying the number of positions that provoked symptoms by the score. This number is then divided by 2,048. An MSQ score of 0 indicates no symptoms whereas a score of 100 means severe dizziness in all positions.

Examination of Eye Movements

Owing to the direct relationship between vestibular receptors in the inner ear and eye movements produced by the VOR, the examination of eye movements is critical for defining and localizing vestibular pathology. The key tests include observation for nystagmus, the Head Impulse Test (examination of the VOR at high acceleration), the Head-Shaking Induced Nystagmus (HSN) test, positional testing, and the Dynamic Visual Acuity (DVA) test.

Name: _____ Age: _____ Gender: _____ Date: _____

Baseline Symptoms	INTENSITY	DURATION	SCORE
1. Sitting-to-supine			
2. Supine-to-left side			
3. Supine-to-right side			
4. Supine-to-sit			
5. Left Hallpike-Dix test			
6. Return from Hallpike-Dix test			
7. Right Hallpike-Dix test			
8. Return from Hallpike-Dix test			
9. Sitting: nose toward left knee			
10. Return to sitting			
11. Sitting: nose toward right knee			
12. Return to sitting			
13. Sitting: head rotation 5×			
14. Sitting: head flexion and extension 5×			
15. Standing: turn right (180°)			
16. Standing: turn left (180°)			
Intensity: rated from 0 to 5 (0 = no symptoms; 5 = severe symptoms) Duration: rated from 0 to 3 (5-10 sec = 1 point, 11-30 sec = 2 points, ≥30 sec = 3 points)			

Motion sensitivity quotient: $\frac{\#\text{Provoking positions} \times \text{score} \times 100}{2048} =$ _____ Total

Note: An MSQ score of zero means no symptoms and 100 means severe dizziness in all positions.

Observation for Nystagmus

Nystagmus is the primary diagnostic indicator used in identifying most peripheral and central vestibular lesions. An involuntary eye movement, nystagmus due to a *peripheral vestibular lesion* is composed of both slow and fast components. The direction of the nystagmus is named by the direction of the fast component. For individuals with a unilateral vestibular lesion, the slow component is due to relative excitation of one side of the vestibular system. The fast component is generated from the parapontine reticular formation in the brainstem and repositions the eye to the center of the orbit. For example, in left-beating nystagmus, the eyes move slowly to the right (VOR), and the resetting eye movement is to the left (fast component). Therefore, the direction opposite the quick component of the nystagmus localizes the side of the vestibular reduced firing rate (possible hypofunction).

Nystagmus due to a vestibular lesion is most commonly seen after an acute unilateral insult, *spontaneous* (at rest) *nystagmus*. This type of nystagmus occurs in the absence of motion because of the asymmetry between the healthy functioning and reduced/absent functioning vestibular systems. The brain perceives the asymmetry as active stimulation from the more neutrally active (i.e., healthy) ear. Resolution of spontaneous nystagmus in the light typically occurs within 3 to 7 days but may vary, and it can last as long as 2 months.[46,47] Spontaneous nystagmus may always be present in the dark after a unilateral loss of vestibular function. Regardless, resolution of spontaneous nystagmus in the light or dark occurs when symmetry between the resting firing rates of both vestibular systems is reestablished.[48]

Vestibular nystagmus can be suppressed in light and when a person visually fixates on a target.[49] As a result, the observation of nystagmus should be performed under conditions in which the person cannot see. This can be achieved with Frenzel lenses or an infrared camera system. Frenzel lenses look like large goggles with magnifying lenses that enable the clinician to observe for nystagmus while preventing the patient from fixating on a target. An infrared camera uses infrared light to illuminate the eyes while the patient remains in complete darkness.

Head Impulse Test (Examination of the VOR at High Acceleration)

The head impulse test (HIT) is a widely accepted clinical tool used to examine semicircular canal function.[50-54] Cervical range of motion (ROM) should be determined before performing the head impulse test and the physical therapist should explain why the head must be moved quickly. The head impulse test is performed by having the patient first fixate on a near target (e.g., the clinician's nose). When testing the horizontal SCC, the head is flexed 30°. Patients are asked to keep their eyes focused on a target while their head is manually rotated in an unpredictable direction using a small-amplitude (5° to 15°), moderate-velocity (approximately 200°/sec), and high-acceleration (3,000 to 4,000°/sec^2) angular impulse (Figs. 21.9 and 21.10). When the VOR is functioning normally, the eyes move in the direction opposite to the head movement and gaze will remain on the target. In a patient with a loss of vestibular function, the VOR will not move the eyes as quickly as the head rotation and the eyes move off the target. The patient will then make a corrective saccade to reposition the eyes (fovea) on the target. A corrective **saccade** is a rapid eye movement used to reposition the eyes to the target of interest. The appearance of corrective saccades indicates vestibular hypofunction as determined by the HIT and occurs because inhibition of vestibular afferents and central vestibular neurons on the intact side (persons with unilateral vestibular hypofunction) are less effective in encoding the amplitude of a head movement than excitation. A patient who has a unilateral peripheral lesion or pathology of the central vestibular neurons will not be able to maintain gaze when the head is rotated quickly toward the side of the lesion. A patient with a bilateral loss of vestibular function will make corrective saccades after a head impulse to either side. The HIT provides a sensitive indication of vestibular hypofunction in patients with complete loss of function in the affected labyrinth that occurs following ablative surgical procedures, such as labyrinthectomy.[50,53-55] The test is less sensitive in detecting hypofunction in patients with incomplete loss of function.[56-59]

Head-Shaking Induced Nystagmus Test

The **head-shaking induced nystagmus (HSN)** test is a useful aid in the diagnosis of a unilateral peripheral vestibular defect. During this test vision is occluded. The patient is instructed to close his or her eyes. The clinician flexes the head 30° before oscillating horizontally for 20 cycles at a frequency of 2 repetitions per second (2 Hz). On stopping the oscillation, the patient opens the eyes and the clinician checks for nystagmus. In subjects with normal vestibular function, nystagmus will not be present. An asymmetry between the peripheral vestibular inputs to central vestibular nuclei, however, may result in HSN. Typically, a person with a UVH will manifest a horizontal HSN, with the quick phases of the nystagmus directed toward the healthy ear and the slow phases directed toward the lesioned ear.[60] Not all patients with a UVH will have HSN. Patients with a complete loss of vestibular function bilaterally will not have HSN because neither system is functioning. As a result, there is no asymmetry between the tonic firing rates. The presence of vertical nystagmus after either horizontal or vertical head shaking suggests a central lesion.

Positional Testing

Positional testing is commonly used to identify whether otoconia have been displaced into the SCC, causing a condition referred to as **benign paroxysmal positional vertigo (BPPV)**. The addition of the otoconia into the

Figure 21.9 Normal horizontal canal head impulse test to the left **(A, B),** abnormal to the right **(C–E).** The examiner applies the head impulse test (HIT) to the patient. Large arrow denotes direction the head will be turned. **(A)** Initial starting position places subject's head into cervical flexion; eyes are focused on the target. **(B)** On stopping the head turn, the eyes are still on target and no corrective saccade is observed. In photographs **A** and **B,** the subject's eyes stay fixed on the examiner's nose throughout the test. **(C)** Initial starting position places subject's head into cervical flexion; eyes are focused on the target. **(D)** As the head is turned rapidly to the right, the eyes fall off the target and move with the head. **(E)** The subject must make a corrective saccade (small arrows) to bring the eyes back to the target of interest. For patients with cervical spine pathology, the clinician may choose to perform the horizontal canal HIT by first positioning the head in 15 degrees of rotation and then returning the head to center. *From Schubert et al,[59, p. 153] with permission of the American Physical Therapy Association.*

endolymph makes the semicircular canals sensitive to changes in head position. The **Dix-Hallpike test** is the most common positional test used to examine for BPPV.[61] The patient is moved from a long-sitting position with the head rotated 45° to one side, to a supine position with the head extended 30° beyond horizontal, head still rotated 45° (Fig. 21.11). The maneuver places each of the SCCs in a gravity-dependent position and the physical therapist should observe the eyes for nystagmus. The direction of the nystagmus is unique to the involved SCC. The direction and duration of the resultant nystagmus can help determine whether the patient has BPPV or a central lesion. An alternative form of the Dix-Hallpike test asks the patient to move into a side-lying position (Fig. 21.12). In both versions illustrated, the ear toward the ground is the labyrinth being tested. If horizontal SCC BPPV is suspected, the roll test can be used instead (Fig. 21.13). In this test, the patient is positioned supine with the head flexed 20°. Rapid rotations to the sides are done separately and the clinician observes for nystagmus and vertigo. To prevent neck injury, the patient may move his or her own head in rotation.

Dynamic Visual Acuity Test

Dynamic visual acuity (DVA) is the measurement of visual acuity during horizontal motion of the head. A "bedside" and computerized form of the test can be used to identify the functional significance of the vestibular hypofunction.[62,63] Head velocities need to be greater than 100°/sec at the time DVA is measured to ensure that the vestibular afferents from the contralateral side are driven into inhibition and the letters (acuity chart) are not identified with a **smooth pursuit** eye movement. To perform the test, static visual acuity is determined first. The patient is asked to "Read the lowest line you can see" on a wall-mounted acuity chart. Lighthouse ETDRS (Early

Figure 21.10 Vertical semicircular canal head impulse test (HIT), examiner's hands not shown here. There are two ways to investigate the VOR from each coplanar pair; methods **A–C** and **D–F** illustrate the two methods for the left anterior right posterior (LARP) VOR. **(A)** The head is placed in a neck neutral position. Next the head is rapidly moved pitch down while being rolled to the left **(B)** as if the head were moving diagonally. This examines the VOR from the left anterior SCC. From here, the clinician should return to **(A)** before rapidly moving the head pitch up and rolled to the right **(C).** This examines the VOR from the right posterior canal. Alternatively, the head is rotated 45° to the right **(D).** From this static position, the head is rapidly pitched down **(E)** examining the left anterior SCC. The head should be returned to the start position **(D)** and then the head rapidly moved pitch up to examine the right posterior SCC **(F)**. In this figure, the HIT is normal for the LARP plane, since the eyes remain gazing straight ahead.

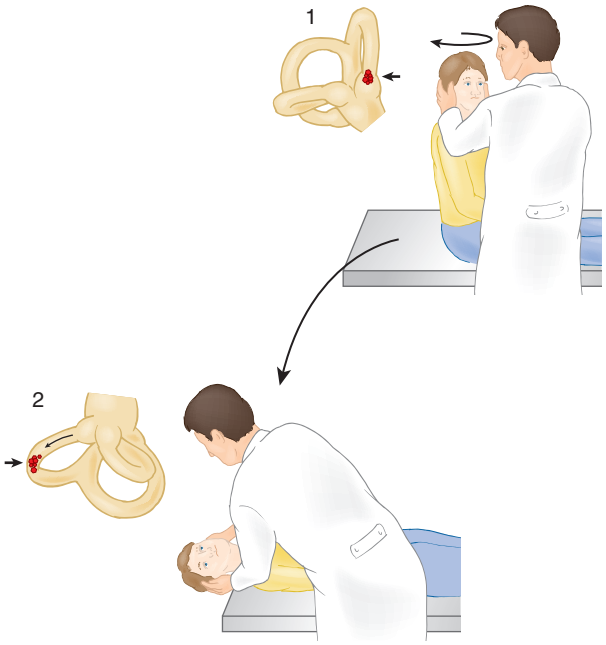

Figure 21.11 The Dix-Hallpike test. (1) The patient sits on the examination table and the clinician turns the head horizontally 45°. (2) As the examiner maintains the 45° rotation, the patient is quickly brought to a supine position with the neck extended 30° beyond the horizontal. The examiner must look for nystagmus and ask the patient if vertigo is being experienced. The patient is then slowly brought back to the starting position, and the other side is tested. The side that reproduces nystagmus and vertigo is the side that has the benign paroxysmal positional vertigo (BPPV). Shown here for testing right posterior or right anterior semicircular canal BPPV.

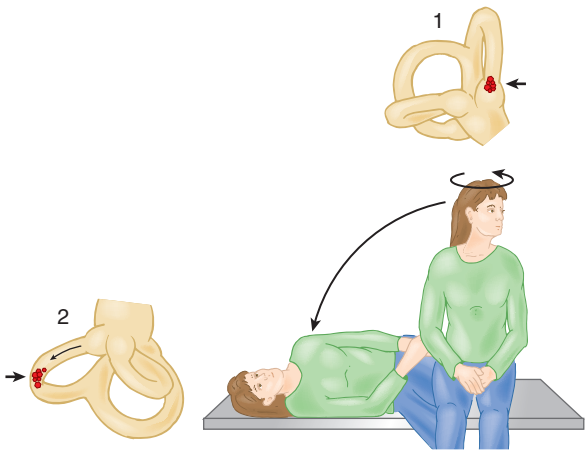

Figure 21.12 The Dix-Hallpike test (side-lying). (1) The patient sits on the edge of the examination table. The clinician turns the head horizontally 45°. (2) As the examiner maintains the 45° rotation, the patient is quickly brought down to the side opposite the head rotation (pictured here as the right side). The examiner checks for nystagmus and vertigo, and then slowly brings the patient to the starting position. The other side is then tested.

Treatment Diabetic Retinopathy Study) wall charts are recommended because they provide uniform light luminance for each of the letters. The patient then attempts to read the chart while the clinician horizontally oscillates the patient's head at a frequency of 2 Hz. A metronome can be useful to ensure correct frequency of the oscillation. For patients with loss of vestibular function, the eyes will not be stable in space during head movements. This causes a decrement in DVA compared with visual acuity

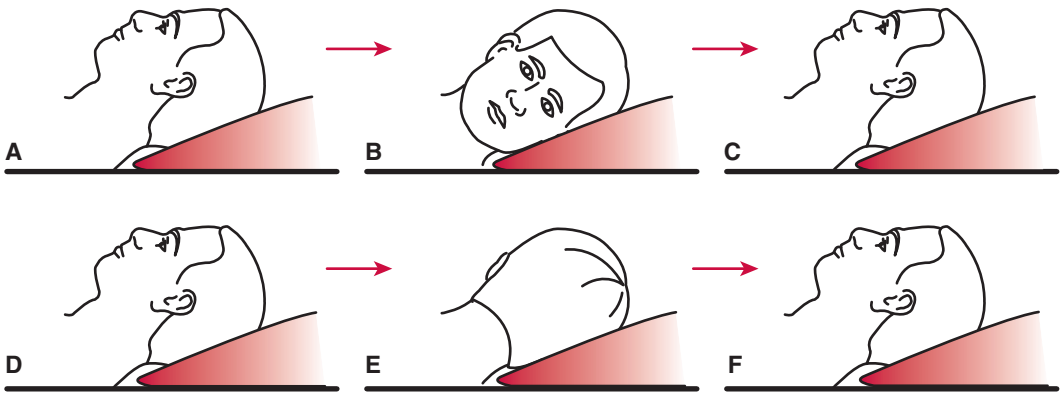

Figure 21.13 Roll test for horizontal semicircular canal BPPV. The patient is positioned in supine. **(A)** Initially, the patient's head should be placed in 20° cervical flexion. **(B)** The head is quickly turned 90° to the left side. The clinician then checks for nystagmus and vertigo. **(C)** The head is then gently returned to the neutral starting position. **(D–F)** The test is repeated to the other side (head is quickly turned 90° to the right side). The therapist again must check for nystagmus and vertigo. The head is then returned to the neutral starting position.

when the head is still. Using the acuity chart, a 3-line or more decrement in visual acuity during head movement is suggestive of vestibular hypofunction.[63] For people with normal vestibular function, head movement results in little or no change of visual acuity compared with the head still (less than 1 line difference). Computerized DVA has been found to correctly identify the side of lesion in patients with unilateral hypofunction for self-generated and unpredictable head motion[63,64] and can be used to identify single SCC lesions.[65]

Examination of Gait and Balance

Examination of gait and balance problems is important for determination of a patient's functional status. Testing should address both static and dynamic balance (e.g., weight shifting, automatic postural responses, and ambulation). Gait and balance tests *cannot* uniquely identify pathology within the vestibular system. Table 21.4 includes common balance tests and expected results.

Vestibular Function Tests

Semicircular Canal Tests

The more common SCC tests include *electro* or *videonystagmography* (ENG, VNG) testing and *rotational chair tests* and are commonly performed in a clinical vestibular function test laboratory. ENG includes a battery of tests that measure *oculomotor* and *inner ear* function. The test also examines for nystagmus in different head positions. The ENG oculomotor tests typically examine saccadic and smooth pursuit including velocity, latency, and gain. The inner ear test is known as the *caloric test* and infuses the external auditory canal with separate cold and warm air or water. This stimulus introduces a temperature gradient. In the presence of gravity, this temperature gradient results in the convective flow of endolymph that deflects the cupula and generates nystagmus from the horizontal SCC. This test is particularly useful for determining the side of the deficit, because each labyrinth is stimulated separately. A variation with ice water is useful to determine whether minimal function exists in the vestibular system for patients with severe loss. However, the caloric test provides limited information since only the horizontal SCCs can be stimulated and that stimulation corresponds to a frequency (0.025 Hz) that is much lower than the natural frequencies of head movement (1 to 20 Hz).[66]

The rotational chair test stimulates each SCC by rotating subjects in the dark. In subjects with normal vestibular function, nystagmus should be generated by the rotation. In the presence of a vestibular disorder, the extent of pathology can be determined by comparing VOR gain and phase from rotations toward one ear with rotations toward the opposite ear. In addition, VOR gain and phase of people with normal vestibular function can be compared with that of people with suspected vestibular hypofunction. The rotational chair test is considered the standard test for bilateral vestibular hypofunction. Rotational chair testing is limited because only the horizontal SCCs are routinely tested to determine extent of pathology.

Otolith Tests

Advances in vestibular diagnostic testing have extended the region of identifiable pathology to include the otolith organs.[67-69] The *vestibular-evoked myogenic potential (VEMP)* test is a laboratory test that has gained broad clinical use and includes two subtypes: *cervical* and *ocular* VEMP. Both types use threshold and amplitude of a muscle contraction (electromyography [EMG]) to classify pathology. The cervical VEMP test exposes patients

Table 21.4 Common Balance Tests and Expected Results Related to Specific Diagnosis

Test	BPPV	UVH	BVH	Central Lesion
Romberg	Negative	Acute: positive Chronic: negative	Acute: positive Chronic: negative	Often negative
Tandem Romberg	Negative	Positive, eyes closed	Positive	Positive
Single-legged stance	Negative	May be positive	Acute: positive Chronic: negative	May be unable to perform
Gait	Normal	Acute: wide-based, slow, decreased arm swing and trunk rotation Compensated: normal	Acute: wide-based, slow, decreased arm swing and trunk rotation Compensated: mild gait deviation	May have pronounced ataxia
Turn head while walking	May produce slight unsteadiness	Acute: may not keep balance Compensated: normal	May not keep balance or slows cadence	May not keep balance, increased ataxia

BPPV = benign paroxysmal postural vertigo; BVH = bilateral vestibular hypofunction; UVH = unilateral vestibular hypofunction.

to aural stimuli in the form of a series of ipsilateral loud (95-decibel [dB]) clicks. During the sound application, the ipsilateral sternocleidomastoid (SCM) muscle is tested for myogenic potentials. In people with healthy vestibular function, an initial inhibitory potential (occurring at a latency of 13 milliseconds [msec] after the click) is followed by an excitatory potential (occurring at a latency of 21 msec after the click). For patients with vestibular hypofunction, the VEMPs are absent on the side of the lesion. The saccule has been implicated as the site of afferent stimulation during cervical VEMP testing because saccular afferents provide ipsilateral inhibitory disynaptic input to the SCM muscle,[70] are responsive to click noise,[71-73] and are positioned close to the footplate of the stapes (inner most auditory ossicle) and therefore are subject to mechanical stimulation.[68,71]

The ocular VEMP exposes subjects to loud clicks (aural stimuli) or bone vibration applied to the central forehead, at the hairline. During the stimulus, EMG is measured from the inferior oblique muscle while subjects look upward to bring the muscle belly closer to the surface electrode. The ocular VEMP is a crossed, excitatory otolith-oculomotor response and in patients with UVH will be absent from the contralateral superior oblique.[74] The ocular VEMP is considered a test of the utricle and the superior vestibular nerve based on its absence in patients with abnormal caloric but preserved cervical VEMP.[74]

The *subjective visual vertical (SVV)* and *subjective visual horizontal (SVH)* tests are used to examine otolith function, though they cannot be used to uniquely detect saccular or utricular pathology. During the SVV test, patients are asked to align a dimly lit luminous bar (in an otherwise darkened room) with what they perceive as being vertical. The SVH test asks patients to align a bar with what they perceive as being horizontal. In the absence of vestibular problems, subjects typically align the bar within 1.5° of true or horizontal. Patients with UVH generally align the bar more than 2° from true vertical or horizontal with the bar tilted toward the lesioned side.[69,75]

VESTIBULAR SYSTEM DYSFUNCTION

Peripheral Pathology

Mechanical

The most common cause of vertigo, BPPV, is a biomechanical disorder. Symptoms of BPPV include nystagmus and vertigo with change in head position, and occasionally nausea with or without vomiting, and dysequilibrium. In the most common form, latency to onset of the vertigo and nystagmus occurs within 15 seconds once the head is in the provoking position. The duration is usually less than 60 seconds. The vertigo and nystagmus are direct impairments caused by the misplaced otoconia. BPPV is believed to occur via one of two mechanisms: *cupulolithiasis* and *canalithiasis.* Both of the theories involve the otoliths becoming dislodged from the utricle and falling into the SCCs. Schuknecht[76] first theorized that fragments of otoconia break away and adhere to the cupula of one of the SCCs (cupulolithiasis). When the head is moved into certain positions, the weighted cupula is deflected by the pull of gravity. This abnormal signal results in vertigo and nystagmus, which persists as long as the patient is in the provoking position. Cupulolithiasis, therefore, does not explain the brief duration of the vertigo common in BPPV.[77] A second theory was proposed, canalithiasis, in which the otoconia are floating freely in one of the SCCs.[78] When a patient changes head position, the pull of gravity causes the freely floating otoconia to move inside the SCC resulting in endolymph movement and deflection of the cupula. Figure 21.14 illustrates BPPV occurring from cupulolithiasis or canalithiasis.

Decreased Receptor Input

The most common causes of UVH leading to decreased or eliminated receptor input are viral insults, trauma, and vascular events.[79,80] Patients who sustain a UVH will experience direct impairments of vertigo, spontaneous nystagmus, oscillopsia during head movements, postural instability, and dysequilibrium. Initially, the patient will experience the vertigo and nystagmus impairments due to the asymmetry created when one vestibular system is no longer functioning. This resolves within 3 to 7 days assuming the patient is exposed to common daylight conditions.[81] Spontaneous nystagmus in room light, beyond this time period, should alert the clinician to a possible central lesion or an unstable peripheral vestibular lesion. The direct impairments of visual blurring, postural instability, and dysequilibrium respond to physical therapy intervention. Because vertigo owing to asymmetry typically resolves within 7 days, persistent symptoms of vertigo beyond 2 weeks should be considered chronic, also necessitating vestibular rehabilitation.

The most common cause of a bilateral vestibular hypofunction (BVH) is **ototoxicity**. Certain classes of antibiotics such as aminoglycosides (e.g., gentamicin, streptomycin) are readily taken up by the hair cells of the vestibular apparatus and continue to build in this system even after the person has stopped using the antibiotic. Less common causes of BVH include meningitis, autoimmune disorders, head trauma, tumors on each eighth cranial nerve (including bilateral vestibular schwannoma), transient ischemic episodes of vessels supplying the vestibular system, and sequential unilateral vestibular neuronitis.[82-84] The primary complaint is dysequilibrium though oscillopsia and gait ataxia are common clinical signs with a BVH diagnosis, all direct impairments. Unless the BVH is asymmetrical, the patient will not experience nausea, vertigo, or nystagmus because there is no asymmetry in the tonic firing rate of the vestibular neurons. Halmagyi et al[85] reported that patients with gentamicin ototoxicity have posture and gait abnormalities, decreased visual acuity with head movement, and

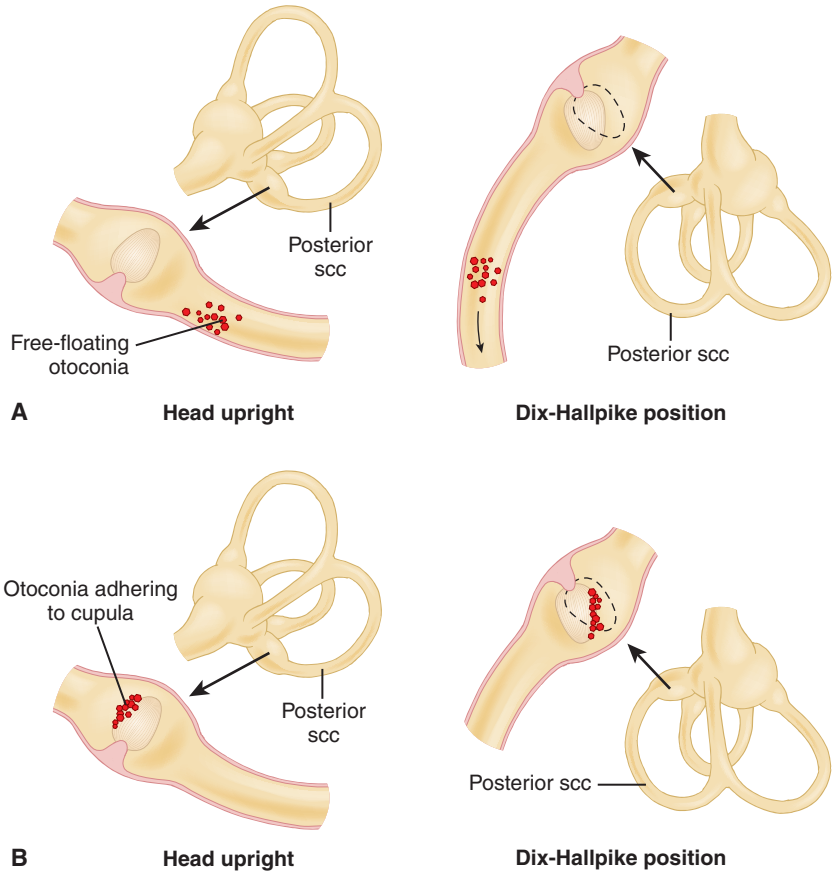

Figure 21.14 Illustrated is benign paroxysmal positional vertigo (BPPV) of the posterior SCC. **(A)** Canalithiasis indicates free-floating otoconia within the SCC. When the head is moved into a position that places the SCC parallel to the pull of gravity (e.g., Dix-Hallpike position), the free-floating otoconia move to the dependent position within the canal. The movement of the free-floating otoconia results in deflection of the cupula. **(B)** Cupulolithiasis indicates otoconia adhering to the cupula. When the head is moved to a position placing one of the SCCs parallel to the pull of gravity (e.g., Dix-Hallpike position), the cupula is continually displaced. Illustrated is BPPV of the posterior SCC; also note the cupular deflection. Note that the cupula is drawn with the superior aspect detached from the ampulla.

reduced VOR gains resulting in a positive head impulse test. These impairments are likely permanent though patients with BVH can return to high levels of activity.

Central Nervous System Pathology

Various central nervous system (CNS) injuries can affect the vestibular system.[86] Cerebrovascular insults involving the *anterior-inferior cerebellar artery (AICA), posterior-inferior cerebellar artery (PICA),* and *vertebral artery* may cause vertigo, though other signs associated with these infarcts are present and help clarify the site of pathology. Signs and symptoms between an AICA and PICA infarct can be difficult to distinguish though hearing loss is usually more common with AICA infarcts. Lesions of the vertebral artery may affect the cerebellum only and can mimic a peripheral vestibular hypofunction in its clinical presentation. Most patients with cerebellar lesions however, will have associated signs such as dysdiadochokinesia or past pointing.[87] Individuals with transient ischemic attacks may present with sudden vertigo that lasts minutes and also include complaint of hearing loss. For more thorough reading discerning types of central vestibular pathology, see Brandt and Dieterich[86] and Delaney.[87]

Signs and symptoms associated with *vertebrobasilar insufficiency* (VBI) typically do not involve the classic signs and symptoms of vestibular pathology. The most common cause of VBI is motor vehicle accident (MVA).[88] A recent study identified the most common symptoms of VBI as visual field cuts,[89] whereas an older study reported visual dysfunction, drop attacks (sudden, spontaneous falls), and unsteadiness/incoordination as the three most common symptoms.[90] Another cause of VBI is cervical spondylosis. In these patients, vertigo and decreased blood flow velocity through vertebral arteries after head rotation has been reported.[91]

Patients who have sustained a traumatic brain injury (TBI) due to labyrinthine or skull fractures may complain of vertigo.[92] As much as 78% of patients sustaining a mild head injury had acute complaints of vertigo, and 20% to 37% still experienced the vertigo 6 months to 5 years later.[93,94] Abnormal central processing as well as reduced receptor input may cause the perseveration of the vertigo reported in patients with TBI.

Demyelinating diseases such as multiple sclerosis (MS) can affect cranial nerve VIII where it enters the brainstem. In such a case, signs and symptoms may be identical to a UVH. A magnetic resonance image scan will need to be performed to ensure an accurate diagnosis of MS.

Discerning Peripheral Vestibular Pathology from Central Vestibular Pathology

Observation of nystagmus is a useful tool for assisting in determining a diagnosis of CNS pathology. Nystagmus from a cerebellar lesion may be in a pure vertical

direction.[95] The nystagmus may not have a slow component and the eyes therefore oscillate at equal speeds, called *pendular nystagmus.* Pendular nystagmus is often indicative of congenital disorders, such as the absence of central vision (cortical visual processing). Another clue to discern a central versus a peripheral vestibular pathology is the recovery time. Unlike nystagmus following a peripheral vestibular lesion, nystagmus from a central vestibular lesion often never resolves.

Vertigo can be a symptom with central pathology but is rare and if present, is often much less intense than with a peripheral vestibular lesion.[96] Patients with lesions of the vestibular nuclei can present with vertigo, nystagmus, and dysequilibrium similar to the patient with a peripheral vestibular lesion. However, central lesions above the level of the vestibular nuclei will manifest lateropulsion, head tilt, and visual perceptual difficulties, as well as oculomotor signs. *Lateropulsion* refers to the person's tendency to fall to one side.

Brandt et al[97] classify central vestibular syndromes from a clinical consensus of establishing perceptual, oculomotor, and postural signs. They report that the most sensitive signs of unilateral brainstem infarct are tilt of the patient's SVV and ocular torsion. Ocular torsion refers to the superior pole of the eyes moving together in a role direction.

Ocular torsion combined with head tilting and skew deviation encompass a triad of signs termed a complete *ocular tilt reaction* (OTR) (Fig. 21.15).[98] Skew deviation of the eyes appears as one eye being superiorly displaced in comparison with the other eye. Kattah, et al examined 101 subjects with symptoms that may have been due to a central pathology (acute vertigo, nystagmus, nausea/vomiting, head-motion intolerance, unsteady gait). Each subject underwent neuroimaging and admission (generally 72 hours after symptom onset). Cerebrovascular accidents (CVAs) were diagnosed by magnetic resonance imaging (MRI) or computed tomography (CT). The initial MRI diffusion-weighted imaging was falsely negative in 12% (48 hours after symptom onset) of subjects. However, the presence of normal horizontal head impulse test, direction-changing nystagmus in eccentric gaze, or skew deviation was 100% sensitive and 96% specific for stroke. Furthermore, the presence of skew deviation correctly predicted lateral pontine stroke in 2 of 3 cases in which an abnormal horizontal head impulse test erroneously suggested peripheral localization. In conclusion, skew is an important predictor of brainstem involvement and can identify CVA when an abnormal horizontal head impulse test may falsely suggest a peripheral lesion. The study recommended a 3-step bedside oculomotor examination (HINTS: Head-Impulse, Nystagmus, Test-of-Skew) as a more sensitive measure for stroke than early MRI.[99]

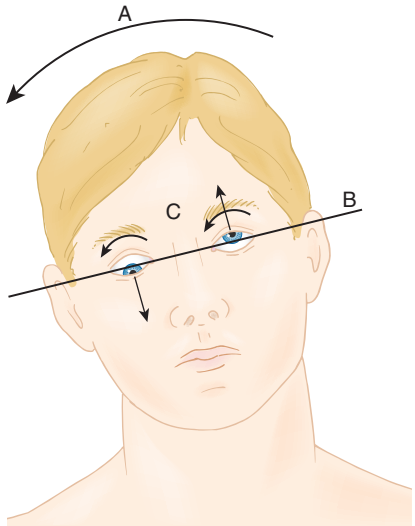

Figure 21.15 The ocular tilt reaction (OTR) consists of a triad of signs: **(A)** Head tilting to the right, indicated with the large arrow. **(B)** Skew deviation of the eyes (right eye is down, left eye is up), indicated with the bisecting line and straight arrows. **(C)** Torsion of the eyes to the right, indicated with the two smaller rounded arrows.

"Red flags" that should alert the physical therapist to a central vestibular etiology include horizontal or vertical diplopia lasting longer than 2 weeks after the onset of signs or symptoms thought to be due to UVH, persistent pure vertical *positional nystagmus* (anterior canal cupulolithiasis should be ruled out), a spontaneous up-beating nystagmus (rare), and a positive test for skew deviation. The therapist should refer a patient with these manifestations to a neurologist.

It is not within the scope of this chapter to expand on the differential diagnosis within the CNS, identifying the site of lesion. However, the physical therapist must recognize the difference between central and peripheral vestibular dysfunction because this guides the treatment strategy. Table 21.5 can be used as a guide to discern central vestibular pathology from peripheral vestibular pathology.

INTERVENTIONS

Benign Paroxysmal Positional Vertigo

The development of specific anticipated goals and expected outcomes for the individual patient with BPPV is based on the following general goals:

- The otoconia will be returned into the vestibule.
- The patient will demonstrate reduced vertigo associated with head motion.
- The patient will demonstrate improved balance.
- The patient will demonstrate independence in daily activity (basic activities of daily living [BADL]; instrumental activities of daily living [IADL]) involving head motion.

Because BPPV is the most common peripheral vestibular pathology, physical therapists should be familiar with treatment of this disorder. The type of nystagmus generated as result of placing the SCCs in gravity-dependent positions indicates which SCC

Table 21.5 Common Symptoms Associated with Central versus Peripheral Vestibular Pathology

Central Vestibular Pathology	Peripheral Vestibular Pathology
Ataxia often severe.	Ataxia mild.
Abnormal smooth pursuit and abnormal saccadic eye movement tests.	Smooth pursuit and saccades usually normal; positional testing may reproduce nystagmus.
SX usually do not include hearing loss; if so, it is often sudden and permanent.	SX may include hearing loss (insidious—may recover), fullness in ears, tinnitus.
SX might include diplopia, altered conscious, lateropulsion.	
SX of acute vertigo not usually suppressed by visual fixation.	SX of acute vertigo usually suppressed by visual fixation.
	SX of acute vertigo usually intense (more than central vestibular pathology).
Pendular nystagmus (eyes oscillate at equal speeds).	Nystagmus will incorporate slow and fast phases (jerk nystagmus).
Pure persistent vertical nystagmus persists regardless of positional testing (persistent downbeat nystagmus in Hallpike-Dix test may indicate anterior canal BPPV).	Spontaneous horizontal nystagmus usually resolves within 7 days in a patient with UVH.

BPPV = benign paroxysmal postural vertigo; SX = symptoms; UVH = unilateral vestibular hypofunction.

Table 21.6 Type of Nystagmus Based on SCC Location and Mechanism of BPPV

SCC[a]	Mechanism	Nystagmus[b]	Incidence (%)[10]
Right posterior	Cupulolithiasis Canalithiasis	Persistent UBN and right torsion[c] Transient UBN and right torsion	62
Left posterior	Cupulolithiasis Canalithiasis	Persistent UBN and left torsion Transient UBN and left torsion	
Horizontal[d]	Cupulolithiasis Canalithiasis	Persistent ageotropic Transient geotropic	35
Right superior	Cupulolithiasis Canalithiasis	Persistent DBN and right torsion Persistent DBN and right torsion	3
Left superior	Cupulolithiasis Canalithiasis	Persistent DBN and left torsion Persistent DBN and left torsion	

[a]Testing for BPPV in the SCC assumes the patient is in the appropriate positional test.
[b]Nystagmus is labeled by the direction of the fast component up-beat nystagmus (UBN) means the fast component of the nystagmus is beating upwards, DBN = down-beat nystagmus.
[c]The torsional rotation is noted as it relates to the superior poles of the eyes, from the perspective of the examiner.
[d]When BPPV occurs in the horizontal SCC, nystagmus will be present when the head is positioned to either side.
Ageotropic nystagmus = fast component beats away from the ground; geotropic nystagmus = fast component beats toward the ground.

is involved (Table 21.6) and directs the clinician to choose an appropriate treatment approach. Three different treatment approaches have been developed, each based on pathophysiological theories of this disorder. The techniques include the canalith repositioning maneuver, the Liberatory (Semont) maneuver, and Brandt–Daroff exercises.

The *canalith repositioning maneuver* (CRM) is based on the canalithiasis theory of free-floating debris in the SCC.[100] The patient's head is moved into different positions in a sequence that will move the debris out of the involved SCC and into the vestibule (general term for the location of the utricle and saccule) (see Fig. 21.1). Once the debris is in the vestibule, the signs and symptoms should resolve. The positions used in the treatment of posterior and anterior SCC canalithiasis can be the same. Figure 21.16 illustrates the CRM as applied to either the left posterior or left anterior SCC. It is important to instruct the patient that horizontal movement of the head should be performed to prevent stiff neck muscles. Patients may wish to limit vertical head motion. CRM has also been adapted for application to the horizontal SCC (Fig. 21.17), although BPPV is less common in either the horizontal or anterior SCC.[101] The original

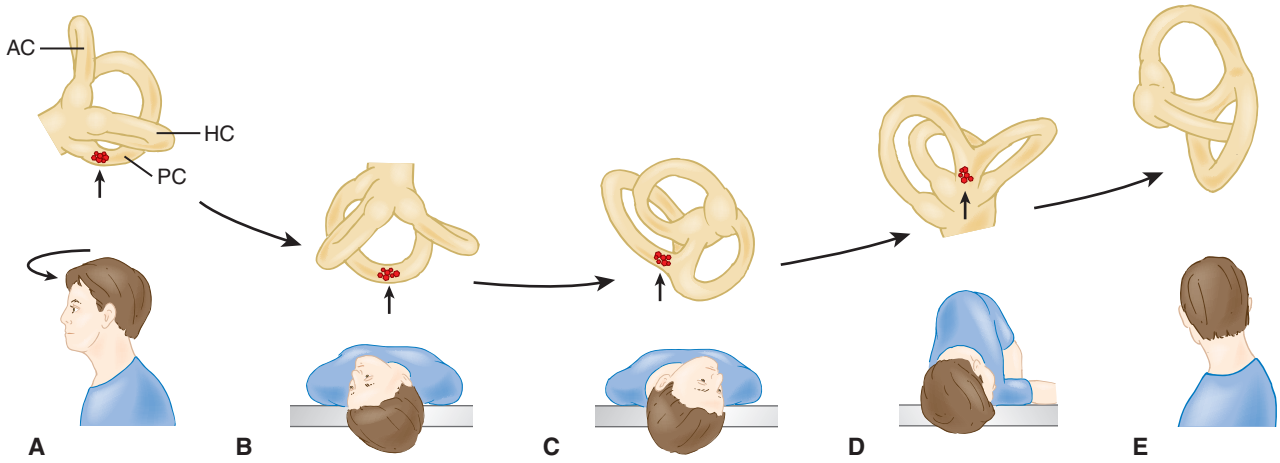

Figure 21.16 Canalith repositioning maneuver (CRM) for posterior or anterior semicircular canal BPPV. **(A)** The patient's head is first rotated 45° toward the involved side, pictured here as the left. **(B)** The patient is then moved into the Dix-Hallpike position with the affected left ear toward the ground. **(C)** Next, the head is rotated 90° to the right. It is important to maintain the 30° neck extension during this step. The head should now be positioned 45° to the right. **(D)** The patient is rolled onto the right shoulder and **(E)** slowly brought up to sitting position, head still rotated 45° to the right. The patient may then be fitted with a soft collar. Note the orientation of the labyrinth for each stage. The arrow points to the free-floating debris and shows its movement through the canal into the common crus **(D).** AC = anterior SCC; PC = posterior SCC; HC = horizontal SCC. Between each step, the clinician should wait 1 to 2 minutes or until the vertigo and nystagmus has stopped to ensure otoconia flow through the canal.

post-CRM instructions asked patients to remain upright for one to two nights (sleep in a recliner chair) and then to avoid sleeping on the involved side for five additional nights. There is no evidence to support sleeping upright after CRM.[102] Recurrence of BPPV varies depending on the study involved.[103,104] There is no evidence that prophylactic CRM prevents recurrence.[105]

The *Liberatory (Semont) maneuver* was first offered as a treatment for posterior SCC BPPV based on the cupulolithiasis theory.[106] It involves rapidly moving the patient through positions designed to dislodge the debris from the cupula (Fig. 21.18). Data suggest it is effective as an alternative treatment for canalithiasis, though it is more difficult for the patient to tolerate.[107,108]

Brandt–Daroff exercises were originally designed to habituate the CNS to the provoking position.[109] They may also act to dislodge debris from the cupula or by causing debris to move out of the canal. Figure 21.19 illustrates the exercises. The exercise should be performed for 5 to 10 repetitions, three times a day until the patient has no vertigo for 2 consecutive days. If the patient has severe vertigo or complaints of nausea, decreasing the number of repetitions to three, performed three times a day, may render the exercises more tolerable. It is important to explain to the patient that the movements must be performed rapidly and that this will probably provoke the patient's vertigo. Patient education should also include informing the patient that it is normal to have some residual symptoms of dysequilibrium and nausea on completing the exercises. The residual symptoms are usually temporary and patients need to continue the exercises.

The goal of performing CRM and liberatory procedures is to replace the otoconia into the vestibule, where the calcium crystals can be reabsorbed or perhaps dissolved. The Brandt–Daroff exercises, although originally designed to habituate the peripheral vestibular response, have also led to a complete remission of symptoms, sometimes after the first exercise session.[109] Physical therapy outcomes should also include teaching the patient how to use the appropriate techniques at home, in the case of recurrence. See Table 21.7 for suggested guidelines for use of the CRM, the Liberatory (Semont) maneuver, and Brandt–Daroff exercises.

Unilateral Vestibular Hypofunction

The development of specific anticipated goals and expected outcomes for the individual patient with UVH is based on the following general goals:

- The patient will demonstrate improved stability of gaze during head movement.
- The patient will demonstrate diminished sensitivity to motion.
- The patient will demonstrate improved static and dynamic postural stability.
- The patient will be independent in proper performance of a home exercise program (HEP) that includes walking.

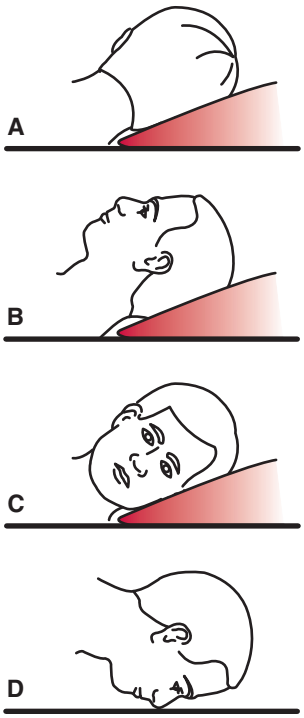

Figure 21.17 Canalith repositioning maneuver (CRM) for right horizontal semicircular canal BPPV. Initially, the patient's head should be placed in 20° cervical flexion. **(A)** For treating a right-sided horizontal canal BPPV, the patient's head is initially placed 90° to the right. **(B)** Next, the head is rotated 90° to the left. The therapist should wait in this position for 15 seconds or until the vertigo and nystagmus stops. **(C)** The head should then be rotated another 90° to the left; again the therapist must wait for 15 seconds or until the vertigo and nystagmus stops. **(D)** The patient must then roll into prone position and await the signs or symptoms to stop. The therapist must attempt to keep the head in 20° flexion during the transition from **C** to **D.** If the CRT has been successful, nystagmus and vertigo should resolve once the patient is in the prone position. The patient may need assistance to sit up from the prone position.

Patients with UVH should be informed that recovery time after initiating vestibular rehabilitation averages 6 to 8 weeks. To ensure adherence with the vestibular rehabilitation exercises, patients should be encouraged frequently and the mutually agreed on goals and outcomes regularly reinforced.

Gaze Stability Exercises

The purpose of these exercises is to improve the VOR and other systems that are used to assist gaze stability with head motion. Vestibular adaptation exercises are designed to expose patients to retinal slip. **Retinal slip** occurs when the image of an object moves off the fovea of the retina, resulting in visual blurring. Retinal slip is necessary as this is the signal used to drive vestibular adaptation within the brain. Because the brain can tolerate small amounts of retinal slip yet see a target clearly, the patient must try to keep the target in focus. Otherwise, head motion that is too rapid will result in excessive retinal slip. The two primary paradigms of vestibular adaptation are ×1 (times 1) and ×2 (times 2) exercises.[110] In the ×1 exercise the patient is asked to move the head horizontally (and vertically if appropriate) as quickly as possible while maintaining focus on a stable target. The patient must learn to slow the head movement if the target becomes blurred. A good target to use is a business card, asking the patient to focus on a word or a letter within a word. The starting target distance should be an arm's length away. The ×2 paradigm requires the patient to move the head and target in opposite directions (Fig. 21.20). Both paradigms should be made increasingly more difficult as the patient improves. Examples of increasing difficulty include the use of a distracting background while the patient attempts to focus on the letter or word (checkerboard, venetian blinds), varying the distance from which the patient performs the exercises, moving the head more rapidly, and performing the exercise while standing or walking. The *computerized DVA* test is a useful measure of improved gaze stability for individuals with UVH and TBI.[63,111]

Postural Stability Exercises

The purpose of postural stability exercises is to improve balance by encouraging the development of balance strategies within the limitations of the patient, be they somatosensory, visual, or vestibular. The exercises should challenge the patient and be safe enough to perform independently (Table 21.8). Exercises must be updated and progressed to incorporate more challenges (Fig. 21.21). In addition, it is important to incorporate head movement into the exercises because many patients with vestibular loss tend to decrease their head movement.

Habituation Exercises (Motion Sensitivity)

Habituation exercises are warranted when a patient with a UVH has continual complaints of dizziness. *Habituation* is defined as the reduction in response to a repeatedly performed movement. These exercises were the first successful methods used to treat persons with vestibular disorders. Various investigators[45,112] have developed versions of positional tests based on the original exercises and studies by Cawthorne,[14] Cooksey,[15] Norre and DeWeerdt,[113] and Dix.[114,115] As our knowledge of the vestibular system improves, however, we are able to provide more specific exercises than what habituation offers. Clinicians should not treat all vestibular patients with habituation exercises.

To determine which habituation exercises to prescribe, the physical therapist must determine the provoking positions first (see Fig. 21.8). When a position elicits a mild to moderate dizziness, the patient remains in the provoking position for 30 seconds or until the

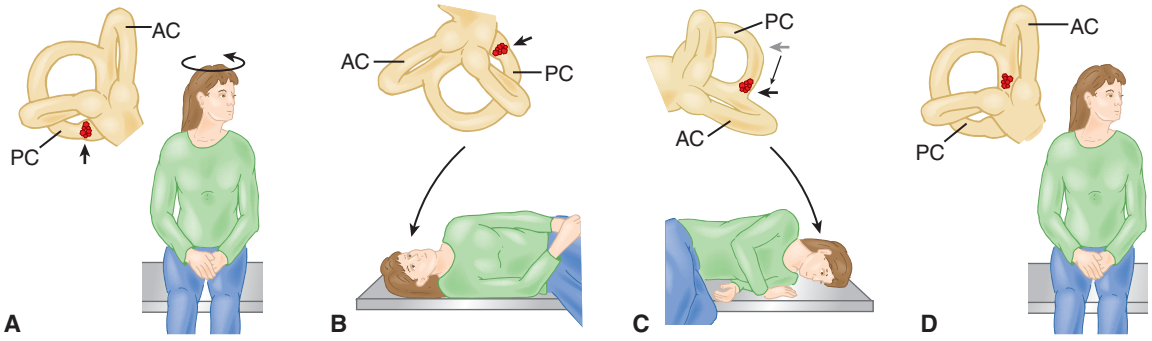

Figure 21.18 Liberatory (Semont) maneuver for right posterior SCC BPPV. The physical therapist should assist the patient through this positioning procedure. Note the otoconia adherent to the cupula in **A** and **B. (A)** The head is rotated 45° to the left side. **(B)** With assistance, the patient is then moved from sitting to right side-lying and stays in this position for 1 minute. **(C)** The patient is then rapidly moved 180°, from right side-lying to left side-lying. The head should be in the original starting position, left rotated (nose down in final position) in this example. Note that the otoconia have been dislodged from the cupula. After 1 minute in this position, **(D)** the patient returns to sitting. AC = anterior SCC; PC = posterior SCC.

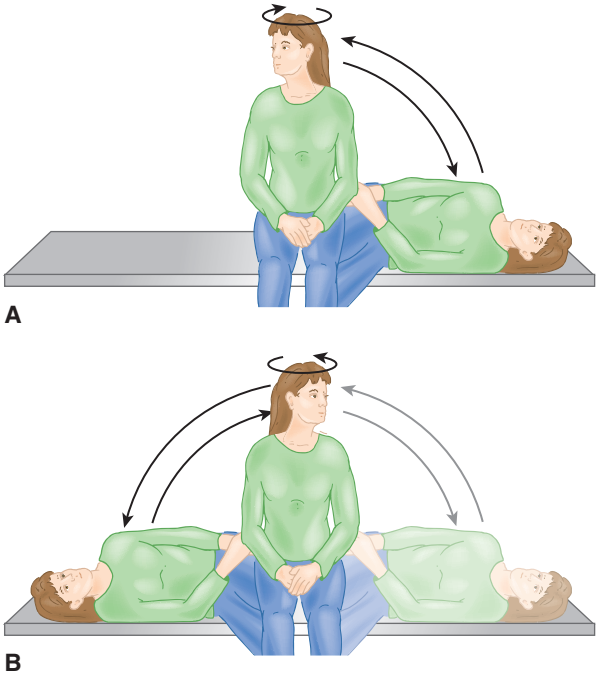

Figure 21.19 Brandt-Daroff exercises for posterior SCC BPPV. **(A)** The patient starts in a sitting position and turns the head 45° to one side (*left*) then quickly lies down on the opposite shoulder (*right*). The patient should be instructed to remain in this position for 30 seconds or until the vertigo stops. The patient then slowly returns to the starting position **(A)**, maintaining the head rotation (*left*) until sitting upright. **(B)** Next, the patient turns the head to the opposite direction (*right*) and lies down on the other shoulder (*left*), observing the similar 30-second time guidelines. The exercise should be done 10 to 20 times, three times per day until the patient is without vertigo for two consecutive days.

Table 21.7 Benign Paroxysmal Positional Vertigo Treatment Techniques

Treatment Procedure	Diagnosis/Symptoms
CRM	BPPV due to canalithiasis Posterior SCC canalithiasis is the most common
Liberatory maneuver	BPPV due to cupulolithiasis Posterior SCC cupulolithiasis is the most common
Brandt–Daroff exercises	Persistent/residual or mild vertigo (even after CRM) For the patient who may not tolerate CRM

BPPV = benign paroxysmal positional vertigo; CRM = canalith repositioning maneuver; SCC = semicircular canal.

symptoms abate, whichever comes first.[109] The patient is provided with a home exercise program (HEP) based on the results of the positional test.[45,109] The provoking exercises are performed from three to five times each, two to three times a day. Figure 21.22 provides an example of an HEP using vestibular habituation training. An activity diary can be a useful method to monitor response to training. The exercises are designed to reproduce the dizziness and the patient should be encouraged that the symptoms normally decrease within 2 weeks. If after 2 weeks the symptoms are no better, the habituation exercises should first be changed. If this is not helpful, the patient should be referred to either a physical therapist with special training in vestibular rehabilitation and/or a physician for further evaluation.

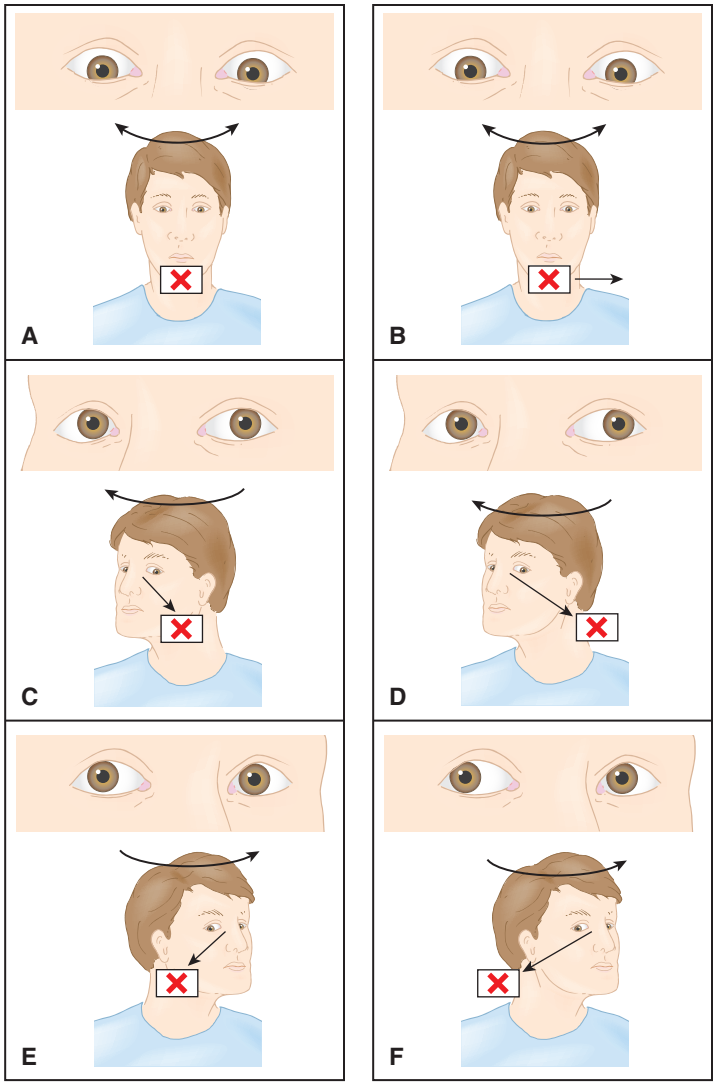

Figure 21.20 Gaze stability exercises. **(A,C,E)** ×1 paradigm: The patient is instructed to focus the eyes on a near target. While maintaining focus on the target, the patient horizontally rotates the head keeping the target still. **(B,D,F)** ×2 paradigm: The patient is instructed to focus the eyes on a near target. While the focus is maintained, the patient horizontally rotates the head and the target in *opposite* directions. Both ×1 and ×2 paradigms require vigilance of the patient to ensure clear vision during the motions. Both exercises are typically performed for 1 to 2 minutes, five times a day. It can be repeated using vertical head movements.

Table 21.8 Balance Exercises and Progressions

Begin With	Progress To	Purpose
1. Stand with feet shoulder-width apart, arms across the chest.	Bring feet closer together. Close eyes. Stand on a sofa cushion or foam.	Enhance the use of vestibular cues for balance by decreasing base of support. Eyes closed increases reliance on vestibular cues for balance.
2. Practice ankle sways: medial-lateral and anterior-posterior.	Doing circle sways. Close eyes.	Teaches the patient to use a correct ankle strategy.
3. Attempt to walk with heel touching toe on firm surface.	Do the same exercise on carpet.	Enhance the use of vestibular cues for balance by decreasing base of support. Doing the exercise on carpet alters proprioceptive input, increasing difficulty.
4. Practice walking five steps and turning 180° (left and right).	Making smaller turns. Close eyes.	Turning provides a greater challenge to the vestibular system.
5. Walk and move the head side-to-side, up and down.	Counting backward from 100 by threes.	Use distracting cognitive or motor demands to challenge balance.

Note: This table presents a limited number of exercises that are effective at improving functional balance. Each of the balance exercises should be performed three times a day for 1–2 minutes each repetition.

Figure 21.21 Example of a more difficult balance exercise. Instruct the patient to gently place his or her foot on a plastic cup and maintain his or her balance without crushing the cup. Initially, the patient should be advised to use a handhold. The exercise can be progressed to eyes closed, no handhold, or stepping while alternating foot placement on the cup.

Bilateral Vestibular Hypofunction

The development of specific anticipated goals and expected outcomes for the individual patient with BVH is based on the following general goals:

- The patient will demonstrate improved stability of gaze during head movement.
- The patient will demonstrate reduced subjective complaints of gaze instability.
- The patient will demonstrate improved static and dynamic balance.
- The patient will be independent in proper performance of an HEP that includes walking.
- The patient will demonstrate enhanced decision making skills regarding performance of basic and instrumental activities of daily living.

Treatment of patients with a BVH is designed to address the primary complaints of gaze instability during head motion, dysequilibrium, and gait ataxia. Gaze stability exercises can be similar to the ×1 paradigm described in treatment for UVH. Use of the ×2 paradigm is generally not recommended for a patient with a BVH because this exercise may cause excessive retinal slip. (However, many patients have an asymmetrical BVH, in which the ×2 exercise may be useful.) Instead, exercises that incorporate sequenced eye and head movements and the use of imaginary targets may improve gaze stability by enhancing central preprogramming of eye movements (Table 21.9).

Patients with BVH depend on somatosensation and/or vision to maintain postural stability. Balance exercises should enhance the use of these cues. Care must be taken that the exercises are performed safely because people with BVH are likely to fall.[116] It is imperative to begin the patient on a walking program, daily if tolerated. This can be progressed to ambulating on different surfaces (grass, gravel, sand) and in different environments (grocery store, mall). Recovery from a lesion involving both vestibular systems takes much longer than a unilateral lesion. Patients should be informed that as long as 2 years may be necessary to ensure as complete a recovery as

Instructions for the Patient:
Once in the provoking position, wait for 10 seconds to determine if the dizziness will occur. If you experience symptoms of dizziness, remain in the position for an additional 20 seconds (30 seconds total) or until the dizziness abates, whichever comes first. If you do not experience any symptoms you may return to your starting position. Now that you have returned to your starting position, remain here for 10 seconds to monitor your dizziness. If you are dizzy, remain in the return position for an additional 20 seconds (30 seconds total) or until the symptoms abate, whichever comes first. Repeat five times.

Example of Exercises:
1.) Quickly move from sitting upright to bending at the trunk as if to touch your nose to your knee.
2.) Quickly move from sitting at the edge of the bed to lying flat.
3.) In supine, roll onto your left then right side.

Guidelines for the Therapist:
Often, the patient may complain of a certain movement that provokes the symptoms which the examination does not incorporate. This movement can be adapted to be a part of the patient's home exercise program.

	Mon	Tues	Wed	Thur	Fri	Sat	Sun
Duration (0–30 seconds)							
Intensity (0–5)							

Figure 21.22 Example of a home exercise program using habituation therapy. Intensity refers to symptoms (or dizziness) on a five-point scale (0 = none; 5 = most severe).

Table 21.9 Bilateral Vestibular Lesion Exercises to Improve Central Preprogramming of Eye Movements

Begin With	Progress To
1. In sitting, hold two targets at arm's length from your head (i.e., `X' and `Y'). Look with your eyes first to one of the targets (`X') and make sure your nose is pointed to the `X' as well. Now look at the `Y' with your eyes only, followed by turning your head horizontally to point your nose to the `Y'. Repeat this sequence of alternating between the two targets. Attempt to do this for 60 seconds. The patient should be instructed to always first make an eye rotation followed by a head rotation.	Progress to increasing the distance used to see the target. Use a busy background (checkerboard, venetian blinds). Progress to doing this standing.
2. In sitting perform exercise #1 above using vertical head turns.	Same as above.
3. In sitting, hold one target at arm's length from your head. Close your eyes and turn your head horizontally away from the target, attempting to keep your eyes focused on the target. Open your eyes only after having turned your head.	Progress to doing this standing. Progress to decreasing base of support.

possible. For this reason, patient education emphasizing daily activity is a high priority. Daily activity must continue beyond the course of vestibular rehabilitation. Other recommended activities include exercises in a pool and Tai Chi. A pool provides an environment of buoyancy, allowing the patient to move safely without the risk of falling quickly to the ground. Tai Chi incorporates slow, controlled motions used to improve balance, flexibility, and increase strength. In most cases, a person with a BVH will incur an activity limitation or disability. Certain activities may always be limited, such as walking in the dark, night driving, or sports involving quick movements of the head.[117] Older patients may have to use an assistive device such as a cane for safe ambulation at night or on uneven surfaces. Habituation exercises do not work for the patient with a bilateral vestibular loss.[45]

Vestibular adaptation exercises are an excellent starting point for rehabilitation of patients with vestibular hypofunction (UVH and BVH). Research supports the beneficial effects of vestibular adaptation exercises on gait, posture, and DVA (Box 21.1 Evidence Summary).[39, 118-127]

Abnormal Central Vestibular Function

The development of expected goals and anticipated outcomes for the individual patient with a central vestibular lesion is based on the following general goals:

- The patient will demonstrate enhanced decision making skill regarding fall prevention strategies and necessary safety precautions to allow safe functioning within the home and community.
- The patient will demonstrate enhanced decision making skills regarding use of compensatory strategies to assist in gaze stability.
- The patient will be independent in performance of an HEP that includes walking.

Once an accurate diagnosis of central vestibular pathology is made, the physical therapist must be careful in choosing rehabilitation strategies. Expectations for recovery should be described initially to the patient. Generally, the time to recover will be 6 months or more, and may be incomplete.[128] Many of the adaptive mechanisms thought responsible for recovery of the vestibular system are central processes that may have been damaged in the initial central lesion. Physical therapists treating patients with TBI must be careful not to be too aggressive thereby greatly exacerbating the patient's symptoms. Though vestibular rehabilitation offers promise for treating persons with TBI,[129] it may not always be the treatment of choice owing to its irritative nature.

The physical therapy intervention for a central vestibular lesion at the level of the brainstem (vestibular nuclei) likely will be similar to a UVH, with the same expectations for recovery. Vestibular cortical lesions may also recover, similar to the process in which recovery from a CVA might occur.

Because many patients with central vestibular lesions complain of dizziness, a good treatment approach is to start with habituation exercises. However, the exercises should not be too aggressive, thereby aggravating the patient's condition. In addition, gait and balance exercises designed to incorporate somatosensory, visual, and vestibular contributions are also effective with this patient population.

Patient Education

The vestibular system requires movement to recover from most lesions. This basic tenet should be thoroughly discussed when educating patients about returning to daily activity, exercising independently at home, and as a general guideline for their recovery. (Appendix 21.A includes web-based resources for clinicians, families, and patients.) The vestibular system will not improve maximally without head motion. The challenge for both outpatient and inpatient management is determining the amount of exertion the patient can tolerate and creating an effective vestibular rehabilitation strategy without causing deleterious effects.

Box 21.1 Evidence Summary Outcome Studies Using Vestibular Adaptation Exercises to Improve Gait, Balance, and Dynamic Visual Acuity in Subjects with Vestibular Hypofunction

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Krebs et al[118] (1993)	8 subjects E ($N = 4$) BVH Mean age 67.3 ± 15.9 C ($N = 4$) BVH Mean age 61.1 ± 12.2	RCT; treatment outcome study; control group E: Vestibular adaptation and substitution exercises C: Isometric exercises and general conditioning	Each group: outpatient PT once per week and HEP 1 or 2×/day	E: quicker preferred gait velocity, reduced time in double support; tolerated COM to deviate from the COP for increased distance; no change in rotary chair test, caloric test, VVOR test, or DHI scores for either E or C groups	First controlled study investigating efficacy of vestibular rehabilitation in patients with BVH
Herdman et al[119] (1995)	E: ($N = 11$); UVH due to AN resection; mean age 59.3 ± 10.9 years; C: ($N = 8$); mean age 47.9 ± 10.4 years; EC: patients with noncerebellar and/or brainstem tumor encroachment or musculoskeletal deficits	RCT; pre-test/ post-test treatment study with control group; E: Vestibular adaptation exercises, ambulation exercises C: Smooth pursuit exercises (placebo) and ambulation exercises	Exercises started on POD 3 Each group performed exercises (adaptation or smooth pursuit) for 1 minute, 5×/day for a total of 20 minutes per day	CDP main outcome measure E: less dysequilibrium; at POD 3: 64% E subjects could do RomEC vs. 25% controls; at POD 3: E had less A-P sway for conditions 4–6 of CDP; at POD 6, 80% E subjects could do RomEC vs. 57% controls	First study advocating VR as an early postoperation intervention for AN; each subject (E and C) was age-matched due to significant difference in age
Strupp et al[120] (1998)	39 patients with stable UVH due to neuritis E: ($N = 19$); mean age 51.7 ± 11.1 C: ($N = 20$); mean age 52.4 ± 9.9 EC: reduced visual acuity, diseases impairing mobilization, central vestibular disorders, prior history of vestibulopathy	RCT; pre-test/ post-test with control group; intervention: both groups received general walking program; E group also performed saccades, VOR, smooth pursuit, balance exercises, and cervico-ocular reflex enhancement	E: performed unique exercises 3×/day for 30 minutes each for 5–7 days; to be continued independently for 3 weeks via video instruction C: received walking program; encouragement	No difference in ocular torsion, subjective visual vertical, or mean slow eye velocity due to caloric irrigation; E group showed greater reduction in total sway path during stance on platform posturography	Outcome measures examined central vestibular function. Important study showing many outcome measures of static vestibular imbalance recover spontaneously.

Box 21.1 Evidence Summary Outcome Studies Using Vestibular Adaptation Exercises to Improve Gait, Balance, and Dynamic Visual Acuity in Subjects with Vestibular Hypofunction—cont'd

Reference	Subjects	Design/ Intervention	Duration	Results	Comments
Cohen and Kimball[121] (2003)	53 subjects with chronic vestibulopathy; assigned to 1 of 3 groups EC: Ménière's disease, BPPV, acute vestibular neuritis or labyrinthitis, orthopedic limitations, head trauma, neurological disease, otologic disease, use of vestibular suppressant medication	RCT; pre-test/ post-test noncontrolled; each group performed exercises at home only (HEP); Group 1: slow head rotation while seated without visual fixation Group 2: quick head rotation with visual fixation, seated and standing Group 3: same as Group 2 with phone call follow-up for encouragement	All 3 groups: 5–10 minutes of exercise 5×/day at home (HEP); posttest after 4 weeks of HEP	No difference between 3 groups in reduction of vertigo intensity, vertigo frequency, or symptoms generated during ADL skills	HEP beneficial for patients with vestibular hypofunction; outcome measures all subjective making functional significance uncertain; difficult to discern that results are not due to natural recovery without a true control group (i.e., no treatment or no head rotation)
Krebs et al[122] (2003)	84 subjects UVH: ($N = 33$); mean age 59.42 ± 20.37 BVH: ($N = 51$); mean age 59.56 ± 18.97 EC: BPPV, Ménière's disease, unstable vestibulopathy	RCT; double blind with control; gait stability measures at baseline, 6 weeks, 12 weeks, 1 year E: Vestibular adaptation and substitution exercises; balance retraining exercises; VR HEP C: Isometric exercises and general conditioning; outpatient VR	E: outpatient PT 1×/week for 6 weeks; then 6 weeks of VR HEP C: outpatient PT 1×/week for 6 weeks; then 6 weeks of VR (1×/week)	At 6 weeks measure, only E group had significantly increased preferred gait velocity, reduced BOS, reduced double support time, reduced M-L sway, reduced lateral velocity, increased distance subjects tolerated their COM to deviate from the COP; 61% of E group demonstrated these improvements; at 1 year, significant treatment effects noted for preferred gait velocity, reduced BOS, reduced M-L sway, and reduced lateral velocity	First long-term study to document VR benefits; BVH subjects recovered by similar amounts as the UVH subjects

DIAGNOSES INVOLVING THE VESTIBULAR SYSTEM

Ménière's Disease

Ménière's disease is confirmed by a documented low-frequency hearing loss and episodic vertigo. The patient may also complain of a sense of fullness in the ear and tinnitus. The symptoms gradually increase in severity and can last several hours per episode. During an episode, vestibular exercises are not recommended. Chronic Ménière's disease, however, can result in a UVH, for which rehabilitation is appropriate. The pathophysiology of Ménière's disease, in part, probably involves an increase in endolymphatic fluid causing distention of the membranous tissues.[130] Medical treatment is therefore directed toward reducing or preventing fluid buildup. Many patients can manage the symptoms well with a controlled diet. Patients with Ménière's disease are often placed on a 2 g/day or less sodium diet. This is the most important dietary restriction to follow. Other substances to be avoided are caffeine and alcohol. Sometimes medical management includes use of a diuretic to control the amount of water in the body. Surgery to either prevent the fluid buildup in the inner ear (endolymphatic shunt placement) or to stop the abnormal vestibular signal (vestibular nerve section, or chemical ablation using transtympanic gentamicin injection) may be indicated if the episodes are frequent enough to disturb daily function. Physical therapy is beneficial in treating the effects of a UVH owing to chronic Ménière's disease, although the therapy will not stop the episodes of vertigo. Gaze and postural stability exercises may be appropriate. Physical therapy is also useful in the treatment of dysequilibrium occurring after a vestibular neurectomy or chemical ablation.

Perilymphatic Fistula

Perilymphatic fistula (PLF) is most commonly caused by a rupture of the oval or round windows, membranes that separate the middle and inner ear. A rupture of these membranes results in leakage of the perilymph into the middle ear. The result is vertigo and hearing loss. Normally, perilymph bathes the SCCs and serves as a protective barrier between the bony and membranous labyrinth. PLF usually is caused from a traumatic event, such as excessive pressure changes as in deep-water diving, blunt head trauma without skull fracture, or extremely loud noise.[131] This diagnosis is much debated and the treatment for PLF is similarly ambiguous. Patients often are treated first with bedrest in hopes of allowing the membrane to heal. Surgical patches of the fistula are also performed. Physical therapy is contraindicated for most patients with PLF; however, it can be beneficial for those patients who have continual dysequilibrium or develop a vestibular hypofunction postoperatively. Medical management will likely include strict limitations on activities, warranting good communication between physical therapist and physician.

A form of PLF not debated is superior semicircular canal dehiscence. In this condition, the region of the temporal bone normally covering the superior SCC is thin or missing, rendering the membranous SCC susceptible to stimuli that it normally should not (e.g., sound, change of cranial pressure, vibrations).[132] The patient will notice a disturbing syndrome of vestibular and auditory signs that may include eye movements induced by loud noises or effort that increase intracranial pressure (e.g., coughing), sudden or progressive hearing loss, conductive hyperacusis, conductive hearing loss that can mimic otosclerosis (abnormal bone growth near middle ear), autophony (person's own voice sounds amplified), imbalance with noise, vertigo, or motion sensitivity. Some patients even report hearing their eyeballs, "as if scratching sandpaper!"

Vestibular Schwannoma

Vestibular schwannomas (VSs), historically known as **acoustic neuromas**, are benign tumors arising from the Schwann cell of the eighth cranial nerve, often in the internal auditory canal (IAC). The IAC also contains the facial nerve (cranial nerve VII) and the internal auditory artery along with the vestibulocochlear nerve. Symptom presentation is usually related to where the tumor arises. If the tumor arises in the IAC, then tinnitus and hearing loss are often the first symptoms. However, if the growth occurs in the cerebellar-pontine angle, the tumor may become quite large before symptoms of hearing loss are revealed. Thus, although unilateral hearing loss is often the initial sign of VS, the pathogenesis of the associated structures within the space can sometimes result in vestibular (i.e., vertigo, imbalance), facial, or even vascular symptoms. Generally, VS tumors grow slowly. As a result, the extent of impaired vestibular or facial nerve function is often not appreciated until the tumor is removed. This is because the tumor gradually compresses the cranial nerves, and in the case of vestibular function, allows the brain to compensate. However, as the VS enlarges, symptoms of hearing loss, tinnitus, and vestibular hypofunction worsen, resulting in the primary deficits. Treatment usually involves surgical excision of the tumor, though gamma knife radiation is also an option. On tumor removal, most unilateral vestibular afference is lost and the brain now perceives asymmetrical vestibular input. Optimally, physical therapy is initiated during the early postoperative period to help the patient resolve symptoms of dysequilibrium and oscillopsia.[119] Outpatient treatment should be considered similar to the treatment for a UVH.

Motion Sickness

Motion sickness is a normal sensation that in some people becomes debilitating. The predominant explanation for motion sickness is the *sensory conflict theory.*[133] The three sensory inputs of proprioception, vestibular, and visual information do not match stored neural patterns the brain expects to recognize. As a result, persons experience pallor, nausea, emesis, diaphoresis, and motion sensitivity. Physical therapy has been successfully used to reduce motion sensitivity.[134] Other methods reported to combat motion sickness include the use of cognitive-behavioral management, medications, biofeedback, and habituation training.[135-138]

Migraine-Related Dizziness

Migraine-related dizziness can be deceptively similar to a peripheral vestibular lesion, be it BPPV or UVH. Migraine-related symptoms include vertigo, dizziness, imbalance, and motion sickness. A recent study reported 100% of migraineurs had abnormal nystagmus during a migraine episode, if they were positionally tested as part of an oculomotor examination.[139] The prevalence of migraine is significant, affecting 6% of men and 15% to 18% of women between the ages of 25 and 55.[140] The clinical examination will often provide the differential diagnosis between vestibular pathology and migraine. The history is crucial and important questions to patients in whom migraine is suspected include asking if symptoms worsen when barometric pressure changes, and whether headache or eating certain foods are associated with any of the symptoms. If the therapist suspects migraine the patient should be referred to a neurologist, preferably one with a special interest in headache. Migraine is often well controlled with medication and diet. Migraine that is not controlled may become worse with exercises such as vestibular rehabilitation, which stimulate the peripheral vestibular end organ and central VOR pathways.[141] Vestibular rehabilitation in patients with migraine can be very helpful, but patients with both vestibular hypofunction and migraine do not respond as well.[142] Strupp et al[143] provide a thorough discussion of this topic.

Multiple Sclerosis

MS can affect cranial nerve VIII where it enters the brainstem and causes identical symptoms to a unilateral vestibular pathology. An MRI scan will ensure an accurate diagnosis of MS.

Multiple System Atrophy

Multiple system atrophy (MSA) is a progressive degenerative disease of the nervous system involving four clinical domains: cerebellar ataxia, autonomic dysfunction, Parkinson's disease–like symptoms, and corticospinal dysfunction. MSA has been found to be a cause of dizziness and imbalance.[144] The effect of physical therapy for persons with MSA has not been thoroughly investigated, though a case study has been reported.[144]

Cervicogenic Dizziness

Cervicogenic dizziness is a term meant to imply that the cause of symptoms such as dizziness or imbalance arise from pathology affecting the cervical spine or related soft tissue. Unfortunately, *cervical vertigo* is a term still often used, which implies true vertigo as a result of cervical pathology, not documented in humans. The mechanisms of involvement are believed to be from at least two sources. First, the upper cervical spine sends proprioceptive input to the contralateral vestibular nucleus.[145] Soft tissue injury and joint dysfunction might alter the afferent input contributing to spatial orientation. Vestibular rehabilitation appears to be warranted for these individuals.[146] Second, a patient might have VBI (see above section titled Central Nervous System Pathology). If VBI is suspected, vascular compromise must first be ruled out as a cause of the patient's symptoms. The VBI test can be performed while the subject is seated. The patient leans forward and extends the neck. The neck is then rotated 45° to the suspicious side. Persons suspected of having VBI should be referred to a neurologist immediately. Repeated episodes of vertigo without the associated VBI symptoms usually suggest a peripheral vestibular diagnosis.

CONTRAINDICATIONS TO VESTIBULAR REHABILITATION

Physical therapy is not appropriate for unstable vestibular disorders such as Ménière's disease (with the exception mentioned above), uncontrolled migraine, PLF, or an unrepaired superior semicircular canal dehiscence. Other contraindications the physical therapist should be alert to include sudden loss of hearing, increased feeling of pressure or fullness to the point of discomfort in one or both ears, and severe ringing in one or both ears. When treating patients who have had a surgical procedure, the clinician must be observant for discharge of fluid from the ears or nose, which may indicate cerebrospinal fluid leak. Patients with acute neck injuries may not be able to tolerate some components of the physical examination, the CRM, or some of the gaze stability exercises.

SUMMARY

High incidence and prevalence rates of vestibular disorders oblige the physical therapist to recognize signs and symptoms associated with inner ear disorders. It is essential to differentiate a peripheral pathology from a central one. Peripheral and central lesions have separate manifestations and may require different intervention strategies. In addition, all vestibular disorders should not be treated similarly. The most common form of vertigo, BPPV, is a biomechanical problem readily treated often with a single maneuver. This is in stark contrast to a patient with a BVH, which requires a greater rehabilitation effort. Evidence supports the use of vestibular adaptation exercises for patients with vestibular hypofunction.

Research in vestibular rehabilitation is ongoing and remains imperative to answer important questions related to dosing, recruitment of compensatory strategies to assist gaze stability, recurrence prevention for BPPV, and more. Exciting future treatments may involve virtual reality, vibrotactors to alert patients of abnormal posture, and the inclusion of computer gaming platforms. Within the next 5 years, successful implementation of a surgically implanted vestibular prosthesis for BVH is expected. Regardless of technological advances, rehabilitation will still be important in these patients.

The *Vestibular Disorders Association (VEDA)* has a list of physical therapists in each state, interested in treating patients with vestibular disorders. VEDA can be contacted via phone (800-837-8428; 24-hour voice mail), fax (503-229-8064), or through the "contact us" link on their website (www.vestibular.org) (see Appendix 21.A). The supplemental reading list contains other excellent literature for the reader interested in pursuing a greater depth of knowledge in vestibular rehabilitation.

Questions for Review

1. Why is it important to perform the head impulse test using a rapid velocity?
2. What is the name of the linear accelerometers within the vestibular labyrinth?
3. Why does the patient with an acute unilateral vestibular lesion experience spontaneous nystagmus?
4. How will cupulolithiasis present differently than canalithiasis of the posterior semicircular canal?
5. What are the key elements in taking a history for a patient with a suspected vestibular disorder?
6. Explain inhibitory cutoff.
7. Differentiate the ×1 exercise paradigm from the ×2 exercise paradigm.
8. In a patient with vestibular nystagmus, which part of the eye movement (slow or fast) is from the vestibular system? Why?
9. Describe how the Dix-Hallpike test would elicit nystagmus for posterior SCC BPPV.
10. Differentiate between adaptation and habituation training for patients with vestibular dysfunction.

CASE STUDIES

CASE STUDY 1

You are performing an initial examination of a patient with new onset of complaints of imbalance and dizziness. In a sitting position, at rest, the patient is observed to have a purely vertical and pendular nystagmus with head tilting to the left. The nystagmus is not altered with any change in head position, and the head-shaking induced nystagmus test (HSN) is negative.

GUIDING QUESTIONS

1. Do you suspect a central or peripheral pathology as a cause of the imbalance and dizziness?
2. Is physical therapy appropriate at this time?

CASE STUDY 2

On your patient's return to sitting up after you have performed the canalith-repositioning maneuver (CRM) for a left posterior canalithiasis, you notice down-beating and right torsional nystagmus. The patient is complaining of vertigo.

GUIDING QUESTIONS

1. Where is the otoconia now located?
2. How will you treat for benign paroxysmal positional vertigo (BPPV) the second time?
3. Following the second treatment for BPPV, the patient complains of dizziness and neck pain. The vertigo and nystagmus are gone. Can you prescribe any other forms of exercise for the remaining dizziness? What about the neck pain?

CASE STUDY 3

A patient with a unilateral vestibular hypofunction (UVH) complains of feeling worse after 7 days of starting a vestibular rehabilitation program. The patient has had no falls. The complaints consist of increased dizziness with head motion, nausea, and fatigue.

GUIDING QUESTIONS

1. Is your rehabilitation program making the patient worse?
2. How can you modify the program?
3. What information will you tell your patient with a UVH regarding time to recover? What will you tell patients with BPPV, BVH, or central nervous system pathology regarding times to recover?

DavisPlus | For additional resources, including answers to the questions for review and case study guiding questions, please visit **http://davisplus.fadavis.com**

The reader is referred to video **Case Study 13: Patient with Vestibular Disorder** for additional review and study. The full written case study, including tables, figures, charts, and three video segments (examination, intervention, and outcome), appears online at DavisPlus. The case study poses questions for the reader's consideration with suggested answers to the case study questions, also posted online at DavisPlus.

Chapter 22

Amputation

Bella J. May, PT, EdD, FAPTA, CEEAA

LEARNING OBJECTIVES

1. Discuss the role of the physical therapist in the care of any individual following lower extremity amputation.
2. Describe the major etiological factors leading to lower extremity amputation.
3. Explain the major concepts involved in lower extremity amputation surgery.
4. Develop an evaluation plan for any individual following lower extremity amputation.
   a. Prioritize data gathering for the immediate postsurgical period and the preprosthetic phase.
5. Design an effective plan of care for the immediate postsurgical period.
   a. Explain the rationale for and teach patient and caregiver proper positioning.
   b. Teach sitting and standing balance to enhance transfers and mobility.
   c. Ensure continuity of care following discharge from acute care.
6. Design an effective plan of care for the preprosthetic period.
   a. Teach proper residual limb care including bandaging as indicated.
   b. Teach standing balance to help the patient attain the highest functional level of mobility with appropriate ancillary support.
   c. Teach residual limb strengthening exercises to facilitate eventual prosthetic fitting.
   d. Teach ROM exercises to prevent/alleviate secondary contractures.
7. Respond appropriately to patient/family from an awareness of the psychological impact of lower extremity amputation.
8. Analyze and interpret patient data, formulate realistic anticipated goals and expected outcomes, and develop a plan of care when presented with a clinical case study.

SUMMARY *1026*

The major cause of lower extremity (LE) amputation today continues to be peripheral vascular disease (PVD), particularly with associated diabetes. Two-thirds of all LE amputations in the United States today are due to complications of diabetes.[1] Approximately 16 per 1,000 individuals with diabetes over age 75 will undergo an LE amputation as compared with 1.78 of similar individuals who do not have diabetes. Major improvements in noninvasive diagnosis, revascularization, and wound healing techniques have increased the age at which individuals with diabetes may come to amputation. Perioperative mortality has been variously reported between 7% and 13% and is usually associated with other medical problems such as cardiac disease and strokes.[2-4] There are approximately 20.8 million children and adults with diabetes and about 5% of the population is affected with some form of vascular disease.[5] Many of the patients we treat in all types of settings have diabetes although we are usually treating them for some other problem. Physical therapists can help by learning more about diabetes and diabetic foot care and by making patient education an integral part of the plan of care (POC). Several studies have indicated a positive relationship between early patient education and proper foot care and a reduction in amputations.[6,7]

The second leading cause of amputation is trauma, usually from motor vehicle accidents, war, or gunshots. Individuals with traumatic amputations are often young adults, more frequently men, and have often been involved in an active lifestyle before amputation. The incidence of amputation from osteogenic sarcoma has been reduced owing to improved imaging techniques, more effective chemotherapy, and better limb salvage procedures. Amputation may be necessary if the tumor is large and cannot be resected without substantial removal of bone and tissue. However, the surgeon may choose to remove the tumor and incorporate one of several limb salvage procedures. Many factors go into this decision, including the age of the patient, the size of the tumor, and, if the patient is young, the potential for future growth.[8] Tumor excision does not affect 5-year survival rates, which have increased from about 20% in the 1970s to 60% to 70% in more recent years.[9-13] Regardless of the cause of amputation, physical therapists have a major role in rehabilitation. Early onset of appropriate treatment influences the eventual outcome of the episode of care. It is critically important, especially for the older individual, for the therapist in the acute care center to ensure continuity of care once the patient is discharged from the hospital. Too often, the patient is sent home and is not seen again for several weeks or months. By that time the patient has become debilitated and has developed contractures that interfere with prosthetic use and function.

LEVELS OF AMPUTATION

Traditionally, levels of amputation have been identified by anatomical considerations such as below knee and above knee. In 1974, the Task Force on Standardization of Prosthetic-Orthotic Terminology developed an international classification system to define amputation levels. Table 22.1 describes the major terms in common use today.

Table 22.1 Levels of Amputation

Partial toe	Excision of any part of one or more toes
Toe disarticulation	Disarticulation at the metatarsal phalangeal joint
Partial foot/ray resection	Resection of the 3rd, 4th, 5th metatarsals and digits
Transmetatarsal	Amputation through the midsection of all metatarsals
Ankle disarticulation (Syme's)	Ankle disarticulation with attachment of heel pad to distal end of tibia; may include removal of malleoli and distal tibial/fibular flares
Long transtibial (below knee)	More than 50% of tibial length
Transtibial (below knee)	Between 20% and 50% of tibial length
Short transtibial (below knee)	Less than 20% of tibial length
Knee disarticulation	Amputation through the knee joint; femur intact
Long transfemoral (above knee)	More than 60% of femoral length
Transfemoral (above knee)	Between 35% and 60% of femoral length
Short transfemoral (above knee)	Less than 35% of femoral length
Hip disarticulation	Amputation through hip joint; pelvis intact
Hemipelvectomy	Resection of lower half of the pelvis
Hemicorporectomy	Amputation both lower limbs and pelvis below L4–L5 level

Traumatic amputations may be performed at any level; the surgeon tries to maintain the greatest bone length and save all possible joints. A variety of surgical techniques may be necessary to create a functional **residual limb**. Guillotine amputations (skin, muscle, and bone all transected at approximately the same level) may precede secondary closure with skin flaps; occasionally, free tissue flaps, taken from some other area of the body, may be used to cover the wound. Amputations for vascular diseases are generally performed at partial foot, transtibial, or transfemoral levels. The limited vascular supply militates against effective residual limb healing at the ankle disarticulation level in most instances.

Patients with unilateral transtibial amputations regardless of age are quite likely to become functional prosthetic users; many individuals with bilateral transtibial amputations can be successfully rehabilitated. Older adults with unilateral transfemoral amputations with good balance and coordination are also potential prosthetic users, although those who were not independently ambulatory before amputation are likely not to become independent with a prosthesis. Patients with bilateral transfemoral amputations may become prosthetic users given today's computer-driven components. Once again, good balance and coordination are a prerequisite. Hip disarticulations, hemipelvectomies, and hemicorporectomies are generally performed either for tumors or for severe trauma and represent a small percentage of the population of individuals with amputations. The most important factor in determining the prosthetic potential of an individual is her or his prior level of activity. Co-morbidities and the extent of injuries from war and trauma must be considered, but the individual who led an active life before amputation—even an individual with diabetes and related co-morbidities—is likely to become a functional prosthetic user if he or she can demonstrate good balance and coordination.[14]

Figure 22.2 Transfemoral residual limb with incision from equal-length flaps.

SURGICAL PROCESS

The specific type of surgery is determined by the surgeon, whose decision depends on the status of the extremity at the time of amputation. The surgeon must allow for primary or secondary wound healing, and construct a residual limb for optimal prosthetic fitting and function. Numerous factors affect the selection of level of amputation. Conservation of residual limb length and uncomplicated wound healing, for example, are both important. Although a description of each type of surgical procedure is beyond the scope of this chapter, an understanding of the basic principles of amputation surgery is important.

Skin flaps are as broad as possible and the scar should be pliable, painless, and nonadherent. For most transfemoral and transtibial amputations without vascular impairment, equal length anterior and posterior flaps are used, placing the scar at the distal end of the bone (Figs. 22.1 and 22.2). Long posterior flaps are often used in transtibial amputations with compromised circulation because the posterior tissues have a better blood supply than anterior skin. This places the scar anteriorly over the distal end of the tibia; care must be taken to ensure that the scar does not become adherent to the bone (Fig. 22.3). In recent years, the routine use of the long posterior flap has come into question.[15] The skew flap, developed in England, is believed by some surgeons to be a better approach for individuals with severely compromised distal circulation. The skew flap is an angular medial–lateral incision that places the scar away from bony prominences, a problem with the long posterior flap. Research on the use of different skin flaps does not clearly delineate the most advantageous approach, and all indicate similar results in terms of rehabilitation.[16]

Stabilization of major muscles allows for maximum retention of function. Muscle stabilization may be achieved by myofascial closure, myoplasty, myodesis, or tenodesis. In most transtibial and transfemoral amputations, a combination of **myoplasty** (muscle to muscle

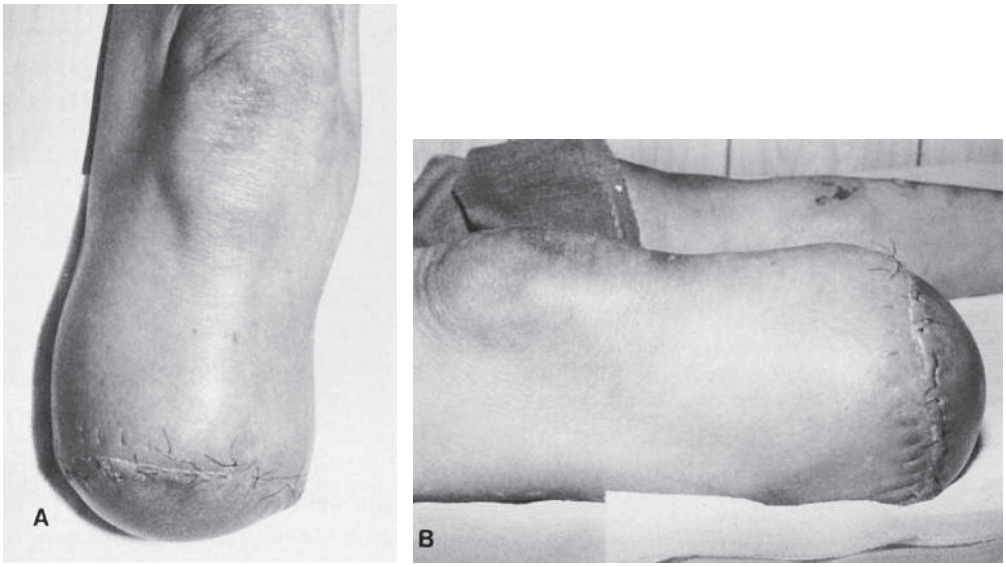

Figure 22.3 **(A)** Anterior view and **(B)** lateral view of a transtibial residual limb with anterior incision from a long posterior flap.

closure) and **myofascial** (muscle to fascial) closure is used to ensure that the muscles are properly stabilized and do not slide over the end of the bone.

In some centers, **myodesis** (muscle attached to periosteum or bone) is employed, particularly in transtibial amputations. More rarely, a **tenodesis** (tendon attached to bone) may be used for muscle stabilization. Whatever the technique, muscle stabilization under some tension is desirable at all levels where muscles must be transected.

Severed peripheral nerves form **neuromas** (a collection of nerve cell ends) in the residual limb. The neuroma must be well surrounded by soft tissue so as not to cause pain and interfere with prosthetic wear. Surgeons identify the major nerves, pull them down under some tension, and then cut them cleanly and sharply and allow them to retract into the soft tissue of the residual limb. Neuromas that form close to scar tissue or bone generally cause pain and may require later resection or revision. **Hemostasis** is achieved by ligating major veins and arteries; **cauterization** is used only for small bleeders. Care is taken not to compromise circulation to distal tissues, particularly the skin flaps, which are important to uncomplicated wound healing.

Bones are sectioned at a length to allow wound closure without excessive redundant tissue at the end of the residual limb and without placing the incision under great tension. Sharp bone ends are smoothed and rounded; in transtibial amputations, the anterior portion of the distal tibia is **beveled** to reduce the pressure between the end of the bone and the prosthetic socket. Care is taken to ensure that the bone is physiologically prepared for the pressures of prosthetic wear. Tissue layers are approximated under normal physiological tension and the incision is closed, usually with regular sutures. A drainage tube may be inserted as necessary.

In a traumatic amputation, the surgeon attempts to save as much bone length and viable skin as possible and preserve proximal joints while providing for appropriate healing of tissues without secondary complications such as infection. In potentially "dirty" (involving foreign substances) amputations, the incision may be left open with the proximal joint immobilized in a functional position for 5 to 9 days to prevent invasive infection. Secondary closure also allows the surgeon to shape the residual limb appropriately for prosthetic wear and function.

Amputation for vascular disease is generally considered an elective procedure; the surgeon determines the level of amputation by examining tissue viability through a variety of measures. Segmental limb blood pressures can be determined by Doppler systolic blood pressure measurement. Transcutaneous oxygen measurement and skin blood flow by radioisotope or plethysmography are also determined. Doppler systolic blood pressure measures have been reported to be quite accurate in predicting viable level of amputation. Improvements in noninvasive examination techniques have greatly reduced the use of arteriography to determine amputation level. Videos of actual amputation surgery at transtibial and transfemoral levels may be seen at the Amputation Surgery Education Center website (www.ampsurg.org).

HEALING PROCESS

Numerous factors influence the course of the healing process in each patient. One of the greatest postoperative concerns is infection, whether from external or internal sources. Individuals with contaminated wounds from injury, infected foot ulcers, or other causes are at greater risk of infection. Research indicates that smoking is a major deterrent to wound healing; one study reported that cigarette smokers had a 2.5% higher rate of

infection and reamputation than nonsmokers.[17] Other factors affecting wound healing are the severity of the vascular problems, diabetes, renal disease, and other physiological problems such as cardiac disease.[15] The physical therapist can influence positive wound healing by teaching proper bed mobility and avoiding pressure on the newly amputated limb.

POSTSURGICAL DRESSINGS

Surgeons have several options regarding the postoperative dressing, including (1) rigid dressing, (2) semirigid dressing, or (3) soft dressing. It is important for some sort of edema control to be used because excessive edema in the residual limb can compromise healing and cause pain. Table 22.2 outlines the major postsurgical dressings in use today with their advantages and disadvantages.

Rigid Dressings

The rigid dressing, developed in the early 1960s, is generally known as an **immediate postoperative prosthesis (IPOP)**.[18-20] The IPOP may be handmade from plaster of Paris by the surgeon or a prosthetist and follows the general configuration of the prosthetic socket. These are not adjustable or removable. The socket must be cut like a cast for removal and a new one applied as the residual limb heals, sutures are removed, and the limb changes shape. There are also **removable rigid dressings** (RRDs) that may be handmade from plaster or prefabricated from plastic materials and come in different sizes. Prefabricated RRDs are adjustable as the limb changes and may be removed as needed for wound inspection.[21] The addition of a pylon and foot allows for early, limited, weight-bearing ambulation.

Use of immediate postoperative rigid dressings varies greatly and is more prevalent in some areas of the country than others. Generally, orthopedic surgeons use the technique more than vascular surgeons. Rigid postsurgical dressings, whether used immediately after surgery or in the early postoperative period, have been found to be successful in reducing postoperative edema and pain and enhancing healing, even in cases of delayed healing.[15]

Semirigid Dressings

There are a number of semirigid dressings that have been reported in the literature and may or may not be used in a particular center. All provide better control of edema than the soft dressing but each has some disadvantage that limits its use. **Unna's dressing**, gauze impregnated with a compound of zinc oxide, gelatin, glycerin, and calamine, may be applied in the operating room. Its major disadvantage is that it may loosen easily and is not as rigid as the plaster of Paris dressing. However, it has been shown to be superior to the soft dressing in enhancing healing and reducing edema.[22]

Soft Dressings

The soft dressing is the oldest method of postsurgical management of the residual limb and probably the one that most physical therapists in acute care hospitals will encounter. Currently there are two forms of soft dressings: the elastic wrap and the elastic shrinker.

Elastic Wraps

The elastic wrap or elastic bandage, 4 inches wide or more, may be applied over the postsurgical dressing if care is taken to ensure proper compression. A dressing is applied to the incision followed by some form of gauze pad, then the compression wrap. The soft dressing is indicated in cases of local infection, but is not the treatment of choice for the majority of individuals. The patient or a family member should learn to apply the wrap as soon as possible after wound care is no longer necessary. Many older individuals with transfemoral amputations do not have the necessary balance and coordination to wrap effectively.

Table 22.2 Postsurgical Dressings

Type of Dressing	Advantages	Disadvantages
Compressible soft dressing	Easy to apply Inexpensive Easy access to incision	Little edema control Minimal residual limb (RL) protection Requires frequent rewrapping
Shrinker	Easy to apply Inexpensive	Not used until sutures are removed Requires changing as RL shrinks
Semirigid dressing	Better edema control than soft dressing RL protection	Needs frequent changing Cannot be applied by patient No access to incision
IPOP	Excellent edema control Excellent RL protection Control of RL pain	No access to incision More expensive than other dressings Requires proper training for use

From May and Lockard,[26, p. 62] with permission.
IPOP = immediate postoperative prosthesis.

Some surgeons prefer delaying elastic wrap until the incision has healed and the sutures have been removed. Leaving the residual limb without any pressure wrap allows for full development of postoperative edema, which may be quite uncomfortable and interfere with circulation in the many small vessels in the skin and soft tissue, thereby potentially compromising healing. The therapist can discuss the benefits of early wrapping with the surgeon if no other form of rigid dressing is used. There is strong evidence in the literature of the benefits of either the IPOP or the RRD.[15,23-25]

One of the major drawbacks of the elastic wrap is that it needs frequent rewrapping. Movement of the residual limb against the bedclothes, bending and extending the proximal joints, and general body movements will cause slippage and changes in pressure. Covering the finished wrap with stockinet helps to reduce some of the wrinkling. However, careful and frequent rewrapping is the only effective way to prevent complications. Nursing staff, family members, and the patient, as well as the physical therapist or physical therapist assistant, need to assume responsibility for frequent inspection and rewrapping of the residual limb. Residual limb wrapping is described in detail later in this chapter.

Elastic Shrinkers

Shrinkers are sock-like garments knitted of heavy, rubber-reinforced cotton; they are conical in shape and come in a variety of sizes (Fig. 22.4). It is difficult to use a shrinker in the postoperative period because the process of donning may put unnecessary stress on the unhealed incision. Shrinkers are best used after healing has taken place and the sutures have been removed.

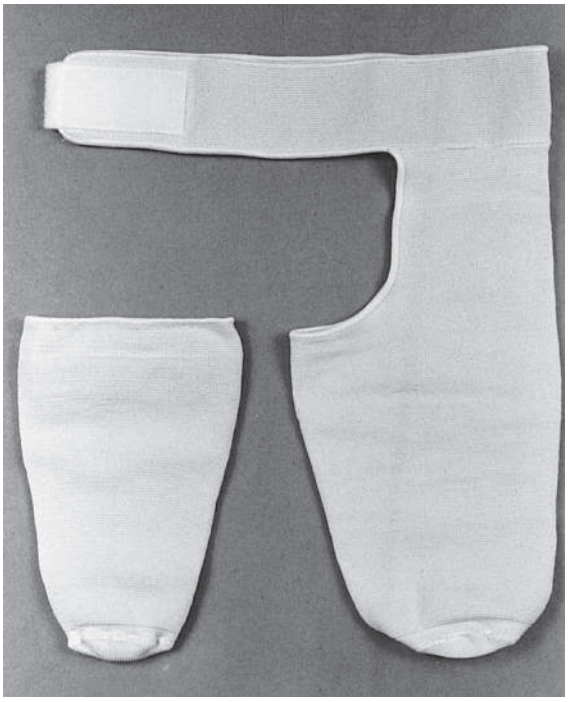

Figure 22.4 (*Left*) Transtibial shrinker. (*Right*) Transfemoral shrinker.

PHASES OF CARE: POSTSURGICAL[26] AND PREPROSTHETIC

Early onset of rehabilitation produces greater potential for success. A long delay is likely to result in the development of complications such as joint contractures, general debilitation, and depressed psychological state. The rehabilitation program can be arbitrarily divided into two phases: (1) the postsurgical phase is the time between surgery and discharge from the hospital; (2) the preprosthetic phase runs from hospital discharge to prosthetic fitting or a decision that the patient is not a candidate for prosthetic fitting. These, of course, are arbitrary periods but each has different goals and emphases within the POC. The desired expected outcome of the episode of care is to help the patient regain the presurgical level of function. For some, it will mean return to gainful employment with an active recreational life. For others, it will mean independence in the home and community. For still others, it may mean living in the sheltered environment of a retirement center or nursing home. If the amputation resulted from long-standing chronic disease, the rehabilitation approach may be to help the person function at a higher level than immediately before surgery.

Postsurgical Phase

The postsurgical phase is the time between surgery and discharge from the hospital. While the primary goal of this phase of care is to get the patient discharged, it is not adequate to give the patient a walker, teach the patient to transfer, and send him or her home. Box 22.1 outlines the general goals of the postsurgical phase of care.

Box 22.2 outlines the critical data necessary to develop a POC for the hospitalized patient following amputation. Naturally, the data gathering must be prioritized according to the person's physiological status and cause of amputation; however, the information obtained on initial examination and subsequent evaluation will influence discharge planning and future care. As indicated previously, it is of critical importance for the physical therapist to act as an ombudsman for the patient and ensure continuity of care following hospital discharge. For all

Box 22.1 Postsurgical General Goals

- Healing residual limb
- Protect remaining limb (if dysvascular)
- Independent in transfers and mobility
- Demonstrate proper positioning
- Begin psychological adjustment
- Understand the process of prosthetic rehabilitation

Box 22.2 Early Postsurgical Evaluation

- Vascularity (if appropriate)
- Functional status
  - Bed mobility, transfers, sitting, standing, balance
- Gross range of motion
  - Unamputated extremity
    - Hip, knee flexion and extension
    - Ankle dorsiflexion/plantarflexion
  - Upper extremity to note any limitations that would interfere with functional activities
  - Amputated extremity

patients, information on the current cardiovascular status, physiological response to surgery, presence of infection, pain level, and medication indicates to what extent the patient will be able to participate in the therapy program. Individuals amputated secondary to severe trauma, blast injuries in war, and similar problems will require a somewhat different approach from individuals with vascular disease. The type of postsurgical dressing will also influence both data gathering and interventions. The person with a rigid dressing will be able to move more easily in bed than someone with a soft dressing. At this point the physical therapy diagnosis will probably reflect an individual with limited mobility and functional capabilities. Depending on the specific findings the individual may also have compromised endurance and pain that interferes with participation in the program. The specific POC is, of course, aimed at the goals and the critical findings.

Intervention

The therapist treating a patient in the hospital has only limited time in which to achieve the goals. The intervention must be aimed at preparing for discharge from acute care and to some form of follow-up care, be it in an acute rehabilitation facility, through a home health service or agency, or an outpatient facility. Box 22.3 outlines the major components of interventions.

Positioning

Figure 22.5 illustrates the major positions for either a patient with a transtibial or transfemoral amputation. Although the figure represents someone with a transtibial amputation, the general principles are the same. It is critical in both instances to prevent hip flexion contractures and the patient should be encouraged to spend some time in the prone position if at all possible. A pillow under the residual limb while the patient is supine is never recommended, nor is prolonged sitting. In the early days, the patient will want to avoid side-lying on the amputated side and the residual limb should be kept in extension at both hip and knee.

Box 22.3 General Plan of Interventions

- Positioning to avoid contractures
- Standing balance and transfer activities
- Mobility training with crutches or a walker
- Residual limb care and protection; bandaging if appropriate
- Care of the remaining lower extremity (if circulation compromised)
- Education on amputation and prosthetics

Balance and Transfers

Sitting balance is usually not a problem with a unilateral amputation but must be a part of the intervention program for individuals with bilateral amputations. Standing balance exercises on the remaining extremity can be quite beneficial in helping the individual regain a sense of his or her body in space. The better the person can balance on the remaining extremity the more likely he or she will be to use crutches and lead a more active life during the period before prosthetic fitting. A variety of balance exercises may be used, including balancing on a compliant surface. In the early postsurgical period the person should stand and transfer leading with the unamputated limb to protect the residual limb from possible injury against the chair or bed.

Mobility

Many physical therapists fit patients with a walker. Although this is appropriate for some individuals, trying to teach the patient safe and independent mobility with crutches is much more beneficial. While there is more stability in a walker, there is greater flexibility in accomplishing activities of daily living (ADL) on crutches. The added balance needed for crutches will also serve the individual well when it is time for prosthetic fitting.

If the patient has been fitted with an IPOP or an RRD and has good control of weight-bearing, the physician might decide to add a pylon and foot to the assembly making partial weight-bearing gait possible. In this instance, the patient must be fitted with crutches because the walker will inhibit the natural function of the prosthetic components.

When teaching mobility to someone with diabetes or any vascular compromise, it is critical that the patient

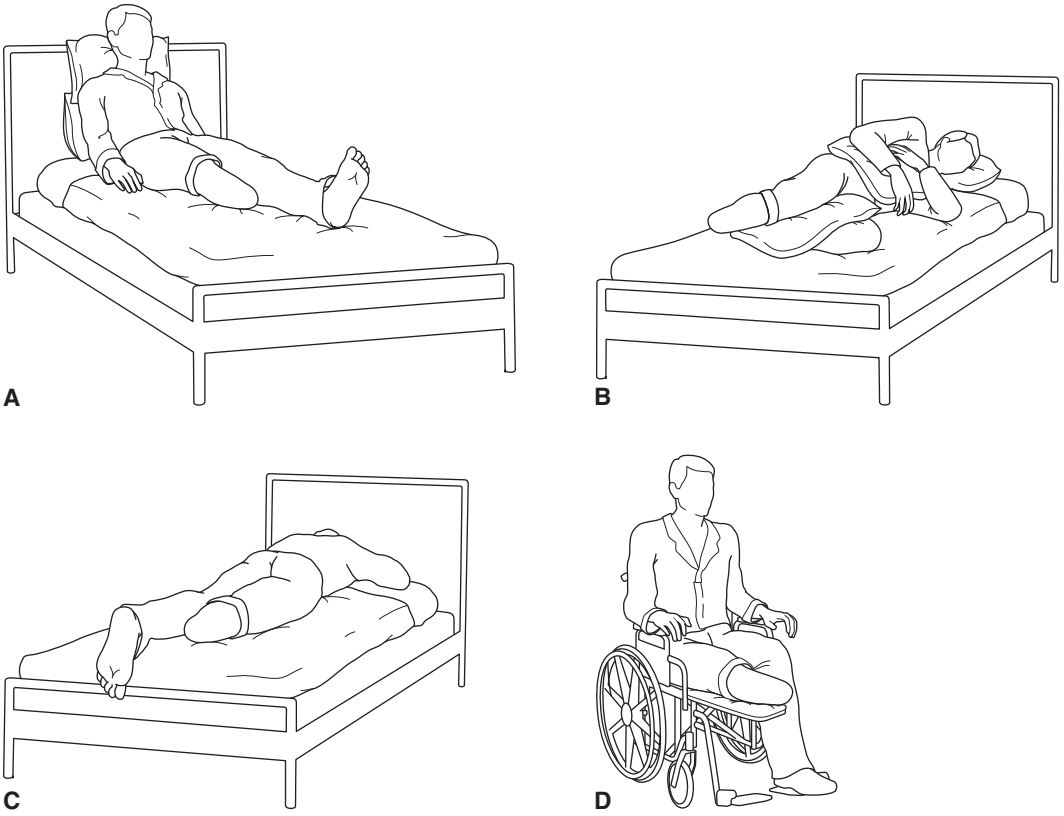

Figure 22.5 Proper transtibial position: **(A)** supine; **(B)** side-lying; **(C)** prone; **(D)** sitting. *From May and Lockard,[26, p. 67] with permission.*

wear a shoe on the remaining foot. Obviously, the remaining foot must be protected from any injury or assault, and hospital-provided slippers, or any slippers, do not provide the necessary protection. The family can bring in a regular shoe and this may be time to consider fitting the patient with an adapted shoe to prevent trauma to this foot.

Residual Limb Care

The physical therapist will need to teach the patient and family how to properly wrap the limb, and, if the patient has been fitted with an IPOP or RRD, the physical therapist needs to be alert to excessive bleeding or draining through the cast. A primary focus at this point is to teach the patient how to protect the residual limb while moving in bed, coming to sitting, and transferring. Obviously the patient should not put pressure on the limb or drag it on the bed. Slightly raising the residual limb and moving it to the side while rolling to the unamputated side is the best way to come to sitting. Careful monitoring of healing status of the residual limb is important at this point. The patient can be encouraged to move the limb gently within a pain-free range both at the knee (transtibial) and at the hip (both levels). Gentle hip extension (for transtibial amputations, with the knee straight) is an excellent exercise to teach the patient while lying on the unamputated side. It can and should be done several times a day. Any resistive exercises for the residual limb are contraindicated at this time.

Care of the Remaining Lower Extremity

Since the majority of individuals undergoing amputation do so as a result of poor circulation, it is important to evaluate the status of the remaining extremity and teach the patient and family proper care as presented in Chapter 14, Vascular, Lymphatic, and Integumentary Disorders. As previously stated, a proper shoe must be obtained before standing and mobility activities.[27]

Patient Education

The more the patient and family understand about the amputation and rehabilitation process the better the outcome. Throughout the examination and implementation of the POC, the physical therapist continuously involves the patient and caregivers, answering questions and providing information at a level and rate commensurate with the capabilities of the individuals. The goals are to have the patient and caregivers assume responsibility for care, understand the need for continued care, and become active participants in the rehabilitation program.[28] A home program needs to be developed and the patient should be encouraged to be as mobile as possible.

By necessity, the home program will be limited until healing has occurred so the importance of continuity of physical therapy care is emphasized. Stineman et al,[29] in a study of 2,673 older veterans, reported that those who received intensive inpatient rehabilitation services had significantly better outcomes than those who did not receive such services.

Preprosthetic Phase

The preprosthetic phase is the time between discharge from the acute care hospital and fitting with a definitive prosthesis, or the decision not to fit the patient with an artificial limb. Regrettably, for many individuals this period lasts too long, does not include a regular program of physical therapy, and often results in poor outcomes. The general goals for the preprosthetic phase of care are presented in Box 22.4, and Box 22.5 provides a general preprosthetic examination guide.

Examination

Residual Limb

Approximately 7 to 12 days after surgery, depending on the condition of the residual limb, the amount of healing, and the postsurgical dressing, specific data about the residual limb and adjacent joint(s) can be gathered. Healing is, of course, of primary importance and residual limb data gathering must be deferred until the residual limb has healed enough to tolerate the stress of handling and resistance. Residual limb measurements are generally taken and reported in centimeters for uniformity with others involved in the care of individuals who have had an amputation. Circumferential measurements of the residual limb are taken after initial postsurgical edema has diminished, then regularly throughout the preprosthetic period. Measurements are made at regular intervals over the length of the residual limb. Circumferential measurements of the transtibial residual limb are started at the medial tibial plateau and taken every 5 to 8 cm depending on the length of the limb. Length of the residual limb is measured from the medial tibial plateau to the end of the bone, then to the end of the skin. Circumferential measurements of the transfemoral residual limb are started at the ischial tuberosity or the greater trochanter, whichever is most palpable, and taken every 8 to 10 cm. Length is measured from the ischial tuberosity or the greater trochanter to the end of the bone, then to the end of the skin. For accuracy of repeat measurements, exact landmarks are carefully noted. If the ischial tuberosity is used in transfemoral measurements, hip joint position is noted as well. Other information gathered about the residual limb includes its shape (conical, bulbous, or cylindrical; presence of redundant tissue), skin condition, sensation, and joint proprioception.

Box 22.4 Preprosthetic General Goals

- Independent in residual limb care
  - Bandaging or shrinker application
  - Skin care
  - Positioning
- Independent in mobility, transfers, and functional activities
  - Partial weight-bearing crutch walking if fitted with IPOP or EPOP
  - Full weight-bearing when tolerated
  - Single-leg ambulation with crutches/walker if fitted with soft dressing
- Demonstrate home exercise program accurately
  - ROM graduating to resistive exercises for all parts of residual lower extremity
  - ROM and strengthening exercises for unamputated lower extremity as needed
- Care of the remaining lower extremity if amputated for vascular reasons

Range of Motion

Gross range of motion (ROM) estimations are generally adequate for examination of the uninvolved extremity but specific goniometric measurements are necessary for the amputated side, bilateral hip extension, and ankle dorsiflexion of the unamputated side. Good balance requires good ankle motion, and many older individuals have developed limited range in ankle dorsiflexion leading to stumbling and catching of toes. Hip and knee measurements are taken following transtibial amputation. Hip flexion, extension, abduction, and adduction measurements are taken following transfemoral amputation. Measurement of internal and external hip rotation is difficult to obtain and unnecessary if no gross abnormality or pathology is evident. Hip flexion contractures are particularly important to note because the patient cannot stand and bear weight properly without adequate hip extension (Fig. 22.6). Additionally, hip extension participates in prosthetic knee control for some transfemoral prostheses.

Muscle Strength

Gross manual muscle testing (MMT) of the upper extremities (UEs) and uninvolved LE is performed as part of the initial examination. MMT of the involved LE must usually wait until most healing has occurred. With a transtibial amputation, good strength in the hip extensors and abductors, as well as the knee extensors and flexors, is needed for satisfactory prosthetic ambulation. For the patient with a transfemoral amputation, good strength of the hip extensors and abductors is a requirement. The strength of these muscles should be monitored throughout the preprosthetic phase. The intervention program addresses these areas.

Skin

- Scar (healed, adherent, invaginated, flat)
- Other lesions (size, shape, open, scar tissue)
- Moisture (moist, dry, scaly)
- Sensation (absent, diminished, hyperesthesia)
- Grafts (location, type, healing)
- Dermatological lesions (psoriasis, eczema, cysts)

Residual Limb Length

- Bone length (transtibial limbs measured from medial tibial plateau; transfemoral limbs measured from ischial tuberosity or greater trochanter)
- Soft tissue length (note redundant tissue)

Residual Limb Shape

- Cylindrical, conical, bulbous end, and so forth
- Abnormalities ("dog ears," adductor roll)

Emotional Status

- Acceptance
- Body image

Vascularity (both limbs if amputation cause is vascular)

- Pulses (femoral, popliteal, dorsalis pedis, posterior tibial)
- Color (red, cyanotic)
- Temperature
- Edema (circumference measurement, water displacement measurement, caliper measures)
- Pain (type, location, duration, intensity)
- Trophic changes

Range of Motion

- Residual limb (specific for remaining joints)
- Other lower extremity (gross for major joints)

Muscle Strength

- Residual limb (specific for major muscle groups)
- Other extremities (gross for necessary function)

Neurological

- Pain (phantom [differentiate sensation or pain], neuroma, incisional, from other causes)
- Neuropathy
- Cognitive status (alert, oriented, confused)

Functional Status

- Transfers (bed-to-chair, to toilet, to car)
- Mobility (ancillary support, supervision)
- Home/family situation (caregiver, architectural barriers, hazards)
- Activities of daily living (bathing, dressing)
- Instrumental activities of daily living (cooking, cleaning)

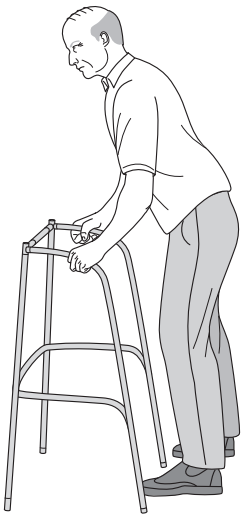

Figure 22.6 Hip flexion contractures prevent balanced standing. *From May and Lockard,[26, p. 111] with permission.*

Status of the Uninvolved Limb

The vascular status of the uninvolved LE is determined and documented. Data gathered include condition of the skin, presence of pulses, sensation, temperature, edema, pain on exercise or at rest, presence of wounds, ulceration, or other abnormalities. Chapter 14, Vascular, Lymphatic, and Integumentary Disorders, presents further information on examination and evaluation of peripheral vascular status.

Functional Status

Activities of daily living and functional mobility skills including transfer and ambulatory status are examined and documented. Balance both sitting and standing on the remaining extremity is very important and should be examined as long as the person's condition permits. Data regarding presurgical activity level and the person's own expected outcomes are obtained through interview and are often indicative of potential functional prosthetic use. An individual who had an active lifestyle before the amputation, regardless of age, is more likely to be able to learn to use a prosthesis well. Individuals with a long history of a sedentary lifestyle may encounter more difficulty, particularly if the amputation is at the transfemoral level.

Phantom Limb

The majority of individuals will encounter **phantom limb sensations** following amputation. In its simplest form, the phantom is the sensation of the limb that is no longer there. The phantom, which may occur initially immediately after surgery or as long as a year after amputation, is often described as a tingling, burning, itching, or pressure sensation, or sometimes a numbness. The distal part of the extremity is most frequently felt although, on occasion, the person will feel the whole extremity. Phantom sensation has been around as long as individuals survived the loss of a limb; however, there has been little agreement over the centuries regarding its cause or treatment. Current researchers are investigating areas of sensory reintegration and reorganization in the somatosensory cortex.[30] A majority of individuals report phantom limb sensation and some report the feeling as noxious, yet it usually does not interfere with prosthetic rehabilitation. It is important for the patient to understand that the sensations are quite normal.[31]

Phantom limb pain is a generalized noxious sensation in the absent limb that is so strong as to interfere with prosthetic fitting. It may be localized or diffuse, continuous or intermittent, and may be triggered by some external stimuli. It may diminish over time or become a permanent and disabling condition. It occurs in only a small number of patients. It is important to differentiate phantom pain from the more common phantom sensations, residual limb pain, or neuroma pain. Sometimes, wearing a prosthesis will ease the phantom pain. On occasion, in the presence of trigger points, injection with steroids or local anesthetic has reduced the pain temporarily. Although the literature is replete with information and studies on phantom sensation, phantom pain, and residual limb pain, there is little agreement about the best approach to treatment of these phenomena.[31] In some studies, particularly of individuals who experienced considerable preoperative pain, intrathecal or epidural anesthetic drips with opioids were used both preoperatively and postoperatively with success.[32] However, others have reported no success with such treatments.[31] Noninvasive treatments such as ultrasound, icing, transcutaneous electrical nerve stimulation (TENS), and massage have been used with varying success. Mild nonnarcotic analgesics have been of limited value; biofeedback, guided imagery, psychotherapy, nerve blocks, and dorsal rhizotomies have all been used with inconsistent results. The treatment of phantom pain can be very frustrating for the clinic team as well as the patient.[31-35]

Emotional Status

Initial reaction to the traumatic loss of a limb is usually grief and depression. The person may experience insomnia and restlessness, and have difficulty concentrating. Some individuals may actually mourn the possible loss of a job or the ability to participate in a favorite sport or other activities rather than the lost limb per se. In the early stages, the person's grief may alternate with feelings of hopelessness, despondency, bitterness, and anger. Socially the patient may feel lonely, isolated, and the object of pity. Concerns about the future, about body image and sexual function, about the responses of family and friends, and about employment all affect the individual's reactions.

If the amputation was the result of vascular disease or other long-term problem, the amputation may actually

come as a relief. The fight to save the limb, sometimes long and painful, is finally over. Responses vary by individuals. Some older individuals may relate the loss of the limb to the loss of independence and may become quite depressed. While not giving the individual false hope, it behooves the physical therapist to educate the patient on the rehabilitation process and the steps toward independence. Often seeing others in the treatment area with similar problems, particularly if involved in prosthetic training, may help the patient with a new amputation realize what can be achieved.

Long-term adjustment depends to a great extent on the individual's basic personality structure, sense of accomplishment, and place in the family, community, and world. In general, many individuals with amputations make a satisfactory adjustment to the loss and are reintegrated into a full and active life. In achieving final acceptance, the individual may go through a number of stages including denial, anger, euphoria, and social withdrawal. Although it is difficult to predict long-range adjustment initially, there is some evidence that early counseling and the opportunity to explore the feelings associated with amputation and rehabilitation may be beneficial for individuals in all age groups.[36]

Some individuals may try to avoid distressing thoughts of the lost limb through conscious self-control or by avoiding situations or people that remind them of the lost limb. Some may display temper tantrums or irrational resentment. Some may revert to childlike states of helplessness and dependence.

Many individuals are not fully aware of the consequences of amputation and may fear other physical limitations as a result of the surgery. Fear of impotence or sterility may lead some men to make grandiose statements or display reckless behavior to mask the fear. Thorough explanations of the amputation process and its implications by the surgeon or other rehabilitation team members may alleviate many of these fears.

Generally, people who have had an amputation may dream about themselves as having an intact limb. This image may be so vivid that they fall as they get up at night and attempt to walk to the bathroom without a prosthesis or crutches. Individuals who have lost their leg through injury may dream about the battle or accident in which they were injured. Such reenactments may lead to insomnia, trembling fits, speech impediments, and difficulty with concentration. In general, individuals with congenital amputations or acquired amputations before age 5 do not have some of the problems mentioned above because their amputation is a part of their developed self-image.

Psychological Support

The patient needs to receive reassurance and understanding from the entire rehabilitation team. Team members should create an open and receptive environment and be willing to listen. The patient should know what to expect during the entire process. The surgeon and therapists should carefully explain the steps and expectations of rehabilitation. Audiovisual media, such as films or photographs, may be helpful. The Amputee Coalition of America (ACA) is a national, nonprofit amputee consumer educational organization representing people who have experienced amputation or were born with limb differences (www.amputee-coalition.org). Members include individuals with amputations, health professionals, family members, and friends of those with amputations. The ACA supports a volunteer visitation program where individuals with amputations who have been trained to provide support will visit patients soon after surgery to help with emotional support. Therapists should be cognizant of the existence of a local ACA chapter and make use of the organization to provide support and education to their patients regardless of age or cause of amputation. The military services also have support programs for individuals with amputations, and a group of veterans organized the Wounded Warrior Project (www.woundedwarriorproject.org) as a nonprofit organization to assist severely disabled veterans.

Patients have various attitudes toward the prosthesis. Most are concerned with function and regaining the greatest level of function possible; others are concerned about its appearance, hoping that it will conceal their disability and give the illusion of an intact body. If individuals with amputations have been told that the prosthesis will replace their own limb, they may have unrealistic expectations that function will be as good as in the nonamputated extremity. Realistic adjustment will be necessary as the person learns to use the artificial substitute. Good predictors for adjustment to the prosthesis are active involvement in the postsurgical and preprosthetic program and consistent attempts to return to an active lifestyle.

The Older Adult

The older individual with a LE amputation is not content to sit in a wheelchair or limp with a walker, but seeks effective rehabilitation services and a meaningful lifestyle. Maintaining independence is a critical issue with the older adult. Any disability requiring the use of an external device, especially amputation, may be seen as the end of an independent lifestyle. To some extent, the previous level of pain and disability and the sudden or gradual onset of the disability will affect the reaction. Individuals who have suffered considerable pain may be grateful that the pain has ended. Clients who underwent extensive medical and surgical procedures may experience a sense of failure that the efforts were not successful. If preoperative attitudes are unrealistically hopeful, postoperative disturbances may be more severe. The elderly person should not be led to expect a total cure. Learning to use an artificial limb may be a slow and discouraging ordeal, and the client may not express

distress or depression in front of the optimism of others. However, the physical therapist must keep in mind that the majority of older individuals, particularly those amputated at transtibial levels, make excellent adjustments to prosthetic function.[37]

Elderly individuals are subject to considerable stress from concerns about financial limitations, loss of control over their lives, and fear of becoming dependent. An elderly individual who requires an amputation must often cope with multiple physical problems. Loss is a part of normal aging—loss of physiological capabilities, loss of a spouse or friends, loss of the self-esteem related to one's career or job, and now, loss of function. It is helpful to give the client as much control over decision making as possible, to provide opportunities to be involved in goal setting and sequencing of activities. As with any client, physical therapists need to be aware of the stressors affecting the client and assist with coping by being reflective listeners and enablers.

It is a myth that elderly individuals cannot learn a new skill, have difficulty remembering, and cannot achieve at the same level as younger individuals. Some elderly individuals may have difficulty learning a new skill, but many are able to adapt successfully to a disability such as an amputation and lead a full and normal life. Although some suffer from dementia, others who are labeled as having dementia because of confusion in the acute care setting may actually only be responding to medications, metabolic imbalances, infection toxicity, insecurity in a strange environment, or the sequelae of anesthesia. It is important to remember that cognitive dysfunction does not preclude satisfactory rehabilitation. Understanding the client's cognitive capabilities will help structure learning experiences appropriately. Goal-oriented statements may be clearer than step-by-step instructions. We do many activities almost automatically—getting up from a chair, turning in bed, and walking. Most of us have developed particular patterns of movements over the years. The physical therapist can draw on such patterns while focusing on the movement goals.

Intervention

Residual Limb Care

The residual limb needs to be completely healed and have lost the postoperative edema and much of the soft tissue slackness to be ready for prosthetic fitting. The residual limb is subjected to considerable and varied pressures during prosthetic walking and is generally not fully healed and prepared for such stresses for 8 to 12 weeks. The most effective method of preparing the residual limb for prosthetic fitting is the rigid dressing, but it is more expensive than the elastic wrap and many insurers will not pay for such fitting. Individuals not fitted with a rigid dressing use elastic wrap or shrinkers to reduce the size of the residual limb. The patient, family member, or professional staff member applies the bandage, which is worn 24 hours a day, except when bathing. Using an elastic wrap or a shrinker to reduce edema is a slow process. Edema in the residual limb may be difficult to control in individuals with diabetes, particularly if they have renal involvement.

Residual Limb Wrapping

Patients tend to wrap their own residual limb in a circular manner, often creating a tourniquet, which may compromise healing and foster the development of a bulbous end. Although the transtibial residual limb can be effectively wrapped in a sitting position, it is difficult to properly wrap and anchor the transfemoral limb while sitting. Older patients often cannot balance themselves in the standing position while wrapping. An effective bandage is smooth and wrinkle free, emphasizes angular turns, provides pressure distally, and encourages proximal joint extension. The ends of bandages are fastened with tape or safety pins, rather than clips, which can cut the skin and do not anchor well. A system of wrapping that uses mostly angular or figure-of-eight turns was developed specifically to meet the needs of the older patient.

The Transtibial Bandage

Figure 22.7 outlines the preferred methods of wrapping the transtibial residual limb. Two 4-in elastic bandages are usually enough to wrap most transtibial residual limbs. Very large residual limbs may require three bandages. The transtibial bandages should not be sewn together so that the weave of each bandage can be brought in contraposition to the other to provide more support. Although an elastic wrap does not provide as much pressure as a rigid dressing, the development of postsurgical edema must be deterred as much as possible; therefore, a firm, even pressure against all soft tissues is desirable. If the incision is placed anteriorly, an attempt should be made to bring the bandages from posterior to anterior over the distal end.

The first bandage is started at either the medial or lateral tibial condyle and brought diagonally over the anterior surface of the limb to the distal end. One edge of the bandage should just cover the midline of the incision in an anterior-posterior plane. The bandage is continued diagonally over the posterior surface, then back over the beginning turn as an anchor. At this point, there is a choice; the bandage may be brought directly over the beginning point as indicated in Figure 22.7 (step 2a), or it may be brought across the front of the residual limb in an "X" design (Fig. 22.7 [step 2b]). The latter technique is particularly useful with long residual limbs and aids in bandage suspension. An anchoring turn over the distal thigh is made making sure that the wrap is clear of the patella and is not tight around the distal thigh.

After a single anchoring turn above the knee, the bandage is brought back around the opposite tibial condyle and down to the distal end of the limb. One edge of the bandage should overlap the midline of the

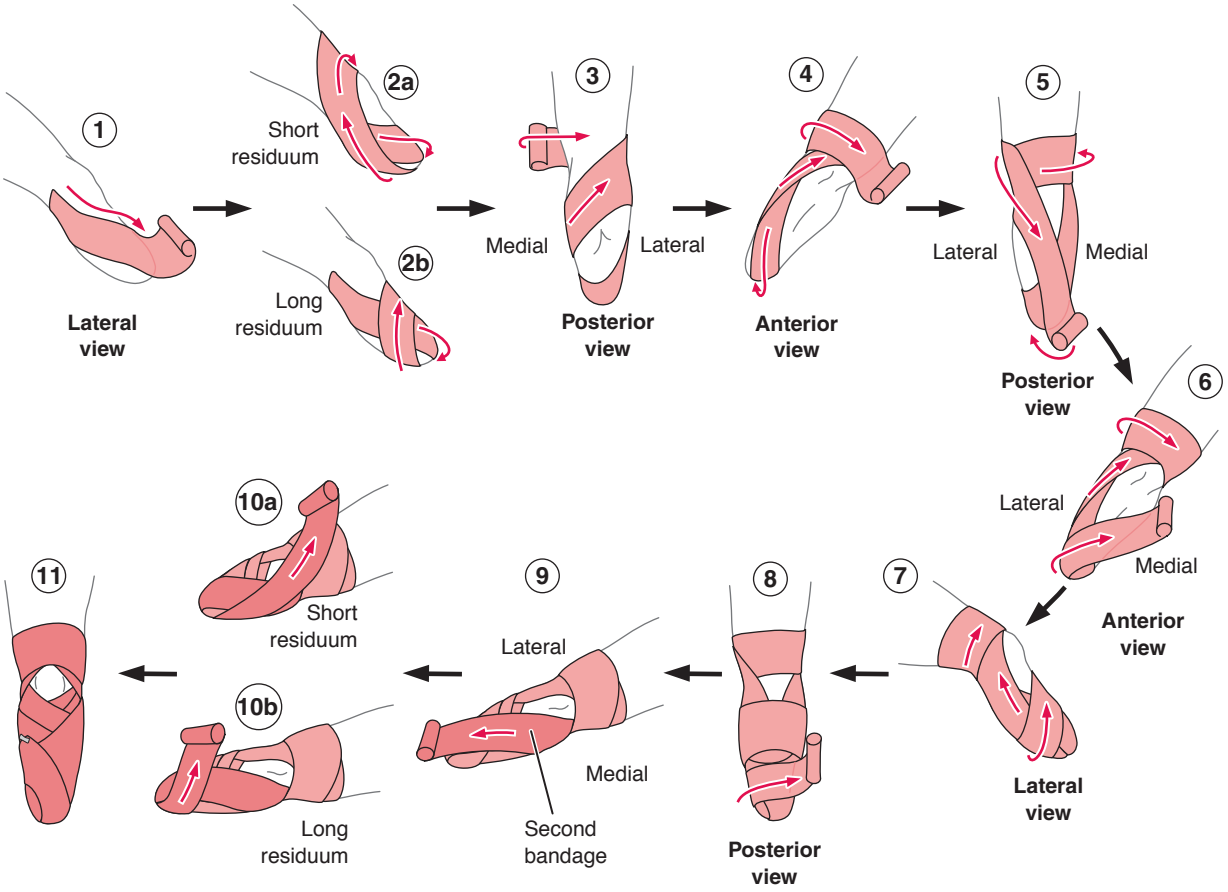

Figure 22.7 Transtibial residual limb bandaging. *From May and Lockard,[26, p. 75] with permission.*

incision and the other wrap by at least 1/2 in (1.25 cm) to ensure adequate distal end support. The figure-of-eight pattern is continued as depicted in Figure 22.7 (steps 5 through 8) until the bandage is used up. Care should be taken to completely cover the residual limb with a firm and even pressure. Semicircular turns are made posteriorly to position the bandage to cross the anterior surface in an angular line. This maneuver provides greater pressure on the posterior soft tissue while distributing pressure anteriorly where the bone is close to the skin. Each turn should partially overlap other turns so the whole residual limb is well covered. The pattern is usually from proximal to distal and back to proximal, starting at the tibial condyles and covering both condyles as well as the patellar tendon. Usually, the patella is left free to aid in knee motion, although with extremely short residual limbs, it may be necessary to cover it for better suspension.

The second bandage is wrapped like the first, except that it is started at the opposite tibial condyle from the first bandage (Fig. 22.7 [step 9]). Bringing the weave of each bandage in contraposition exerts a more even pressure. With both bandages, an effort is made to bring the angular turns across each other rather than in the same direction.

The Transfemoral Bandage

Figure 22.8 depicts the preferred method of wrapping the transfemoral residual limb with the task being done by a family member or caregiver. The side-lying position is preferred for better control of the residual limb with the hip neutral or slightly extended. Wrapping the transfemoral residual limb in the sitting position is difficult and usually leaves an area on the medial thigh uncovered. The patient with good balance on the remaining limb can bandage the residual limb in the standing position.

For most residual limbs, two 6-in bandages and one 4-in bandage will adequately cover the limb. The two 6-in bandages can be sewn together end-to-end taking care not to create a heavy seam; the 4-in bandage is used by itself. The 6-in bandages are used first. While it was noted that the transtibial wraps should not be sewn together to allow for a firmer bandage, sewing the transfemoral 6-in bandages or using a double bandage reduces the end of bandage attachments and makes for a smoother wrap. The first bandage is started in the groin and brought diagonally over the anterior surface to the distal lateral corner, around the end of the residual limb, and diagonally up the posterior side to the iliac crest and

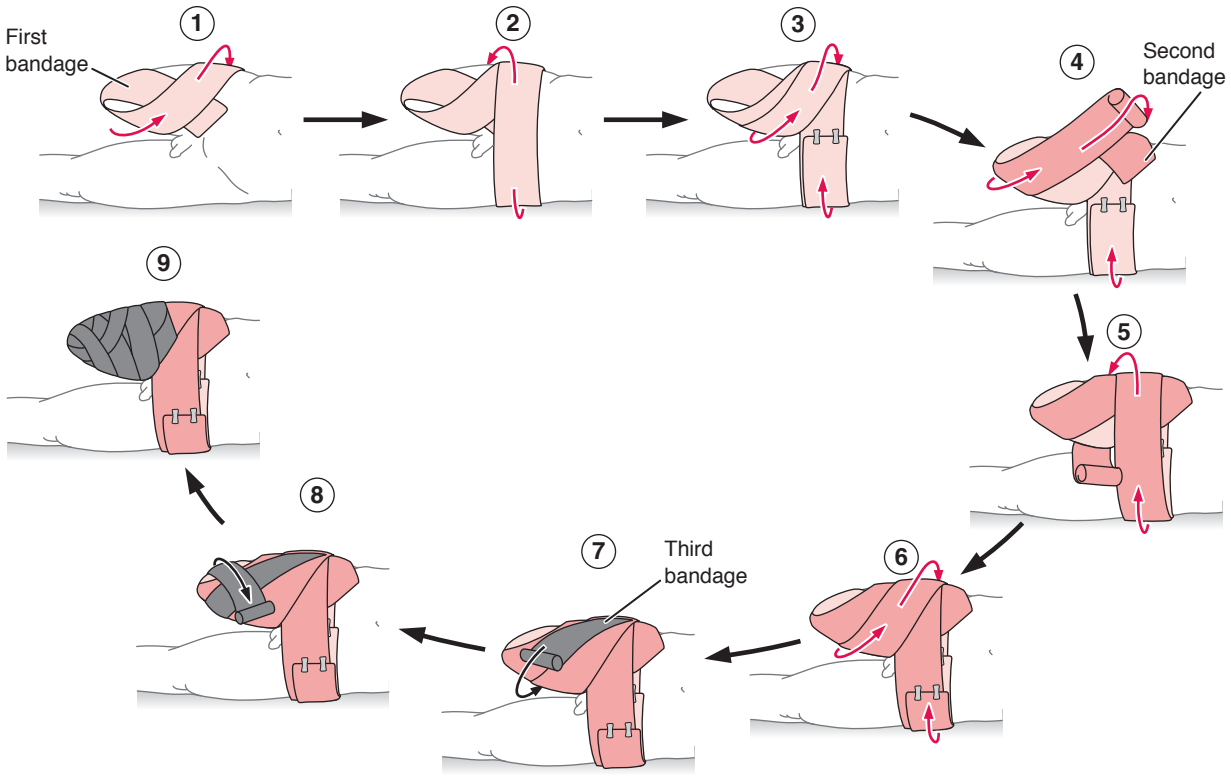

Figure 22.8 Transfemoral residual limb bandaging. *From May and Lockard,[26, p. 76] with permission.*

around the hips in a spica. The bandage is started medially so that the hip wrap (hip spica) will encourage extension. After the turn around the hips, the bandage is wrapped around the proximal portion of the residual limb high in the groin, then back around the hips. Although this is a proximal circular turn, it does not create a tourniquet as long as it is continued around the hips. Going around the medial portion of the residual limb high in the groin ensures coverage of the soft tissue in the adductor area and reduces the possibility of an adductor roll, a complication that can seriously interfere with comfortable prosthetic wear. In most instances, the first bandage ends in the second hip spica and is anchored with tape or pin.

The second 6-in bandage is wrapped like the first but is started a bit more laterally. Any areas not covered with the first bandage must be covered at this time. If a double bandage is used, this wrap can be a continuation of the first anchoring turn. The second bandage is also anchored in a hip spica after the first figure-of-eight and after the second turn high in the groin. While more of the first two bandages are used to cover the proximal residual limb, care must be taken that no tourniquet is created. Bringing the bandage directly from the proximal medial area into a hip spica helps to keep the adductor tissue covered and prevents rolling of the bandage to some degree.

The 4-in bandage is used to exert the greatest amount of pressure over middle and distal areas of the residual limb. It is usually not necessary to anchor this bandage around the hips because friction with the already applied bandages and good figure-of-eight turns limit slippage. The 4-in bandage is generally started laterally to bring the weave across the weave of previous bandages. Regular figure-of-eight turns in varied patterns to cover the entire residual limb are the most effective.

Shrinkers

The transtibial elastic shrinker is rolled over the residual limb to midthigh and is designed to be self-suspending. Individuals with heavy thighs may need additional suspension with garters or a waist belt. Currently available transfemoral shrinkers incorporate a hip spica, which provides good suspension except with obese individuals (see Fig. 22.4). Care must be taken that the patient understands the importance of proper suspension; any rolling of the edges or slipping of the shrinker can create a tourniquet around the proximal part of the residual limb. Shrinkers are easier to apply than elastic bandages and may be a better alternative, particularly for the transfemoral residual limb. Shrinkers are more expensive to use than elastic wrap; the initial cost is greater, and then new shrinkers of smaller sizes must be purchased as the limb volume decreases. However, shrinkers are a viable option for individuals who are not able to properly wrap the residual limb. Shrinkers may not be used until the incision has healed and the sutures have been removed. Sutures can be caught in the

shrinker's mesh, and the distal distraction forces that accompany donning may cause wound dehiscence (splitting open). In a small study involving individuals who were taught proper bandaging techniques, Louie et al[38] found that residual limb wrapping was slightly more effective in reducing edema among individuals with transtibial amputations.

Skin Care

Proper hygiene and skin care are important. The residual limb is treated as any other part of the body; it is kept clean and dry. Individuals with dry skin may use a good skin lotion. Care must be taken to avoid abrasions, cuts, and other skin problems. Friction massage, in which layers of skin, subcutaneous tissue, and muscle are moved over the respective underlying tissue, can be used to prevent or mobilize adherent scar tissue. The massage is done gently, after the wound is healed and when no infection is present. Patients can learn to properly perform a gentle friction massage to mobilize the scar tissue and help decrease hypersensitivity of the residual limb to touch and pressure. Early handling of the residual limb by the patient is an aid to acceptance and is encouraged, particularly for individuals who may be repulsed by the limb.

The patient is taught to inspect the residual limb with a mirror each night to make sure there are no sores or impending problems, especially in areas not readily visible. If the person has diminished sensation, careful inspection is particularly important. Because the residual limb tends to become a bit edematous after bathing as a reaction to the warm water, nightly bathing is recommended, particularly once a prosthesis has been fitted. The elastic bandage, elastic shrinker, or removable rigid dressing is reapplied after bathing. If the person has been fitted with a prosthesis, the residual limb is wrapped at night and any time the prosthesis is not worn until it is fully mature (i.e., does not develop edema when not wearing a prosthesis). Patients have been known to apply a variety of "home and folk remedies" to the residual limb. Historically, it was believed that the skin had to be toughened for prosthetic wear by beating it with a towel-wrapped bottle. Various ointments and lotions have been applied; residual limbs have been immersed in substances such as vinegar, salt water, and gasoline to harden the skin. Although the skin does need to adjust to the pressures of wearing an artificial limb, there is no evidence to indicate that "toughening" techniques are beneficial. Such methods may actually be deleterious; research indicates that soft pliable skin is better able to cope with stress than tough dry skin. Patient education regarding proper skin care can reduce the use of home remedies.

The skin of the residual limb may be affected by a variety of dermatological problems such as eczema, psoriasis, or radiation burns. Some of these conditions may mitigate against fitting or wrapping. Dudek et al[39] found 528 reports of skin problems among 337 residual limbs in a 6-year retrospective study. Each skin problem was treated as a separate entity, whether it occurred in one or more than one individual. Treatment may include ultraviolet irradiation, whirlpool, reflex heating, hyperbaric oxygen, or medication. Care must be taken in using ultraviolet or heat in the presence of vascular disease. The whirlpool may not be the treatment of choice because it increases circulation and edema in the part under treatment.

Range of Motion

One of the greatest deterrents to functional prosthetic rehabilitation is contracture of hip or knee. Contractures can develop as a result of muscle imbalance or fascial tightness, from a protective withdrawal reflex into hip and knee flexion, from loss of plantar stimulation in extension, or as a result of faulty positioning such as prolonged sitting or placing the residual limb on a pillow. The patient should understand the importance of proper positioning and regular exercise in preparing for eventual prosthetic fit and ambulation. For all levels of amputation, full ROM in hip extension is critical in allowing the individual to assume a balanced upright posture.

With the transtibial amputation, full ROM in the hips and knee, particularly in extension, is needed. While sitting, the patient can keep the knee extended by using a posterior splint or a board attached to the wheelchair. The patient with a transfemoral amputation needs full ROM in the hip, particularly in extension and adduction. Prolonged sitting is to be avoided. Some time each day should be spent in the prone position.

Some individuals will present with hip or knee flexion contractures. Mild contractures may respond to manual mobilization and active exercises, but it is almost impossible to reduce moderate to severe contractures by manual stretching, especially hip flexion contractures. Some practitioners advocate holding the extremity in a stretched position with weights for a considerable length of time. There is little evidence that this traditional approach is successful. Facilitated stretching techniques (e.g., proprioceptive neuromuscular facilitation [PNF]) are more effective than passive stretching; hold–relax and hold–relax active contraction that utilizes resisted contraction of antagonist muscles may increase ROM, particularly of the knee. One of the more effective ways of reducing a knee flexion contracture is to fit the patient with a patellar-tendon-bearing (PTB) prosthesis aligned in a manner that places the hamstrings on stretch with each step. Such prosthetic alignment provides a stretch that is quite effective. Hip flexion contractures are more frequently found in persons with transfemoral amputations. It is difficult to "walk out" a hip flexion contracture with the transfemoral prosthesis. In some instances, depending on the severity of the contracture and the

length of the residual limb, the contracture can be accommodated in the alignment of the prosthesis. A knee flexion contracture of less than 15° is not usually a problem. Prevention, however, continues to be the best treatment for contractures.

Exercises

The exercise program is individually designed and includes strengthening, balance, and coordination activities. The type of postsurgical dressing, degree of postoperative pain, and healing of the incision will determine when resistive exercises for the involved extremity can be started. The exercise program can take many forms and must include a home exercise program (HEP). The hip extensors and abductors and knee extensors and flexors are particularly important for prosthetic ambulation. Studies have shown a correlation between strength of the key muscle groups and ability to use a prosthesis effectively.[40-43] Figures 22.9 and 22.10 depict a series of exercises particularly well designed to strengthen key muscles around the hip and knee. These exercises can be adapted for a HEP because they are simple to perform and require no special equipment. Exercises need to be progressed with increased resistance.

A general strengthening program that includes the trunk and all extremities is often indicated, particularly for the older person who may have been quite sedentary before surgery. Proprioceptive neuromuscular facilitation exercises (PNF) are also beneficial. The exercise program needs to be individually developed and emphasize those muscles that are most active in prosthetic function. The exercises depicted in Figures 22.9 and 22.10 are particularly well suited to an HEP and combine the strengthening and coordination necessary for prosthetic ambulation. Corio et al[44] studied the effects of spinal stabilization exercises on the gait of individuals wearing a prosthesis for at least a year. Although a small sample of 34 individuals was used, the results suggest that improvement in spinal stabilization and trunk control may positively influence gait parameters.[44]

Balance and Mobility Activities

Early mobility is important to total physiological recovery. The patient needs to resume independent activities as soon as possible. Balance is a key element to effective mobility and an area too often overlooked. Poor balance and fear of falling have been found to negatively affect successful prosthetic rehabilitation.[45,46] Although individuals with unilateral amputation usually do not have a problem with sitting balance, it is important for the individual to develop good standing balance on the remaining limb. Figure 22.11 shows one type of standing balance exercise on a compliant surface. While care must be taken to protect the remaining foot from injury, particularly in patients with vascular disease, balance exercises with and without shoes as well as with eyes open and closed is an integral part of the program. Weight-bearing through the residual limb is also beneficial to future prosthetic training. This can only be

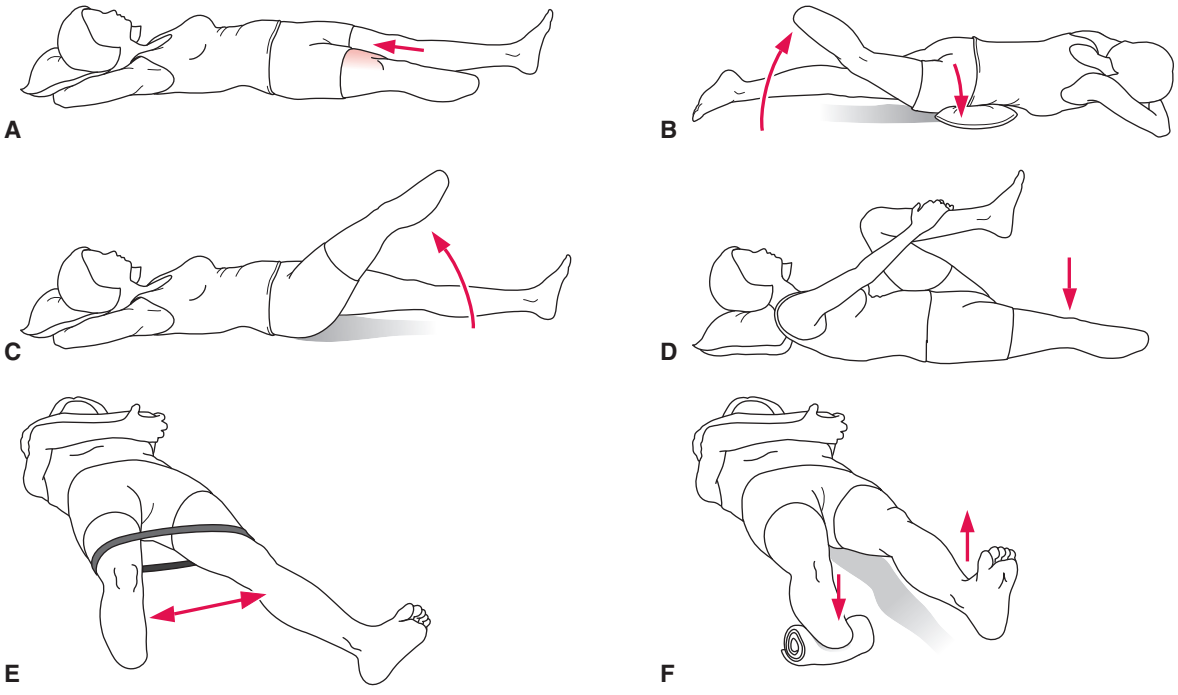

Figure 22.9 Transtibial exercises: **(A)** quad set, **(B)** hip extension with knee straight, **(C)** straight leg raise, **(D)** extension of the residual limb with the knee of the other leg against the chest, **(E)** hip abduction against resistance, and **(F)** bridging. *From May and Lockard,[26, p. 77] with permission.*

safely achieved in patients with transtibial amputations. Figure 22.12 depicts a person kneeling on a cushion in a chair of the appropriate height and shifting her weight on and off the amputated side.

Walking is excellent exercise and necessary for independence in daily life. Gait training can start early and the person with a unilateral LE amputation can become quite independent using a three-point gait pattern on crutches. Many older individuals have difficulty learning to walk on crutches. Some are afraid, some lack the necessary balance and coordination, and others lack endurance. Walking with crutches without a prosthesis requires a greater expenditure of energy than walking with a prosthesis.

Independence in crutch walking is an outcome worthy of therapy time. The individual who can ambulate with crutches will develop a greater degree of general fitness than the person who spends most of the time in a wheelchair. Crutch walking is good preparation for prosthetic ambulation and the person who can learn to use crutches generally will not have difficulty learning to use a prosthesis. However, the individual who cannot learn to walk with crutches independently may still

Figure 22.12 Kneeling on a pillow on a chair provides an opportunity for some weight-bearing. *From May and Lockard,[26, p. 74] with permission.*

become a very functional prosthetic user. An early graduated mobility program is also important for cardiovascular training and the development of endurance. Cardiovascular endurance is necessary for effective prosthetic ambulation, particularly at the transfemoral level.

There are advantages and disadvantages to using a walker for support. Certainly, walking with a walker is physiologically and psychologically more beneficial than sitting in a wheelchair, but it should be used only if the person cannot learn to walk with crutches. A walker is sturdier than crutches but cannot be used on stairs and curbs. It is sometimes difficult for the person who has used a walker following the amputation to switch to crutches or a cane when fitted with a prosthesis. The gait pattern used with a walker is not appropriate with a prosthesis and should not be used for any part of prosthetic training. A walker encourages a step-to gait pattern whereas efficient prosthetic use requires a step-through gait pattern. All individuals with an amputation need to learn some form of mobility without a prosthesis for use at night or when the prosthesis is not worn for some reason.

Temporary Prostheses

Many individuals are not fitted with any type of prosthetic appliance until the residual limb is free from edema and much of the soft tissue has shrunk, a process that can take many months of conscientious limb wrapping and exercises. During this period, the patient is limited to a wheelchair or to ambulation with crutches or a walker. Most individuals cannot return to work or fully participate in ADL while waiting for the residual limb to mature. Once fitted with a definitive prosthesis, the residual limb continues to change in size and a second prosthesis is often required within the first 2 years. A temporary prosthesis today is the same as the definitive prosthesis and uses the same components. Many third-party payers will not fund a temporary prosthesis, so early permanent fitting is advocated, even though the socket will be too big quite quickly. Early bipedal ambulation is a desired goal for most individuals following amputation. The longer the delay in fitting with a prosthesis, the lower the potential for effective rehabilitation. Care should be taken that the patient is fitted with optimum components for his or her expected level of function. Too often, older individuals are fitted with low-cost, low-function components when they probably could have achieved a higher level of function with more functional components. It becomes a vicious cycle with insurance companies depicting statistics showing that older individuals do not achieve independence but not considering that the components that were authorized either do not fit properly or they do not provide the necessary function. There is also a problem with insurers not providing adequate prosthetic training by a physical therapist.

Patient Education

Patient education is an integral and ongoing part of the rehabilitation program. Information on the care of the residual limb, proper care of the uninvolved extremity, positioning, exercises, and diet, if the patient has diabetes or is overweight, are necessary for the patient to be a full participant in the rehabilitation program. Discussions should also be held regarding patient goals, projected activity levels, funding, and prosthetic components. If the patient underwent the amputation for vascular problems, the education program should include information on proper footwear.

Care must be taken not to overwhelm the patient with too much information at one time; information overload leads to forgetfulness. It is more effective to prioritize the information and ask the person to remember one new thing each session rather than try to teach a complex program at one time. Written materials are necessary to supplement the teaching and help the patient remember what is required. It is also important for the program to be tailored to the individual's way of life. Involving the patient in establishing priorities enhances adherence. Appendix 22.A includes web-based resources for clinicians, families, and patients with amputation.

Bilateral Amputation

Intervention for the person with bilateral LE amputations is similar to the program developed for someone with a unilateral amputation except possibly ambulation. If the individual was fitted and ambulated after unilateral amputation, the prosthesis is useful for transfer activities and limited ambulation in the home. Some individuals

may be able to use the prosthesis with external support to get around the house more easily, particularly for bathroom activities.

All individuals with bilateral amputations need a wheelchair on a permanent basis. The chair should be as narrow as possible with removable desk arms and removable leg rests. Elevating armrests are useful to assist in sit-to-stand transfers. Amputee wheelchairs with offset rear wheels and no leg rests are not recommended unless the therapist is sure that the person will never be fitted with prostheses, even cosmetically. It is easier to add anti-tipping devices to the rear of the wheelchair or attach small weights to the front uprights (counterbalance) for use when the footrests are removed.

The exercise program includes mat activities designed to help the person regain a sense of body position and balance, UE and residual limb strengthening exercises, and regular ROM exercises. Functional mobility training should stress independence in bed mobility, transfers, and wheelchair use. With bilateral amputations, individuals spend considerable time sitting and are therefore more prone to develop flexion contractures, particularly around the hip joints. The patient should be encouraged to sleep prone if possible, or at least spend some time in the prone position each day. The therapy program also emphasizes ROM of the residual limbs.

DETERMINING PROSTHETIC POTENTIAL

Not all people with amputations are candidates for a prosthesis, regardless of personal desire. The cost of the prosthesis and the energy demands of prosthetic training require that some judgment be used in selecting individuals for fitting.

There is no general rule that can safely be applied to all patients in making the decision to fit or not to fit. The patient is part of the decision making process, but the fact that the individual wants a prosthesis is not enough. Many people are not aware of the physiological demands of prosthetic ambulation, particularly at transfemoral levels. The development of lightweight prostheses, microprocessor knee mechanisms, stance control assistance, and energy conserving feet have made it possible to successfully fit many more individuals than in the past; however, some consideration for nonfitting is necessary. Medicare has developed a functional classification chart to guide selection of components (Box 22.6). There are several other outcome instruments that may be used to help predict functional potential for patients with amputation.[47-49]

In general, individuals who were ambulatory before amputation who sustain a unilateral transtibial amputation will be able to become independent with a properly fitted prosthesis and physical therapy intervention. Although it takes more balance, coordination, and energy to use a transfemoral prosthesis, many individuals regardless of age can become functional following unilateral transfemoral amputation. Severe hip flexion contractures, obesity, weakness or paralysis of hip musculature, and poor balance and coordination may impede successful ambulation. The person's level of activity and participation in the postsurgical and preprosthetic programs helps in determining potential for prosthetic ambulation.

Fitting or not fitting someone with bilateral amputations is a difficult decision. Young, agile individuals are generally good candidates for prosthetic fitting regardless of level of amputations. Most patients with bilateral transtibial amputations can become quite functional with prostheses. Most older individuals with bilateral transfemoral amputations have considerable difficulty learning to use two prostheses. Patients with one transfemoral and one transtibial amputation generally can learn to use two prosthesis if the first amputation was at the transfemoral level, and if the person successfully used a transfemoral prosthesis before losing the other leg. Fitting decisions for individuals with bilateral LE amputations are individual and dependent on the person's particular capabilities. Certainly, technologically modern components including microprocessors and active components are an aid to the rehabilitation of most individuals with amputation today.

Box 22.6 Medicare Functional Classification Levels

- **Functional level 0:** The patient does not have the ability or potential to ambulate or transfer safely with or without assistance and a prosthesis does not enhance his or her quality of life or mobility.
- **Functional level 1:** The patient has the ability or potential to use a prosthesis for transfers or ambulation on level surfaces at fixed cadence. Typical of the limited and unlimited household ambulator.
- **Functional level 2:** The patient has the ability or potential for ambulation with the ability to traverse low-level environmental barriers such as curbs, stairs, or uneven surfaces. Typical of the limited community ambulator.
- **Functional level 3:** The patient has the ability or potential for ambulation with variable cadence. Typical of the community ambulator who has the ability to traverse most environmental barriers and may have vocational, therapeutic, or exercise activity that demands prosthetic utilization beyond simple locomotion.
- **Functional level 4:** The patient has the ability or potential for prosthetic ambulation that exceeds basic ambulation skills, exhibiting high-impact, stress, or energy levels. Typical of the prosthetic demands of the child, active adult, or athlete.

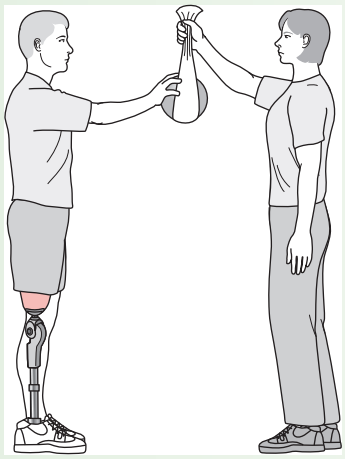
PROSTHETIC TRAINING

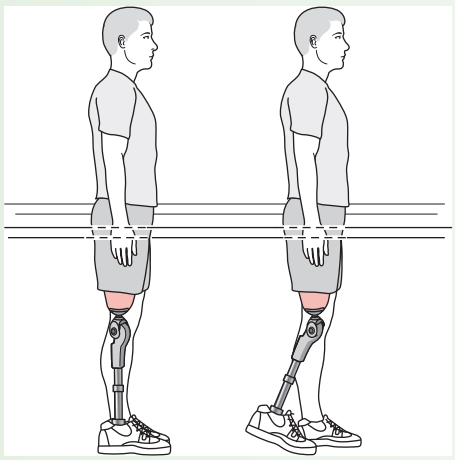
The major goal of prosthetic rehabilitation is for the client to attain a smooth, energy-efficient gait that allows the individual to perform ADL and participate in desired employment and recreational activities. Prosthetic ambulation is a skilled psychomotor activity and the person must learn to adapt well-developed patterns of movement to new situations. Box 22.7 outlines the determinants of an effective prosthetic gait. Effective gait training must guide the individual to integrate the prosthesis into all mobility activities. Table 22.3 presents the critical prosthetic training elements, starting with basic balance and progressing to ambulation. Although the table depicts training with a transfemoral prosthesis, the sequence is equally appropriate for transtibial prosthetic training other than the knee control step. It is important to do as much training as possible without the use of an external support device since many people will be able to walk more efficiently without external support. If found necessary, a cane may be added once the person has good control of weight shifting on and off the prosthesis and stepping through. A walker should never be used as part of prosthetic training unless the individual is so limited as to have used a walker before amputation. It is important for the physical therapist to know the type and function of the components of the prosthesis to appropriately plan training activities. Knee control with a microprocessor is different than with other types of transfemoral knee components.[50]

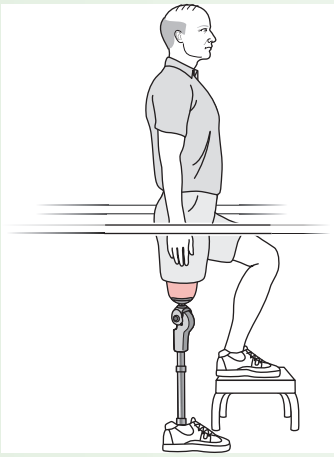
Box 22.7 Factors that Contribute to an Efficient Prosthetic Gait

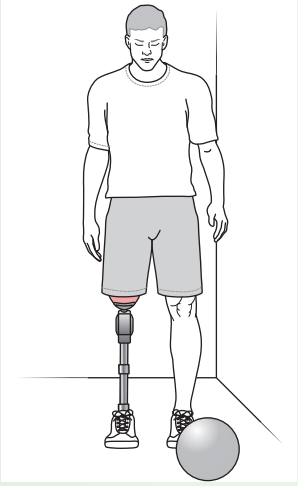
- Accept the weight of the body on each leg
- Balance on one foot in single-limb support
- Advance each limb forward and prepare for the next step
- Adapt to environmental demands

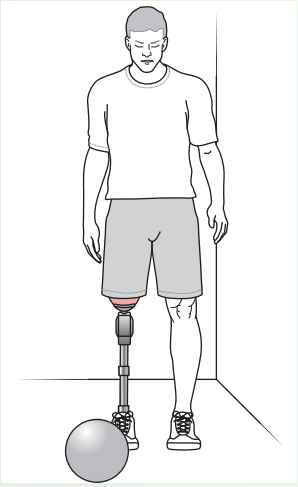
Table 22.3 Critical Training Elements











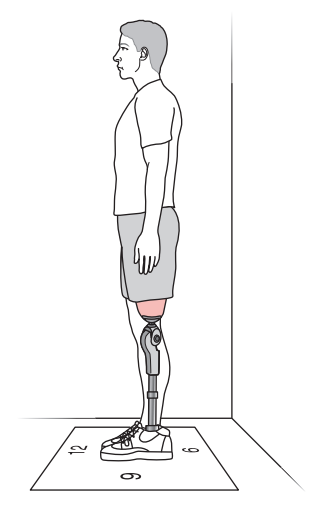
Element	Activity	Details
Stability—both legs (TT/TF) 	Secure standing without hand support; reaching for objects.	Hold an object a reachable distance; patient reaches and touches objects with either hand looking at object. Objects placed high/low/right/left encouraging goal-oriented weight shifting.
Knee control (TF) 	Secure standing without hand support; slightly bend and straighten prosthetic knee to varying degrees.	Encourage patient to develop kinesthetic feel of knee position by socket pressures.

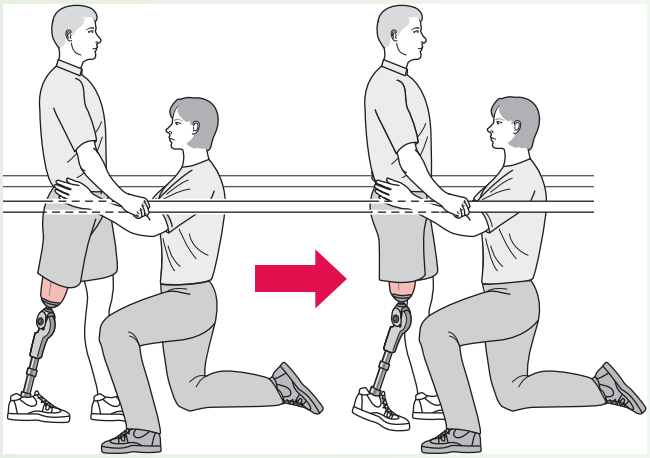
Table 22.3 Critical Training Elements—cont'd

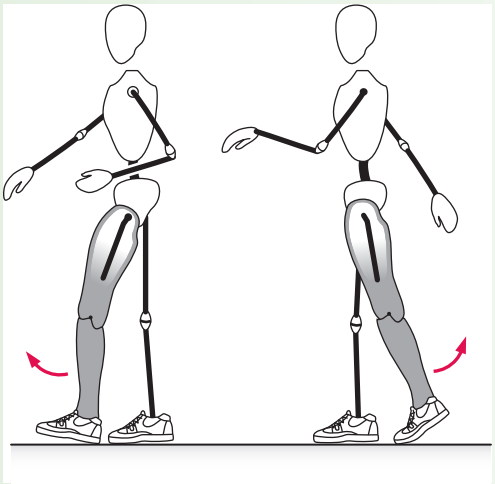
Element	Activity	Details
Stability on prosthesis (TT/TF) 	Secure standing without hand support; place 6–8-in stool directly in front of patient.	In a controlled manner, patient places unamputated foot on stool and back on the floor.
Stability on prosthesis (TT/TF) 	Secure standing without hand support; place soccer ball in front of unamputated leg.	In a controlled manner, patient kicks the ball with the unamputated foot.
Prosthetic control (TT/TF) 	Secure standing without hand support; place soccer ball in front of prosthesis.	In a controlled manner, patient kicks the ball with the prosthetic leg.

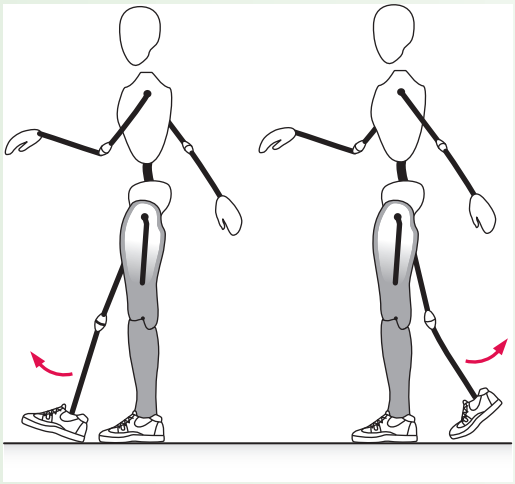
Continued

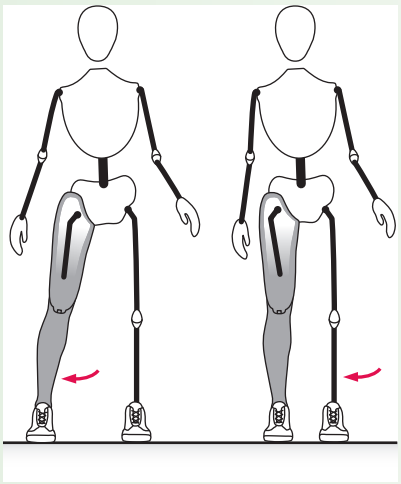
Table 22.3 Critical Training Elements—cont'd











Element	Activity	Details
Proprioception (TT/TF) 	Secure standing both legs on a piece of paper with a clock face drawn and without hand support.	On command, patient shifts weight to 12, 3, 6, and 9 o'clock in random order. Learns to recognize where prosthetic foot is in relation to weight-bearing.
Pelvic control (TT/TF) 	Secure standing without hand support prosthetic leg behind unamputated leg. Provide resistance to forward pelvic progression at initial contact to foot flat.	Encourage patient to transfer weight smoothly with forward and slight lateral pelvic motion by providing resistance as patient brings prosthesis forward.
Stepping with prosthesis (TT/TF) 	Secure standing without hand support, step forward and back with prosthesis.	Start with double leg stance, shift weight to unamputated leg and steps forward with prosthesis. Returns prosthesis to position behind sound leg. Emphasize knee control with TF.

Table 22.3 Critical Training Elements—cont'd

Element	Activity	Details
Stepping with sound leg (TT/TF) 	Secure standing without hand support, step forward and back with unamputated leg	As above but with unamputated leg. Make sure patient brings weight to forward part of foot before stepping on unamputated leg. Emphasize toe-off on TF to activate swing initiation.
Side stepping; backward stepping (TT/TF) 	Consecutive steps to the right, then to the left without hand support. Stepping backward several steps.	Side stepping, emphasize picking up the leg and placing it several inches to the side, then picking up the other leg to the first leg. TF backward stepping generally requires a larger prosthetic step than the unamputated for knee control.

From May and Lockard[26] pp. 136-141 with permission.
TT = patient with transtibial prosthesis; TF = patient with transfemoral prosthesis.

Many insurance companies, including Medicare, do not authorize very much time for gait training. Focusing the training initially on balance and integration of the prosthesis is more desirable than simply handing the patient a walker or crutches just to get him or her walking. If the patient can learn to balance on and off the prosthesis smoothly and feels a sense of control and integration of the prosthesis, he or she will progress further with less therapy than if started walking before the necessary balance was developed. Box 22.8 Evidence Summary presents studies addressing the inclusion of balance training strategies with gait training for patients with amputation.

Advanced Training

Changing the environment is an integral part of the gait training program. It is hardly functional to have the client walk only in the sheltered and simple environment of the physical therapy gym. Functional ambulation takes place in complex environments. Walking around furniture, through narrow doorways, on rugs, and around obstacles is very different from walking in the clear open space of the physical therapy gym. Placing obstacles on the floor to step around or over, walking in a busy hallway of the treatment center, picking something up from the floor, and carrying an object while walking are all more advanced activities that require balance, coordination, and the ability to shift one's weight on and off the prosthesis in different body positions. During advanced training, the client is taught to get up and down from chairs of different heights and seat resilience, especially toilet seats. An interesting obstacle course can be created using chairs, single steps, cones, and blocks to walk around, as well as different surfaces. Hofstad et al[51] studied delayed and decreased obstacle avoidance in individuals wearing one LE prosthesis. Level of amputation was not indicated but electromyography (EMG) was used to examine

Evidence Summary Box 22.8 Balance and Gait

Reference	Subjects	Design Intervention	Duration	Results	Comments
Curtze et al (2011)[a]	18 subjects with transtibial amputations and 17 matched subjects without amputation	Tracked walking on two irregular surfaces in the laboratory	4 trials on each surface	No statistically significant differences between groups.	Emphasizes importance of balance training in rehabilitation of patients with amputation.
Curtze et al (2010)[b]	17 subjects with transtibial amputation and 17 matched subjects without amputation	Forward fall was induced in laboratory setting by having subject on an inclinometer at a set angle with unexpected release	3 trials per subject leading with each leg	Statistically significant differences in response time, and knee flexion at heel strike between groups; no difference in step length, swing time of leading limb or trailing limb. Subjects with amputation used a longer step and showed less knee flexion when leading with prosthesis.	Authors emphasized the importance of incorporating balance and fall recovery activities as part of gait training following amputation.
Raya et al (2010)[c]	72 subjects with LE amputations ages 21–83 using prostheses	Tested for balance, hip strength, 6-Minute Walk Test, Amputee mobility predictor (AMP)	Strength 10 reps each motion AMP and 6-Minute Walk Test 1 time each	Hip abduction and extension strength strongest predictor of performance on 6-Min Walk Test and gait speed. Single-leg balance found important.	The 6-Minute Walk Test is useful to help identify musculoskeletal impairments. Hip strength and single-leg stance balance important.
Hlavackova et al (2009)[d]	12 elderly subjects with transfemoral amputations using prostheses	Subjects stood upright and immobile on plantar pressure data system, first in front of a wall, then in front of a mirror	Three 30-second trials for each condition	Significant decrease in pressure under sound limb when facing the mirror as compared to the wall. No concomitant significant increase in pressure under prosthetic limb.	Asymmetry in weight-bearing during quiet standing is common. Mirror feedback did somewhat increase weight-bearing on the prosthesis and could be used in training.
Vrieling et al (2008)[e]	8 subjects with amputation (3 transfemoral, 5 transtibial) and 9 subjects without amputation	CAREN balance system with anterior-posterior sway for 60 seconds (increasing for 15 sec, stable for 30 sec, decreasing for 15 sec)	3 randomized conditions: eyes open, blindfolded, and dual task with 60-second rest between	All subjects maintained balance through all tests. Subjects with amputation bore significant weight on the nonamputated limb and were more asymmetrical.	Subjects with amputations used the nonamputated limb for adjustment strategy and showed increased trunk movements. Suggests addressing asymmetry during gait training.

responses to obstacles. Results indicated that responses to obstacles were either delayed or decreased on both limbs regardless of which limb had the prosthesis. The authors suggested that obstacle training could be useful.[51]

Steps and Ramps

Individuals wearing transtibial prostheses generally have little difficulty mastering steps and ramps once they have achieved good balance and prosthetic control. Going up step-over-step requires good quadriceps strength and a medium to long residual limb. Some gait adaption may be needed for steep ramps or hills depending on the type of prosthetic foot. The more limitation of dorsiflexion, the harder it is to go up a steep hill step-over-step. Many individuals take a long step with the prosthesis and a shorter step with the unamputated foot. Going down a steep hill again requires good quadriceps strength and prosthetic control but is accomplished by most individuals.

The technique for going up and down stairs and ramps will vary for an individual wearing a transfemoral prosthesis depending on the type of knee component. Generally, the person will ascend stairs one step at a time leading with the unamputated leg. Individuals fitted with a stance phase control knee system will have to go down steps one at a time leading with the prosthesis. All others have the potential of going down step-over-step, although, except for the C-Leg and some hydraulic units, it requires considerable balance. It is necessary for the individual to place the prosthetic heel only on the step to create a flexion moment in the knee as weight is brought forward, thereby allowing the knee to flex and the person to bring the unamputated leg down to the lower step. The process is quite easy with the C-Leg, because the computer program is designed to allow smooth flexion as the person is going down steps or a ramp. Table 22.4 presents general techniques for some advanced activities for individuals with a transfemoral prosthesis. Once good balance, prosthetic control, and gait have been achieved, most individuals will develop their own method of doing each of these activities.

Table 22.4 Advanced Activities (Transfemoral)

Activity	Procedure
Sitting on the floor	Place the prosthesis about half a step behind the sound foot keeping the weight on the sound foot. Bend from the waist and flex at the knees and hips, reaching for the floor with both arms outstretched and pivoting to the sound side. Then, gradually lower the body to the floor. This activity is one continuous movement.
Getting up from the floor	Get on the hands and knees; place the sound leg forward, well under the trunk, with the foot flat on the floor while balancing on the hands and the prosthetic knee. Then, extend the sound knee while maintaining the weight over the sound leg. Move to an erect position by pushing strongly with the sound leg and the arms bringing the prosthesis forward when almost erect.
Kneeling	Place the sound foot ahead of the prosthetic foot keeping the weight on the sound leg. Slowly flex the trunk, hip, and knee until the prosthetic knee can be gently placed on the floor. Clients with transfemoral limbs usually kneel on the prosthetic leg. Getting up from a kneeling position is like getting up from the floor.
Picking up an object from the floor	Place the sound foot ahead of the prosthetic foot with the body weight remaining on the sound leg. Bend forward at the waist flexing the hips and knees until the object can be reached. Care must be taken to maintain the weight on the sound leg if wearing a mechanical knee. Some individuals like to bend sideways rather than forward, whereas others find it easier to keep the prosthetic knee straight and bend the sound leg until the object can be picked up.
Clearing obstacles	Face the obstacle with the sound foot slightly in front and the body weight on the prosthesis. Step over the obstacle with the sound leg, then transfer the body weight to the sound leg. Quickly extend the prosthetic hip, and forcefully flex the prosthetic hip whipping the prosthesis forward over the obstacle. Then step forward with a normal gait pattern. An alternate method is to stand sideways to the obstacle with the sound leg closest to the obstacle. With the weight on the prosthesis, swing the sound leg over the obstacle and transfer the body weight to the sound leg. Then swing the prosthesis forward, up and over the obstacle. The "C" leg and some hydraulic units may allow enough knee flexion to clear a small obstacle.

From May and Lockard,[26] p. 147.

SUMMARY

Most individuals with LE amputations can be helped to return to a full and useful life following the loss of a limb. A program of postoperative care that includes consideration of physical and emotional needs will enable most patients to become functional prosthetic users. Many prosthetic problems can be avoided by properly preparing the individual for prosthetic wear. In this chapter, concepts related to the postoperative and pre-prosthetic management of the individual with an LE amputation have been presented. Through a process of careful evaluation and open communication, a comprehensive program designed to meet the needs of an individual patient can be achieved.

Questions for Review

1. Compare and contrast the advantages and disadvantages of the following dressings: (a) compressible soft dressing; (b) semirigid dressing; and (c) immediate postoperative prosthesis.
2. What are the general goals of the postsurgical phase of amputation care?
3. What critical information would you provide a family member about patient positioning following a transtibial amputation?
4. A 72-year-old man with a history of diabetes, cardiovascular disease, and PVD has been referred for physical therapy 24 hours post right transtibial amputation for gangrene. What examination data are needed to plan an appropriate treatment program? Which are the most critical to obtain on the first visit?
5. What are the determinants of an efficient prosthetic gait?
6. Plan three training activities that could be used to improve stability while using prosthesis.

CASE STUDY

REFERRAL

The patient is a 72-year-old female status post–right transtibial amputation yesterday secondary to arteriosclerotic gangrene.

CURRENT MEDICAL HISTORY

Diabetes type 2 since age 48 controlled by insulin 20 units bid. Arteriosclerosis; hypertension controlled by medication; treated for ulcer plantar surface of right first metatarsal area for past 3 months. Ulcer did not heal leading to amputation.

PAST MEDICAL HISTORY

Hysterectomy at age 42, otherwise unremarkable.

SOCIAL HISTORY

Widow who lives alone. Three grown children and six grandchildren in the area.

PHYSICAL THERAPY EXAMINATION (INITIAL)

Chart Review

Patient alert and awake in no apparent distress. Right residual limb wrapped in soft gauze dressing covered with an elastic wrap. Drain in place. Incision clean on dressing change.
BP: 142/70, pulse 66, respiration normal.
Respiratory therapist reports patient using spirometer properly, normal cough, and no evidence of respiratory problems.
Patient complains of some pain in residual limb (pain medication prescribed).
Patient has been sitting at the side of the bed twice/day.

Examination Data

Gross muscle strength of left lower extremity (LE) and both upper extremities (UEs) grossly within functional limits (WFL). Muscle strength of right hip flexion, abduction, and adduction grossly WFL; hip extension tested side-lying and graded a 3+/5 (Fair+). Demonstrates active motion of right knee flexion and extension with no resistance given at this time.
Residual limb measurements deferred until initial healing has taken place.

Gross range of motion of left LE and both UEs WFL. Left hip extension measurements deferred until patient can lie prone or on right side. Gross range of motion (ROM) of the right hip WFL except hip extension to 0° measured side-lying. Right knee flexion and extension grossly WFL. Specific measurement deferred until dressing can be removed.

Left LE is hairless below the ankle. Skin is warm to touch. Popliteal pulse palpable but not dorsalis pedis pulse. Toes are warm to touch. Proprioceptive sensation intact. Diminished sensation over plantar surface of left foot and dorsum of first metatarsal. No evidence of edema in left LE. Sensation testing of right residual limb deferred secondary to dressing.

FUNCTIONAL STATUS

Bed Mobility

Rolling to left: independent; rolling to right and prone: not tested.

Supine-to-sit and return: modified independent (requires use of "rope ladder" attached to foot of bed).

Transfers

Sit-to-stand with walker: moderate assistance.

Stand-to-sit in chair or bed: moderate assistance.

Locomotion

Ambulation with walker: moderate assistance for 5 feet.

Expected outcomes of physical therapy episode of care (achieved before discharge from hospital):

1. The patient will be independent in all transfers.
2. The patient will be independent in ambulation with crutches or walker for 40 feet.
3. The patient will demonstrate knowledge of proper residual limb positioning, bandaging, and care.
4. The patient will demonstrate knowledge of basic residual limb exercises.
5. The patient will demonstrate knowledge of proper care of the left lower extremity.

PREPROSTHETIC HOME CARE PHYSICAL THERAPY

On discharge from the hospital, the patient was referred to home care physical therapy.

Examination Data

Examination data obtained following discharge from hospital by home care physical therapist:

Residual limb: Sutures in place, incision healing well, no drainage; length 13.6 cm (5.4 in) from medial tibial plateau (MTP).

Circumferential measurements from MTP:

- 5 cm (2 in) below MTP = 35 cm (14 in)
- 10 cm (4 in) below MTP = 38 cm (15 in)
- 12 cm (5 in) below MTP = 37 cm (14.5 in)

Sensation intact.

ROM right knee: WFL.

ROM right hip: extension to 0° (all other motions WFL).

Expected Outcomes

Expected outcomes for physical therapy episode of care during preprosthetic home care intervention:

1. The patient will be independent in care of residual limb including bandaging or using shrinker.
2. The patient will be independent in crutch (or walker) ambulation in and around the home and community.
3. The patient will be independent in home exercise program (HEP).
4. The patient will be independent in self-care and functional activities in the home.

Three months later the patient is fitted with a transtibial prosthesis (patellar tendon bearing [PTB] prosthesis with gel liner, suction suspension, and medium energy return prosthetic foot.

GUIDING QUESTIONS

1. The patient's residual limb was wrapped in a soft dressing after amputation. Compare the advantages and disadvantages of the rigid dressing, the semirigid dressing, and soft dressings. What problems might the patient incur with a soft dressing?
2. Review the initial examination data given for the patient. What data would be important to obtain on the first postoperative visit and what can be deferred? What other data would you obtain and when?

3. How would your evaluation change if your initial contact was after hospital discharge as a home health therapist?
   a. Describe your initial plan of interventions.
   b. Describe your mobility program.
4. What would be the focus of a prosthetic training program for this patient?
   a. Describe your initial balance training program.
   b. How would you teach this person to go up and down steps?

Arthritis

Maura Daly Iversen, PT, DPT, SD, MPH

Marie D. Westby, PT, PhD

Chapter 23

LEARNING OBJECTIVES

1. Describe the epidemiology, pathophysiology, disease course, and clinical manifestations of two common rheumatic diseases, rheumatoid arthritis and osteoarthritis, and be able to differentiate between these two conditions.
2. Identify the medical (clinical) diagnostic procedures commonly used in the examination of patients with arthritis, including laboratory tests and radiography.
3. Describe the medical management of individuals with rheumatoid arthritis and osteoarthritis.
4. Identify clinical examination and outcome measures commonly used in examining individuals with rheumatoid arthritis or osteoarthritis.
6. Discuss the rehabilitation management of individuals with arthritis.
7. Describe psychosocial, environmental, and other personal factors associated with arthritis that affect participation, achievement of anticipated goals, and expected outcomes.
8. Explain the importance of a team approach for persons with arthritis.
9. Analyze and interpret patient data, formulate realistic goals and outcomes, and develop a plan of care when presented with a clinical case study.

SURGICAL MANAGEMENT *1074*

SUMMARY *1075*

The terms *arthritis*, *rheumatism*, and *rheumatic disease* are generic references to an array of more than 100 diseases that are divided into 10 classification categories. Two major forms of arthritis are considered in this chapter. **Rheumatoid arthritis (RA)**, a systemic inflammatory disease, is considered in detail; **osteoarthritis (OA)**, a more localized process that has been known previously as **degenerative joint disease (DJD)**, is also discussed. Rheumatoid arthritis and osteoarthritis account for the majority of arthritis cases treated by physical therapists.

RHEUMATOID ARTHRITIS

RA is a major subclassification within the category of diffuse inflammatory connective tissue diseases that also includes juvenile arthritis, systemic lupus erythematosus (SLE), progressive systemic sclerosis or scleroderma, polymyositis, and dermatomyositis. Rheumatoid arthritis is primarily a disease of the **synovium**. The first clinical description of RA is attributed to A. J. Landre-Beauvais in 1800, although analysis of pictorial art of the late Renaissance suggests the existence of RA in earlier times. Early descriptions of patient symptomatology were

complicated by the lack of uniform agreement about the distinguishing disease characteristics, given its wide spectrum of clinical presentations. The term *rheumatoid arthritis* was first used by Garrod in 1858, but was not accepted by the American Rheumatism Association (ARA) as the official terminology until 1941.[1] Diagnostic criteria and terminology have been developed and, in some cases, revised based on current data.[2,3]

Epidemiology

The estimated prevalence of RA among adults in the United States is approximately 1.3 million,[4] and prevalence increases with age. Women are effected two to four times more often than men. Differences in prevalence exist among certain subpopulations, which suggest a possible role for genetic or environmental factors in the etiology of the disease. For example, African Americans may have a lower prevalence of RA than whites, whereas several Native American groups demonstrate higher prevalence rates. There also is a lower prevalence of RA in native Japanese and native Chinese peoples compared to whites.[4,5]

Etiology

RA is an autoimmune disease of unknown complex etiology. RA is presently believed to have a genetic basis demonstrated by the increased disease risk and clustering in families.[6] Briefly, an **antigen** is a substance, usually foreign to the host, that provokes the immune system into action. The immune system may respond to the antigen directly (cellular immunity) or by the production of **antibodies** that circulate in the serum (humoral immunity). These responses involve two general types of lymphocytes: T cells, which are responsible for cellular immunity, and B cells, which produce circulating antibodies specific to the antigen. Antibodies are immunoglobulins, a type of serum protein.[1]

Given that individuals with RA produce antibodies to their own immunoglobulins, such as rheumatoid factor (RF) and anti–citrullinated protein antibody (ACPA), and these antibodies precede the clinical presentation of RA by years,[7,8] RA is considered an autoimmune disease.[9] It is not clear, however, whether this antibody production is a primary event or results as a response to a specific antigen from an external stimulus. Current theory and research on the cellular basis of autoimmunity suggest that aberrant functioning of cell-mediated immunity and defective T lymphocytes may trigger the autoimmune response that underlies RA.[9] A specific etiological agent for RA has not been identified, even though specific external agents may trigger disease expression.

The external agents that may initiate arthritis do so through various and differing mechanisms. For example, studies of smoking exposure suggest a strong association with tobacco smoke and manifestations of RA symptoms.[10] Bacterial organisms, including streptococcus, clostridia, diphtheroids, and mycoplasmas, have been suggested as triggers but no connections have been definitively proven. There has also been discussion of a viral etiology for RA. As with other investigations seeking to identify an etiology for RA, research remains speculative.[1]

Rheumatoid factors (RFs) are antibodies specific to immunoglobulin G (IgG) and are found in the sera of approximately 70% of all patients with RA. Current theory suggests that RFs arise as antibodies to "altered" autologous (the patient's own) IgG. Some modification of IgG changes its configuration and renders it an autoimmunogen, stimulating the production of RF. IgM is the first class of immunoglobulins formed after contact with an antigen and most RFs are of this class, although RFs may be of any immunoglobulin class.[1] The exact biological role of RF is unknown. Although RF has been implicated in the pathogenesis of RA, the disease occurs in the absence of RF in a substantial number of individuals.[10] Research indicates that the presence of RF affects disease severity, because those who have RF, or seropositive disease, have increased frequency of subcutaneous nodules, vasculitis, and polyarticular involvement.[1]

Ollier and Worthington[6] examined the literature investigating a genetic predisposition to the development of RA.[6] Human leukocyte antigens (HLAs) found on the surface of most human cells are capable of generating an **immune response** when genetically incompatible tissues are grafted to each other, for example, during organ transplants. Genes controlling these HLAs are found on the sixth chromosome. Four loci have been described: HLA-A, HLA-B, HLA-C, and HLA-D. RA has been associated with increased HLA-D and HLA-DR (D-related) antigens, suggesting that certain genes determine whether a host is more or less at risk for an immunological response that leads to RA.[6] A "rheumatoid **epitope**" has been identified through DNA typing of HLA-DR4 as a particular sequence of amino acids common among patients with RA.[11] A recent national case-control study conducted in Sweden focused on citrulline-modified proteins, proteins not normally present in healthy adults but found in about two-thirds of patients with RA, to determine if smoking and the presence of shared epitope (SE) HLA genes triggered RA. The investigators concluded that the interaction of smoking and carrying two copies of the SE gene increases the risk of developing RA by 21-fold.[12] Further studies of genomic organization of the HLA-D region specifically implicate a short sequence on the HLA-DRB1 gene and suggest that HLA-DRB1 alleles (alternate forms of a gene) modify disease expression and progression.[1] Various studies of different ethnic groups have also shown that particular variations of the HLA-DRB1 allele are overrepresented in people with RA.[1]

Pathophysiology

In early RA, synovial inflammation leads to pain, stiffness, and restricted range of motion (ROM). As the

disease progresses, the joint capsule becomes inflamed and immune cells degrade the cartilage. With long-standing RA the synovium appears grossly edematous with slender villous or hair-like projections into the joint cavity (Fig. 23.1). Distinctive vascular changes, including venous distention, capillary obstruction, neutrophilic infiltration of the arterial walls, and areas of thrombosis and hemorrhage, may be evident. Synovial proliferation of vascular granulation tissue, known as **pannus**, dissolves collagen as it extends over the joint cartilage. Eventually, with disease progression, the granulation tissue leads to adhesions, **fibrosis,** or bony **ankylosis** of the joint. Chronic inflammation associated with RA weakens the joint capsule and its supporting ligamentous structures, altering joint structure and function. Tendon rupture and fraying tendon sheaths produce imbalanced muscle pull on pathologically altered joints resulting in the characteristic musculoskeletal deformities seen in advanced RA.[13]

Following alterations in blood flow, rapid changes in the cellular content and volume of the synovial fluid may result owing to low pressure in the joint space and the lack of a limiting membrane between the joint space and synovial blood vessels. High-molecular-weight substances such as macroglobulins and fibrinogens can pass through the synovial capillaries during periods of inflammation and are not easily cleared.[1] Antigen-antibody complexes may be isolated within the joint cavity and stimulate phagocytosis and further development of pannus. Although sustained **synovitis** requires the proliferation of new blood vessels, the exact mechanism of capillary growth is not understood. One hypothesis suggests that activated macrophages, responding to antigen-antibody complexes, may stimulate this development. With established synovitis, polymorphonuclear (PMN) leukocytes are drawn into the joint cavity and coupled with lysosomal enzyme activity contribute to destruction of synovial tissues.[9]

Laboratory Tests

Sensitivity and specificity are two concepts of testing that are useful in explaining the value of laboratory tests in the detection of RA. Test ***sensitivity*** is the proportion of truly diseased individuals who have tested positive. The clinical value of sensitive tests is particularly important when a misdiagnosis (informing the patient that he or she does not have the disease when in fact the patient does have RA) would be deleterious to the health of the patient. In research terms, sensitivity is equivalent to the laboratory test's ability to avoid a false-negative result. ***Specificity,*** on the other hand, refers to the proportion of truly nondiseased individuals who have a negative test. In other words, the specificity of a laboratory test is a measure of its ability to avoid false positives. A diagnostician usually uses a combination of sensitive and specific tests to confirm clinical impressions during the diagnostic process.

Elevated ***erythrocyte sedimentation rate*** *(ESR)* and ***C-reactive protein (CRP)*** are acute phase reactants that indicate the presence of active inflammation. Although patients with RA characteristically have active inflammation, up to 40% may have normal values for these tests despite clinical evidence of inflammation. Normal ESR and CRP values are nonspecific and alone cannot confirm or refute a diagnosis of RA. RF is the result of the binding of two immunoglobulins. The presence or absence of RF alone neither confirms nor rules out a diagnosis of RA. Nearly 25% of people with RA do not have a positive RF (seronegative RA), whereas a positive RF is seen in a number of other immunologic conditions (e.g., leprosy, tuberculosis, chronic hepatitis) and occasionally in individuals with no disease. A positive RF in combination with clinical criteria may help to confirm a clinical impression.

A ***complete blood count*** *(CBC)* is routinely ordered because a number of findings are commonly associated with RA. Red blood cell counts are often decreased, indicating the anemia of chronic disease found in approximately 20% of individuals with RA. By comparison, the white blood cell count is generally normal. *Thrombocytosis,* a high platelet count, is not uncommon in active RA.

Synovial fluid analysis can greatly enhance the process of differential diagnosis. Normal synovial fluid is transparent, yellowish, viscous, and without clots. Synovial fluid from inflamed joints is cloudy, less viscous owing to a change in hyaluronate proteins, and will clot. Significant

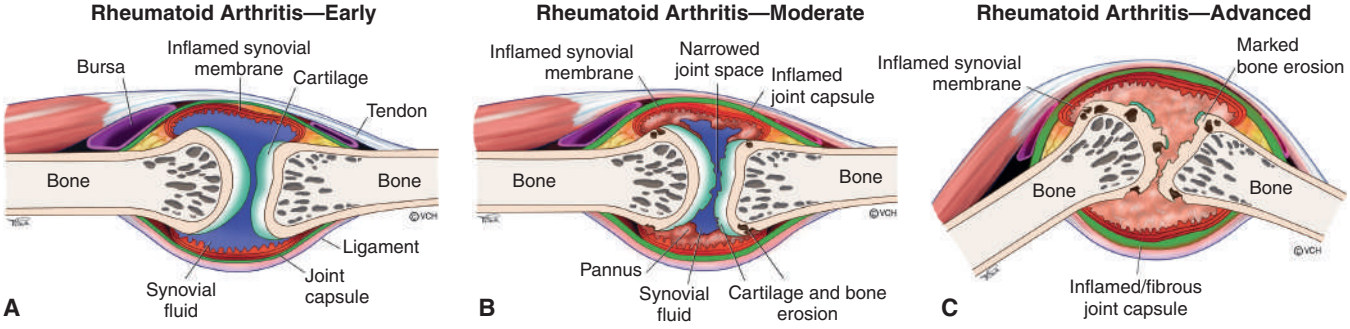

Figure 23.1 Progression of joint changes due to RA inflammation: Early to advanced disease.
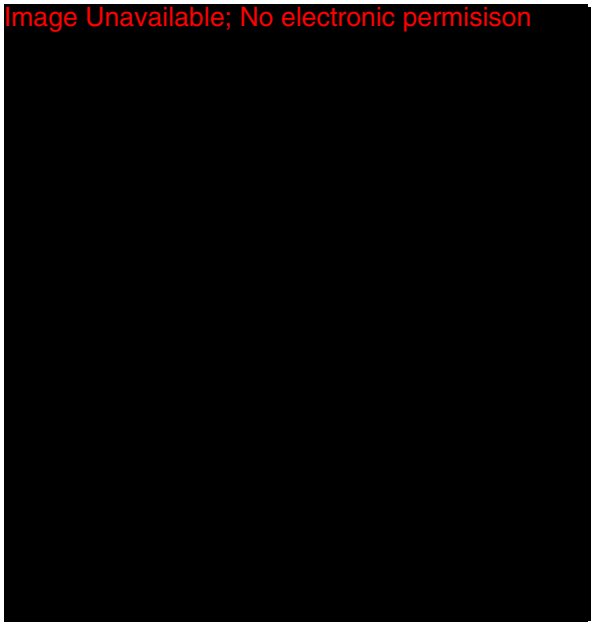
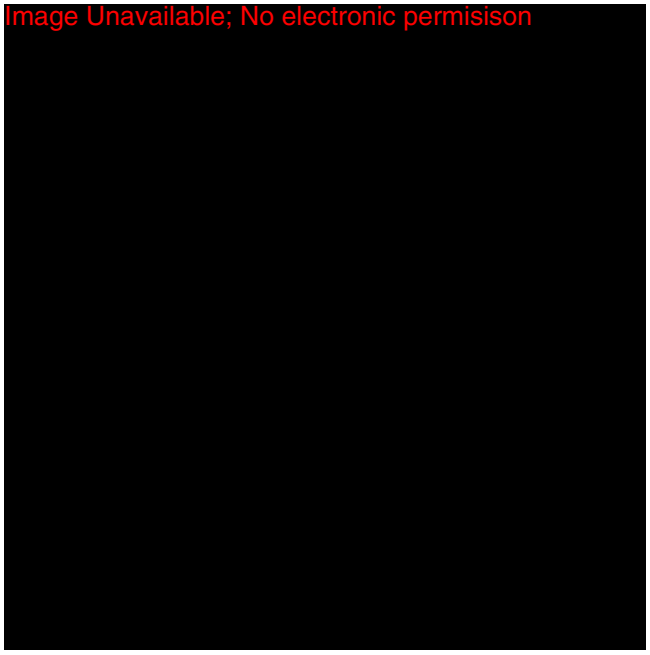
From Mary Pack Arthritis Program, Vancouver Coastal Health, with permission.



inflammation also increases the number of fluid proteins. A culture can be performed to identify potential bacterial agents as the cause of joint inflammation. If the joint is inflamed, white blood cells will elevated in the fluid. Crystals are not common. If present they may confirm the diagnosis of **gout** (urate crystals) or *pseudogout* (calcium pyrophosphate crystals). A mucin clot test (a measure of viscosity) of the synovial fluid can be used to discriminate between acute infectious arthritis and inflammatory arthritis, such as RA. Poor clotting accompanies acute infectious arthritis whereas RA produces fair mucin clotting.[1]



Radiography

Radiographic study is essential in a diagnostic workup for RA. Physical therapists practicing in rheumatology should develop a basic proficiency in identifying abnormalities in joint structure and the surrounding soft tissues as these abnormalities influence the course and outcome of rehabilitation. To identify radiographic abnormalities, the therapist must be able to describe how a normal joint appears on a radiograph. Therapists can orient themselves to a radiograph by considering several parameters: alignment, bone density and surface, and cartilaginous spacing (Figs. 23.2 and 23.3). Normal alignment is present when the long axes of the proximal and distal bones of the joint are in their normal spatial relationships and the convex surface of one bone fits well with the concavity of the other. Bone density, in the absence of **osteoporosis**, should be somewhat opaque and milky and appear evenly distributed throughout. The cortices of each bone should be distinct, appropriately thick, and well defined. The joint soft tissues should conform to known anatomical shape. Soft tissue swelling and evidence of uneven spacing between joint surfaces on radiograph may suggest activity limitations. Uneven, reduced, or absent spacing suggests joint cartilage loss or joint surface erosion. A normal joint surface should be smooth and conform to known anatomical shape without osteophytes. RA progression can be characterized in four sequential stages using periodic radiographic examination (Box 23.1). Radiographic changes evident in early RA are nonspecific and usually limited to soft tissue swelling, joint effusion, and periarticular demineralization. Diagnostic confirmation is made when the disease process leads to bilateral joint space narrowing and erosions in the hands and feet.[1]

Classification and Diagnostic Criteria

The differential diagnosis of RA is predicated on the history, clinical examination of signs and symptoms, and careful exclusion of other disorders. The American College of Rheumatology (ACR) classification criteria,[2] developed using data from patients in outpatient clinics, are commonly used to confirm whether an individual's clinical presentation should be confirmed as a case of RA. Originally these criteria had four classifications of RA: classical, definite, probable, and possible. Some of these classifications were judged to be problematic. The 1987 revised criteria are presented in Table 23.1. In 2010 the ACR and the European League Against Rheumatism (EULAR) revised the 1987 classification criteria for RA[2] to help identify early RA. These criteria are based on a combination of signs, symptoms, and laboratory findings that have persisted for a specified period of time.[3] A diagnosis of definite RA is now established on the confirmed presence of synovitis in at least one joint, absence of an alternative diagnosis that better explains the synovitis, and a total score of 6 or greater (out of a possible 10) from four domains (Table 23.2). The domains are (1)*Joint Involvement,* designating the number and site of involved joints (score range 0–5); (2)*Serology,* indicating serologic abnormalities (score range 0–3);

Box 23.1 Classification of Progression of Rheumatoid Arthritis

Stage I, Early

1. No destructive changes on radiographic examination.[a]
2. Radiographic evidence of osteoporosis may be present.

Stage II, Moderate

1. Radiographic evidence of osteoporosis, with or without slight subchondral bone destruction; slight cartilage destruction may be present.[a]
2. No joint deformities, although limitation of joint mobility may be present.[a]
3. Adjacent muscle atrophy.
4. Extra-articular soft tissue lesions, such as nodules and tenosynovitis, may be present.

Stage III, Severe

1. Radiographic evidence of cartilage and bone destruction, in addition to osteoporosis.[a]
2. Joint deformity, such as subluxation, ulnar deviation, or hyperextension, without fibrous or bony ankylosis.[a]
3. Extensive muscle atrophy.
4. Extra-articular soft tissue lesions, such as nodules and tenosynovitis, may be present.

Stage IV, Terminal

1. Fibrous or bony ankylosis[a]
2. Criteria of stage III

From Schumacher, Klippel, and Robinson (eds): Primer on Rheumatic Diseases, ed 9. Arthritis Foundation, Atlanta, 1988, p 318, with permission.
[a]These criteria must be present to permit classification of a patient in any particular stage or grade.

(3)*Acute-Phase Reactants,* describing elevated acute-phase response (score range 0–1); and (4)*Duration of Symptom* (2 levels; range 0–1).[3] The inclusion of criteria for early RA may help rheumatologists to target treatment at earlier stages of the disease and decrease RA progression.

Patients with RA can also be classified based on global functional status criteria.[14] There are four functional classifications based on a person's ability to complete functional and self-care activities ranging from independence to full dependence. In addition to their clinical relevance, these functional classifications enable clinicians and researchers to classify subjects in clinical trials and inform evidence-based clinical recommendations for therapies(Table 23.3).

Disease Onset and Course

RA is commonly characterized by an exacerbating and remitting disease course. Disease onset is accompanied by complaints of generalized joint pain and stiffness, usually in multiple small joints (**polyarthritis**) though it may be localized to a single joint. Symptoms may appear spontaneously or over a prolonged period of time. Disease progression is highly variable. High titers of RF indicate a more severe disease course. Spontaneous remissions can occur. Some patients experience an intermittent course, characterized by partial to complete remissions longer than the periods of exacerbations. A third group of patients experience the full unremitting destructive process of progressive RA.[1] Comparisons of elderly-onset RA with early-onset RA revealed that abrupt onset and large joint involvement, particularly of the shoulder girdle, were more common in the older adults. The elderly-onset

Table 23.1 The 1987 Revised Criteria for the Classification of Rheumatoid Arthritis[a]

Criterion	Definition
1. Morning stiffness	Morning stiffness in and around the joints, lasting at least one hour before maximal improvement.
2. Arthritis of three or more joint areas	At least three joint areas simultaneously have had soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician. The 14 possible areas are right or left PIP, MCP, wrist, elbow, knee, ankle, and MTP joints.
3. Arthritis of hand joints	At least one area swollen (as defined above) in a wrist, MCP, or PIP joint.
4. Symmetrical arthritis	Simultaneous involvement of the same joint areas (as defined in 2) on both sides of the body (bilateral involvement of PIPs, MCPs, or MTPs is acceptable without absolute symmetry).
5. Rheumatoid nodules	Subcutaneous nodules, over bony prominences, or extensor surfaces, or in juxta-articular regions, observed by a physician.
6. Serum rheumatoid factor	Demonstration of abnormal amounts of serum rheumatoid factor by any method for which the result has been positive in <5% of normal control subjects.
7. Radiographic changes	Radiographic changes typical of rheumatoid arthritis on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints (osteoarthritis changes alone do not qualify).

From Arnett et al,[2, p. 319] with permission.
[a]For classification purposes, a patient shall be said to have rheumatoid arthritis if he or she has satisfied at least four of these seven criteria. Criteria 1 through 4 must have been present for at least 6 weeks. Patients with two clinical diagnoses are not excluded. Designation as classic, definite, or probable rheumatoid arthritis is *not* to be made.

Table 23.2 The 2010 American College of Rheumatology/European League Against Rheumatism Classification Criteria for Rheumatoid Arthritis

Target population (Who should be tested?): Patients who
1. have at least 1 joint with definite clinical synovitis (swelling)*
2. with the synovitis not better explained by another disease.†
Classification criteria for RA (score-based algorithm: add score of categories A–D; a score of 6/10 is needed for classification of a patient as having definite RA)‡

	Score
A. Joint involvement§	
1 large joint¶	0
2–10 large joints	1
1–3 small joints (with or without involvement of large joints)#	2
4–10 small joints (with or without involvement of large joints)	3
> 10 joints (at least 1 small joint)**	5
B. Serology (at least 1 test result is needed for classification)††	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-phase reactants (at least 1 test result is needed for classification)‡‡	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of symptoms§§	
< 6 weeks	0
≥ 6 weeks	1

*The criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of rheumatoid arthritis (RA) with a history compatible with prior fulfillment of the 2010 criteria should be classified as having RA. Patients with long-standing disease, including those whose disease is inactive (with or without treatment) who, based on retrospectively available data, have previously fulfilled the 2010 criteria should be classified as having RA.

†Differential diagnoses vary among patients with different presentations, but may include conditions such as systemic lupus erythematosus, psoriatic arthritis, and gout. If it is unclear about the relevant differential diagnoses to consider, an expert rheumatologist should be consulted.

‡Although patients with a score of 6/10 are not classifiable as having RA, their status can be reassessed and the criteria might be fulfilled cumulatively over time.

§Joint involvement refers to any swollen or tender joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first carpometacarpal joints, and first metatarsophalangeal joints are excluded from assessment. Categories of joint distribution are classified according to the location and number of involved joints, with placement into the highest category possible based on the pattern of joint involvement.

¶"Large joints" refers to shoulders, elbows, hips, knees, and ankles.

#"Small joints" refers to the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists.

**In this category, at least 1 of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular, and so forth).

††Negative refers to IU values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to IU values that are higher than the ULN but 3 times the ULN for the laboratory and assay; high-positive refers to IU values that are 3 times the ULN for the laboratory and assay. Where rheumatoid factor (RF) information is only available as positive or negative, a positive result should be scored as low-positive for RF. ACPA = anti–citrullinated protein antibody.

‡‡Normal/abnormal is determined by local laboratory standards. CRP = C-reactive protein; ESR = erythrocyte sedimentation rate.

§§Duration of symptoms refers to patient self-report of the duration of signs or symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

Aletaha, D, Neogi, T, Silman, AJ, et al: Rheumatoid arthritis classification criteria. Arthritis Rheum 62:2569–2581, 2010, with permission.

Table 23.3 American College of Rheumatology Revised Criteria for Classification of Functional Status in Rheumatoid Arthritis[a]

Class I	Completely able to perform usual activities of daily living (self-care, vocational, and avocational)
Class II	Able to perform usual self-care and vocational activities, but limited in avocational activities
Class III	Able to perform usual self-care activities, but limited in vocational and avocational activities
Class IV	Limited in ability to perform usual self-care, vocational, and avocational activities

From Hochberg, MC, et al: The American College of Rheumatology 1991 revised criteria for the classification of global functional status in rheumatoid arthritis. Arthritis Rheum 35:498, 1992, with permission.

[a]Usual self-care activities include dressing, feeding, bathing, grooming, and toileting. Avocational (recreational and/or leisure) and vocational (work, school, homemaking) activities are patient-desired and age- and sex-specific.

group demonstrated clinical features more commonly associated with *polymyalgia rheumatica,* a separate and distinct disease affecting the shoulder and pelvic musculature leading to muscle inflammation.[15]

Clinical Presentation

Systemic

Systemic features of RA include weight loss, fever, and extreme fatigue. Fatigue greatly affects function and participation in daily life and is often underappreciated on physical examination.[16] A hallmark clinical feature of RA is *morning stiffness* in and around the joints lasting at least 1 hour before maximal improvement.[3] In contrast, OA-induced stiffness results from inactivity. Morning stiffness can be qualified in terms of its severity and duration, both of which are directly related to the degree of disease activity.

Joint Impairments (Articular and Nonarticular)

RA is characterized by bilateral and symmetrical synovial joint involvement. Clinically, patients present with limited mobility and signs of inflammation including pain, redness, swelling, and warm joints. The most common joints involved are the hands, feet, and cervical spine with the hands generally affected early in the disease course.[16] The term **arthralgia** refers to joint pain. The joint examination may reveal **crepitus**, an audible or palpable grating or crunching evident as the joint is moved through its ROM. Crepitus is the result of uneven degeneration of the joint surface.

Cervical Spine and Temporomandibular Joint

The cervical spine is often involved in RA and on examination ROM may be limited in all planes. The occipitoatlantal (occiput–C1) and atlantoaxial (C1–C2) joints are frequently affected due to their extensive synovial tissue. The midcervical region is also a common site of inflammation, leading to decreased ROM, particularly in rotation, accompanied by instability. Three patterns of cervical spine involvement are described: atlantoaxial subluxation (65%), atlantoaxial impaction (20% to 25%), and subaxial subluxation (10% to 15%).[17] Involvement of the C1 and C2 vertebrae may produce life-threatening situations if the transverse ligament of the atlas should rupture or if the odontoid process should fracture or herniate through the foramen magnum, compressing the upper cervical cord. Patients presenting with cervical radiculopathy and neurological signs should be immediately referred to a physician. Magnetic resonance imaging (MRI) is the most effective tool to visualize both the spinal column and the cord.[17] **Ankylosing** (i.e., fusion) of one or more vertebrae of the spine may accompany RA and can lead to loss of ROM and function of the involved joints.

The temporomandibular joint (TMJ) is usually among the last joints involved. Inflammation of the TMJ results in pain, swelling, and limited movement and eventually to ankylosis. With juvenile RA involvement of the TMJ can lead to destruction of the condyle and potential alterations in mandibular growth and facial deformity. With early disease, TMJ x-rays are usually negative but with time and chronic inflammation can demonstrate bone destruction, which may affect the child's ability to open the mouth fully (approximately 2 in [5.08 cm]) with normal side-to-side gliding and protrusion. In resting position, the normal approximation of the upper and lower teeth may be altered following persistent inflammation.[18]

Shoulders and Elbows

Shoulder involvement may be evident in the glenohumeral, sternoclavicular, or acromioclavicular joints leading to joint surface degeneration, pain, and loss of ROM. Shoulder pain is often referred to the deltoid region. The scapulothoracic articulation may secondarily exhibit a loss of ROM as well. Chronic shoulder inflammation causes the capsule and the ligaments to become distended and thinned. As joint surfaces erode, the shoulder eventually becomes unstable. In addition, **tendinitis** and **bursitis** may complicate management.[18] Typical elbow joint findings include effusions between the lateral epicondyle and olecranon prominence, bilateral swelling of the olecranon bursa (more prevalent with severe disease), and rheumatoid nodules on the olecranon or extensor surface of the proximal ulna.[17] Inflammation, capsular and ligamentous distention, and joint erosion may lead to instability and irregular or catching movements. Flexion contractures frequently develop, due to patient posturing to reduce pain and persistent spasm.

Wrists

Early synovitis among the carpal bones and the ulna leads to a fairly rapid development of a flexion contracture, which ultimately diminishes the individual's ability to grasp. Additionally, **carpal tunnel syndrome** may occur due to compression of the median nerve in the carpal tunnel. Chronic inflammation around the ulnar styloid coupled with laxity of the radioulnar ligament produces the *piano key sign* on examination. The piano key sign is defined as an up and down movement of the styloid in response to point pressure from the examiner. Over time ulnar deviation or drift may occur from chronic inflammation causing movement of the wrist toward the ulna (Fig. 23.4). Chronic inflammation of the proximal row of carpals can lead to a volar **subluxation** of the wrist and hand on the radius, accentuating the normal 10° to 15° of volar inclination of the carpus on the distal radius (Fig. 23.5). In addition, radial deviation of the distal carpals can occur due to loss of radial ligamentous support, destruction of the extensor carpi ulnaris and the fibrocartilage on the distal side of the ulna. This allows the proximal carpals to slide down the distal radius toward the ulna, contributing to radial deviation of the distal row of carpals relative to the two bones of the forearm, where normally there is 5° to 10° of ulnar deviation.[19] Stenosing tenosynovitis of the first dorsal compartment of the wrist (*deQuervain's disease*) may also occur.

Hand Joints

Metacarpophalangeal Soft-tissue swelling around the metacarpophalangeal (MCP) joints, especially the index and long fingers, is common. The volar subluxation and **ulnar drift** of the MCPs frequently seen in RA results from exaggeration of the joints' normal structural shape that tilt the proximal phalanges in an ulnar direction.

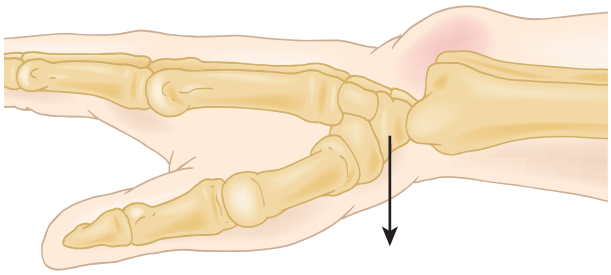


Figure 23.5 Volar subluxation of the wrist seen with rheumatoid arthritis. The chronic inflammation of the proximal carpals can eventually lead to a volar subluxation of the wrist and hand on the radius, accentuating the normal 10° to 15° of volar inclination of the carpus on the distal radius.

The anatomical placement and length of the collateral ligaments, which are most stretched during MCP flexion, and the insertions of the intrinsics, which also pull from an ulnar direction, contribute to ulnar drift at the MCPs during hand motion. Weakened ligaments cannot resist a pull toward volar subluxation during power pinch or grasp when flexor tendons bowstring across MCPs through frayed tendon sheaths damaged by long-term synovitis. The *bowstring effect* results from moving the fulcrum of the flexor tendons distally, placing an ulnar and volar pull on the proximal phalanges (Fig. 23.6). Radial deviation of the carpals further enhances MCP ulnar drift as the phalanges try to compensate for the loss of normal ulnar deviation at the wrist. This is known as the *zigzag effect,* where forces in the hand try to move the index finger back into its normal functional position in line with the radius. A **trigger finger** may be evident whereby a snapping sensation is

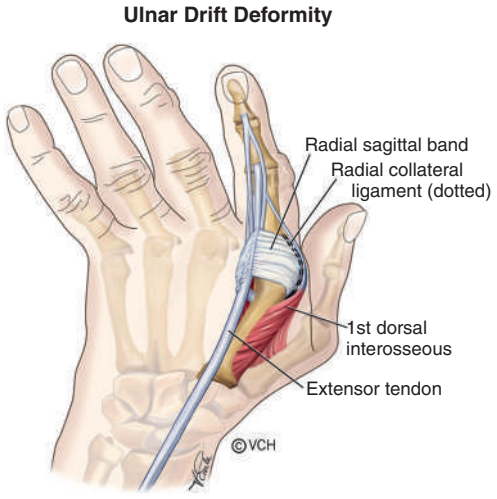

Figure 23.4 Ulnar drift (deviation) of the fingers. This drawing depicts the impact of metacarpophalangeal joint swelling, soft tissue laxity due to synovitis, which leads to ulnar deviation of the fingers in RA.

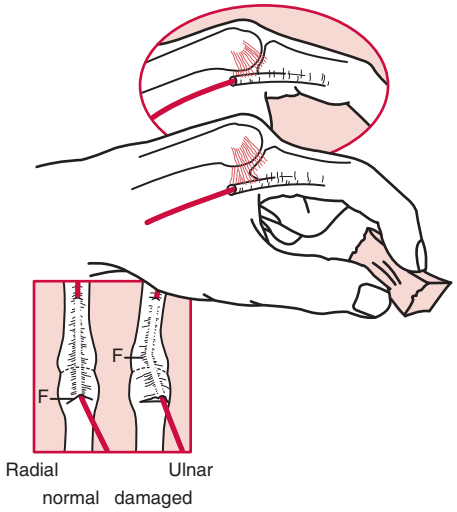

Figure 23.6 Influence of the long flexors (F) in metacarpophalangeal drift deformity. *Adapted from Melvin,[19, p. 283] with permission.*

felt when flexing or extending the finger due to flexor tenosynovitis and resultant slippage of the tendon, friction with movement, or presence of tendon nodules.[17,20]

Proximal Interphalangeal Swelling of the proximal interphalangeal (PIP) joints is common and is easily appreciated with lateral joint palpation. There are two characteristic irreversible deformities (if not surgically repaired early) seen at the PIPs in individuals with severe RA. The first of these is known as **swan neck deformity** and consists of PIP hyperextension and distal interphalangeal (DIP) flexion (Fig. 23.7). Swan neck deformities arise in three distinct ways, depending on the site of initial involvement. Most commonly, swan neck deformity follows from initial synovitis of the MCP, where the pain of chronic synovitis leads to reflex muscle spasm of the intrinsics. The biomechanical force of the intrinsics then combines with the hypermobility found in the chronically inflamed and structurally changed PIP, resulting in volar subluxation and PIP hyperextension. Swan neck deformity may also result when the volar capsule of the PIP is stretched, the lateral bands move dorsally, and tension is placed on the flexor digitorum profundis by the PIP flexes the DIP. In these instances, a rupture of the flexor digitorum sublimus further predisposes an individual to swan neck deformity. A third mechanism for developing swan neck deformity involves a rupture of the extensor digitorum communis at its insertion on the DIP resulting in DIP flexion and PIP hyperextension owing to unrestrained pull by the flexor digitorum profundis.[17,19]

The other characteristic deformity of the PIP is known as a ***boutonniere deformity*** and consists of DIP extension with PIP flexion (Fig. 23.8). As a result of chronic synovitis, the insertion of extensor digitorum communis into the middle phalanx (known as the central slip) lengthens, and the lateral bands slide volarly to force the PIP into flexion. Bony formation or outgrowths around the end of a joint are termed ***osteophytes.*** Those found at the PIP are known as ***Bouchard's nodes,*** and may be seen in OA. They are unrelated to RA, although an individual may have both kinds of arthritis at the same time.[17,20]

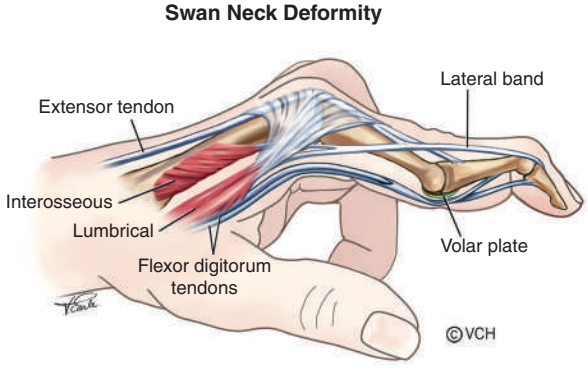

Figure 23.7 Swan neck deformity is characterized by PIP hyperextension and DIP flexion. *From Mary Pack Arthritis Program, Vancouver Coastal Health, with permission.*

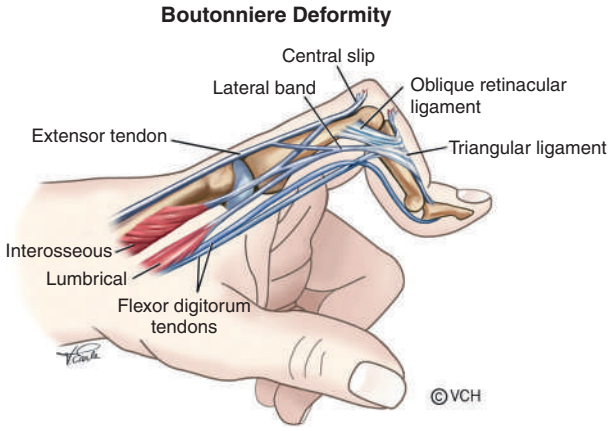

Figure 23.8 Features of a boutonniere deformity include DIP extension with PIP flexion. *From Mary Pack Arthritis Program, Vancouver Coastal Health, with permission.*

Distal Interphalangeal The distal interphalangeal (DIP) joints are rarely affected in RA. Osteophytes are, however, common in OA and are called ***Heberden's nodes.*** Occasionally, a ***mallet finger*** deformity will result from rupture of the tendon of the extensor digitorum communis, pulling the DIP into flexion as force from the flexor digitorum profundis is unopposed.[20]

Thumb A number of deformities can occur in the thumb due to synovitis. The most prevalent is a **flail IP** in which the patient loses the ability to flex the interphalangeal (IP) joint. The fibers of the dorsal hood mechanism over the MCP, the joint capsule and the collateral ligaments, and the tendons of extensor pollicis brevis and extensor pollicis longus are particularly affected. The exact mechanism of thumb deformities depends on the particular combination of affected structures. Similar to other hand deformities, the actual presentation depends on the site of initial synovitis, the direction of imbalanced muscle forces, and the integrity of the surrounding joint structures. A *type I deformity*, consisting of MCP flexion with IP hyperextension without involvement of the carpometacarpal (CMC) joint, is most commonly seen. *Type II deformity* is assigned when the CMC is subluxed and the IP is held in hyperextension. CMC subluxation and MCP hyperextension is classified as a *type III deformity*, and is more common in RA than a type II deformity.[17-20]

Mutilans Deformity (Opera-Glass Hand) Grossly unstable thumbs and severely deformed phalanges are indicative of *mutilans-type deformity.* Also known as opera-glass hand, the transverse folds of the skin of the thumb and fingers resemble a folded telescope. Radiographic study of the bones of the hand reveal severe bone resorption, erosion, and shortening of the MCP, PIP, radiocarpal, and radioulnar joints especially. The negative impact of this deformity on hand function and activities of daily living (ADL) is significant.[20]

Hips and Knees

Radiographic hip disease is evident in approximately half of all patients with RA. Patients may present with complaints of pain in the groin and medial thigh. Pain over the greater trochanter often is secondary to trochanteric bursitis. Severe inflammatory destruction of the femoral head and the acetabulum may push the acetabulum into the pelvic cavity, a condition known as ***protrusio acetabuli***. With progressive hip disease, patients may require a total hip **arthroplasty**.[17]

The clinical presentation of the knee joint frequently includes synovitis, causing accumulation of relatively large amounts of fluid. The knee ballottement test is used to examine for excess fluid. The examiner presses on the patella with the index finger, resulting in a downward motion of the patella; a sensation of bogginess indicates effusion of the knee. Posterior accumulation of fluid in the knee produces a ***Baker's cyst***. If a Baker's cyst ruptures it produces pain, swelling, and heat in the posterior calf similar to symptoms of a deep vein thrombosis. The bulge test is a simple procedure to examine for anterior synovitis. With this procedure the examiner strokes the medial aspect of the knee in an upward motion, then presses on the lateral aspect of the knee. A positive sign is a *wavelike* movement of fluid medially. Chronic synovitis results in distention of the joint capsule, attenuation of the collateral and cruciate ligaments, and destruction of the joint surfaces. Painful knees may be held in slightly flexed positions, ultimately resulting joint tightness or flexion contractures.[17]

Ankles and Feet

Early inflammation of the feet is often evident in the forefoot where patients note pain with compression of the forefoot on examination. Chronic synovitis accentuates the natural tendency of the talus to glide medially and plantarward, resulting in pressure on the calcaneus and leading to hindfoot pronation. The spring ligament is also stretched by these occurrences, flattening the medial longitudinal arch (Fig. 23.9). The calcaneus may erode or develop bony **exostoses** known as spurs. As synovitis weakens the transverse arch, the metatarsals spread and a splayed forefoot (*splayfoot*) may develop (Fig. 23.10). Instability of the talocalcaneal joint, if severe, can lead to the need for surgical fusion. Synovitis of the metatarsophalangeal (MTP) joints is extremely common and ***metatarsalgia*** (pain over the metatarsal heads) may develop. A ***hallux valgus*** and ***bunion*** (a painful bursitis over the medial aspect of the first MTP joint) may also be present. When volar subluxation of the MTP combines with flexion of the PIP and hyperextension of the DIP joints, this condition is commonly referred to as **hammer toes** (Fig. 23.11). The MTPs may also exhibit volar subluxation of the metatarsal head with flexion of the PIP and DIP joints, known as *cock-up* or ***claw toes*** (Fig. 23.12). As the capsule and intertarsal ligaments are weakened and stretched, the proximal phalanges move dorsally on the metatarsal head (Fig. 23.13). Similar to conditions observed in the hand, the long toe extensors "bowstring" over the PIP joints while the flexors are displaced into the intertarsal spaces.[17]

Muscle Involvement

Muscle atrophy around affected joints may be present early. It is not definitively known, however, whether this atrophy results from disuse or selective attrition of muscles owing to some unknown mechanism specifically

Image Unavailable; No electronic permisison

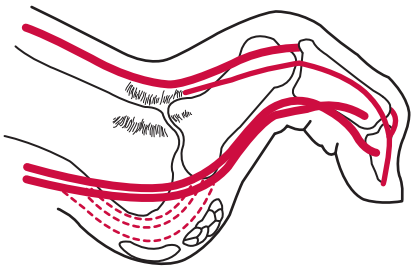

Figure 23.13 Relationship of structures to the metatarsal heads in metatarsalgia. *From Moncur, C, and Shields, M: Clinical management of metatarsalgia in the patient with arthritis. Clin Manage Phys Ther 3:7, 1983, p 10, with permission.*

related to the disease process. Atrophy in the hand intrinsics and the quadriceps is particularly evident in long-standing disease, although the mechanisms for these changes may not be the same. It appears that individuals with RA experience selective attrition of Type II (phasic) muscle fibers through some unknown mechanism.[21,22] There is also some evidence that Type I (tonic) muscle fibers of the quadriceps will undergo selective atrophy following anterior cruciate ligament damage.[23] Loss of muscle bulk may also be the result of a peripheral neuropathy, **myositis**, or steroid-induced myopathy. Muscle weakness may be due to either reflex inhibition secondary to pain or atrophy.[21-23]

Tendon Involvement

Tenosynovitis, inflammation of the lining of the sheath that surrounds a tendon, may occur with active disease and interferes with the smooth gliding of the tendon through the sheath. Inflammation may directly damage the tendon, eventually leading to a tendon rupture. Common sites of tenosynovitis are wrist flexors, thumb flexors, patella, and Achilles tendons. Trigger finger and *deQuervain's disease* may occur. A patient with tendon damage or muscle weakness may exhibit a ***lag phenomenon,*** which refers to a substantial difference in passive versus active ROM. This is a nonspecific finding that therapists need to examine carefully to determine its cause and design appropriate treatment.[20]

Deconditioning

Deconditioning is a significant clinical feature of RA. Research assessing physical fitness in persons with RA has demonstrated diminished cardiorespiratory status, muscular strength and endurance, flexibility, and altered body composition among these individuals when compared with healthy individuals of the same age and gender without arthritis. Deconditioning results from both direct and indirect impairments.[24,25] Direct impairments of RA include loss of Type II muscle fibers, systemic fatigue, *cachexia* (wasting of lean body mass),[25] and shortening of contractile tissues. Indirect impairments of RA include deconditioning secondary to inactivity and elevated resting energy expenditure (calories required by the body during a 24-hour period under resting conditions). Immune system activity and inflammation, even in individuals with well-controlled disease, create an increased metabolism with subsequent loss of lean body tissue.[25]

Rheumatoid Nodules

Rheumatoid nodules occur in approximately 20% to 25% of patients and are associated with a positive serological test for RF. Nodules are generally tender and accompany severe disease. When nodules are present in early RA they are suggestive for a greater likelihood of severe **extra-articular** manifestations. Nodules are found in the subcutaneous or deeper connective tissues in areas

subjected to repeated mechanical pressure such as the olecranon bursae, the extensor surfaces of the forearms, and the Achilles tendons. The presence of nodules on tendon mechanisms may lead to mechanical breakdown and tenosynovitis.[17,20]

Vascular and Neurologic Complications

Vasculitis, or inflammation of the blood vessels, has been found in 25% to 30% of individuals with RA on autopsy.[20] Most forms of vascular lesions associated with RA are silent and difficult to diagnose due to variability in the size of blood vessels affected. Skin vasculitis is the easiest to observe and can present as discoloration of the nail beds, purpura (red or purple discoloration), and petechiae (red or purple spots). The fulminant form of *rheumatoid arteritis* (arterial inflammation associated with a rheumatoid disorder) can be life threatening, and accompanied by malnutrition, infection, congestive heart failure (CHF), and gastrointestinal bleeding. Vasculitis of the vessels supplying nerves can lead to peripheral neuropathies such as foot or wrist drop.[1] Peripheral neuropathies may also occur secondary to mechanical compression of nerves such as carpal tunnel or tarsal tunnel syndrome. Spinal cord compression may result from inflammation in the cervical spine (see section on cervical spine and temporomandibular joint), and if clinical signs of cord compression are present, this requires immediate medical attention.[1]

Cardiopulmonary Complications

Morbidity and mortality from cardiovascular disease is elevated in persons with RA due to a greater prevalence of ischemic heart disease, secondary to accelerated atherosclerosis. Although the exact etiology of accelerated atherosclerosis is unclear, it is hypothesized that metabolic and vascular effects of chronic inflammation may be the causative factor.[24] Subclinical pericarditis may be present and has been demonstrated at autopsy. Pulmonary involvement is frequent and more prevalent in men than women. Pleuritis and pulmonary nodules may be present. Pulmonary nodules are related to presence of nodules elsewhere and found among seropositive patients with profuse synovitis. Nodules may be .40 to 3 in (1 to 8 cm) in size and affect gas exchange.[17]

Ocular Complications

Episcleritis, a benign and self-limiting process, and scleritis, a serious condition that can lead to blindness, may be present. The difference between these two is difficult to detect with clinical symptoms. Therefore, patients with RA should undergo annual eye examinations, and, if symptoms of suspected eye disease are present, they should be referred to an ophthalmologist.[20]

Activity Limitation and Participation Restriction

Patients with milder forms of RA may suffer from activity limitations and decreased participation in ADL due to joint destruction. Almost 50% of individuals with RA will eventually have marked restrictions in ADL.[1] Late-onset RA is generally associated with better functional outcomes and less activity limitations and participation restrictions, though the cause of these findings is unclear. Table 23.3 presents a broad classification of functional status in RA that characterizes the progressive impact of the disease.[14] Loss of income is a major consequence of RA and is directly attributable to work disability. In a large international comparison study, work disability rates were high in persons with RA and disability was associated with disease factors as well as societal factors.[26]

Prognosis

RA causes increased morbidity and reduces life span. The question of mortality associated with RA is controversial. Previously, it was believed that RA itself was not usually a cause of death, although conditions such as systemic vasculitis and atlantoaxial subluxation could be fatal. There is presently a growing body of evidence that individuals with RA have decreased survival compared to their siblings and may not live as long as their counterparts without disease, especially if the early years of RA were marked by aggressive disease and poor functional status. Causes of death occurring more frequently in patients with RA as compared to the general population are infections, ischemic heart disease, and renal, respiratory, and gastrointestinal disease.[17,20,27]

Although numerous prognostic factors have been identified in the literature, there is no firm consensus regarding specific prognostic factors. Research demonstrates that individuals with a positive RF are more likely to progress to severe disease, as are those with high ESR and CRP at baseline. Baseline CRP is also associated with radiographic changes later in life.[28] Similarly, baseline radiographics are strongly associated with pattern of progression. Genetic research suggests that a shared epitope in the hypervariable region of the HLA-DR is associated with disease severity in a dose-dependent manner.[29]

Remission Criteria

In 2011, in response to the increasing ability to achieve remission with appropriate medical management, the American College of Rheumatology (ACR), the European League Against Rheumatism (EULAR), and the ACR Outcomes Measures in Rheumatology Initiatives developed a rigorous set of remission criteria. *Remission*, described as little if any active disease, can be operationally confirmed based on one of two definitions: (a) when scores on the tender joint count, swollen joint count, CRP (in mg/dL), and the Patient Global Assessment (0–10 scale rating how patient feels overall) are all less than or equal to 1, or (b) when the score on the Simplified Disease Activity Index (numerical sum of all of the above plus the score on the Physician Global Assessment) is less than or equal to 3.3.[30]

OSTEOARTHRITIS

Osteoarthritis (OA) is primarily confined to one or more synovial joints and its surrounding soft tissues. Two predominant, pathological features once defined OA: the progressive destruction of articular cartilage and the formation of bone at the margins of the joint.[1] OA is now recognized as a disease involving the entire joint including the periarticular musculature[31] (Fig. 23.14). Accordingly, the impairment, activity limitations, and participation restrictions related to OA extend far beyond the perimeters of the synovial joint. Data on the personal and societal impact of OA increasingly demonstrate its importance as an individual and public health issue.

Epidemiology

Osteoarthritis is the most common form of arthritis and extremely prevalent among individuals over 40 years of age. Based on data from several large population-based studies, it is estimated that approximately 12% of the U.S. population or 27 million adults age 25 and older have clinical OA of some joint.[32] It is widespread in adults older than 65, and affects men more than women before age 50, but reverses after age 50.[1] Studies concerning racial predisposition to OA have yielded conflicting data, depending on the joint studied. Data from the third National Health and Nutrition Examination Survey (NHANES) reveal that the prevalence of radiographic knee OA was highest in non-Hispanic African Americans (52.4%) compared to non-Hispanic whites (36.2%) or Mexican Americans (37.6%).[32]

Etiology

Similar to RA, no single factor that predisposes an individual to OA has been identified. Although aging is indeed strongly associated with OA, it must be emphasized that aging in itself does not cause OA, nor should OA be considered synonymous with the "normal" aging process.[1,33] In fact, many OA-related changes seen at both a cellular and tissue level are opposite those seen with normal aging.[34] Several factors related to aging may, however, contribute to its development. Genetic factors account for between 39% and 65% of radiographic OA of the hand, hip, and knee in women and as much as 70% of OA cases of the spine.[35] Trauma before adulthood may initiate a remodeling of bone that alters joint mechanics and nutrition in a way that becomes problematic only later in life. The role of repetitive *microtrauma* in the etiology of OA has also received attention.[1] Specifically, occupational tasks involving heavy lifting are associated with the development of hip OA,[36] and those involving kneeling and heavy lifting are related to the development of knee OA.[37,38] Malalignment, including *varus* and *valgus* deformities, and leg length discrepancy are associated with greater prevalence of knee and hip OA, respectively.[38,39] The strongest predictor of disease progression in the knee is varus malalignment.[40] At the hip, there is increasing recognition of the role of *femoroacetabular impingement (FAI)* (a mechanical mismatch between the femoral head and acetabulum) in development of OA.[41] Finally, obesity has been shown to be a risk factor for the development of OA in later life; most evident in the knee joint and to a lesser extent in the hip and hands.[1,39] The relationship between obesity and incidence of OA is stronger in women than in men.[39] Risk factors for OA can be classified as either systemic or local (Box 23.2), and OA most likely results from the combined effect of multiple factors acting on a vulnerable joint that leads to disease.[39] It is imperative that physical therapists understand and are able to counsel patients on those factors that are modifiable and amenable to therapeutic interventions.

Pathophysiology

Animal models involving knee trauma have provided much of the basis for what we now know about the earliest changes associated with OA in humans. Thus, it

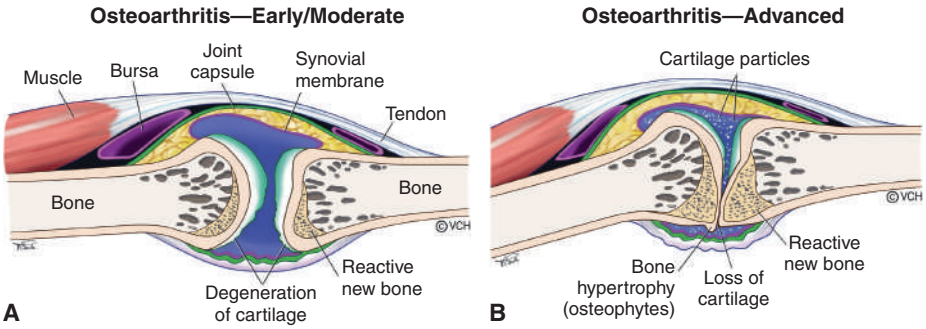

Figure 23.14 Early-advanced osteoarthritis joint changes. Early joint changes are characterized by superficial damage to articular cartilage and mild inflammation. Progression to moderate joint changes includes joint space narrowing with full-thickness damage to cartilage and thickening of the subchondral bone. Advanced joint changes are marked by bony hypertrophy (marginal osteophytes), significant joint space narrowing, and possible angulation (deformity). *From Mary Pack Arthritis Program, Vancouver Coastal Health, with permission.*

Box 23.2 Risk Factors for Osteoarthritis[1,38,39]

Systemic Factors	Local Factors
Age	Obesity
Gender	Major joint trauma (e.g., ACL rupture)
Race	Repetitive stress (occupation)
Genetics	Muscle weakness
Metabolic/endocrine	Altered joint biomechanics
High bone density	Joint malalignment
Nutritional status (e.g., vitamin D deficiency)	Proprioceptive impairments
Congenital/ developmental	
Obesity	

is possible that subtle, crucial, and as yet undiscovered differences in humans may alter our understanding of OA in the future.

Normal Cartilage

Healthy articular cartilage is composed of an extracellular matrix and chondrocytes. Water makes up between 65% and 80% of the matrix by weight, mostly Type II collagen contributes approximately 10%, and *proteoglycans* (molecules found in articular cartilage), noncollagenous proteins, and glycoproteins the remainder.[38,42] It is the matrix that protects the chondrocytes from damage during normal joint use.[42] *Chondrocytes*, the only cells in articular cartilage, secrete the matrix yet make up only 1% of the total volume of adult human articular cartilage.[42] Chondrocytes are dispersed throughout the extracellular matrix but most concentrated in the deep layer. The superficial layer has the highest concentration of water and collagen fibers giving this zone the greatest tensile stiffness and strength and ability to resist shearing forces.[42] Proteoglycans consist of a protein core and one or more glycosaminoglycans (GAGs), including hyaluronic acid and chondroitin sulfate. Proteoglycan concentration is highest in the middle and deep zones.[42]

Articular cartilage contains no nerves, blood vessels, or lymphatic vessels. It receives its nutrition and eliminates waste via diffusion through synovial fluid and by facilitated *imbibition* (absorption of fluid by a solid body).[38] The multiple roles of articular cartilage include decreasing friction between articulating joint surfaces, distributing static and dynamic joint forces to the underlying bone and absorbing shock.[38,43] Cartilage's shock-absorbing function is minimal (1% to 3% of load forces), however, compared to that of subchondral bone (30%)[38] and periarticular muscles (which requires timely and coordinated muscle contraction). These joint structures together with ligaments, menisci, capsule, synovium, and synovial fluid serve to protect the joint from regular wear and tear and damaging forces. Regular forces acting on the articular cartilage include body weight, muscle contractions, and ground reaction forces that vary with the rate and duration of loading and the available load-bearing surface.[38,42] Extremes of joint loading in either direction can lead to detrimental morphological and metabolic changes in the cartilage whereas moderate, cyclic loading enhances proteoglycan synthesis and concentration.[38,42]

Joint Pathology

The first osteoarthritic change in articular cartilage, which has been confirmed in humans, is an increase in water content. This increase suggests that the proteoglycans have become swollen with water far beyond normal. This process, together with disruption of other components of the extracellular matrix, decreases the stiffness of the matrix and leads to further mechanical damage.[42] In later stages of disease progression, proteoglycans are lost, which diminishes the water content of cartilage. As proteoglycans are lost, articular cartilage loses its compressive stiffness and elasticity, which, in turn, results in the transmission of compressive forces to underlying bone. Collagen synthesis is increased initially, although there is a shift from type II collagen fibers to a larger proportion of type I collagen, the kind found in skin and fibrous tissue. Chondrocytes attempt to respond to this early tissue damage by synthesizing new matrix molecules and proliferating and forming clusters of cells.[42] As the articular cartilage is destroyed, the joint space narrows.[31] In summary, the early phases of cartilage degeneration are characterized by biosynthesis and repair as the chondrocytes attempt to restore the damaged matrix while the later phase is degradative in nature as catabolic enzyme activity digests the matrix and erodes the cartilage.

One of the first noticeable changes in cartilage is the mild fraying or "flaking" of superficial collagen fibers. Deeper fraying, or "fibrillation," of the upper third of the cartilage follows in areas of greater weight-bearing and may progress to full-thickness fissures (Fig. 23.15). As the cartilage degenerates, there are accompanying changes in the subchondral bone including increased bone density or subchondral sclerosis, creation of cyst-like bone cavities, and formation of marginal **osteophytes.**[1] The cartilage may degenerate to the point that the exposed subchondral bone becomes necrotic and *eburnated* (polished or ivory-like) (Fig. 23.16). The stiffer than normal subchondral bone further decreases the shock-absorbing properties of the joint and results in greater impact loading.[38] The traditional view of OA is that the disease process starts with an unrepaired injury to articular cartilage; however, there is also evidence that reduced compliance in subchondral bone and periarticular structures may initiate the degenerative processes.[38,42]

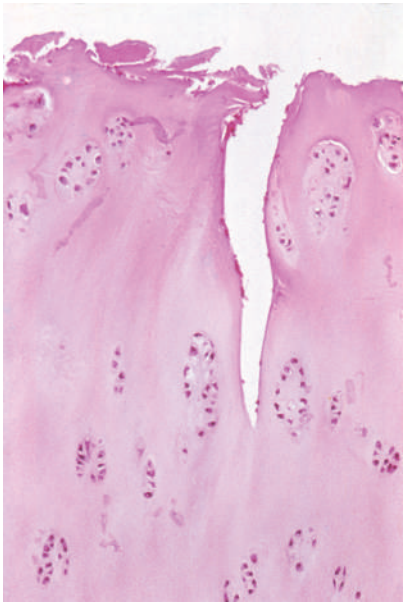

Figure 23.15 Osteoarthritis: cartilage, clefts and fibrillation (histological specimen). *Used by permission of the American College of Rheumatology.*

Osteophytes may be fibrous, cartilaginous, or bony in composition and marginal prominences are palpable and often tender in more superficial joints.[42] The process of **osteophyte** formation in OA is not well understood. Current hypotheses have implicated increased vascularity in the deepest layers of the degenerated cartilage, venous congestion from subchondral cysts and thickened subchondral trabeculae, and the continued sloughing of articular cartilage.[44] Each of these hypotheses may explain how this bony growth contributes to the pain and loss of motion that accompany OA. Subchondral cysts containing **myxoid**, fibrous or cartilaginous tissue along with bone marrow lesions identified through MRI, are associated with painful knee OA.[31]

Figure 23.16 Osteoarthritis: knee, gross pathology. *Used by permission of the American College of Rheumatology.*

Although traditionally viewed as a non-inflammatory disease, improved detection methods suggest that inflammation does play a role and that inflammatory pathways are up-regulated (increased responsiveness).[1,43] Further inflammatory reactions occur in response to cartilage fragments in the synovial cavity and resultant low-grade synovitis.[38]

Radiography

It is widely recognized that radiographic findings are not strongly related to clinical symptoms and pain severity[39] and add little to the accuracy of the clinical diagnosis. In knee OA, muscle strength and pain are more explanatory of functional loss than radiographic findings.[45] Although the diagnosis of OA can be made through history and clinical assessment, radiographs are frequently used to confirm the extent of joint damage and disease progression and continue to be a component of the ACR diagnostic criteria.[31] The Kellgren and Lawrence 5-point classification system remains the most widely used criteria for grading radiographic changes both clinically and for purposes of research.[46]

- Grade 0: normal radiograph
- Grade 1: doubtful narrowing of the joint space and possible osteophytes
- Grade 2: definite osteophytes and absent or questionable narrowing of the joint space
- Grade 3: moderate osteophytes and joint space narrowing, some sclerosis, and possible deformity
- Grade 4: large osteophytes, marked narrowing of joint space, severe sclerosis, and definite deformity

In Figure 23.17, early OA changes of the right hip are depicted. Newer imaging techniques including high-resolution MRI are able to detect early structural changes and pathology in pain-sensitive structures well before changes are observable on radiographs.[31,47] Real-time ultrasound allows visualization of both bony and soft tissue structures and is more sensitive than clinical examination in detecting effusion, synovitis, and early osteophytes in OA.[47] Ultrasound imaging has greater potential for routine use in clinical practice than MRI.

Disease Onset and Course

OA typically starts in an insidious fashion and may progress undetected in some individuals when early, aneural articular cartilage is the only involved tissue. Pain is initially episodic and triggered by specific activity. In later disease, pain becomes a chronic, dull ache

Figure 23.17 Osteoarthritis: Mild degenerative changes right hip, total hip replacement in left. *Used by permission of the American College of Rheumatology.*

accentuated with episodic severe pain.[31] It is pain that leads an individual to seek medical help. Unlike RA, there are no systemic features such as fatigue, fever, or malaise with the onset of OA.

OA is typically a slowly progressive condition; however, most people with radiographic evidence of joint damage in their hips or knees stabilize and do not require joint replacement surgery.[1] The pathological process involved in OA appears to be cyclical with active periods of increased matrix protein turnover interspersed with inactive phases.[48] The prognosis is variable and not necessarily bad. However, in combination with normal aging, co-morbidities often present in older adults, and high levels of inactivity in this population, OA can contribute to increasing disability.[1]

Classification and Diagnostic Criteria

Most researchers have used Kellgren and Lawrence's grade 2 definition (the presence of definite osteophytes) as the criterion for identifying disease, although a few others have required evidence of joint space narrowing (grade 3 corresponding to clinically identified disease) to designate OA.[46] Although radiographic evidence of joint space narrowing and osteophytes may help confirm the diagnosis and classify the stage of OA, the clinical criteria for hip,[49] knee,[50] and hand[51] OA are described primarily in terms of pain and limitation of motion (Box 23.3).

OA is typically differentiated in two ways: *primary* (idiopathic) and *secondary* disease.[1] When the etiology of the disease is unknown with no known prior event, it is termed *primary* or *idiopathic* OA. This category can be further divided into *localized* (one or two joints affected) or *generalized* OA (affecting three or more joints).[1] Generalized OA typically involves the hands in a more symmetrical fashion not unlike inflammatory forms of arthritis and has a stronger genetic association.[1] OA is classified as *secondary* when the etiology (e.g., trauma, biomechanical factors, congenital malformation, or other musculoskeletal disease) can be identified. There is increasing evidence that many cases categorized as idiopathic are more appropriately recognized as secondary disease as our ability to detect subtle and early biochemical, histological, morphological, and biomechanical factors improves.

Box 23.3 Clinical Classification Criteria for Knee, Hip, and Hand Osteoarthritis

Knee Osteoarthritis[a][5]

- Persistent knee pain
- Limited morning stiffness ≤30 minutes
- Reduced function
- Crepitus
- Bony enlargement
- Restricted movement

Hip Osteoarthritis[b][49]

Pain present in combination with either:

- Hip internal rotation ≥15°; morning stiffness ≤60 minutes; and age >50 years, and pain on internal rotation, *or*
- Hip internal rotation <15°, and hip flexion <115°

Hand Osteoarthritis[c][51]

- Presence of Heberden's nodes
- Age more than 40 years
- Family history of nodes
- Joint space narrowing in any finger joint

[a]Correctly diagnoses 99% of knee OA when all 6 criteria are met.[5]
[b]86% sensitivity, 75% specificity.[49]
[c]Correctly diagnoses 88% of patients when all 4 criteria are met.[51]

Clinical Presentation

Signs and Symptoms (Impairments)

As noted above, the clinical diagnosis is often made on the basis of signs and symptoms (e.g., pain and swelling, loss of ROM, and bony deformity). Not all joints are equally affected by OA. In the upper extremity (UE), the finger DIP and PIP joints and CMC of the thumb are commonly involved. The cervical and lumbar spine, hips, knees, and MTP of the great toe are also sites for OA. The MCP joints, wrists, elbows, and shoulders are usually spared in primary OA.[1] Unlike RA, OA does not have a bilateral, symmetrical presentation (with the exception of generalized OA).[1]

A single joint or any combination of joints may be affected and of differing "etiological origins." OA is not a systemic disease, and is therefore not associated with systemic complaints such as fatigue, generalized morning stiffness, fever, or loss of appetite. Individuals with OA may experience some stiffness in particular joints on awakening that is similar to the stiffness felt when moving the same joints after inactivity during the day, but this stiffness (articular gelling) typically does not last more than 30 minutes, nor is it generalized to the entire body.[1,31] Crepitus is a common clinical finding in OA and may progress from a painless grating sensation to an extremely painful, high-pitched sound as a result of bone-on-bone articulation.

Although cartilage degeneration is the primary manifestation of OA, cartilage is aneural, and therefore not the cause of a person's pain. Pain in OA can arise from any innervated tissue and may be attributed to incongruent articulations of joint surfaces, periosteal elevation secondary to bone proliferation at the joint margin (osteophytes), vasocongestion in subchondral bone, trabecular microfractures, distention of the joint capsule, and muscle spasm or strain.[31,42] Many patients will also experience a secondary synovitis and effusion, especially when the knee is involved.[43,52]

As noted earlier, symptoms do not always match the severity of the disease on radiographs. Further, some patients with OA may have an amplified pain experience and central pain sensitization at the spinal or cortical level.[43] Unlike individuals with RA who often report more pain and stiffness at rest, the pain associated with OA is likely to occur or worsen with motion, except in the later stages of the disease when it is present at rest and with activity.[1,31]

Joints

Hands and Fingers Osteoarthritis may present differently and result in varied levels of impairment depending on the joints involved. In the hand, DIP and PIP involvement may result in reduced ROM, poor grip strength, bony nodes, and joint angulation as a result of stretched collateral ligaments or bone erosion. **Bouchard's nodes** at the PIP joints and **Heberden's nodes** at the DIP joints are often tender in the early stages and can lead to marked restrictions in finger ROM and fine motor skills later in the disease (Fig 23.18). Osteoarthritic damage in the first CMC joint results in pain or aching at the base of the thumb and can lead to decreased pinch strength and squaring of the thumb (thickening and prominence of CMC due to subluxation of first metacarpal) as a result of weakness and contracture of the thenar muscles.[53,54] This in turn affects abduction, extension, and opposition ROM of the thumb and greatly affects grip strength and hand function. In cases of generalized OA, the hands are always affected and in a more symmetrical pattern.[1] Painful inflammation with synovitis, erosive changes, cystic swellings, and osteophytes are present in this less common form of OA and may lead to ankylosis of the DIP and PIP joints.[1,54]

Hips Symptoms of hip OA are usually insidious in onset and may include a limp and decreased ROM with a tendency for the hip to be held in a somewhat flexed, abducted, and externally rotated position. Internal rotation is usually restricted and painful.[55] Pain arising from the hip joint is commonly experienced in the groin, but can also be felt in the buttock, trochanteric, or knee region.[55] Decreased hip ROM is associated with decreased walking speed, decreased stride length, poor balance, and increased energy expenditure. Hip OA is also associated with increased risk of falls.[56]

Knees Early presentation of knee OA includes pain with weight-bearing activities such as climbing stairs and squatting. In later stages, both pain and stiffness are reported after prolonged sitting such as with watching a movie. Symptoms of joint locking and buckling (giving way) may also occur with damage to stabilizing menisci and ligaments[55] and lead to increased risk of falls.[31] Knee OA more commonly affects the medial joint due to the higher weight-bearing load placed on this compartment. As a result, medial joint space narrowing often results in **pseudolaxity** of the medial collateral ligament, stretching of the lateral collateral counterpart, and a genu varus deformity (Fig. 23.19). Genu valgus as a result of greater lateral compartment involvement is less common. A **flexion deformity** of several degrees can develop quickly in the painful knee and contribute to a functional leg length discrepancy, decreased step length, and quadriceps muscular fatigue or strain. Patellofemoral compartment OA, with its hallmark anterior knee pain, can occur in isolation as a result of patella malalignment, abnormal tracking and loading, and direct trauma to the patella.[55]

Feet and Toes The first MTP joint is the most common site of OA affecting the foot and may result in hallux rigidus or hallux valgus deformities. Changes in

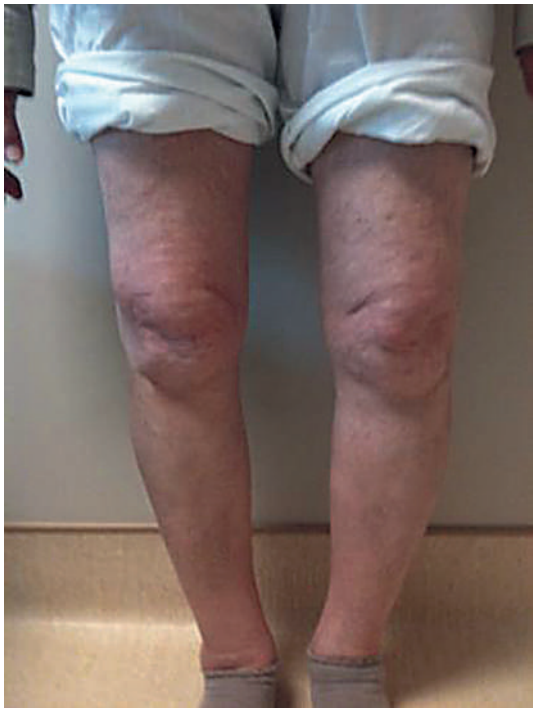

Figure 23.19 Bilateral genu varum. *Dr. Basram Masri, with permission.*

the other MTP joints and toes as a result of OA and resultant shortening of the long extensors can lead to hammer toes. Forefoot involvement contributes to poor push-off in the terminal stance phase of gait and balance issues.[57]

Spine The lower cervical and mid to lower lumbar regions of the spine are most susceptible to OA. All spinal articulations can experience degenerative changes; however, the facet (zygapophyseal) joints are the only true synovial joints in the spine.[58] Facet joint osteophytes can contribute to lateral and central lumbar stenosis and subsequent nerve root impingement[58] (Fig. 23.20). Pain from facet joint OA can originate from the joint itself and affected nerve roots (radicular pain) and in the lumbar area, and typically increases with spinal extension, rotary motions, and when standing or sitting.[58] Lying and spinal flexion lead to pain relief.

Activity Limitations and Participation Restrictions

Overall, OA of the knee can impose functional limitations to a degree equivalent to heart disease, CHF, and chronic obstructive pulmonary disease (COPD) and accounts for a substantial proportion of the burden of disability among community-living elders.[59]

Patients with the most severe disease may not move their joints as often or in the ways that exacerbate their symptoms. Therefore, pain, disease severity, and functional disability in individuals with OA are interrelated. Among elders, it has been shown that the functional loss associated with severe radiographic OA without pain is more likely than the loss associated with symptomatic but milder disease.[60] One explanation of this finding is that individuals with OA limit their functional activities to avoid movements that are painful. In the clinical examination it is important to determine functional status even in the absence of pain. Given that individuals with OA may reduce or eliminate their symptoms by avoiding certain activities, clinicians should explore activity limitations and physical inactivity–related symptoms in patients with OA separately from the evaluation of symptoms.

Greater self-reported disability in advanced knee OA was associated with pain, joint laxity, age, and body mass index (BMI) among Finnish adults ages 60 to 80 years while performance-based functioning was related to the self-report *Western Ontario and McMasters Universities Arthritis Index* (WOMAC) function score, pain, and obesity.[61] Of interest, the authors found no association between radiographic severity of knee OA and self-reported and performance-based function.[61] The comprehensive International Classification of Functioning, Disability, and Health (**ICF**) **Core Set** of impairments, activity limitations, and participation restrictions has been established through an international team of researchers, clinicians, and patients to identify those areas of functioning that are affected by OA, with the shorter **Brief ICF Core Set** created for clinical purposes.[62,63] OA is a leading cause of disability and

major contributor to work-related disability, reduced productivity, and absenteeism.[64]

Prognosis

OA is a slow progressing disease that can be self-limiting or progress to advanced joint and soft tissue damage leading to complete failure of that joint. In such a case, joint surgery including **arthrodesis** of some joints in the foot, or arthroplasty, for example, of the knee is the final treatment option to help the patient regain function. However, rapidly progressive joint damage is uncommon and in most cases patients stabilize.[1] Increasing disability may be more related to advancing years, co-morbidities, and inactivity.

MEDICAL MANAGEMENT

Pharmacological Therapy in Rheumatoid Arthritis

Joint destruction and irreversible damage are most pronounced early in the disease course. Current medical management is based on the implementation of an early and aggressive approach to disease management to halt or decrease progression. Medical therapies also focus on decreasing pain and inflammation. Early aggressive pharmacological therapy is associated with diminished joint damage and long-term maintenance of function. The major classifications of drugs used in RA management include nonsteroidal anti-inflammatory drugs (NSAIDs) and disease-modifying antirheumatic drugs (DMARDs), which include the biological response modifiers (BRMs) and corticosteroids.[65] Table 23.4 lists the most common drugs used in the management of RA.[20]

Nonsteroidal Anti-inflammatory Drugs

NSAIDs provide both *analgesic* and *anti-inflammatory* effects depending on the dose prescribed; however, they do not alter disease progression. Discontinuance of NSAIDs quickly leads to exacerbation of symptoms. Thus, NSAIDs are generally given in combination with other disease-modifying agents. At lower doses, the NSAID effect is analgesic, through the peripheral inhibition of pro-inflammatory prostaglandin synthesis. At higher doses, the effect is anti-inflammatory, probably through both prostaglandin inhibition and alterations in macrophage and neutrophil function. Due to the mechanism of action of these medications, adverse effects include gastrointestinal (GI) complaints and renal effects. Mild GI adverse effects include distress and

Table 23.4 Drugs in the Management of Osteoarthritis and Rheumatoid Arthritis

Drug	Common Brand Names	Adverse Effects	Cautions and Contraindications
Analgesics			
Acetaminophen	Tylenol, Excedrin caplets, Panadol, Anacin-3	Potential for renal and liver toxicity, possible GI ulceration and bleeding at doses >3g/day	Not recommended with high alcohol consumption or liver disease
NSAIDs, traditional	**OTC:** Advil, Motrin IB, Nuprin, Actron, Orudis KT, Aleve **Prescription:** Voltaren, Lodine, Nalfon, Ansaid, Indocin, Motrin, Orudis, Meclomen, Relafen, Naprosyn, Anaprox, Daypro, Feldene, Clinoril, Tolectin	GI bleeding, ulcers, nausea, diarrhea, indigestion, rash, dizziness, drowsiness, slowed blood clotting, tinnitus, fluid retention	Sensitivity or allergy to similar drugs; kidney, liver, or heart disease; hypertension; asthma; ulcers; anticoagulant therapy
COX-2 inhibitors	celecoxib (Celebrex), meloxicam (Mobic), nabumetone (Relafen)	May result in serious adverse events including cardiac complications and less serious GI side effects than traditional NSAIDs; allergic reactions; elevated blood pressure	Same as above; allergy to sulfa-containing drugs for celecoxib

Table 23.4 Drugs in the Management of Osteoarthritis and Rheumatoid Arthritis—cont'd

Drug	Common Brand Names	Adverse Effects	Cautions and Contraindications
Corticosteroids			
Systemic: oral or intravenous	Prednisone, prednisolone, methylprednisolone, triamcinolone, cortisone, hydrocortisone, dexamethasone	With long-term/high-dose: Cushing syndrome, osteoporosis, cataracts, insomnia, hypertension, immune suppression, elevated blood sugar, mood changes, weight gain, altered mental status, glaucoma, restlessness, increased appetite	Diabetes, infection, hypothyroidism, hypertension, osteoporosis, gastric ulcer
Injection	Triamcinolone, prednisolone, methylprednisolone, dexamethasone, hydrocortisone, betamethasone	Post-injection flare (4–24 hours), transient systemic reaction, increased diabetic symptoms, soft tissue disruption from direct injection	Presence of infection, previous failure to respond
DMARDs			
Methotrexate	Rheumatrex	Common adverse effects: decreased appetite, abdominal discomfort, nausea, diarrhea, skin rash, itching, oral ulcers, photosensitivity, infection, unusual bleeding/bruising Serious: bone marrow suppression; liver, lung, or kidney toxicity; fetal death; congenital abnormalities	Liver or lung disease, alcoholism, immune system or bone marrow suppression, infection, pregnancy
Injectable gold	Myochrysine, Solganal	Stomach cramps/vomiting; severe allergic reactions (rash, hives, difficulty breathing, tightness in the chest, and so forth); blood in urine; cough; dark urine; metallic taste; mouth sores; nausea; pain or numbness in the hands or feet; persistent diarrhea; purple blotches or other skin spots; seizures; shortness of breath; sore throat; weakness; vision problems	Kidney disease, bone marrow suppression, colitis
Oral gold—Auranofin	Ridaura	Individual drugs may also have other specific toxicities and increase risk for other conditions	Previous adverse reaction to gold compound; kidney, liver, or inflammatory bowel disease

Table 23.4 Drugs in the Management of Osteoarthritis and Rheumatoid Arthritis—cont'd

Drug	Common Brand Names	Adverse Effects	Cautions and Contraindications
Azathioprine	Imuran	Nausea/vomiting, diarrhea, allergic reactions, chest pain or tightness; dark urine; dizziness; fever, chills, or sore throat; increased or painful urination; muscle pain or aches; pale or fatty stools; shortness of breath; unusual bleeding or bruising; unusual growths or lumps; unusual weakness or fatigue; yellowing of the eyes or skin	Kidney or liver disease, pregnancy
Cyclophosphamide	Cytoxan	Interferes with wound healing Serious: secondary malignancies, fetal harm	Kidney or liver disease, pregnancy, infection, leucopenia, thrombocytopenia
Cyclosporin	Sandimmune Neoral		Kidney or liver disease, pregnancy, infection
Hydroxychloroquine	Plaquenil		Antimalarial drug allergy, retinal abnormality, pregnancy
Penicillamine	Cuprimine Depen		Penicillin allergy, blood disease, kidney disease
Sulfasalazine	Azulfidine		Sulfa or aspirin allergy, kidney or liver disease, blood disease, bronchial asthma
Leflunomide Minocycline	Arava Minocin		Liver disease Tetracycline or sun sensitivity
Biologic Response Modifiers (TNF-alpha inhibitors)			
Humanized antibody Fab fragment	Etanercept (Enbrel), adalimumab (Humira), anakinra (Kineret), infliximab (Remicade), Certolizumab pegol (Cimzia), Golimumab (Simponi)	• Serious infection: increased risk of serious infection leading to hospitalization or death, including TB, bacterial sepsis, invasive fungal infections, and infections due to other opportunistic infections • Malignancy: lymphoma and other malignancies, some fatal, have been reported in children and adolescent patients treated with TNF blockers Infection at injection site, headache, rash	Serious infection Malignancies Anaphylaxis or serious allergic reactions Hepatitis B virus reactivation Demyelinating dx, exacerbation or new-onset cytopenias, pancytopenias Heart failure, worsening or new onset Lupus-like syndrome Require subcutaneous injection or intravenous infusion (infliximab); increased risk for lymphoma

Table 23.4 Drugs in the Management of Osteoarthritis and Rheumatoid Arthritis—cont'd

Drug	Common Brand Names	Adverse Effects	Cautions and Contraindications
Other Biologicals			
Fusion protein, selective T-cell costimulation modulator	Abatacept (Orencia)	Headache Upper respiratory tract infection Nasopharyngitis Nausea	Concomitant use with a TNF antagonist can increase the risk of infections and serious infections Hypersensitivity, anaphylaxis, and anaphylactoid reactions History of recurrent infections or underlying conditions predisposed to experience more infections Discontinue if serious infection develops Screen for latent TB infection before initiating therapy Patients testing positive should be treated before initiating abatacept Live vaccines should not be given concurrently or within 3 months of discontinuation
Chimeric murine/human monoclonal antibody to CD20 antigen	Rituximab (Rituxan) Tocilizumab (Actemra)	Upper respiratory tract infection Nasopharyngitis Urinary tract infection Bronchitis Infusion reactions	Infusion reactions Tumor lysis syndrome Severe mucocutaneous reactions Progressive multifocal leukoencephalopathy
Humanized anti-human IL-6 receptor monoclonal antibody		Serious infections Cardiovascular events	Cardiac arrhythmias and angina Bowel obstruction and perforation Do not administer live virus vaccines before or during rituximab Monitor CBC at regular intervals

nausea. However, approximately 2% to 4% of patients experience serious adverse effects including gastrointestinal bleeding, ulcers, and perforation. Patients are encouraged to take these medications with food, to monitor GI signs, and/or are given prophylactic therapy to decrease gastrointestinal damage. Renal and other adverse effects associated with continued use and high doses of NSAIDs include dizziness, drowsiness, headache, tinnitus (ringing in the ears), kidney dysfunction, and elevation of liver enzymes. Complete blood counts (CBCs) and stool guaiac analyses for occult blood should be conducted every 3 to 4 months to monitor for potential adverse effects.[65]

There are two primary categories of NSAIDs, based on whether they inhibit COX-1 and COX-2 enzymes or COX-2 enzymes alone. These enzymes are responsible for synthesis of prostaglandins. Traditional NSAIDs block both COX-1 and COX-2 enzymes. The main function of the COX-1 enzyme is synthesis of prostaglandins in the endothelium and gastric mucosa, tissues present in the stomach lining and kidneys. Caution should be taken when prescribing NSAIDs to specific groups of patients at risk for GI complications such as the elderly, smokers, those taking corticosteroids, and those with severe arthritis, co-morbidities, and history of GI symptoms. The selective COX-2 inhibitors were designed to decrease the risk of GI toxicity by inhibiting only the COX-2 enzyme, which is responsible for the pain and swelling associated with inflammation. Early studies of short duration exposure supported the reduced risk of GI side effects and increased tolerability of COX-2 inhibitors.[66] However, studies of longer selective COX-2 exposure and systematic evaluation of the data from numerous trials indicate that patients on selective COX-2 inhibitors are at greater risk of acute myocardial infarction and other cardiovascular events.[67-69]

NSAIDs are an accessible and relatively inexpensive drug to manage inflammation; however, the decision to prescribe an NSAID must be based on risk factors, known toxicities, and dosing preferences. Individual response to an NSAID is extremely variable in terms of both effectiveness and tolerance. Therefore, it often requires several month-long trials to find the best product. Taking more than one NSAID increases the risk of toxicity with no increase in benefit. NSAIDs are prescribed for patients with RA at the onset of symptoms to provide rapid pain relief and control of inflammation while waiting for the slower-acting DMARD to become effective.

Disease-Modifying Antirheumatic Drugs

DMARDs are the primary class of drugs for managing disease progression in RA. An array of drugs with varying chemical structures, modes of actions, clinical indications, and toxicities are classified as DMARDs. Typical DMARDs used to manage RA include antimalarials, methotrexate, sulfasalazine, and leflumonide. Although DMARDs are effective in reducing disease progression, these medications do not provide an analgesic effect and are slow acting, taking from 3 weeks to 3 months to take effect. A drug that is classified as a DMARD must show evidence of affecting the course of RA for at least 1 year (improved function, reduced inflammation, and slowing or prevention of structural damage). DMARDs may be given alone or in combination for best effectiveness. Individuals taking DMARDs should be monitored regularly for the toxicities accompanying the specific drug. DMARDs are most often used to treat adult-onset RA; however, some are used to treat juvenile RA, ankylosing spondylitis, psoriatic arthritis, and systemic lupus erythematosus. The most commonly used DMARD to manage RA is methotrexate.[20]

Biological Response Modifiers

Biological response modifiers (BRMs) are a class of disease-modifying agents in use since 1998 that are biologically engineered to mimic the activities of targeted immune cells to reduce or block the inflammatory process. These drugs are approved to treat moderate to severe RA that is nonresponsive to traditional therapy. The mechanism of action of BRMs varies and includes inhibition of cytokine activity, by blocking either tumor necrosis factor–alpha or interleukin-1. Evidence demonstrates both inhibition of the progression of structural damage and improvement of physical function in RA and represents a significant advance in the treatment of RA. Patients who begin BRMs usually continue with their NSAIDs or corticosteroids. Adverse effects of these medications can be quite serious and patients must be monitored for signs of infection, including colds and flus, which can rapidly progress during immunosuppression. Those with a history of tuberculosis (TB) are at risk for reactivation of TB and may be excluded from this form of therapy. The number of diseases in which these agents are useful continues to expand as do the number and types of agents available.

Corticosteroids

Corticosteroids are powerful anti-inflammatory drugs creating rapid and potent suppression of inflammation. Corticosteroids are generally not given alone and may be administered orally, intravenously, or via intra-articular or periarticular injection. Unfortunately, these potent inflammatory medications also produce serious adverse effects when used long-term or in high doses. Potential adverse effects include thinning of the skin, osteoporosis, muscle wasting, adrenal suppression, increased susceptibility to infections, impaired wound healing, cataracts, glaucoma, hyperlipidemia, and aseptic bone necrosis. These drugs are generally prescribed in the presence of unremitting disease and severe extra-articular inflammation and are given in combination with other RA medications (e.g., DMARDs). Corticosteroids are often prescribed in *pulse doses* (low tapering doses over a specific time period) to reduce the risk of side effects. Patients on corticosteroids should have their blood counts, serum potassium, and glucose levels monitored and be observed for potential side effects.[20]

When inflammation is confined to a specific location, steroid injections into a joint, bursa, tendon, or tendon sheath may be administered. However, use of steroid injections is commonly limited to no more than two to four per year to reduce the risk of osteonecrosis and soft tissue damage.

Pharmacological Therapy in Osteoarthritis

To date, drug therapy in OA has no effect on disease progression and is ancillary to nonpharmacological approaches to pain management including patient education and self-management, weight loss, joint protection, and exercise.[40,70-72] The goals of drug therapy in patients with OA are to relieve pain and decrease inflammation when it is present. Oral analgesics, NSAIDs, and corticosteroid injections are the primary medications used in OA management (see Table 23.4).[1,70-72]

Acetaminophen, an oral analgesic, is usually the drug of first choice.[40,70-73] Acetaminophen-containing compounds (Tylenol, Panadol, Anacin-3) have been cited as having almost no toxicity in recommended doses (up to 4 g/day) and little or no GI side effects. However, there is no anti-inflammatory effect; acetaminophen cannot be substituted for NSAIDs in this regard. Earlier clinical studies in OA demonstrated symptom relief from acetaminophen (3 to 4 g/day) greater than that of a placebo and slightly less than that of NSAIDs.[74] However, newer evidence suggests that acetaminophen has

minimal clinically important effects on pain and no significant effect on stiffness or physical function in patients with symptomatic knee OA.[73] Further, acetaminophen use can lead to liver and, less commonly, kidney toxicity, especially in individuals who drink excessive amounts of alcohol. As well, there is increasing evidence of an increased incidence of hospitalization due to GI perforation, peptic ulceration, and bleeding with acetaminophen use of more than 3 g/day compared to lower doses (less than 3g/day).[73]

NSAIDs have a place in the management of persons with OA who do not respond to acetaminophen and nonpharmacological measures.[72] NSAIDs may be used in combination with acetaminophen, and should be kept to the lowest effective dose to minimize GI toxicity. The COX-2 NSAIDs, described for RA management, had been prescribed for people who are at increased risk for GI problems until longer-term trials called their safety into question.

Intra-articular corticosteroid injections are often used for acute episodes with a moderate effect for pain relief, irrespective of the number of injections.[72] The knee is the most common site; however, soft tissue injections for subacromial, anserine, and trochanteric bursitis also may be effective.

Viscosupplementation or intra-articular injections of the knee with a form of hyaluronic acid (HA) is sometimes used. A number of synthetic forms are available (Synvisc, Hyalgan, Artzal). Hyaluronic acid is a naturally occurring polysaccharide that contributes to the thickness and viscosity of joint fluid in the healthy joint. In the OA knee, the levels of HA are lower and the joint fluid is thinner and less dense, reducing the ability of the fluid to lubricate and attenuate shock. Viscosupplementation therapy consists of a series of weekly injections. The reported effects of treatment are reduced pain and stiffness and improved function in people with mild to moderate knee OA, which may last for several months.[72] It is not clear if HA injections are more effective than corticosteroid injections, NSAIDs, or placebo injections. The injected HA does not replace normal joint fluid to achieve its effect as most is absorbed and cleared from the joint within a week. The risk of adverse effects is low. The most serious reported adverse event is an allergic reaction and less serious effects are injection site reactions and joint swelling. There is no evidence that supports increased efficacy of one product over another; however, high-molecular-weight hylan (Synvisc) may have greater efficacy.[72]

Glucosamine sulphate (GS) and glucosamine hydrochloride (GH) have been examined in placebo-controlled trials and found to be moderately effective for pain relief; however, the size of the effect diminishes when only high-quality trials are considered.[73] In one long-term follow-up study, patients who had taken GS, 1,500 mg/day for at least 12 months, were half as likely to undergo total knee replacement (TKR) at 5 years.[73] The structural-modifying effects of glucosamine products in hip and knee OA remain uncertain.

Topical agents include analgesics and anti-inflammatory preparations. Topical analgesics may be either rubifacients, which contain methyl salicylate, chemical compounds that produce a counterirritant effect, or capsaicin compounds, which reduce pain through depletion of the neurotransmitter substance P in peripheral nerves. To date, the only topical analgesic to show consistent efficacy in controlled clinical trials is capsaicin. Capsaicin is an alkaloid derived from red chili peppers and is available in topical analgesic creams in varying concentrations (Zostrix, Capsaicin-P, Dolorac). It has been shown to decrease pain approximately 33% when applied to specific joints four times daily.[72] The initial stinging or burning sensation disappears after several days of use; however, the need for frequent daily applications may limit the acceptability of this therapy for some patients.[72] Topical NSAIDs (diclofenac) are recommended as alternative or adjunctive therapy in symptomatic knee OA. Topical preparations delivered through gel, liquid, or patch formulations are absorbed through the skin with the help of an absorption enhancer are slightly less effective than oral NSAIDs with fewer adverse events.[31,72]

REHABILITATIVE MANAGEMENT

The chronic progressive nature of arthritis dictates a plan of care (POC) that includes patient education and self-management beyond the initial presentation. Although RA is systemic and OA is a more localized condition, both diseases can significantly affect health, function, participation, and quality of life. The rehabilitation of persons with arthritis requires comprehensive and coordinated efforts of a team of health professionals, including physical therapists, and ensures that the patient is first and foremost in treatment planning. The patient's ability to self-manage successfully is a major predictor of better health outcomes.[75] The physical therapist plays a pivotal role in helping the patient with minimal disability gain confidence and experience in using self-management skills to deal with the condition. The general goals and outcomes for persons with RA and OA are similar (see Box 23.4).

The remainder of this chapter will discuss physical therapist examination and interventions for people with RA and OA of the hip and knee. Although OA also presents at other joints, these two are the most common and disabling sites for OA and are most frequently seen by a physical therapist.

Physical Therapy Examination

A comprehensive and multisystem examination and history is an essential component of physical therapy management. Whether the patient is a direct access client or

seen in a system-based clinical setting, collaboration and communication with other care providers working with the patient is imperative. As with all patient-centered care, the patient is the primary stakeholder and should be actively engaged in goal setting and in the development of the POC.

Careful observation of the patient during the initial meeting and history can help inform the process. For example, observation of the patient's gait, ability to remove outerwear, and transfer into a chair for the history will provide the therapist with a quick assessment of functional ability.

History

The medical and social history will direct and inform the examination and provide insight into the development of a POC and need for potential resources. Ascertaining the patient's understanding of the disease and the implications of the disease is an important component of the interview process. In particular, the therapist should be concerned with identifying "red flag" signs and symptoms that indicate the need for immediate medical follow up (Table 23.5).[76] Pain assessment questions should include location, duration, pattern, quality, and intensity. Specific details regarding joint inflammation such as joint heat, swelling, and erythema should be recorded and confirmed during the physical examination. A determination of joint stiffness (morning versus after prolonged static posture), previous activity level, pattern and degree of fatigue, presence of co-morbidities, and current medication is also essential. Use and effectiveness of previous therapeutic interventions and complementary approaches should be noted. Although many physical therapy tests and measures are used during the examination, specific adaptations may be made to tailor the examination to the person with RA or OA. Especially in RA, the tender and swollen joint count appears to be a sensitive measure of systemic disease activity and guides the exercise prescription.[16]

Range of Motion

Tenderness and subjective reports of pain on passive range of motion (PROM) are highly indicative of inflammation; thus, gentle pressure and appropriate hand position is paramount during examination. Goniometric measurement of PROM is indicated and necessary at all affected joints after a gross joint screening to assist in monitoring treatment effectiveness. Standardized procedures are essential for reliable and valid measures. Otherwise, potential variations in intrarater and interrater reliability will reduce the accuracy of data comparison throughout the disease course.[77] If joint pain or poor activity tolerance prohibits measurement of PROM, the therapist may consider substituting a functional ROM test by asking the patient to touch various body parts (e.g., the top of the head and small of the back) to determine the available ROM for performing self-care activities. The therapist should note any tenderness, crepitus, or pain during examination of ROM.

Regardless of whether the patient has OA and monoarticular involvement or RA with polyarticular involvement, the impact of an involved joint on the kinematic chain or on the contralateral side should not

Table 23.5 "Red Flags" Suggesting the Need for Urgent Evaluation and Management

Flag	Differential Diagnosis
History of significant trauma	Soft tissue injury, internal derangement, or fracture
Hot, swollen joint	Infection, systemic rheumatic disease, gout, pseudogout
Constitutional signs (e.g., fever, weight loss, malaise)	Infection, sepsis, systemic rheumatic disease
Weakness	
Focal	Focal nerve lesion (compartment syndrome, entrapment neuropathy, mononeuritis multiplex, motor neuron disease, radiculopathy[a])
Diffuse	Myositis, metabolic myopathy, paraneoplastic syndrome, degenerative neuromuscular disorder, toxin, myelopathy,[a] transverse myelitis
Neurogenic pain (burning, numbness, paresthesia)	
Asymmetrical	Radiculopathy,[a] reflex sympathetic dystrophy, entrapment neuropathy
Symmetrical	Myelopathy,[a] peripheral neuropathy
History of significant trauma	Soft tissue injury, internal derangement, or fracture
Claudication pain pattern	Peripheral vascular disease, giant cell arteritis (jaw pain), lumbar spinal stenosis

[a]Radiculopathy and myelopathy may be due to infectious, neoplastic, or mechanical processes.

be overlooked.[78] When there is OA in a hip or knee, active motion in functional positions should be examined in all joints of both lower extremities (LEs). It is important to observe motion for symmetry and smoothness during gait, stair climbing, and rising from a chair. Ascending stairs requires the greatest amount and velocity of knee flexion and may be one of the best activities to determine knee function.[79] Decreased ROM at the hip and knee increases the risk for injury and falls. Approximately 50° hip flexion and 90° knee flexion are required to recover balance from a stumble during walking.[80]

Strength

Pain and joint effusions impede muscle contraction, limiting examination of strength. A patient may be able to generate force in the pain-free range but unable to completely contract in the painful range secondary to reflex inhibition. Traditional strength tests (e.g., manual muscle tests) are not appropriate in the presence of severely deformed and/or deranged joints. Functional strength assessments are more appropriate and will provide sufficient data to formulate treatment goals. Individuals who demonstrate a lag phenomenon will have limited active range and will not be candidates for traditional grading systems, because these are not sensitive to changes in the quality and quantity of muscle contraction. When documenting strength, it is important to include information on required modifications made to preferred testing positions, grade of strength exhibited in that arc of motion, and the method of strength testing used (e.g., break test, isometric holding at the end of range, or resistance throughout the ROM). Modifying the test protocol to include an isometric break test at midrange or most comfortable joint position generally yields higher grades than would be received if full range testing were done. Any modifications to standardized test protocols must be carefully documented. It is also important to document the time of day the patient was tested, as well as the use and timing of medications that might alter performance or exercise tolerance.

The functional threshold for LE strength has yet to be determined. However, reports from studies that have examined knee strength as a percentage of body weight suggest that isokinetic strength measured at velocities between 60° and 180° per second should be 20% to 30% body weight for knee extension and 20% to 25% for knee flexion.[78,79] Isometric knee extension below 10 kg (22 lb) of force (measured with the hip at neutral and knee at 90°) corresponded to marked disability in a study of persons with OA of the knee.[81] It is also important to perform strength testing of the muscle groups proximal to the affected joints to detect deficits that can affect function and contribute to abnormal biomechanics.

Joint Stability

Joint stability is essential for normal biomechanics, function, and independence. Inflammatory aspects of RA can lead to joint instability and eventual deformity. Intra-articular ligaments are highly susceptible to inflammatory and erosive changes in RA. Thus, ligamentous laxity of any affected joint should be fully investigated. Pseudolaxity, often detected in unicompartmental knee OA, should be differentiated from true ligamentous laxity.

Cardiovascular Status

Fatigue is one of the systemic manifestations of RA and frequently unappreciated. Individuals with OA also report fatigue. To best ascertain the impact of fatigue on patient functioning and independence, assessments should be made over the course of a single day and over several days. The increased incidence of asymptomatic cardiovascular disease, elevated risk for ischemic heart disease, and decreased cardiovascular fitness of individuals with RA demands specific attention.[24] Heart rate, respiratory rate, blood pressure and ratings of perceived exertion should all be measured during a functional activity that is reasonably stressful for the patient's current level of fitness. Excessive increases in perceived exertion may indicate the presence of inflammation or impairment of pulmonary and cardiac function that requires more extensive and formal evaluation. It is also important to determine cardiovascular fitness in individuals with OA, because cardiovascular deficits and increased risk for coronary artery disease are clearly associated with long-standing or severe disease.[24,82]

Functional Examination

Functional examination measures provide a rich and patient-centered approach to assessment. Functional measures may include ADL, work, and leisure activities (see Chapter 8, Examination of Function). The selection of a functional measure is based on the demographic features of the patient (e.g., age, gender), the level and depth of information required, and the measure's sensitivity/responsiveness in gauging the efficacy of treatment.[83-85] As with goniometric measurement, the reliability and validity are important for individual and comparative purposes. The *Functional Status Index* (FSI), a valid and reliable measure, was designed for use in outpatient rheumatologic settings to assess an individual's function in a sample of typical ADL. FSI parameters include pain, level of difficulty, and dependence (Appendix 23.A).[86,87] The *Health Assessment Questionnaire* (HAQ) is a generic measure consisting of the following five domains or subscales: disability, discomfort, pain, drug side effects (toxicity), and costs of care (Appendix 23.B).[88] The HAQ is a component of the ACR core of measures for

rheumatoid arthritis[89] and has been shown to correlate highly with measures of disease progression in RA (x-ray changes).[17] The modified HAQ, an abbreviated version of the HAQ, is a quick, easy to complete and score instrument that assesses the impact of disease activity on function and disability. Both versions are available for free online. Another arthritis-specific instrument, the revised *Arthritis Impact Measurement Scales 2* (AIMS2), expands the concept of function to include performance in psychological and social domains as well as physical function. The AIMS2 also measures the patient's satisfaction with current functional status and individual preferences for outcome.[90] The AIMS2 is not well suited for program evaluation or research purposes due to its complicated scoring algorithm and associated costs. The WOMAC is a widely used, valid, and reliable self-report instrument of 24 items in three categories specific to OA of the hip and/or knee (pain, stiffness, and function). The WOMAC takes about 10 minutes to administer and is easily scored by hand. It is available in either Likert form (0–4) or visual analogue scale.[91] Both the AIMS2 and the WOMAC are sensitive to clinical intervention and provide excellent clinically feasible, standardized measures in the domains of function and disability to monitor change over time. The *Knee Injury and Osteoarthritis Outcome* (KOOS) measure was developed using the WOMAC as a base and includes sports, recreation, and leisure items. This measure is readily accessible, is relatively easy to score, and demonstrates strong validity, reliability, and responsiveness in adults.[92] A modified version of the KOOS was developed for persons with hip osteoarthritis (HOOS).[93]

Mobility, Gait, and Balance

A complete and detailed gait examination is one of the most important contributions of the physical therapist to the rehabilitation team's understanding of the individual's functional abilities and serves to identify additional areas for examination and intervention.[94,95] (See Chapter 7, Examination of Gait, for a complete discussion.) Substantial differences in fall risks,[56] knee ROM, and gait velocity between patients with either OA or RA and their peers without arthritis have been demonstrated.[95,96]

Sensory Integrity

With RA, alternations in sensation may be evident with the presence of ***Raynaud's disease*** or with compression of nerves due to inflammation or joint derangement. Any indication of peripheral neuropathy or nerve involvement should be investigated using standard examination procedures (see Chapter 3, Examination of Sensory Function). Sensory changes resulting from other co-morbidities or from the normal aging process should be considered when appropriate.

Psychological Status

Individuals with chronic arthritis experience years of functional and social loss that would stress any person's ability to cope and adapt.[97] Although pain is significantly correlated with self-reports of depression, no firm association with function has been identified.[98] The overall psychological status of the individual with RA is generally similar to those individuals with other chronic diseases that threaten a severe change in body image and disruption of social integration (see Chapter 26, Psychosocial Disorders). Individuals respond to these threats with various coping strategies to maintain psychological well-being. No single strategy can be deemed definitely better than another, although for individual patients some strategies will lead to better coping and more positive outcomes than others. Exploration of the patient's attitude toward rehabilitation and readiness to make health behavior changes, as well the availability of social support, can assist the therapist in shared goal setting and identifying realistic expectations of future functional ability. Persons with RA face the additional challenges of living with a chronic disease that is characterized by a fluctuating disease course and must learn to adapt their lifestyle, activity level and medication and sleep schedule according to their disease activity. Thus, it is paramount that the therapist works with the patient to set realistic, achievable goals and educate the patient about warning signs of flares to help the patient self-manage.

Anxiety and depression are also common in patients with OA and may alter the pain experience, function, and response to treatment interventions.[99] Chronic pain, fatigue, loss of function, and reduced activity levels can all contribute to emotional distress. It is therefore important to recognize the signs of anxiety and depression and, if indicated, refer to appropriate screening services and resources to help individuals manage their psychological symptoms through improved coping skills.[100] Participation in the Arthritis Self-Management Program has been shown to improve coping.

Environmental Factors

Therapists should be aware of environmental factors in the home, work, and leisure environments that might serve as facilitators or barriers to functioning and warrant specific identification, examination, and recommendations to address (see Chapter 9, Examination of Environment.) A discussion about the home and work environments may reveal conditions that threaten independence that can be addressed through ergonomic and environmental modifications and school or workplace accommodations. The costs of such changes may be a limiting factor for implementing these recommendations. The work environment affects employment and

disability in more ways than the physical setting and task requirements. Acceptance and understanding by supervisors and co-workers of the disease and self-management requirements of the worker with arthritis are important determinants of maintaining employment and income. Other environmental factors common to both the RA and OA ICF Core Sets include technology and assistive devices for ADL, mobility, transportation, and employment; design and access to buildings; climate; and attitudes of family, friends, and health professionals.[62,63,101,102]

Physical Therapy Intervention

The development of specific goals and expected outcomes for the individual with arthritis is based on the following general goals and expected outcomes developed in conjunction with the patient (Box 23.4).

The specific goals and outcomes identified for each patient will depend on the type of arthritis, disease activity level, the clinical presentation, and patient preferences in line with patient-centered care. Mutual goal setting promotes patient participation in treatment. It is the physical therapist's responsibility to document the POC, implement that plan safely and effectively, and delegate responsibility appropriately to ensure that the patient's goals can be reached. The therapist should ensure that treatment goals and objectives are measurable, attainable, and documented, with specific timeframes included (e.g., increase left shoulder flexion ROM by 10° in 2 weeks, and independent ambulation with platform crutches on level surfaces for at least 250 feet without fatigue within 1 month). Failure to achieve goals within the stated timeframe indicates the need for reevaluation and reformulation of the goals. Goals and outcomes should be revised to reflect changes owing to both personal and environmental factors that may affect progress or alter the proposed time frames (see Chapter 1, Clinical Decision Making).

Box 23.4 Examples of General Goals and Outcomes for Patients with Arthritis

Impact of impairments is reduced.

- Pain is decreased.
- ROM of all joints is maximized sufficient for functional activities.
- Muscle activation and strength is maximized sufficient for functional activities.
- Joint stability is maximized and biomechanical stress on all affected joints are decreased, deformity prevented.
- Endurance is increased for all functional activities and desired leisure activities.

Ability to perform physical actions, tasks, or activities is improved.

- Independence in ADL is promoted, including dressing, transfers, and self-care.
- Efficiency and safety of gait pattern and balance are improved.
- Patterns of adequate physical activity or exercise to maintain or improve musculoskeletal and cardiovascular fitness and general health are established.

Health status and quality of life are improved.

- Patient, family, and caregivers are educated to promote the individual's capacity for self-management, including joint protection.

Adapted from *Guide to Physical Therapist Practice.*

Modalities for Pain Relief

A variety of physical agents are available to relieve pain and prepare the patient for passive and dynamic stretching and other exercise interventions. The most common form is thermotherapy.

Heat

Superficial heat, heat that penetrates only a few millimeters, produces localized analgesia and increases circulation in the vicinity where it is applied. Types of superficial heat include moist hot packs; dry heating pads; and lamps, paraffin, and hydrotherapy. The evidence supporting the effectiveness of these modalities is weak, but patients often report that they gain comfort from moist heat. Paraffin is particularly useful in delivering superficial heat to irregularly shaped joints or to individuals who cannot tolerate the weight of a moist hot pack. Hydrotherapy allows the therapist to combine heating of tissues with exercise, and provides the patient the experience of aquatic therapy, although it is expensive. Systematic reviews of heat and cold therapy in arthritis suggest small to modest effects.[103,104]

Deep heating modalities, such as ultrasound, may affect the viscoelastic properties of collagen and increase the plastic stretch of ligaments, providing modest improvements in pain and function in individuals with knee OA.[105] However, their efficacy in RA is not demonstrated.[106] Their use in treating individuals with RA during the acute stage of inflammation is contraindicated because they may stimulate collagenase activity within the joint, furthering its destruction.[107,108] Furthermore, modalities that do not readily translate to home use foster a dependency on clinical care and do not promote self-management.

Cold

Local applications of cold will also produce local analgesia, increase superficial circulation at the site of application following an initial period of vasoconstriction,

and decrease intra-articular temperature.[109] Cold is particularly useful around joints that are inflamed and swollen, a condition that usually worsens with the application of superficial heat modalities. Therapists may use either wet or dry application techniques. Superficial cold is contradicted in patients with Raynaud's phenomenon or *cryoglobulinemia,* linked to an abnormal protein (cryoglobulins) in the blood that gels at low temperatures. Both may be associated with RA.

Electrical Agents

Therapists may also wish to consider using other modalities for pain relief in treating the individual with RA, including transcutaneous electrical nerve stimulation (TENS), although the value of TENS as reported in the literature is inconsistent.[110,111] A meta-analysis of studies investigating TENS for knee OA pain concluded that the mode of TENS applied did affect results, repeated use was more effective than a single application, and use for at least 4 weeks was the most effective.[111]

Orthoses, Splints, and Braces

In RA, hand and wrist orthoses may be used to immobilize specific joints and help reduce pain and swelling by providing local rest and support. There are three primary types of splints: functional (used to restore or improve function), corrective (used to improve alignment), and resting (used to maintain joint alignment and reduce pain). Resting splints are worn at night or periodically during the day. There is evidence of small benefits for pain reduction and increased function with the use of functional splints. Hand splints may improve grip and pincher strength.[112] There is evidence that wearing functional wrist splints decreases grip strength and does not affect pain, morning stiffness, pinch grip, or quality of life with regular wear.[113] A study that investigated the effect of functional wrist splint wear on task performance reported that wearing a commercially available elastic wrist orthosis resulted in some decrement in performance speed on a number of common tasks, though pain was significantly reduced for all tasks.[114] There is consistent evidence supporting the use of splints for short- and long-term pain relief in hand OA.[115]

Foot orthoses also may be used to alleviate pain through biomechanical support or correction for individuals with knee OA. A lateral wedge insole designed to reduce medial compartment stress appears to reduce pain and NSAID use in some individuals with knee OA.[116] Other methods that show promise in treating knee OA pain are patellofemoral taping,[117] and load shifting or unloader knee braces (stress shifted away from most involved area).[116] All orthotic interventions require professional evaluation, selection, education, and monitoring of use.

Rest

Complete bed rest is rarely recommended. Adequate quality and quantity of sleep at night and short rests during the day are preferred. General recommendations include 8 to 10 hours of sleep per night and brief 30-minute rest periods during the day. Inactivity is a common problem for people with arthritis and may lead to deconditioning, depression, lower pain thresholds, diminished bone and soft tissue health, and increased risk for other serious health conditions. Thus, a major goal of therapy is to assist the person to maintain or regain adequate levels of physical activity and avoid the unnecessary consequences of inactivity.[16]

Range of Motion and Flexibility Exercise

A major factor affecting joint mobility in individuals with RA is the level of inflammation and resting position in which specific joints are maintained. For example, intra-articular pressure is reduced when the knee is slightly bent. Although helpful in reducing joint pain, this flexed position may lead to capsular and musculotendonous shortening and eventual contracture. Patients should be taught proper positioning when resting and should be encouraged to perform daily, active ROM as tolerated to maintain motion. Active-assisted, passive, and proprioceptive neuromuscular facilitation (PNF) techniques may also be applied to shortened muscles.[118] Pain should be respected at all times and should be minimal during and after exercise. Evoking a pain response during stretching may lead to a reflex contraction of the agonist muscle as opposed to creating a relaxation response. Stretching exercises to lengthen shortened muscles should be performed slowly, held for 20 to 30 seconds two to three days a week or more often if indicated. It is important to educate the patient not to do stretching exercises that involve inflamed, swollen joints because they are at risk for capsular stretching and rupture.[119] Common wisdom recommends that *exercise-induced pain should subside within 1 hour*. If the patient reports discomfort lasting longer than 1 hour, it may indicate that either the technique, intensity, or duration of the exercise was too great and should be reduced or modified at the next exercise session. Patients should be encouraged to exercise on their own during those times of the day when they feel best. Local pain relieving modalities before or immediately after exercise may be useful and increase exercise adherence.

In hip and knee OA, manual therapy may offer some additional benefit within a comprehensive treatment program that includes exercise.[118] Manual therapy is not generally recommended for individuals with RA who have joint inflammation or resultant laxity.

Strengthening Exercise

Decreased muscle function (strength, endurance, power) in persons with arthritis arises from both direct and indirect effects of the disease. These include intra-articular

and extra-articular inflammatory disease elements, side effects of medication, disuse, reflex inhibition in response to pain and joint effusion, impaired proprioception, and loss of mechanical integrity around the joint. A variety of conditioning programs can be effective for improving strength, endurance, and function without exacerbation of pain or disease activity.

Initially, isometric exercise may be indicated to improve muscle tone, strength, and static endurance; to recruit or activate specific muscles; and to prepare joints for more vigorous activity. Although isometric exercise does avoid dynamic joint stress and mechanical irritation, it can produce other unwanted effects. Isometric exercise performed at more than 50% of maximal voluntary contraction constricts blood flow through the exercising muscle, leading to post-exercise muscle soreness, and the increased peripheral vascular resistance produces increased blood pressure.[119] In the knee and hip, high-intensity isometric contractions are associated with significant increases in intra-articular pressure and reduce synovial circulation.[120-122] Patients with cardiovascular disease should perform these exercises with caution and be sure to breathe during the contraction because holding one's breath can increase intra-abdominal pressure (Valsalva maneuver). Patient instructions for isometric exercise should include the cautions to (1) maintain the contraction for no more than 6 seconds; (2) avoid maximal effort because it is neither necessary nor desirable; (3) exhale during the contraction and inhale during a similar time period of relaxation; and (4) not contract more than two muscle groups at a time.

Dynamic exercise includes both shortening (concentric) and lengthening (eccentric) contractions. Strength and endurance may be improved through resistance (physiological overload) supplied by weight of the body part or external resistance in the form of free weights, elastic bands, or a variety of resistive exercise equipment. A cautious approach to resistance training is recommended to protect unstable or inflamed joints from damage.[16,119] Strengthening exercise should be performed within the pain-free range. Maximum benefit and maintenance can be achieved by incorporating functional movements and body positions in the recommended exercise routine. The use of well-controlled smooth movement toward the end part of the range is advised, and modifications to resistance, repetitions, or frequency are recommended as needed. Gradual progression of resistance and repetition is recommended. Reduce exercise intensity, frequency, or motion if increased joint swelling or pain occurs (local inflammatory response).

Individuals with RA benefit from maintaining or restoring muscular fitness. A number of well-controlled studies have reported on strengthening programs that provide overload with results indicating positive adaptations in muscle and functional performance with no exacerbation of disease symptoms. Data from selected RA exercise studies are presented in Box 23.5 Evidence Summary.[123-135] Loads of up to 70% one repetition maximum (1RM) used in a circuit training resistance program for persons with controlled RA demonstrated no exacerbation in joint symptoms and significant improvements in strength and function.[123,124,126,128]

Designing exercise interventions for individuals with RA requires careful consideration of the patient's disease activity, disease severity, and systemic disease features. Persons with RA in an active flare-up should limit their exercise to daily ROM exercises incorporated into ADLs to promote adherence to active joint movement and isometric exercises to promote strength. Walking as tolerated is encouraged together with daily periods of rest and a full night of sleep to manage fatigue. When the disease activity subsides, the exercise program can be progressed by adding dynamic strengthening exercises, with caution to avoid stress on deranged joints or cysts, and greater repetitions of isometric exercises as well as greater engagement in physical activity. When the disease is in remission, aerobic exercises and dynamic exercises with resistance should be considered to promote cardiovascular health and improve strength and conditioning.[16]

In persons with knee OA, the evidence is strong and consistent that LE exercise that includes neuromuscular and functional training reduces pain and improves function. Interventions have included isometric, isotonic, and functional exercise, as well as proprioceptive and balance training. Interventions have been tested in both clinically supervised and self-directed settings with positive results and acceptable adherence.[97,136] Evidence supporting the use of exercise in the management of knee and hip OA is presented in Box 23.6 Evidence Summary.[137-142] Physical therapists should routinely incorporate strategies to enhance patient motivation and adherence to the therapeutic exercise and home exercise programs (HEPs) including exercise booster sessions (periodic follow-up appointments), goal setting, and other self-efficacy enhancing practices.[119]

Cardiovascular Training

Individuals with RA or OA are usually deconditioned compared to their age-matched peers. A number of systematic reviews and well-controlled trials have reported improvements in aerobic capacity and activity levels through regular cardiovascular conditioning without aggravating joints and other disease symptoms.[16,24,125,130] Programs and guidelines appropriate for healthy adults or older individuals can be instituted following the

Box 23.5 Evidence Summary Therapeutic Exercise in the Management of Rheumatoid Arthritis (RA)

Author (yr)	Design and Sample	Intervention	Adherence	Outcomes
Hakkinen et al[123] (2001)	RCT. 70 pts w/recent onset RA. 24 month study. No pt had taken glucocorticoids or DMARDs previously. Random assignment to 2 groups. Randomization performed by clustering pts according to age (<50, >50 yo) and sex to keep groups comparable.	Strength training group: all major ms @ 50-70% 1RM. 8-12 reps x 2. ~45' per session 2x/wk. (intensity re-evaled every 6 months) Total mins/wk: 90' ROM group: no resistance, only ROM and stretching 2x/wk. All encouraged to participate in recreational activities 2-3x/wk (30-45' ea.) Training diaries examined @ 6-month intervals. All treated w/meds to achieve disease remission.	62 pts completed study. Strength group compliance = 1.4-1.5x/wk.	Sig incr ms strength (19-59%). Sig improvements in clinical disease activity parameters, HAQ scores, and walking speed in the strength group. Improvements in ms strength, disease activity parameters, and phys funx in control group but < strength group. *"Regular dynamic strength training combined w/endurance-type PA improves ms strength and phys funx, but not BMD*, in pts w/early RA, w/out detrimental effects on disease activity."*
Baillet et al [124] (2009)	RCT. Data collected at 1, 6, and 12 months. 50 patients. All pts treated with DMARD before enrollment. ECG performed on every pt, all had consultation w/cardiologist (pts > 45 yo, + CVD risk factors or abnorm ECG). Exclusion criteria: tx w/ >10 mg glucocorticoid/day, no/unstable DMARD regimen, disease activity score 28 variation >1.2 past 3 months, an age <18 >70 yo and global funx status RA class III or IV. Pts unable to follow the programme (complete ex, follow-ups, educational programme or complete questionnaire) excluded. Needed: 38 pts in DEP group. 76 pts in control group (conventional jt rehab). *But sample size limited to 50.*	DEP group: 1st week = educational/testing meetings 2nd week = occupational therapy – RA on ADLs 3rd week = OT skill ex and ADLs w/incr intensity (against resistance). 4th week = ex focused on office tasks. Training programme: improve ms strength, flex, endurance, balance. 5x/wk in gym (45'/day) and pool (60'/day). Cycling activity = HR 60-80% HRM. Resistance/intensity ex designed individually. Scheduled breaks and relaxation sessions for p! tolerance/psycho-soc. "warm-up" and "cool-down" for each session. Pts kept a diary. Control group: Multidisciplinary prog – 3 day intervention (~20H) designed to incr knowledge of disease, management, jt protection. Hydrotherapy (45' @ 35°C) 1st day, relaxation 45' 2nd day, phys ex (45 min/day) to prevent atrophy and tension.	25 randomly placed on DEP. 25 into control group. 2 individuals left after randomization. No pts lost to follow-up. 1 not assessed for NHP and AIMS2-SF @ 1 month. 3 pts not assessed @ 6 months. 4 not assessed @ 12 months.	HAQ (primary outcome) improved throughout length of trial in the DEP group** improvement > DEP than standard joint rehab group @ 1 month but not 6 months or 12. DEP improved NHP (Nottingham HealthProfile) and aerobic fitness @ 1 month but not after. DEP improved DHI, SODA, DAS 28, AIMS2-SF, but not sig.

Author (yr)	Design and Sample	Intervention	Adherence	Outcomes
de Jong et al[126] (2003)	RCT. Testing effectiveness and safety of a 2-yr intensive ex program (RAPIT) w/those of PT – aka UC – usual care. 309 RA pts assigned to RAPIT or UC. Primary end points funx ability (MACTAR), Pt preference disability questionnaire, and HAQ and effects on x-ray progression in large joints.	Stratified for age (<50 and >50) and sex put into random digit generator. RAPIT: 2x/wk ex prog 1.25 hrs/session. 2.5 hrs/week. 3 parts per session: bike training (20'), ex circuit (20') and sport/game (20'). Each session had "warm-up" and "cool-down". Bike settings based on 1) HR during ride 2) RPE (0-10). HR kept @ ~70-90% HRM and RPE @ 4-5. Ex circuit: 8-10 ex for ms strength, endurance, jt mobility, ADLs. Ex: rest→ 90 sec/60 sec 1st weeks – 90 sec/30 sec after 6 months. Each ex repeated 8-15x. Sport/game section: impact-delivering sport activities. Impact loading also during "warm-up" and "ex circuit" portions. UC group: Tx by PT only if regarded as necessary by MD. All pts MDs had choice for med selection and other tx strategies (except high-intensity WB ex).	Needed 119 pts/group for statistical sig. planned to enroll @ least 150/group. Used 309 pts. RAPIT group slightly younger 45 yo vs 47 yo mean. > proportion of females – 79% vs 72%. 9 pts randomized but refused participation. Lost 5 pts in UC and 14 in RAPIT over the 2 yrs. 14 other RAPIT pts failed to attend ex classes but were reg evaled. Median % of sessions attended was 74%. 65% had high attendance rate first 6 months, 49% second 6 month period and stable thereafter.	After 2 yrs RAPIT > improvement in funx ability than UC. Mean difference in change of MACTAR was 2.6 1st year and 3.1 2nd year. 2 yr mean HAQ change -0.09. Median x-ray damage didn't incr in either group. Both groups w/considerable baseline damage showed progression in damage (more obvious in RAPIT group). RAPIT effective in improving emotional status. No detrimental effects on DA were found. *"Long-term high-intensity ex program is more effective than UC in improving funx ability of RA pts. Intensive ex does not incr x-ray damage of the lrg jts, except possibly in pts w/considerable baseline damage of the lrg jts."*
Eversden L, et al[127] (2007)	RCT. Hydrotherapy vs Land Ex. Effects on overall response to tx, phys funx, and QOL. 115 pts randomly assigned. Men and woman 18 yo+ w/RA in funx classes 1-3 in Birmingham clinics Required to understand and follow simple instructions in English. Stable dose of DMARDs for 6 weeks and NSAIDs for 2 weeks before entry. No injections of corticosteroids allowed in 4 wks before study. Excluded pts w/sx 3 months prior or scheduled, pts who'd received PT or hydrotherapy in 6 months before study. Pts w/chlorine sensitivity,	30' session 1x/wk for 6 weeks (both water and land groups). Pts allowed to default up to 3 sessions as long as 6 were completed. HEP given to all pts – not required to do ex b/n tx but could if desired. Group sizes 1-4 for hydro and 1-6 for land ex @ a time. Ex tailored to each pts ability. "Warm up" = mobilizing and stretching. Core ex focused on jt mobility, ms strength, and funx activities. Degree of difficulty reviewed weekly to ensure progress. "Cool down" phase after each session.	11 pts did not complete tx in land ex. 4 pts did not complete in hydrotherapy. Goal to recruit 60 pts into each of the groups. 115 pts were randomized. 57 pts in hydrotherapy (46 had data collection – primary outcome). 58 pts in land (40 pts had primary outcome data).	Primary outcome: self-rated global impression of change – 7pt scale. Secondary outcomes: EuroQol health related QOL, EuroQol health status valuation, HAQ, 10m walk time, p! scores – collected @ baseline, after tx, 3 months later. Hydrotherapy pts sig "much better" or "very much better" than land ex.10m walk test improved in both groups. No sig diff b/n groups in HAQ, EQ-5D utility score EQ VAS and pain VAS. "Pts w/RA treated w/hydrotherapy are more likely to report feeling much better or very much better than those w/land ex immediately on completion of the tx programme. This perceived benefit was not reflected by differences b/n groups in 10m

	infected open wound, incontinence of faeces, poorly controlled epilepsy, HTN, DM, and fear of water were excluded from hydroptherapy. Excluded: pregnant women, pts w/co-morbid conditions preventing safe use of hydrotherapy, known carries of staph in the URT and weighing >102 kg b/c of safety procedures for the pool.			walk times, funx scores, QOL measures and pain scores.
Lemmey et al[128] (2009)	RCT. "Efficacy of high-intensity progressive resistive training (PRT) in restoring ms mass and funx in pts w/RA" also to "investigate the role of the insulin-like growth factor (IGF) system in ex-induced ms hypertrophy in the context of RA." 28 pts w/est controlled RA. Conducted July 2004-January 2007.	2 groups: 2x/wk PRT (n=13) or range of mvt home ex control group (n=15). Dual x-ray absorptiometry-assessed body comp; objective phys funx; disease activity; and ms IFG's assessed @ weeks 0 and 24. Stratified by age, sex and estrogen status. Assessments done @ baseline and immediately following 24 wk training period. Pts required to fast and refrained from ex for 24 hrs. PRT group: 24 wks, 2x/wk. 3x8 @ load of 80% 1RM per ex. 1-2' rest b/n ex. leg press, chest press, leg ext, seated row, leg curl, triceps ext, standing calf raises, and bicep curl. Goal to achieve hypertrophy. 1 set completed in 1st week 2 sets 2nd week 15 reps/set @ 60% of 1RM wks 1-4. 12 reps/set @ 70% 1RM 5-6 wks. 8 reps/set @ 80 % max weeks 7-24. 1RM reassessed every 4 wks. "warm up" and "cool down" periods – 10' ea. Low-intensity ROM ex. asked to perform these 2x/wk at home (ROM ex). ROM was control condition b/c most commonly prescribed for Pts w/RA. All completed training diary to check for compliance and adverse effects. Control pts phoned every 2 weeks.	Needed sample size for each group = 5 subjects. Aimed for 18 subjects to cover drop out. (36 total) 36 individuals were randomized into 2 groups. 28 attended baseline assessment and commenced training. PRT: 48 scheduled sessions – completed avg 34.6 sessions. (73%) ROM ex group: good compliance avg 25.9 sessions (54%).	PRT incr LBM and ALM (appendicular lean mass); reduced trunk fat mass by 2.5 kg (not sig); and improved training-specific strength by 119%, chair stands by 30%, knee ext strength by 25%, arm curls by 23%, and walk time by 17%. Body comp and phys funx remained unchanged in control patients. Changes in LBM and regional lean mass assoc w/changes in objective funx. Coinciding w/ms hypertrophy, previously diminished ms levels of IGF-1 and IGF binding protein 3 both incr following PRT. "*In an RCT, 24 weeks of PRT proved safe and effective in restoring lean mass and funx in pts with RA. Ms hypertrophy coincided w/sig elevations of attenuated ms IGF levels, revealing a possible contributory mechanism for rheumatoid cachexia. PRT should feature in disease management.*"

Box 23.5 Evidence Summary Therapeutic Exercise in the Management of Rheumatoid Arthritis (RA)—cont'd

Author (yr)	Design and Sample	Intervention	Adherence	Outcomes
Smidt et al[129] (2005)	Summarize available evidence on effectiveness of ex therapy for pts w/ disorders of ms, nervous, respiratory, and cv systems. *Systematic reviews*. **OA:** 7 reviews for hip/knee OA. 3 reasonable/good quality reviews: ex therapy, consisting of strengthening, stretching and funx ex is effective for pt with knee OA compared to no tx. Indications that ex therapy is effective for pts w/hip OA – based on 1 large RCT. Insufficient evidence to support/refute the effectiveness of a specific type of ex therapy (individual, group, hydro tx) for pts w/knee or hip OA. *(Fransen et al 2002, McCarty and Oldham 1999, Pendleton et al 2000, Petrella 2000, Philadelphia Panel 2001a, Puett and Griffin 1994, van Baar et al 1998a, Van Baar et al 1999, van Baar et al 2001)* "Ex therapy, consisting of strengthening, stretching, and functional exercises, is effective for patients with knee OA, compared to no tx" – *Fransen, Philadelphia panel, van Baar 1998a, Van Baar 1999, and 2001*. One large RCT stated "ex therapy is effective for pts w/hip OA" – *van Baar et al 1998b*. "Insufficient evidence to support or refute the effectiveness of a specific type of exercise therapy (individual, group therapy, or hydrotherapy) for pts with knee or hip OA."	Used overview of each systematic review (>60 pts) was made. Categorized according to quality score: good (>80), reasonable quality (60-79), mod quality (40-59), poor (20-39) and very poor (<20). Used reasonable (60-70) and good (>80). Conclusions were discussed with panel of experts and categorization of conclusion based on 2 research questions: A) What is the effectiveness of ex therapy, compared to no tx, a placebo, or a wait-and-see policy? B) What is the effectiveness of ex therapy, compared to other tx (steroid injections)? Is one specific type of ex therapy more effective than others?	104 sys reviews selected. 45 = good quality. Overall inter-rater agreement for quality assessment was (86%). Most disagreements caused by differences interpretation when discussing the power of RCT and heterogeneity of RCT and outcomes. **RA:** 2 systematic reviews investigated the effectiveness of ex therapy for pts with RA. *(Augustinus et al 2000, van den Ende et al 1998, van den Ende et al 2002)*. One systematic review → conclusion there is insufficient evidence to support or refute the effectiveness of ex therapy for patients w/ rheumatoid arthritis. (*van den Ende 1998 and 2002)*.	Ex therapy effective for pts w/knee OA, sub-acute (6-12 wks) and chronic (>12 wks) lbp, therapy is effective for pts w/ ankylosing spony, hip OA, Parkinson's disease, pts w/stroke. *Insufficient evidence* to support/refute effectiveness for neck pain, shld pain, repetitive strain injury, RA, asthma, and bronchiectasis. NOT effective for pts w/acute LBP. Effective for wide range of chronic disorders.

Box 23.5 Evidence Summary Therapeutic Exercise in the Management of Rheumatoid Arthritis (RA)—cont'd

Author (yr)	Design and Sample	Intervention	Adherence	Outcomes
Ottawa Panel [130] (2004)	Create guidelines for the use of ther ex and manual therapy in the management of adult patients (.18 yo) w/a dx of RA. Evidence from comparative controlled trials ID and synthesized using Cochrane Collaboration methods.	Set inclusion/exclusion criteria with a panel of 9 experts. Performed Lit search for RCTs – expanded to case-control, cohort, and non RCTs. *Rehab interventions:* IDed as specific funx strengthening ex, whole-body funx strengthening ex, and PA. comparators = placebo, untx or use of ed pamphlets or written instructions for self-management.	16 studies out of 2,280 potential articles. 862 articles for manual therapy – 4 had potential – none included. *Concluded:* ther ex – including specific funx strengthening and whole-body funx strengthening are a beneficial intervention for pts with RA – benefit may vary according to disease acuity and the time frame during which the outcomes are measured. *Clinical benefits:* pain relief, upper-limb (grip) and lower-limb force, and funx status *Other benefits:* improved overall funx, and decr number of sick leaves.	6 + recommendations clinical benefit were developed on therapeutic ex. The efficacy of manual therapy intervention could not be determined for lack of evidence. 6 + recommendations of clinical benefit were developed on ther ex. efficacy of man therapy interventions could not be determined for lack of evidence. *Panel recommends use of ther ex for RA. Further research is needed to determine efficacy of manual therapy in the management of this disease.* Recommend: knee funx strengthening, whole-body funx strengthening, general PA, and whole-body, low-intensity ex, for the management RA. Evidence is lacking for shld/hand strengthening ex and whole-body, high-intensity ex or manual therapy.
Bearne [131] (2002)	Compare quadriceps sensorimotor funx, lower limb funx performance and disability in pts w/RA and healthy subjects and to investigate the efficacy and safety of a brief rehab regime. Quad strength, voluntary activation, proprioceptive acuity and the aggregate time to perform 4 common activities – compared b/n 103 RA pts w/lower limb involvement and 25 healthy subjects.	*Quad strength/voluntary activation:* strain gauge system attached to specially constructed chair – seated w/hip/knee flex 90 deg. Used percutaneous estim on voluntary isometric contraction. Recorded 3 max voluntary contractions and analyzed. Weakest leg = "index leg". Recorded ms strength and voluntary activation using strongest MVC of the index leg for analysis.	Measured: Health Assessment Questionnaire, clinical disease activity and plasma concentration of proinflammatory cytokines were measured in the RA pts.	RA pts had weaker quads, poorer activation, and proprioceptive acuity and took longer to perform AFPT. Rehab incr quad strength and voluntary activation and subjective disability w/out exacerbating disease activity. All improvements maintained @ 6 month follow-up. No change during control period.

Box 23.5 Evidence Summary Therapeutic Exercise in the Management of Rheumatoid Arthritis (RA)—cont'd

Author (yr)	Design and Sample	Intervention	Adherence	Outcomes
		Rehabilitation: 47 pts randomized to begin immediately, 41 pts delayed. 10 ex sessions (2 x/wk x 5 wks) – simple, progressive, individually prescribed ex designed to incr quad strength, address each pt's disabilities and improve balance and coordination, using inexpensive and unsophisticated equip. Each ex session had warm-up ex (i.e., 5 mins cycling), 24 isometric MVCs (4 sets x 6 contractions – 1 min rest between each) @ 90 deg knee flex to incr quad strength, 3 individually prescribed funx ex (sit-to-stand, step-ups etc) and 3 balance ex – 1-5 min and # reps recorded. *Pts were encouraged and given feedback on performance.* *Each ex session = 30-40 mins.*		
Brorsson et al[132] (2009)	*"To eval the effects of hand ex in pts with RA, and to compare the results with healthy controls."* 40 women (20 w/RA and 20 healthy) performed hand ex programme. Results evaluated after 6 and 12 wks w/hand force measurements. Hand funx was evaluated with Grip Ability Test (GAT) and with patient relevant questionnaires – Disability of the arm, Shoulder, and Hand – DASH and Short Form-36. US measurements performed on EDC for analysis of ms response to ex programme.	*Study period:* 18 wks – examined @ 6 wk intervals. 2 baseline exams completed before ex regimen began. (week 0). Ex prog performed for 12 wks. Designed according to Flat (reference 12) and performed: 5x/wk, each task x 10 and position of max effort held 3-5 sec with 20 sec rest b/n reps. Ex sessions separated by @ least 1 day. *Ex program took 10 min to complete* – used therapeutic putty (85g). pts chose soft, medium, or firm putty. *Pts kept diaries during training period to declare all ex.*	40 subjects recruited – 2 control and 2 RA pts withdrew = 36 completed the study.	"The ext and flex force improved in both groups after 6 wks. Hand funx (GAT) also improved in both groups. The RA group showed improvement in the results of the DASH questionnaire. The cross-sectional area of the EDC incr significantly in both groups measured with US." Conclusion: *"A sig improvement in hand force and hand funx in pts with RA was seen after 6 weeks of hand training; the improvement was even more pronounced after 12 wks. Hand ex is thus an effective intervention for RA pts, leading to better strength and funx."*
Crowley [133] (2009)	"Review of literature....evaluate the effectiveness of HEP for pts w/RA." Searched 7 databases.		8 papers out of 18 were included. All had high risk of bias. *"Results show that HEP are effective in*	"The results of this review highlight the benefits of HEP for pts w/RA, when encompassed physical, funx, and QOL domains. Further research is needed to confirm these findings."

Box 23.5 Evidence Summary Therapeutic Exercise in the Management of Rheumatoid Arthritis (RA)—cont'd

			improving ms strength, jt mobility, shld funx, and self-efficacy and reducing morning stiffness, number of tender/swollen jts, and p! w/out incr inflammation or disease activity."	
Hsieh et al [134] (2009)	"Compare the effectiveness and safety of supervised aerobic ex and home aerobic ex in female Chinese pts with RA". *Single-blind RCT.* 30 patients w/RA assigned to group. Supervised aerobic ex prog supervised by PT, home program done @ home after 1 instructional session.	1 hr ex: 3 x/wk x 8 wks. Aerobic capacity and disease-related variables, including p! intensity, funx ability, psychological status and jt funx were measured. 10 min stretching, 10 min warm-up, 30 min pool ex, 10 min cool down. Objective to allow target HR of 50-80% VO2 peak for @ least 30 mins. Multiple short sessions were allowed for total of 30 mins. Used daily logs for self-monitoring of duration intensity and freq of ex. called every 2 wks and checked ex log @ end of 8wk prog.	38 patients recruited → 30 pts randomized into 2 groups. All completed study. Most pts ACR class II.	"An 8 wk supervised aerobic ex prog induced sig improvement in aerobic capacity of female Chinese patients w/RA, and was superior to a home aerobic ex prog. Both prog of aerobic ex were safe for female Chinese pts with RA." Compliance in SAE = 100%, HAE = 52% ranging 32-75%. No sig diff in baseline data b/n groups. *Within-group:* variables of ex tolerance test (VO2, MET, work, O2 pulse, SBP @ peak CV response and VO2, MET @ ventilator threshold) = sig improvement found in SAE group but not HAE. Stat sig diff observed for b/n group comparisons b/n SAE and HAE w/changed score b/n baseline data and post-ex data in Vo2, MET, work, O2 pulse, and SBPT @ peak CV response. Sig diff b/n group comparison in changed score of VO2 and MET @ vent threshold. SAE induced mean improvements of 20%, 16%, 14% in VO2 peak, peak workload, and O2 pulse respectively. No sig difference b/n groups for disease-related measures except global self-assessment and global MD assessment. *Within group SAE* = sig diff for global p! intensity, ADL p! scale, grip strength, walking time, and global self-assessment. HAE group = sig ex effect in global p! intensity, ADL pain scale, and walking time. *No sig b/n group diff regarding changed score b/n baseline data and post-ex data for disease-related measures.*

Author (yr)	Design and Sample	Intervention	Adherence	Outcomes
Kennedy[135] (2006)	Eval the outcome of intensive ex prog for pts with RA on bone mineral density and disease activity. Searched 6 databases. Included: papers investigating the effect of aerobic and/or strengthening prog on pts w/RA. 11 papers out of 30 returned were included; 4 of 11 had low risk of bias. 1999-2004.	***van den Ende et al 2000 –*** 20 female pts. Sample size 64. *Isometric and isokinetic ms strength + bicycling for 15 min, 3x/wk @ 60% age predicted max + usual care vs usual care (ROM + isometric).* Outcome measures: disease activity, ms strength, jt mobility, funx ability. Results: Incr ms strength and physical funx w/no incr disease activity in intensive ex group. ***de Jong et al 2003 –*** 237 female pts, n = 309. RAPIT prog: 2x/wk: (i) bike training (20 in @ 70-90% max HR); (ii) ex circuit (20 min)p (iii) sport/game (20 min) vs usual care. Outcome measures: Disease activity, funx ability, physical capacity, emotional status, radiographic damage. Results: No detrimental effects on disease activity. Funx ability improved more than "usual care" group. Emotional status improved in RAPIT group. Pts w/baseline jt damage showed more progression of jt damage. ***de Jong et al 2004 –*** 237 female, n = 309. *Intervention same as above.* Outcome measures: Disease activity, physical capacity, funx ability, radiological damage of small and lrg jt x-rays, BMD of hip and lumbar spine. Results: Decr in BMD in femoral head only both groups, smaller decr in RAPIT groups. ***de Jong et al 2004 –*** 237 female, n = 309. *Intervention per de Jong 2003.* Outcome measures: Rate of radiographic progression of damage in hands and feet (Larsen score) Results: sig less radiological damage in small jts.	30 articles = RCTs of ex in RA. Used a total of 11 papers. Only 4 studies had low level of bias. Review focused on results of the 4 low biased studies.	"Ex prog for pts w/RA don't incr disease activity, are safe, and slow down the loss of bone mineral in the hip. Results of this review highlight the safety and benefits of aerobic and dynamic strengthening ex prog for pts w/RA."

Box 23.5 Evidence Summary Therapeutic Exercise in the Management of Rheumatoid Arthritis (RA)—cont'd

Author (yr)	Design and Sample	Intervention	Adherence	Outcomes
Williams et al 136 (2010)	"To evaluate the feasibility and gait stability and balance outcomes of a 4-month individualized HEP for women w/ arthritis." Pre-post interventional study.	Initial assessment, then all participants received home balance ex from PT based on assessment findings and ex available from commercially available kits. All measures repeated 4 months later. *Main outcome measures:* Falls risk and balance measures. *Intervention:* Pts visited @ home by PT to start prog. Complete ex 5x/wk for 4 months. Balance, strengthening and walking ex were selected from Otago ex prog and Visual Health Information Ex Prescription Kits – Balance & Vestibular Rehab set. Participants received an ex folder including: description, graphics and dosage of each ex, ex calendar for each moth of prog. If ex weights were required = provided by PT. *Given b/n 4-8 ex (~20-30 mins including rests) as well as recommendation to walk in the community @ least 3x/wk. Reviewed ex @ home on 2 occasions. 4 and 8 wk marks. Modifications made as needed.*	N = 49, females. LL OA or LL RA. Only 39 were eligible and completed study. 66.7% adherence to prog.	"At baseline, 64% of participants reported falling in the preceding 12 months, avg falls risk – Falls Risk of Older People – Community Setting – score was 14.5 w/42% rated as moderate risk. Pts achieved and improved performance on most balance and related measures after ex prog including falls risk, activity levels, fear of falling, funx reach test, rising index for sit to stand, step width in walking, and body mass index." "An individualized balance training hEP is feasible for older women with OA and RA and may improve stability during walking and other funx activities."

ADL = activities of daily living; BMD = bone mineral density; DMARDs = Disease Modifying Anti-Inflammatory Drugs; DEP = Dynamic Exercise Programme; DM = diabetes mellitus; ECG = electrocardiogram; ex = exercise; funx = functional; HAQ = Health Assessment Questionnaire (HAQ); HR = heart rate; HEP = home exercise program; HRM = heart rate max; hydro = hydrotherapy; HTN = hypertension; mins = minutes; ms = muscle; NSAIDs = nonsteroidal anti-inflammatory; OT = occupational therapy; OA = osteoarthritis; phys = physical; pts = patients; QOL = quality of life; RA = rheumatoid arthritis; RCT = Randomized Clinical Trial; RM = repetition maximum; ROM = range of motion; RPE = Ratings of Perceived Exertion; Ss = subjects Tx = treatment; WB = weight-bearing.

Centers for Disease Control and Prevention (CDC) recommendations for exercise, which suggest 30 minutes of moderate-intensity exercise five times per week[143] or the more recent guidelines to accumulate 150 minutes each week.[144] If weight-bearing is a barrier to exercise, low– or non–weight-bearing activities such as stationary cycling, pool-based aerobics, or deep water running may be options.[16,127,145] For most people, walking and stationary bicycles are a safe and effective means of aerobic exercise.[16,145] Furthermore, patients who have engaged in such a program often report an increase in self-esteem and improved emotional status.[16] Medical screening as appropriate for age and medical condition (e.g., Revised Physical Activity Readiness Questionnaire [PAR-Q]) should be performed before beginning an aerobic exercise program.

Functional Training

Functional training for the individual with arthritis proceeds in the same fashion as for other individuals with similar deficits. Therapists may choose to reduce the functional demands of an activity either temporarily, such as under conditions of acute inflammation, or permanently by incorporating a variety of adaptive equipment into ADL that substitute for lost ROM and strength. These modifications can include long-handled appliances and devices with built-up handles for easier grasp. There are aids for dressing and grooming, as well

Box 23.6 Evidence Summary Therapeutic Exercise in the Management of Knee and Hip Osteoarthritis (OA)

Reference	Subjects	Methods	Duration/Dosage	Results/Comments
Bartels et al [137] (2007)	Patients with OA in one or both knees or hips. 800 subjects in total with mean reported age ranging from 66 to 71 years.	Systematic review of 6 RCTs or quasi-experimental studies up to May 2006, compared aquatic-exercise interventions to land-based exercise.	Aquatic exercises ranged from 6 weeks to 3 months and 2 to 3 sessions/week.	Mixed findings, with small to moderate short-term improvements in function and HRQoL, and minimal to large reduction in pain immediately following intervention. No changes in stiffness or walking ability. Authors commented that aquatic exercise may be a beneficial first step in an exercise therapy program to get particularly disabled patients introduced to training.
Pisters et al [141] (2007)	Patients with OA of the hip or knee. 1721 subjects in total. No mean ages provided.	Systematic review of 11 RCTs or controlled clinical trials up to Nov 2005 in Dutch, German, or English languages. Compared long term (≥ 6 month follow-up) effects of exercise therapy compared to a control intervention.	Exercise therapy ranged from 1 to 12 months and follow-up period from 6 to 15 months.	Significant small to moderate benefits for pain that weren't maintained at long-term follow-up. Nonsignificant effects on self-reported function and conflicting evidence for performance-based function. Moderate evidence that additional post-treatment booster sessions had a positive influence on maintenance of the post-treatment effects in the long term. Authors comment that better adherence was associated with better patient outcomes and future research should focus on how exercise behavior can be stimulated and maintained in the long term.
Fransen and McConnell [138] (2008)	Adults with established diagnosis of knee OA or self-reported knee OA. 3719 subjects in total with mean age ranging from 61 to 74 years.	Systematic review of 32 RCTs up to Dec 2007, compared land-based, therapeutic exercise to non-exercise control group.	Exercise intervention ranged from 4 weeks to 12 months and <1 to 3x/week.	Small to moderate short-term beneficial treatment effects for pain and self-reported physical function. Benefits, however, are comparable to reported estimates for current simple analgesics and NSAIDs taken for knee pain. Authors also noted that it is clear that most people with knee OA need some form of ongoing monitoring or supervision to enable an exercise program to provide optimal clinical benefits.

Box 23.6 Evidence Summary Therapeutic Exercise in the Management of Knee and Hip Osteoarthritis (OA)—cont'd

Reference	Subjects	Methods	Duration/Dosage	Results/Comments
Fransen et al [139] (2009)	Adults with established hip OA. 204 subjects in total with mean age ranging from 65 to 70 years.	Systematic review of 5 RCTs up to Aug 2008, comparing some form of land-based therapeutic exercise with non-exercise control group.	Exercise intervention ranged from 6 to 12 weeks and 1 to 3x/week.	Small short-term beneficial treatment effect for pain, but no benefit for self-reported physical function. With most studies including people with either hip or knee OA, authors raise the question as to whether a non-joint specific exercise program can maximize treatment benefit.
McNair et al [140] (2009)	Patients with clinically and/or radiographic confirmed hip OA only. 356 subjects in total with mean age ranging from 66 to 72 years	Systematic review of 6 RCTs and quasi-experimental studies up to June 2008, compared a minimum of 3 weeks of exercise therapy to comparison intervention.	Exercise interventions ranged from 5 to 8 weeks and 1 to 2 sessions/week	Only 1 high quality trial, "insufficient evidence" to support exercise as treatment to reduce pain, improve function, and limited evidence for enhanced HRQoL. Exercise programs in included studies did not meet current exercise guidelines (intensity, volume, progression). Authors commented that this was insufficient description of progression of training regimens, a fundamental requirement of successful exercise programs. The authors further commented that there remains a paucity of articles addressing the effects of exercise on hip OA specifically.
Jansen et al [142] (2011)	Adults with knee OA	Systematic review of 12 RCTs; compared strength training alone, exercise therapy alone and exercise therapy plus manual therapy compared to non-exercise control.	Variable durations	Small to moderate beneficial effects of each intervention type for pain. Exercise plus manual mobilization improved pain significantly more than exercise alone. Each intervention also improved physical function significantly.

DMARDs = Disease Modifying Anti-Inflammatory Drugs; HRQoL = health-related quality of life; OT = occupational therapy; OA = osteoarthritis; RCT = randomized clinical trial;

as personal hygiene. By breaking down functional tasks, such as rising from a chair or climbing stairs, into smaller movements, the therapist can help the patient identify faulty movement patterns and address specific components of the movement that are causing difficulty.

UE involvement in RA, particularly of the wrist and hands, may complicate the choice of an ambulatory assistive device by precluding any weight-bearing on these affected joints. In these instances, platform attachments can be used to transform the forearm into a weight-bearing surface. Rearranging the home or work environment also can improve a person's functional abilities. Raising beds or chairs can reduce the effort needed to stand up. Railings placed around the bed, bath, and along stairways also can help increase an individual's independence.

Gait and Balance Training

Specific deviations will be evident throughout the gait cycle. These may include gait asymmetries, decreased velocity, cadence and stride length, prolonged period of double support, inadequate initial contact and push-off, and diminished joint excursion through both swing and stance. Gait deviations in the patient with RA, specifically owing to foot pain or deformities, may also be evident (Table 23.6).[146,147] Therapists should address the underlying joint and muscle impairments that contribute to these deviations in the gait training program with persons with any type of arthritis.

The degree to which the gait of an individual with arthritis should, or can, approximate normal is one of the most difficult questions in designing a therapeutic program. Some "abnormalities" such as antalgic limping may in fact reduce joint loading. Joint destruction may necessitate the introduction of assistive devices as simple as a standard cane or as cumbersome as platform crutches or rolling walkers with platform attachments. The gait of the individual with RA or OA should be safe, functional, and cosmetically acceptable to the patient rather than an unattainable idealized version of the norm. Use of a properly fitted, standard cane in the contralateral hand is associated with decreased joint loading and pain in individuals with both hip and knee OA.

Decreased walking speed in arthritis is common, and there is general agreement that increased speed is a meaningful measure of functional improvement. For example, a person's ability to walk fast enough to cross the street with the timing of the traffic light is important for functional and safe community locomotion. However, increased walking speed without attention to joint biomechanics may be undesirable. In a clinical trial of a nonsteroidal drug for persons with knee OA, all with a varus deformity, gait variables were included as outcome measures. The researchers found that self-reported pain diminished and walking speed increased in the active therapy group. At the same time, kinetic analysis of joint forces showed the increased speed was accompanied by increased adductor moment at the knee and greater loading of the medial compartment.[148] This additional loading of the joint and increased stress on lateral supporting tissue may not be worth the gains of increased speed. Attention to biomechanical factors thus should be considered in comprehensive management, even when drug therapy decreases pain and improves gait speed.

Decreased proprioceptive input, impaired neuromuscular reflexes, altered joint biomechanics, pain, and muscle weakness contribute to static and dynamic balance problems in the individual with LE arthritis. Balance training may include progression from static postures moving from double- to single-limb support, stable to unstable surfaces, and adding perturbations where safe. Dynamic balance activities include maintaining postural alignment while shifting weight from one limb to the other in various directions and walking on different surfaces to challenge the vestibular and proprioceptive systems (see Chapter 10, Strategies to Improve Motor Function). Table 23.7 provides a summary of outcome measures for RA and OA organized by ICF Categories.

Joint Protection

Joint protection is a key component of arthritis management, due to the impact of the disease on the joint and supportive structures. A randomized controlled trial for persons with hand OA compared the effects of a 3-month education-behavioral joint protection program to standard education (each consisting of a 20-minute session and provision of a piece of Dycem [nonslip matting] to use when opening jars). This single-blinded study demonstrated that patients in the joint protection and exercise group increased grip strength by 25% and both groups reported better hand function with the joint protection information.[16,149] Patients should be encouraged to incorporate joint care into all ADL to minimize pain and conserve energy (see Appendix 23.C, Joint Protection, Rest, and Energy Conservation).

In addition to reducing pain and improving function, orthoses also may provide support and protection for vulnerable and painful joints. Foot orthotics or specially designed shoes can serve the dual purpose of relieving biomechanical stresses and enhancing function for the person with RA foot involvement.[150,151] The cost of special shoes may not be reimbursable under many insurance programs. A good shoe will provide support and eliminate unnecessary joint motion in the talocalcaneal joint with a firm and wide heel counter. It should also help to maintain normal bony alignment and accommodate all existing foot deformities within a toe box of adequate dimensions. Pressure should be evenly distributed along the plantar surface of the foot during weight-bearing. Commercially available gel inserts may be helpful and are inexpensive; however, with more advanced biomechanical changes in the foot, the fabrication of orthoses may be required. A *rocker sole* (shoe sole that is curved at the toe) can be used to facilitate push-off with limited ankle motion. A controlled trial was conducted of the effect of off-the-shelf extra-depth orthopedic footwear for people with RA and at least 1 year of foot pain. Outcomes were measures of pain, gait, and physical function after 2 months of wearing the extra-depth shoes. The footwear group improved significantly on self-reported disability, weight-bearing and non–weight-bearing pain, and gait. In addition to extra depth in the shoe toe box, the shoes provided greater rear foot stability, an arch support, a stiff shank, and a padded heel collar above the counter for improved fit. This study reported that walking pain accounted for 75% of the variability in physical function level of the subjects.[152]

Table 23.6 Analysis of Gait Deviations, Physical Examination Findings, and Treatment Goals

Gait Deviations	Physical Examination Findings	Treatment Goals
Pronated Foot		
Shuffled progression Decreased step length Initial contact with medial border of foot Decreased single-limb balance Prolonged double-support phase Late heel rise Plantarflexion of ipsilateral ankle in swing Genu valgus with weight-bearing	Tenderness over subtalar midtarsal area Limited inversion range Weak and painful posterior tibialis muscle Pronated weight-bearing posture of foot Lax medial collateral ligament of knee	Relieve subtalar and midtarsal joint stresses Increase ankle inversion Strengthen posterior tibialis muscle Stabilize hypermobile joints with rigid orthosis Maintain neutral alignment in stance by foot positioning
Hallux Valgus		
Lateral and posterior weight shift Late heel rise Decreased single-limb balance	Lateral deviation of great toe Swelling of first MTP joint Shortening of flexor hallucis brevis muscle Tenderness of great toe Weakness of great toe abduction	Accommodate foot with wide toe box shoe Increase extension of great toe Relieve weight-bearing stresses
Metatarsophalangeal Joint Subluxation		
Diminished roll off Decreased single-limb stance Apropulsive progression Decreased single-limb balance	Painful MTP heads with weight-bearing Callus formation over MTP heads Ulcerations over MTP heads Limited MTP flexion Prominent MTP heads	Redistribute pressure with metatarsal bar Relieve pressure with soft cutout shoe insert Increase flexion mobility of MTP joints Accommodate foot with extra-depth shoe
Hammer or Claw Toes		
Diminished roll off Decreased single-limb stance Apropulsive progression Decreased single-limb balance	Posture of MTP joint hyperextension with proximal and distal interphalangeal joint flexion Posture of MTP and distal interphalangeal joint hyperextension with proximal interphalangeal flexion Callus formation at plantar tips and dorsum of proximal interphalangeal joint Limited MTP flexion	Improve toe alignment with metatarsal bar Accommodate foot with extra-depth shoe Diminish pressure with soft insert Increase toe mobility
Painful Heel		
Toe-heel pattern No heel contact in stance Decreased stride length Decreased velocity Plantarflexion of ankle in swing Increased hip flexion in swing Decreased step length of contralateral limb	Painful active plantarflexion Painful passive and active dorsiflexion Swelling and pain at Achilles insertion Tenderness over spur Decreased ankle dorsiflexion range	Decrease inflammation with steroid injection or modalities Relieve weight-bearing stress Decrease pressure over spur with soft shoe insert Maintain ankle mobility

From Dimonte and Light,[94] with permission.
MTP = metatarsal-phalangeal.

Table 23.7 Outcome Measures for RA and OA Organized by ICF Categories

	Body Structure and Function	Activity and Participation	Quality of Life and Personal Factors
RA	• VAS or NPRS for pain • Active joint count[a] or Simplified Disease Activity Index (SDAI) • ROM (goniometry) • Strength (manual or myometry) including grip strength • Joint stability • Visual gait assessment • Multidimensional Assessment of Fatigue (MAF) • Balance (e.g., single leg stance)	• HAQ-DI or Modified HAQ • AIMS2 • Patient Specific Functional Scale (PSFS) • Arthritis Hand Function Test • Dynamic/functional balance (e.g., Berg Balance Scale, Timed Up and Go) • 6-Minute Walk Test	• EuroQoL (EQ5D) • Self-efficacy scales[a] • Readiness to Manage Arthritis Questionnaire (RMAQ) • Patient and health professional global assessment
OA	• VAS or NPRS for pain • ROM (goniometry) • Strength (manual or myometry) including grip strength • Joint stability • Visual gait assessment • Balance (e.g., single leg stance)	• Hip disability and osteoarthritis outcome score (HOOS) • Knee injury and Osteoarthritis Outcome Score (KOOS) • Lower Extremity Functional Scale (LEFS) • Patient Specific Functional Scale (PSFS) • Disabilities of the Arm, Shoulder and Hand (DASH) • Arthritis Hand Function Test • Dynamic/functional balance (e.g., Berg Balance Scale, Timed Up and Go, sit-to-stand test) • 6-Minute Walk Test	• EuroQoL (EQ5D) • Self-efficacy scales[a] • Readiness to Manage Arthritis Questionnaire (RMAQ)

[a]See Appendix 23.D, Web-Based Resources.
AIMS2 = Arthritis Impact Measure Version 2; HAQ-DI = Health Assessment Questionnaire—Disability Index; NPRS = numeric pain rating scale; ROM = range of motion; VAS = visual analogue scale.

Education and Self-Management

Patient education in the rheumatic diseases has been shown to result in positive changes in knowledge, health behaviors, beliefs, and attitudes that affect health status, quality of life, and health care utilization. A recent review of the literature documented the well-established benefits of self-management programs on mental health.[75] As in any chronic illness, education should include information needed to deal with the condition (taking medications, exercise), self-management skills necessary to carry out important social and vocational roles, and resources needed to deal with the emotional consequences of chronic illness such as depression, fear, and frustration. The evidence is overwhelming that education designed to teach self-management skills and increase client self-efficacy for these tasks is the most effective.[75,153] The *Arthritis Foundation* (1330 West Peachtree Street, Atlanta, GA 30309, www.arthritis.org) can supply the clinician or the individual with a variety of educational materials, pamphlets, and self-help courses that will increase cognitive understanding of the disease process and self-management skills. Many local chapters of the Arthritis Foundation hold individual and family support groups to increase psychosocial adaptation, as well as conduct aquatic and land exercise programs in public facilities. The *Association of Rheumatology Health Professionals,* a division of the American College of Rheumatology (www.rheumatology.org), can provide the therapist with scientific and clinical resources for enhanced practice, as well as a network of professional colleagues who work in rheumatology. See Appendix 23.D for additional Web-based resources.

SURGICAL MANAGEMENT

Surgery represents one of the greatest advances in the management of arthritis in the last 50 years. Surgery is not appropriate, however, for every individual with either RA or OA, and the careful selection of the patient and the timing of the procedure are critical. The primary indications for surgery are pain, loss of function, and progression of deformity, although the last two are not always correlated. Surgical outcomes are greatly affected by personal characteristics of the individual patient, such

as anxiety, depression, expectations, and motivation,[154] and external factors, such as access to quality postoperative rehabilitation. General postoperative rehabilitation goals are to restore ROM to the affected joint, promote stability within the joint, regain neuromuscular control of joint motion, restore gait and balance, and improve quality of life.

In general, there are three procedures that may be performed on soft tissues: **synovectomy**, soft tissue release, and tendon transfers. Similarly, there are three general bone and joint procedures: osteotomy, prosthetic arthroplasty, and, less frequently, arthrodesis. The choice of specific postoperative physical therapy procedures will depend on the particular surgical intervention, the extent of joint involvement before surgery, individual characteristics of the patient (including co-morbid health conditions and physical activity level), and other manifestations of the disease. It is particularly important to remember that a patient with RA, compared to a peer with OA, will have multiple joint involvement, which will ultimately affect the functional outcome of the procedure. A patient with RA is also likely to be a surgical candidate at a much younger age than a patient with OA and is at greater risk for infection following surgery due to the systemic disease process and greater use of immunosuppressive drugs.[1]

More than 800,000 total joint arthroplasty (TJA) surgeries of the hip or knee are performed in the United States annually, the majority of which are for patients with OA.[155] These highly successful procedures have revolutionized the management of disabling arthritis in the LE with significant long-term benefits,[156,157] including recovery of physical functioning.[158] The primary goals following TJA are to restore function, decrease pain, and gain muscle control to enable the individual to return to previous, or improved, levels of functioning. Immediate postoperative and rehabilitation management is shaped by a variety of factors, including the occurrence of perioperative complications, as well as surgical factors (type of prosthesis, surgical technique, and approach). Initial treatment includes therapeutic exercise, transfer and gait training, and instruction in ADL.[159,160] Once the individual has achieved an adequate level of function and is released from surgical precautions, instruction in establishing a routine of regular exercise and physical activity to support musculoskeletal and cardiovascular fitness is crucial to long-term outcomes and quality of life. A meta-analysis reviewing recovery of short- and long-term physical functioning after total hip arthroplasty (THA) found that patients had recovered between 46% and 81% of self-reported functioning compared to age-matched controls 6 to 8 months after surgery. Walking speed, daily activity in the home, and other measures of functional capacity all recovered to about 80% of that of controls 6 to 8 months after THA.[158, 161] Recovery of physical functioning and quality of life after total knee arthroplasty (TKA) is more protracted and frequently less optimal than that of THA.[156] TKA and THA improve clinical outcomes in knees and hips damaged by RA and have a positive secondary systemic effect on RA disease activity; however, there are inconsistent benefits on long-term health-related quality of life.[162]

SUMMARY

RA and OA are the two kinds of arthritis that a physical therapist is likely to see in clinical practice. The primary activity limitations and participation restrictions in the individual with RA or OA result from disease activity, musculoskeletal impairments, and cardiovascular deconditioning. Joint surface irregularities, loss of joint space and ROM, muscle weakness, and atrophy contribute directly to limitations in ADL and the ability to work. Pain secondary to changes in normal joint structure and function often limits functioning as well. Musculoskeletal impairments related to arthritis may also lead to impairments of other systems, such as decreased cardiovascular endurance for functional activities. The physical therapist is well suited to evaluate and treat these impairments, remediate the activity limitations, and educate the patient in self-management skills to avoid unnecessary participation restrictions. Rehabilitation of the individual with arthritis is most often directed toward restoring or maintaining joint mobility and strength and emphasizes functional retraining and prevention of secondary health conditions.

Questions for Review

1. What epidemiological factors are related to RA?
2. What are the major pathological changes seen in RA?
3. State two hypotheses concerning the pathogenesis of RA.
4. Describe four modifiable risk factors that may predispose an individual to OA.
5. Describe two changes in articular cartilage associated with OA.

6. Name at least two laboratory tests used in the diagnosis of RA and state their purposes.
7. Describe the parameters used in examining radiographs of arthritic joints.
8. Describe the typical joint changes seen with RA for the following joints: occipitoatlantal, atlantoaxial, temporomandibular, carpals, knees, and talocalcaneal.
9. Define the following deformities: ulnar drift, swan neck, boutonniere, hammer toes, claw toes, and hallux valgus.
10. Describe the overall goals of medical management for RA and OA.
11. What are the primary indications for surgery in RA?
12. Describe the key points in taking a history for the individual with arthritis.
13. What adaptations of standard tests and measures might be required in examining the individual with RA?
14. What are the general physical therapy goals for individuals with RA or OA?
15. Explain the goals, modifications, and progression of a typical strengthening program.
16. Discuss treatment strategies for increasing ROM.
17. Design a cardiovascular conditioning program for an individual with LE arthritic joint involvement.
18. Describe strategies to enhance patients' adherence to therapeutic exercise programs.
19. State at least four principles of joint protection and give a practical application of each.
20. What criteria guide the selection of shoes for the individual with RA?
21. What are the purposes of splints?
22. What changes in gait are commonly associated with RA? What impairments contribute to static and dynamic balance problems in the individual with LE arthritis?

CASE STUDIES

Two case studies are presented: Case 1 presents a patient with rheumatoid arthritis and Case 2 considers a patient with osteoarthritis.

CASE 1: RHEUMATOID ARTHRITIS

HISTORY

The patient is a 52-year-old married woman who has two children in high school. She is a nurse and works about 40 hours a week. She has had symptoms of joint swelling and pain, fatigue, and increasing weakness for 2 years. During initial onset of symptoms, a primary care physician diagnosed her with carpal tunnel syndrome, knee osteoarthritis, fibromyalgia, and Lyme disease. However, her symptoms continued to worsen on NSAIDs. She was also prescribed antidepressants, and she was referred to the rheumatologist 3 months ago. Based on her history, physical examination, laboratory values (Disease Activity Score [DAS] = 3.2; RF= 12.30; ESR = 26), and radiographic evidence the rheumatologist confirmed a diagnosis of seropositive RA. She began a course of methotrexate and has been referred to physical therapy.

PHYSICAL THERAPY EXAMINATION

At the initial physical therapy examination, she reports that her morning stiffness is now less than 30 minutes (previous high of 3 hours). The pain and swelling in her hands, feet, and elbows is markedly decreased, and she is feeling more energetic. Systems review of the integumentary system is unremarkable except for a slight edema and redness of the distal finger joints and wrist R > L. Her blood pressure and respiratory rate are within normal limits. Her resting heart rate is 72 but increases to 96 with modest exertion.

ROM is limited at the shoulder, elbows, wrists, and MCPs. She lacks 10° of knee extension and has no ankle dorsiflexion or hip extension beyond neutral. Bilateral strength is good minus. She exhibits a forward head, rounded shoulder posture, with the beginning of a marked kyphosis. Her pain is most prominent in her wrists, elbows, and ankles (4/10 visual analogue scale [VAS]) and indicates general fatigue. She has flat feet and moderate swelling of the metatarsal heads. She is relieved that at last she has been diagnosed with a condition for which there is effective treatment and she trusts her rheumatologist. Her immediate goals are to regain comfortable motion, strength, and stamina and to avoid deformity.

GUIDING QUESTIONS

1. Identify the general anticipated goals and expected outcomes of physical therapy for this patient.
2. What self-management strategies would you recommend and/or instruct the patient to use?
3. Describe the types of community resources you would recommend the patient explore.
4. What supportive devices might be used to decrease symptoms and increase function?
5. How would her physical therapist optimally schedule her return visits to clinic?

CASE 2: OSTEOARTHRITIS

HISTORY

The patient is a 64-year-old Caucasian woman whose low back and bilateral knee pain have increased over the past year. She is 5 ft 7 in tall and weighs 195 lb. She has hypertension and chronic renal insufficiency for which she takes prescribed medication. She works part-time as a teacher's assistant in a local elementary school and lives alone in a 3rd floor walk-up apartment. On weekends she serves as the assistant building manager, which includes both cleaning and minimal maintenance duties. She has difficulty using stairs, getting up and down from sitting, getting on and off the bus, and walking for more than 15 minutes at a time. She has had progressively greater knee pain and stiffness for the past 3 years and has recently experienced episodes of "giving way" in the right knee. Her low back pain is worse after prolonged sitting, vacuuming, and at the end of the day. She avoids over-the-counter medications due to her underlying kidney disease but reports moderate pain relief with topical diclofenac applied to both knees. The patient recently joined a local seniors' fitness club but admits to rarely attending classes.

On a recent visit to her primary care physician, she underwent radiographs of both knees, which revealed bilateral joint space narrowing, with the right knee more affected than left and greater lateral compartment involvement than medial. There is evidence of bony sclerosis, osteophytes, and mild malalignment (genu valgum) greater on the right. Her physician has suggested continued use of the topical NSAID, use of a cane, and referred her to a physical therapist for evaluation and exercise advice. The patient and her doctor have agreed to discuss surgical options for the knee if she is not satisfied with her condition in 3 to 6 months.

PHYSICAL THERAPY EXAMINATION

During the initial history and systems review, the patient reports that she is finding both of her part-time jobs difficult, and in particular her cleaning responsibilities in the apartment building. She is frequently tired and lacks the energy to go to the fitness classes despite enjoying the session she last attended about 2 months ago. She admits to not sleeping well and having to take occasional sick days from her school-based job. She is concerned about finances and feels that she needs to continue working for at least another 3 years. Her pain is intermittent during the day but wakes her up frequently during the night. Her heart rate is 82, her blood pressure is 140/85, and her respiratory rate is 16. Her skin and circulation in the lower extremities are unremarkable and sensory integrity and reflexes are intact. Her concerns are being able to keep working and to avoid knee surgery.

Selected tests and measures reveal weakness and loss of motion in hips and knees bilaterally, and an antalgic and slow gait. Her spinal ROM is restricted in extension and rotation. Anterior-posterior knee stability is good, but there is moderate pseudolaxity of the lateral collateral ligaments bilaterally. Using a numeric pain rating scale (NPRS), she rates her left knee pain as 7 out of 10 while walking and 8 out of 10 while climbing stairs, and right knee pain at 6 out of 10 for all activities. She is wearing unsupportive slip-on shoes and shows marked ankle pronation on the right and bilateral hallux valgus.

GUIDING QUESTIONS

1. What anticipated goals should the physical therapist discuss with the patient for the episode of care?
2. Formulate a home exercise program for this patient and determine an optimal schedule for follow-up by the physical therapist.
3. What kind of orthotic device(s) would reduce this patient's symptoms and increase her function?
4. What should be included in patient-related instruction to maximize this patient's function?
5. What strategies would maximize this patient's adherence to a home exercise program and regular physical activity?
6. What other health professional(s) and/or community resources would you recommend for this patient?

Division of Immunology and Rheumatology

Name _____ Date _____

In this section we are interested in learning how your illness affects your ability to function in daily life. Please feel free to add any comments on the back of this page.

Please check the response which best describes your usual abilities OVER THE PAST WEEK:

	Without ANY difficulty	With SOME difficulty	With MUCH difficulty	Unable to do
Dressing & Grooming				
Are you able to:				
• Dress yourself, including tying shoelaces and doing buttons?	_____	_____	_____	_____
• Shampoo your hair?	_____	_____	_____	_____
Arising				
Are you able to:				
• Stand up from a straight chair?	_____	_____	_____	_____
• Get in and out of bed?	_____	_____	_____	_____
Eating				
Are you able to:				
• Cut your meat?	_____	_____	_____	_____
• Lift a full cup or glass to your mouth?	_____	_____	_____	_____
• Open a new milk carton?	_____	_____	_____	_____
Walking				
Are you able to:				
• Walk outdoors on flat ground?	_____	_____	_____	_____
• Climb up five steps?	_____	_____	_____	_____

Please check any AIDS or DEVICES that you usually use for any of these activities:

__Cane __Devices used for dressing (button hook, zipper, long-handled shoehorn)
__Walker __Built-up or special utensils
__Crutches __Special or built-up chair
__Wheelchair __Other (specify) _____

Please check any categories that you usually need HELP FROM ANOTHER PERSON:

__Dressing and Grooming __ Eating
__Arising __ Walking

Please check the response which best describes your abilities OVER THE PAST WEEK:

	Without ANY difficulty	With SOME difficulty	With MUCH difficulty	Unable to do
Hygiene:				
Are you able to:				
• Wash and dry your body?	_____	_____	_____	_____
• Take a tub bath?	_____	_____	_____	_____
• Get on and off the toilet?	_____	_____	_____	_____
Reach:				
Are you able to:				
• Reach and get down a five-pound object (such as a bag of sugar) from just above your head?	_____	_____	_____	_____
• Bend down to pick up clothing from the floor?	_____	_____	_____	_____
Grip:				
Are you able to:				
• Open car doors?	_____	_____	_____	_____
• Open jars which have been previously opened?	_____	_____	_____	_____
Activities				
Are you able to:				
• Run errands and shop?	_____	_____	_____	_____
• Get in and out of the car?	_____	_____	_____	_____
• Do chores such as vacuuming and yard work?	_____	_____	_____	_____

Please check any AIDS or DEVICES that you usually use for any of these activities:

__Raised toilet seat __Bathtub bar
__Bathtub seat __Long-handled appliances for reach
__Jar opener (for previously opened jars) __Other (specify)_____

Please check any categories that you usually need HELP FROM ANOTHER PERSON:

__Hygiene __Gripping and opening things
__Reach __Errands and chores

We are also interested in whether or not you are affected by pain because of your illness.

How much pain have you had because of your illness IN THE PAST WEEK:

PLACE A VERTICAL (|) MARK ON THE LINE TO INDICATE THE SEVERITY OF PAIN

No Pain Severe Pain
0 **100**

Joint Protection, Rest, and Energy Conservation

appendix 23.C

JOINT PROTECTION

Why Is Joint Protection Important?

Overuse and abuse of arthritic joints may lead to progressive deterioration of the joint and its surrounding tissues. Positive action is necessary to protect joints, conserve energy, and preserve function.

During activity, a normal joint is protected by the muscles around it that absorb the forces on the joint, preventing undue strain on the tendons, ligaments, and cartilage. A diseased joint is mechanically weak and poorly stabilized, which can contribute to the overstretching of the tendons and ligaments and damage to the cartilage. This increased stress can increase the destruction of the joint and cause increased pain.

How Can Joints Be Protected?

The main idea in joint protection is to minimize the strain on joints in daily activities. Joint protection techniques try to reduce the force on the joint, to slow down the joint damage. Good posture and positioning, changing the method of an activity, and pacing all help to protect the joint.

Which Joints Need Protection?

People with a local type of arthritis, such as osteoarthritis, need to pay close attention to the joints that are involved with the arthritis. People with a systemic or whole-body type of arthritis, such as rheumatoid arthritis, need to reduce the stress on all their joints. In addition to the joint protection principles and examples listed below, people with rheumatoid arthritis should look at the section below titled Additional Reminders for Protection of the Rheumatoid Hand.

In planning your joint protection, start by concentrating on the joints that are currently giving you the most trouble. Check off the principles that apply most strongly to you, and list several examples of how you can apply that principle to your problem joints.

Joint Protection Principles	Your Examples
☐ 1. *Respect Pain.*	
a. It is important to distinguish between discomfort and pain.	_____
b. Pain that lasts for more than 1 to 2 hours after an activity indicates that the activity is too stressful and needs to be modified.	_____
c. If there is a sharp increase in pain during activity, stop and rest, then modify the activity.	_____
d. If there is unusual pain or stiffness the next day, look back at the previous day's activities to see if they were too strenuous.	_____
☐ 2. *Avoid Positions of Deformity.*	
The foremost position of deformity for most joints is flexion, bending of the joint. Maintaining a bent position increases the possibility of deformity.	_____
a Stand erect, with weight evenly divided on both feet.	_____
b. Lay as flat as possible in bed; do not curl up or prop yourself up on several pillows.	_____
c. Work with your hands flat.	_____
d. Avoid tight grip or squeezing.	_____
☐ 3. *Avoid Awkward Positions.*	
Use each joint in its most stable and functional position. Extra strain is placed on a joint when it is twisted or rotated.	_____
a. Rise straight up from sitting, rather than leaning to one side for support.	_____
b. Reposition feet rather than twisting trunk or knees.	_____
c. Stand on a stool to reach overhead.	_____
d. Reposition yourself closer to object rather than stretch your reach.	_____
e. Sit to clean or garden, rather than squatting or kneeling down.	_____
f. Use good posture when you stand, sit, and lie down.	_____

Continued

Joint Protection Principles	Your Examples
☐ 4. *Use Strongest Joints or Distribute the Force over Several Joints.*	
The stress on each individual joint is less if it is divided over several joints. The larger joints have greater muscles surrounding them to absorb the stress.	_____
a. Use two hands whenever possible.	_____
b. Carry packages in both arms rather than in one.	_____
c. Carry a shoulder purse or purse handle over forearm rather than in fingers.	_____
d. Use knapsack to carry packages on back.	_____
e. Lift objects from underneath, using wrist and elbow, rather than pinch gripping the sides.	_____
f. Lift objects with your knees bent, your back straight.	_____
g. Move large objects with body weight behind it, the push coming from the legs.	_____
h. Push with open palm or forearm rather than fingers.	_____
☐ 5. *Use Adapted Equipment.*	
Find equipment that will reduce the stress on the joint or make the job easier.	
The Self-Help Manual for People with Arthritis is a catalog of adapted equipment available from the local Arthritis Foundation.	_____
a. Equipment can be modified by:	
1. Building up the handle so it is easier to grasp.	_____
2. Extending the handle so it is easier to reach.	_____
b. Equipment available:	
Walking aids	
Self-care aids	
Bathroom safety	
Homemaking equipment	
Job modification equipment	
Joints that need protection: _____	_____
Activities to be modified: _____	

Additional Reminders for the Protection of the Rheumatoid Hand

1. Through exercise, maintain wrist extension (ability to pick hand up off table) to ensure power grip.
2. Through exercise, maintain supination (ability to turn palm up) to ensure ability to hold and to carry objects.
3. Avoid positions of deformity.
a. Finger flexion

1. Avoid making fist or tight grip—use built-up handles.
2. Work with hand flat—use dust mitts, sponges.
3. Avoid prolonged holding of objects: pen, book, pan, needle.
4. Avoid putting any pressure on bent knuckles.
b. Ulnar deviation (tendency of fingers to slide to little finger side)

1. Avoid pressure toward little finger side of hand.
2. Any twisting of hand, open door knobs, jars, and so forth should be turned toward thumb.
3. Grip objects parallel across palm, not diagonal; for example, hold utensil like dagger to cut food, stir with wooden spoon.
4. Avoid stress on small joints of hand.
a. Use two hands whenever possible.
b. Substitute larger stronger joints: for example, lift or carry with palms or forearm, not small finger joints; carry bag over elbow or shoulder, not in fingertips.
c. Avoid activities involving pinching motions.
d. Avoid twisting and squeezing motions with hands.

GETTING ADDITIONAL REST

Rest is important because it reduces the pain and fatigue that accompany arthritis. In addition, it aids the body's healing process and helps control the inflammation. Rest also may reduce the stress on joints and protect them from further damage. All of these benefits are important in managing arthritis.

Each day you need to make sure you get enough whole body rest, local joint rest, and emotional rest. There are many options: Mark off the options that may be possible for you.

☐ **1.** *Plenty of Nightly Rest*
Get the usual 8 to 10 hours of nightly rest. It is not as important that you sleep for that length of

time, but make sure you stretch out with your joints supported, so that your body can rest.

☐ **2.** *Daily Rest Periods*
Ideally, several times a day you can stretch out for 15 to 60 minutes with your joints supported. Again, it is the body rest, not sleep, that is most important.

☐ **3.** *Five-Minute "Breathers"*
Partway through a task, sit back and take it easy for a few minutes. This will allow you to finish the task almost as quickly but more comfortably and with less fatigue.

☐ **4.** *Local Joint Rest*
When a joint hurts, stop and rest. If your hip or knee hurts while walking, sit down for a few minutes with your legs supported; if your hand hurts while writing, stop and lay it flat for a few minutes. Splints can be used to rest painful wrists or fingers. If your neck hurts, lay down with just a small pillow supporting the curve of your neck. Any painful joint can be given extra rest.

☐ **5.** *Take Time for Relaxing Activities*
Listening to music, reading, playing cards, or other light leisure activities all can be a pleasant change of pace and can be restful and refreshing for you. There are unlimited options for getting additional rest. It takes creativity to find ways to fit extra rest into your schedule; then it takes self-discipline to make sure you follow through, incorporating the additional rest in your activities. Making the effort to get more rest can pay off in a reduction of pain and fatigue.
Ways to get more rest: ____
Systemic, whole body rest
Local joint rest _____
Emotional rest _____

ENERGY CONSERVATION TO REDUCE FATIGUE

Why Is Energy Conservation Important?

One of the major symptoms of arthritis may be fatigue—getting tired very easily. In the inflammatory types of arthritis, fatigue may be part of the disease process. In all types of arthritis, pain and difficult movement may use up energy, so you tire more easily.

It is important to avoid getting overtired. Fatigue may increase the possibility of a flare-up in inflammatory types of arthritis such as rheumatoid arthritis. In all types of arthritis, fatigue may make the pain and stiffness seem worse, and it will make activities more difficult. We hope to reduce this fatigue by conserving energy and using it carefully.

How Can You Reduce Fatigue?

Some people try to conserve energy and reduce fatigue by staying in bed all day. Others stop doing anything that is not absolutely necessary each day. Unfortunately, the activities that are usually cut out are the leisure activities—the enjoyable things people do for themselves or for fun. These are not good ideas.

You can conserve energy and reduce fatigue by modifying and simplifying your activities, pacing yourself, getting additional rest, and using adapted equipment.

Energy Conservation

By conserving your energy, you may be able to do as much or more activity with less pain and fatigue. We are trying to avoid both overactivity and underactivity. Conserving your energy and simplifying your work is *not* being lazy. It is not sensible to overtire yourself. Overwork will not keep your joints mobile, but it may damage your joints further.

It is not so much *what* you do, but *how* you do it that can help control your fatigue. An attempt should be made to modify any activities that leave you overly tired or cause pain that continues for more than 1 to 2 hours.

You will need to identify ways that your own daily activities can be simplified. As you read through the energy conservation strategies, check off strategies that may work for you, and list several of your own examples.

☐ **1.** *Plan the Task.*
Your Examples
a. Think the task through. ____
b. Decide when and where the job is best done. ____
c. Plan out the simplest approach to the job. ____
d. Gather all supplies before you begin. ____
e. Arrange step sequence so that it moves in one direction (usually left to right). ____
f. Use fewer, more efficient movements to complete task. ____

☐ **2.** *Eliminate Extra Trips.*
a. Organize your shopping list according to how the store is laid out. ____
b. Stay in the laundry room until your laundry is finished. ____
c. Clean one area at a time. ____

☐ **3.** *Use Good Posture and Body Mechanics.*
a. Sit to work; you will be more stable and use your strength more efficiently. ____
b. Use large strong muscle groups, rather than straining individual muscles and joints. ____
c. Lift with your knees bent, your back straight. ____
d. Carry objects close to your body. ____
e. Push objects, with body weight behind it, rather than pulling or carrying. ____
f. Avoid awkward bending, reaching, and twisting. ____

☐ **4.** *Don't Fight Gravity.*
a. Slide rather than lift objects. ____
b. Use wheeled cart. ____

c. Use lightweight equipment. ____
d. Stabilize pitcher on surface and tilt to pour, rather than picking it up. ____

☐ **5.** *Pace Yourself.*
a. Get plenty of nightly rest. ____
b. Plan several rest periods during the day. ____
c. Rest before you get tired. ____
d. Avoid a rush. ____
e. Work at a steady rate with rest period. ____
f. Develop a rhythm to your movements. ____

☐ **6.** *Use Energy-Saving Devices.*
a. Convenience foods. ____
b. Adapted equipment. ____

Strategies to be tried:	Activities to be modified: ___

Chapter 24

Burns

Reginald L. Richard, PT, MS
R. Scott Ward, PT, PhD

LEARNING OBJECTIVES

1. Describe the anatomy and physiology of the skin as an organ in the healthy state and damaged condition that occurs with a burn injury.
2. Discuss the pathology, symptoms, and sequelae of burn injuries.
3. Compare the treatment for various depths and extent of burn injury in relation to medical, surgical, and rehabilitation management.
4. Identify the consequences of contracture formation after burn injury and the treatment of this condition.
5. Differentiate the options for management of hypertrophic scars.
6. Determine the type of skin care necessary after burn wound healing.
7. Design a physical therapy plan of care that appropriately incorporates positioning, splinting, and exercise.
8. Analyze and interpret patient data, formulate realistic goals and outcomes, and develop a plan of care when presented with a clinical case study.

SUMMARY *1115*

Burn injuries are one of the major health problems of the industrial world. In the United States, 450,000 to 500,000 burn injuries require medical treatment each year with an estimated 3,500 related deaths.[1] In addition, it has been estimated that burn injuries account for 45,000 hospitalizations per year, with about 25,000 patients being admitted to specialized burn treatment centers and the balance to other types of medical facilities.[1]

Although these data report the extent of the health care problem caused by burn injury, recent medical advances have significantly reduced the number of deaths from burn injuries and have improved the prognosis and functional abilities of surviving patients.[1-3] The survival rate has improved annually owing to improved resuscitation techniques, the acute medical and surgical care now practiced, and continued research into the management and care of the patient with burns. The American Burn Association (ABA) reported an overall survival rate of 94.8% from 2000 to 2009.[1] As a result of improvements in care, treatment, and survival of patients with burns, more physical therapists will become responsible for treating these patients for a significant portion of their rehabilitation in settings other than a hospital burn center (e.g., outpatient clinics, community hospitals).

This chapter introduces the clinical presentation of different depths of burn injury and the complications that can result from thermal destruction of the skin. Current techniques used in the medical, surgical, and rehabilitative management of the patient who has been burned will be described. For more in-depth information regarding the examination and treatment of the patient with a burn injury, the reader is referred to additional sources.[4-7]

EPIDEMIOLOGY OF BURN INJURIES

Although the morbidity and mortality rate of patients with burns has dramatically decreased in recent years, the epidemiology of burns remains basically the same. The most common cause of burn injury in children 1 to 5 years of

age is from scalds from hot liquids.[8-11] The primary cause of burn injury in adolescents and adults is accidents with hot liquids. Men, especially those between ages 16 and 40, have the highest incidence of injury.[1,8] Fires that occur in homes and other structural dwellings are the leading cause of burn injury in other age groups.[12] Most of the deaths associated with home or structure fires are due to inhalation injury. The number of burn-related accidents has decreased presumably because of better preventative measures, such as smoke detectors, education, and more stringent fire codes.[13]

A major reason for the improved prognosis and survival of patients with severe burn injury is the availability of specialized burn centers.[2] The advent of the burn center and the concentrated team care and focused research that has been generated by these facilities has improved the outcome of the most severely burned patient, as well as reduced the average hospital stay in most cases. The ABA[14] has established criteria for admission to a designated burn center as follows:

- Partial-thickness burns greater than 10% of total body surface area (TBSA)
- Full-thickness burns in any age group
- Burns that involve the hands, feet, face, perineum, genitalia, or skin overlying major joints
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting illness that could complicate management
- Patients with a burn and coexistent trauma (e.g., fractures)
- Patients who require special social, emotional, or long-term rehabilitation, including cases involving suspected child abuse
- Children with burns in hospital settings without qualified burn management personnel or equipment

Thirty-five years ago, there were only 12 specialized burn centers in the United States. Today there are over 120 specialized centers for the care of patients with burn injuries and other skin disorders. This accounts for approximately 1,700 beds.[15] Burn centers now have the opportunity to undergo a process of verification (voluntary quality assurance review) through the ABA.[16] Currently, over half of the burn centers in the United States are verified.

A burn center is staffed by specialists from multiple disciplines—physicians, nurses, physical therapists, occupational therapists, dietitians, psychiatrists, psychologists, social workers, child life therapists, chaplains, pharmacists, vocational rehabilitation specialists, and other support personnel—who direct their professional expertise toward the care, treatment, and rehabilitation of the patient with a burn injury. Each member is an integral part of the team, and the most effective burn centers are successful because of their team approach to the care of each patient.[2] It is historically noteworthy that burn personnel, with the founding and establishment of the ABA in 1967, initiated the interdisciplinary "team" approach to patient care.

SKIN ANATOMY AND BURN WOUND PATHOLOGY

The skin is the largest organ of the body, comprising approximately 15% of total body weight. Anatomically, the skin consists of two distinct layers of tissue: the **epidermis**, which is the outermost layer exposed to the environment, and the deeper layer, termed the **dermis** (subdivided into the *papillary* and *reticular* dermis).[17] Although not part of the skin per se, a third layer involved in the anatomical consideration of the skin is the subcutaneous fat cell layer directly under the dermis and above muscle fascial layers. These layers are illustrated in Figure 24.1.

The epidermis, composed of multiple layers, is avascular and performs several vital functions. The layers of the epidermis include (1) the *stratum corneum,* which gives the skin its waterproof characteristic and serves the role of protection from infection; (2) the *stratum granulosum,* which is the layer responsible for water retention; (3) the *stratum spinosum,* which adds a layer of protection; and (4) the *stratum basale* layer, which contains cells that enable the epidermis to regenerate, as well as melanocytes, the cells that determine skin pigmentation. The interface between the epidermis and the dermis is termed the *rete peg region*. This area consists of an extensive series of epidermal-dermal ridges and valleys that serve to increase the surface area between the epidermis and the dermis. These ridges act as a reservoir of skin and are needed to overcome frictional forces that skin is exposed to in daily activity. Lack of these ridges in the healed burn wound will result in blisters from abrasion and poor adherence of the new epidermal tissue when it comes in contact with clothing or other surfaces.

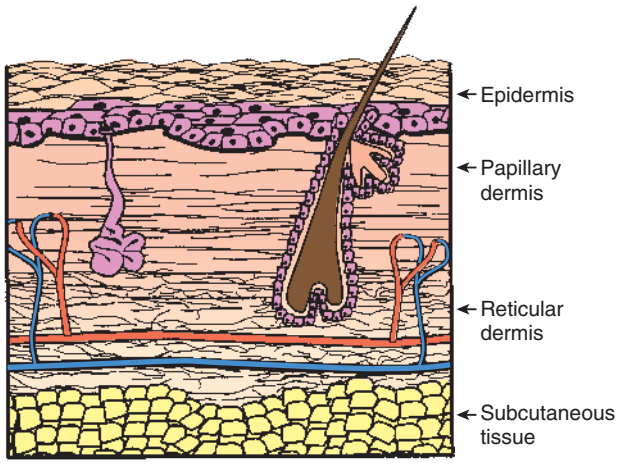

Figure 24.1 Cross section of skin.

In earlier literature, the dermis is often referred to as the *corium* or "true skin," because it contains blood vessels, lymphatics, nerves, collagen, and elastic fibers. It also encloses the epidermal appendages (sweat ducts and sebaceous glands, and hair follicles), which provide a deep source of epidermal cells for wound healing. The dermis is 20 to 30 times thicker than the epidermis. It is comprised primarily of interwoven collagen and elastic fibers, which provide the skin with its tensile strength and elasticity to resist deformation. The predominantly parallel orientation of normal collagen in the dermis is different than the whorls of collagen typically seen in scar tissue that result from burn injury.[18] Also, the tiered location of sensory receptors in the skin is an important consideration in determining depth of burn injury (Table 24.1). The dermis is subdivided into two layers: the superficial *papillary* layer and the deep *reticular* layer.[17] The papillae of the papillary layer project upward and interlock with the epidermis. The papillae are vascular plexuses that serve, in part, to nourish the epidermis through osmosis. Morphologically, this layer is composed of a loose basket-weave network of collagen fibers. The reticular dermis lies below the papillary dermis and is composed of densely interwoven collagen fibers. The reticular dermis attaches to the subcutaneous tissue by an irregular interlacing network of fibrous connective tissue.

In addition to the functions mentioned already, the skin is important in temperature regulation through the emission of sweat and electrolytes, secretion of oils from the sebaceous glands to lubricate the skin, vitamin D synthesis, and contributes to cosmetic appearance and identity. As the result of a burn injury, some or all of these functions may be impaired and/or lost, and a patient's protective barrier defense mechanisms will be compromised.

One basic pathophysiological consideration in a burn injury is the alteration of vascular integrity, which results in the formation of edema in the interstitial spaces.

Table 24.1 Sensory Receptors, Location by Layer of Skin, and Sensation Mediated

Sensory Receptor	Location	Sensation Mediated
Free nerve ending	Epidermis	Pain, itch
Free nerve ending	Dermis	Pain
Merkel's disks	Stratum spinosum	Touch
Meissner's corpuscle	Papillary dermis	Touch
Ruffini's corpuscle	Papillary dermis	Warmth
Krause's end bulb	Papillary dermis	Cold
Pacinian corpuscle	Reticular dermis	Pressure, vibration

Edema formation occurs in the area of burn as well as in adjacent tissues. An initial concern of the physical therapist on the burn team is a decrease in joint range of motion (ROM) due to swelling.

The amount of skin destruction is based on temperature and length of time the tissue is exposed to heat.[19] The type of insult (i.e., flame, liquid, chemical, or electrical) also will affect the amount of tissue destruction. A tremendous amount of heat is not required to cause damage. At temperatures below 111°F (44°C), local tissue damage will not occur unless the exposure is for prolonged periods. In the temperature range between 111°F and 124°F (44°C and 51°C), the rate of cellular death doubles with each degree rise in temperature, and short exposures will lead to cell destruction.[19,20] At temperatures in excess of 124°F (51°C), exposure time needed to damage tissue is extremely brief.

CLASSIFICATIONS OF BURN INJURY

In the past, burn injury depth was categorized as *first*, *second*, and *third* degree. Although the lay public may use these classifications, most medical literature now classifies burn injuries by the depth of skin tissue destroyed (Table 24.2).[20] The *Guide to Physical Therapist Practice* also describes impairments of the integument in relation to the depth of the tissue injury.[21] The depth to which a burn injury causes damage depends on many factors, including the duration and intensity of heat, skin thickness of area, the distance of the area from the source of heat, the extent (percentage) of body area exposed, vascularity, and age.

The different classifications of burn wounds will present different clinical pictures, and each can change dramatically during the course of treatment. In addition to the amount of direct tissue damage from a burn, a patient's metabolic, physiological, and psychological condition can greatly affect the patient's clinical status. This section presents general clinical signs and symptoms seen in each of the burn wound classifications (see Table 24.2).

Epidermal Burn

An epidermal burn, as the name implies, causes cell damage only to the epidermis (Fig. 24.2). This depth of burns correlates to practice pattern 7B, Impaired Integumentary Integrity Associated with Superficial Skin Involvement, in the *Guide to Physical Therapist Practice*.[21] The classic "sunburn" is the best example of an epidermal burn. Clinically, the skin appears red or erythematous.[22] The erythema is a result of epidermal damage and dermal irritation, but there is no injury to the dermal tissue. There is diffusion of inflammatory mediators from sites of epidermal damage and release of vasoactive substances from mast cells. The surface of an epidermal burn is dry. Blisters will be absent, but slight edema may be apparent. After an epidermal burn, there is usually a delay in the development of pain, at which point the area becomes tender to the touch. Following epidermal damage, the injured

Table 24.2 Burn Wound Classification: Differential Diagnosis

Depth of Burn	Color/Vascularity	Surface Appearance/Pain	Swelling/Healing/Scarring
Epidermal	Erythematous, pink or red; irritated dermis	No blisters, dry surface; delayed pain, tender	Minimal edema; spontaneous healing; no scars
Superficial partial-thickness	Bright pink or red, mottled red; inflamed dermis; erythematous with blanching and brisk capillary refill	Intact blisters, moist weeping, or glistening surface when blisters removed; very painful, sensitive to changes in temperature, exposure to air currents, light touch	Moderate edema; spontaneous healing; minimal scarring; discoloration
Deep partial-thickness	Mixed red, waxy white; blanching with slow capillary refill	Broken blisters, wet surface; sensitive to pressure but insensitive to light touch or soft pinprick	Marked edema; slow healing; excessive scarring
Full-thickness	White (ischemic), charred, tan, fawn, mahogany, black, red (hemoglobin fixation); no blanching; thrombosed vessels; poor distal circulation	Parchment-like, leathery, rigid, dry; anesthetic; body hairs pull out easily	Area depressed; heals with skin grafting; scarring
Subdermal	Charred	Subcutaneous tissue evident; anesthetic; muscle damage; neurological involvement	Tissue defects; heals with skin graft or flap; scarring

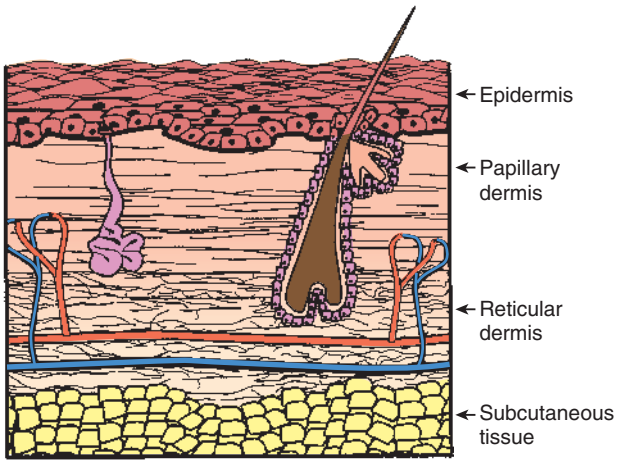

Figure 24.2 Red shading represents depth of skin involved in an epidermal burn.

epidermal layers will peel off or desquamate in 3 to 4 days. Epidermal healing is spontaneous; that is, the skin will heal by itself, and no scar tissue will form.

Superficial Partial-Thickness Burn

With a **superficial partial-thickness burn** (Fig 24.3) damage occurs through the epidermis and into the papillary layer of the dermis. The epidermal layer is destroyed completely, but the papillary dermal layer sustains only mild to moderate damage. This depth of burn corresponds to practice pattern 7C, Impaired Integumentary Integrity Associated with Partial-Thickness Skin Involvement and Scar Formation, in the *Guide to Physical Therapist Practice*.[21] The most common sign of a superficial partial-thickness burn is the presence of intact blisters over the area that has been injured.

Although the internal environment of a blister is considered sterile, it has been shown that blister fluid contains substances that increase the inflammatory response and retard the healing process, and it is recommended that blisters be evacuated.[23-27] Healing will occur more rapidly if the damaged skin is removed and an appropriate topical agent and wound dressing applied.[28] Once blisters have been removed, the surface appearance of the burn area will be moist. The wound will be bright red because the dermis is inflamed. The wound will **blanch**, which means if pressure is exerted against the tissue with a finger, a white spot appears as a result of displacement of blood in the capillaries under pressure. On release of pressure, the white area will demonstrate brisk capillary refill. Edema can be moderate.

This type of burn is extremely painful secondary to irritation of the nerve endings contained in the dermis. When the wound is open, the patient will be highly sensitive to temperature changes, exposure to air, and light touch. In addition to pain, fever may be present if areas become infected.

Some topical antimicrobial creams will cause the wound to develop a gelatin-like film that eventually will

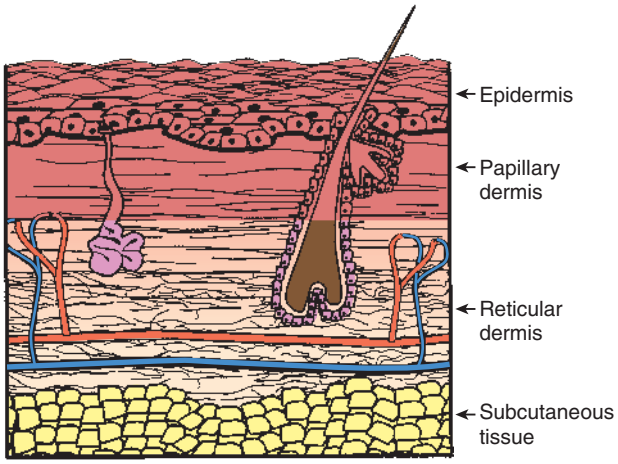

Figure 24.3 Red shading represents depth of skin involved in a superficial partial-thickness burn.

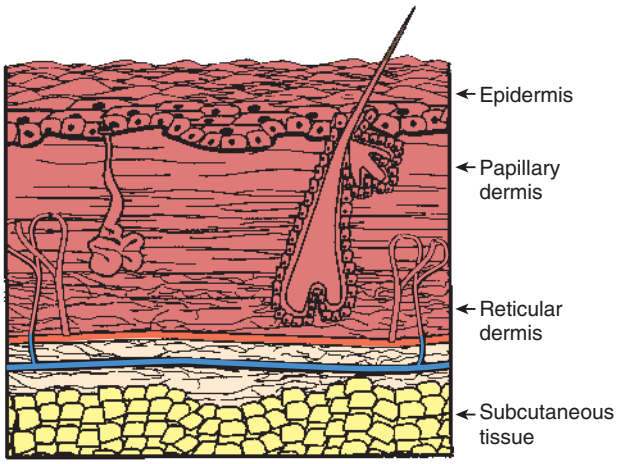

Figure 24.4 Red shading represents depth of skin involved in a deep partial-thickness burn.

peel off, similar to the **desquamation** that occurs with sunburn. This exudate is a coagulum of the topical antibiotic used to prevent infection and serum that seeps from the wound as a result of the insult to capillary integrity.

Superficial partial-thickness burns heal without surgical intervention, by means of epithelial cell production and migration from the wound's periphery and surviving skin appendages. Coverage by new epithelium resumes the barrier function of the skin, and complete healing should occur in 7 to 10 days. There may be some residual skin color change owing to destruction of melanocytes, but scarring is minimal.

Deep Partial-Thickness Burn

A **deep partial-thickness burn** (Fig. 24.4) involves destruction of the epidermis and papillary dermis with damage down into the reticular dermal layer. As this burn nears the deepest dermis it begins to resemble a full-thickness burn, and the depth best matches practice pattern 7C, Impaired Integumentary Integrity Associated with Partial-Thickness Skin Involvement and Scar Formation, in the *Guide to Physical Therapist Practice*.[21] Most of the nerve endings, hair follicles, and sweat ducts will be injured because most of the dermis is destroyed.

Deep partial-thickness burns appear as a mixed red or waxy white color. The deeper the injury, the more white it will appear. Capillary refill will be sluggish after the application of pressure on the wound. The surface usually is wet from broken blisters and alteration of the dermal vascular network, which leaks plasma fluid. Marked edema is a hallmark sign of this burn depth. There is a large amount of evaporative water loss (15 to 20 times normal) because of tissue and vascular destruction.[19,25,29] An area of deep partial-thickness burn has diminished sensation to light touch or sharp/dull discrimination but retains the sense of deep pressure due to the location of the Pacinian corpuscle deep in the reticular dermis. Healing occurs through scar formation and re-epithelialization. By definition, the dermis is only partially destroyed; therefore, some viable epidermal cells may remain within the surviving epidermal appendages and serve as a source for new skin growth.

The depth of a deep partial-thickness injury is sometimes difficult to determine, so allowing the wound to demarcate (between normal and damaged tissue) during the first few days is necessary. Demarcation becomes evident after several days as the dead tissue begins to slough. Hair follicles that penetrate into the deeper dermal regions below the burn level remain viable. Preservation of hair follicles and new hair growth will indicate a deep partial-thickness burn rather than a full-thickness injury, and there is a corresponding greater potential for spontaneous healing. Particularly important factors that determine which epidermal structures survive and which die include the thickness of the skin in a particular location and/or the distance of the area from the source of heat.

Deep partial-thickness burns that are allowed to heal spontaneously will have a thin epithelium and may lack the usual number of sebaceous glands to keep the skin lubricated. New tissue usually appears dry and scaly, is itchy, and is easily abraded. Creams are necessary to artificially lubricate the new surface. Sensation and the number of active sweat ducts will be diminished.

A deep partial-thickness burn generally will heal in 3 to 5 weeks if it does not become infected. It is critical to keep the wound free of infection, because infection can convert a deep partial-thickness burn into a deeper injury. The development of **hypertrophic** and **keloid scars** is a frequent consequence of a deep partial-thickness burn.

Full-Thickness Burn

In a **full-thickness burn** (Fig. 24.5) all of the epidermal and dermal layers are destroyed completely. In addition, the subcutaneous fat layer may be damaged to some extent.

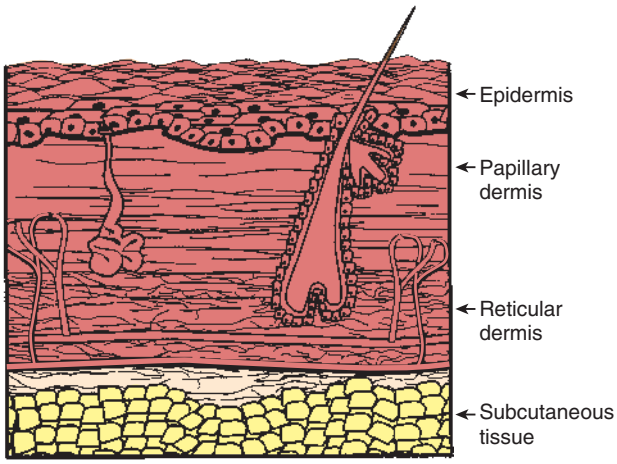

Figure 24.5 Red shading represents depth of skin involved in a full-thickness burn.

Figure 24.6 Escharotomy of the right upper extremity. *From Richard and Staley,[4, p. 113] with permission.*

This burn depth is consistent with practice pattern 7D, Impaired Integumentary Integrity Associated with Full-Thickness Skin Involvement and Scar Formation, in the *Guide to Physical Therapist Practice*.[21]

A full-thickness burn is characterized by a hard, parchment-like eschar covering the area. **Eschar** is devitalized tissue consisting of desiccated coagulum of plasma and necrotic cells. Eschar feels dry, leathery, and rigid. The color of eschar can vary from black to deep red to white; the latter indicates total ischemia of the area. Frequently, thrombosis of superficial blood vessels is apparent and no blanching of the tissue is observed. The deep red color of the tissue results from hemoglobin fixation liberated from destroyed red blood cells.

Hair follicles are completely destroyed, so body hairs pull out easily. All nerve endings in the dermal tissue are destroyed so the wound will be *insensate* (without feeling); however, a patient still may experience a significant amount of pain because adjacent areas of partial-thickness burn usually surround a full-thickness injury.

A major problem that arises from deep burns is the damage to the peripheral vascular system. Because large amounts of fluid leak into the interstitial space beneath unyielding eschar, the pressure in the extravascular space increases, potentially constricting the deep circulation to the point of occlusion (see later discussion of cardiovascular complications in the section titled Complications of Burn Injury). Because eschar does not have the elastic quality of normal skin, edema that forms in an area of a circumferential burn can cause compression of the underlying vasculature. If this compression is not relieved, it may lead to eventual occlusion with possible necrosis of tissue distal to the site of injury. To maintain vascular flow, an **escharotomy** may be necessary. An escharotomy is a midline lateral incision of the eschar the length of an extremity or chest wall.[30,31] Figure 24.6 shows an escharotomy and the result of pressure that forces the incision to gape. Following an escharotomy, pulses are frequently examined to monitor restoration of circulation. If the escharotomy is successful, there will be an immediate improvement in the peripheral blood flow, demonstrated by normal pulses distal to the wound and by return of normal temperature and capillary refill of the distal extremity.

Although at times it may be difficult to differentiate a deep-partial from a full-thickness burn in the early postburn period, the differences will become evident after several days. With a full-thickness burn, there are no sites available for re-epithelialization of the wound. All epithelial cells have been destroyed, and skin grafting will be necessary. Grafting is discussed in detail in the section titled Surgical Management of the Burn Wound.

Subdermal Burn

An additional category of burn, the **subdermal burn**, involves complete destruction of all tissue from the epidermis down to and through the subcutaneous tissue (Fig. 24.7). This depth of injury correlates with practice pattern 7E, Impaired Integumentary Integrity Associated with Skin Involvement Extending into Fascia, Muscle, or Bone and Scar Formation, in the *Guide to Physical Therapist Practice*.[21] Muscle and bone are subject to necrosis when burned. This type of burn occurs with prolonged contact with a heat source and routinely occurs as a result of contact with electricity. Extensive surgical and therapeutic management is necessary to return a patient to some degree of function.

ELECTRICAL BURN

The signs and symptoms of an **electrical burn** may vary according to the type of current, intensity of the current, and the area of the body the electric current passes

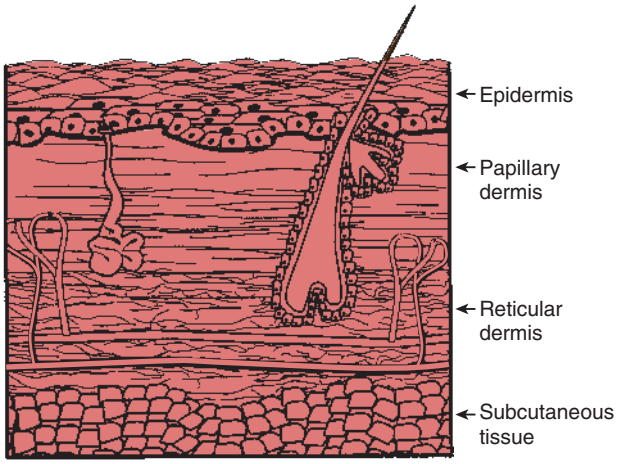

Figure 24.7 Red shading represents depth of skin involved in a subdermal burn.

through.[32] A burn results from the passage of an electric current through the body after the skin has made contact with an electrical source. Electric current follows the course of least resistance offered by various tissues. Nerves, followed by blood vessels, offer the least resistance. Bone offers the most resistance. Tissue damage results from tissue resistance to the passage of the current or by direct electrical current.[33,34]

Typically contact sites will exist where the patient first came into contact with the electricity and a second site where the patient was grounded. The wound where initial contact was made (sometimes referred to as the *entrance wound*) will appear charred and depressed, and many times, is smaller than the ground site. The skin appears yellow and ischemic. The ground site (sometimes referred to as the *exit wound*) often appears as though there was an explosion out of the tissue at the site. It is dry in appearance. Tissues along the pathway of the current may be damaged owing to heat that developed as a result of tissue resistance to current passage. An extremity or area that appears viable after an injury may become necrotic and gangrenous in a few days. Arteries may undergo spasm, and there may be necrosis of the vascular wall. The blood supply to the surrounding tissues, including muscle, may be altered. Damaged muscle will feel soft. Because the course of tissue destruction is unpredictable, there may be unequal and uneven muscle damage. Time will be required to determine which tissues will remain viable and which will not.

There can be other consequences of electricity passing through the body such as cardiac arrhythmias and acute renal failure secondary to fluid and electrolyte imbalances and release of myoglobin (protein present in muscle) into the blood. One of the most severe complications of electrical current damage is acute spinal cord damage or vertebral fracture. Clinically, these patients will have spastic paresis but may or may not have any sensory pathway changes over concomitant areas of spasticity. Possible causes of death from electrical burns are ventricular fibrillation and respiratory arrest.

Burn Wound Zones

A burn wound typically consists of three zones (Fig. 24.8).[20] In the **zone of coagulation** cells are irreversibly damaged and skin death occurs. This area is equivalent to a full-thickness burn and will require a skin graft to heal. Because of the lack of viable tissue and the amount of eschar, the risk of infection is increased. This potential complication emphasizes the need for careful monitoring, the use of antibiotics, and the treatment of a burned patient in a specialized burn center. The **zone of stasis** contains injured cells that may die within 24 to 48 hours without diligent treatment. It is in the zone of stasis that infection, drying, and/or inadequate perfusion of the wound will result in conversion of potentially salvageable tissue to completely necrotic tissue and enlargement of the zone of coagulation. Splints or compression bandages, if applied too tightly, can compromise this area. Finally, the **zone of hyperemia** is a site of minimal cell damage, and the tissue should recover within several days with no lasting effects.[35]

Extent of Burned Area

A major consideration when determining the severity of a burn is the extent of body surface involved. To calculate rapidly an estimate of the percentage of total body surface area (TBSA) burned, Pulaski and Tennison[36] developed the **Rule of Nines**. The Rule of Nines divides the body surface into areas of 9%, or multiples of 9%, of the TBSA. Figure 24.9 shows the percentages using the Rule of Nines for adults and children. Lund and Browder[37] modified the percentages of body surface area to account for a continuum of age and to accommodate for growth of different body segments. This latter method is the more accurate means of the two methods to determine the extent of burn injury. Figure 24.10 shows the relative percentages of burned area for children and adults according to the Lund and Browder formula. Although this formula provides an accurate determination of TBSA, the use of the Rule of Nines is more practical in the emergent triage of a patient with an acute burn injury.

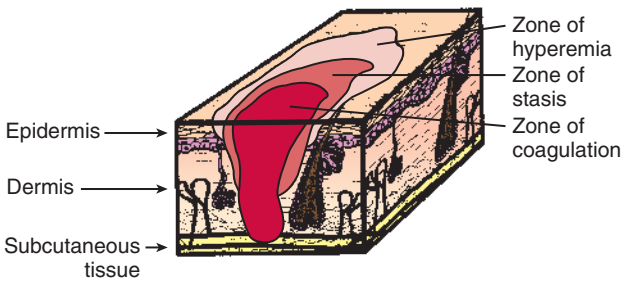

Figure 24.8 Zones of tissue damage as the result of a burn injury.

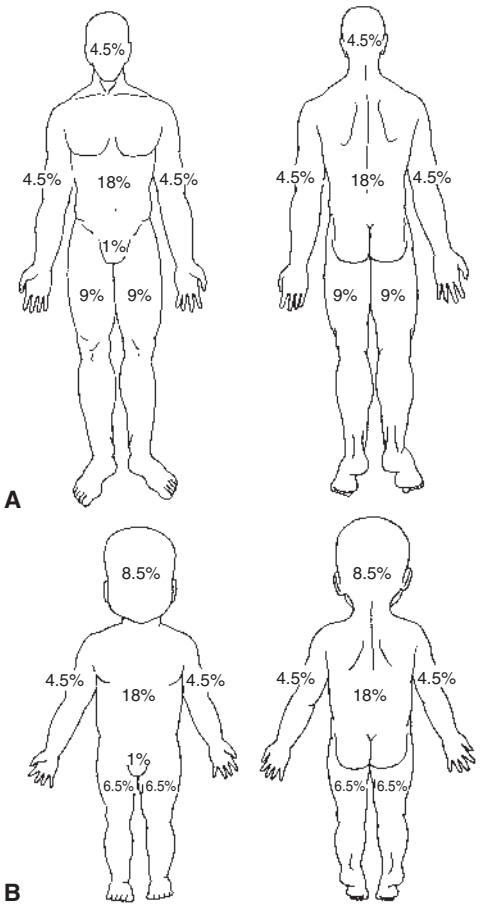

Figure 24.9 Rule of Nines to determine percentage of body surface area burn in adults **(A)** and children **(B).**

COMPLICATIONS OF BURN INJURY

Depending on the extent of burn injury, the depth of the burn, and the type of burn, there may be secondary systemic complications.[38] In addition, the health, age, and psychological status of a patient who is burned will affect these complications. This section will highlight selected systemic complications a patient may experience after a significant burn injury.

Infection

Infection, in conjunction with organ system failure, is a leading cause of mortality from burns.[39] Some virulent strains of *Pseudomonas aeruginosa* and *Staphylococcus aureus* are resistant to antibiotics and have been responsible for epidemic infections in burn centers.[1,39] Microbial invasion from the burn wounds to other healthy tissue can create sepsis.[40,41]

Systemic antibiotics are used to treat both burn and general system infections once they have been documented.[39,42] A bacterial count in excess of 10^5 per gram of tissue constitutes burn wound infection and levels of 10^7 to 10^9 are usually associated with lethal burns. Most wounds are treated with topical antibiotics; these will be discussed in a later section titled Medical Management of Burns.

Pulmonary Complications

Any patient who has been burned in a closed space should be suspected of having an **inhalation injury**.[43] Among patients with burns, the incidence of smoke inhalation may be in excess of 33%,[44] and this rises to 66% in patients with facial burns.[45] The incidence of pulmonary complications is extremely high after severe burns, and death due to pneumonia alone is attributed to a majority of the deaths following burn injury.[46] Direct trauma to the upper airways can also occur from the inhalation of hot gases.[47]

Signs of an inhalation injury include facial burns, singed nasal hairs, harsh cough, hoarseness, abnormal breath sounds, respiratory distress, and carbonaceous sputum and/or hypoxemia.[46]

The primary complications associated with this injury are carbon monoxide poisoning, tracheal damage, upper airway obstruction, pulmonary edema, and pneumonia. Lung damage from inhaling noxious gases and smoke may be lethal. To determine the extent of inhalation injury, several diagnostic procedures can be performed. The most helpful diagnostic procedure is bronchoscopy.[46]

Metabolic Complications

Thermal injury causes a great metabolic and catabolic challenge to the body. Most of the recent advances in burn treatment and rehabilitation have come directly from the increased understanding of the metabolic demands of a burn injury and from the ability to improve the patient's nutritional status to meet these demands.[48] Metabolic rates may increase up to 50% in a 25% TBSA burn and much more as the burn size increases.[49-51] The consequences of the increased metabolic and catabolic activity following a burn are a rapid decrease in body weight, negative nitrogen balance, and a decrease in energy stores that are vital to the healing process.[52]

As a result of the increased metabolic activity, there will be an increase of 1.8°F to 2.6°F (1°C to 2°C) in core temperature that seems to be due to a resetting of the hypothalamic temperature centers in the brain.[1] Wilmore et al[53] hypothesized that there is a significant relationship between the increased evaporative heat loss from the impaired skin barrier over a burn and the hypermetabolic state. In any event, if individuals with burns are placed in a room with normal ambient temperature, excessive heat loss will be exhibited, and this will further exaggerate the stress response seen in these patients.[1,53] Therefore, it is recommended that room temperature be kept at 86°F (30°C), which will significantly reduce the metabolic rate.

As part of the patient's altered metabolism, protein from muscle tissue is preferentially used as a source of energy. This situation, coupled with the effects of

bedrest, causes muscles to atrophy and renders patients weak from both their burn injury and hospitalization.

Much of the improved management of burns has been attributed to the greater focus of research on the nutritional needs of patients. It is beyond the scope of this chapter to detail nutritional supplementation, and the interested reader is referred to several excellent reviews of advances in burn nutrition.[54-56]

Cardiovascular Complications

Hemodynamic changes result from a shift in fluid to the interstitium, which subsequently reduces the plasma and intravascular fluid volume in a patient with a burn.[57,58] The fluid shifts occur as a result of local and temporary systemic changes in capillary dynamics. This shift of fluid to the interstitium can result in significant edema. Capillary permeability returns to normal after about 24 hours. Also, with these fluid shifts, there will be a tremendous initial decrease in cardiac output, which may reach as low as 15% of normal within the first hour after injury.[59,60] Fluid replacement therapy is utilized initially to manage the loss of circulatory fluid. This additional fluid allows perfusion of vital organs but also increases the amount of tissue edema.[58,61]

Hematological changes also occur after a severe burn injury. These changes include alterations in platelet concentration and function, clotting factors, and white blood cell components; red blood cell dysfunction; and decreases in hemoglobin and hematocrit.[62] These physiological alterations, coupled with cardiac changes and injured vascular beds, will significantly affect initial resuscitation efforts and, if the patient survives, how rapidly he or she will recover. Additionally, patients will exhibit decompensation from an endurance standpoint resulting in functional deterioration.

Heterotopic Ossification

Patients with burns greater than 20% TBSA are highly susceptible to development of **heterotopic ossification (HO)**, as shown by prospective studies demonstrating a very high reported incidence.[63-66] However, the actual number of cases that progress on to become clinically problematic ranges from 1% to 3% and therefore is relatively low.[65-68] Why HO occurs in patients with burn injuries is uncertain. Suspected etiologies beyond TBSA involved include immobilization, microtrauma, high protein intake, and sepsis. The most common areas affected are the elbows, followed by the hips and shoulders; however, HO can appear anywhere throughout the body.[65,66] Usually HO occurs in areas of full-thickness injury or sites that remain unhealed for prolonged periods of time. Symptoms appear late in a patient's course of recovery and include decreased ROM, point-specific pain, and a reported quality of pain that differs from the generalized pain that patients usually report.

Neuropathy

Peripheral neuropathy in patients with burns can take two forms: **polyneuropathy** or local neuropathy.[69] The cause of polyneuropathy is unknown. As with patients with HO, patients with peripheral neuropathy generally have a large TBSA burn, and the condition may be associated with sepsis. Fortunately, most neuropathies resolve over time but some may be long-term.

Local neuropathies can be caused by a number of factors, most of which center around burn treatment issues, such as compression bandages applied too tightly, poorly fitted splints, or prolonged and inappropriate positioning.[69] The most common sites of involvement are the brachial plexus, ulnar nerve, and common peroneal nerve.

Pathological Scars

Burn scars occur in areas of deep partial-thickness burn that are allowed to heal spontaneously and in full-thickness burns that have been skin grafted, but where graft coverage is incomplete. If maturing tissue demonstrates a greater rate of collagen production than degradation, a scar becomes raised and thick.[70,71] Scars become pathological when they take on the form of **hypertrophy**, contracture, or both. Each of these scar conditions is unique and should not be viewed as synonymous. A patient can have a hypertrophic scar that does not interfere with movement or a scar contracture band that is not hypertrophied. However, both conditions can exist simultaneously, and specific treatment for each is discussed later in this chapter.

BURN WOUND HEALING

The burn wound has been described and the causes and complications of burn injury have been reviewed. The remaining sections of this chapter concentrate on the various types of medical and surgical interventions and physical rehabilitation of the patient with a burn. First, however, it is necessary to outline the healing process of a burn wound.[72]

The two layers of the skin—the epidermis and dermis—differ morphologically, and they heal by separate mechanisms. In the following sections, the physiology of each component is described, and the clinical implications of burns to these areas are addressed.

Epidermal Healing

When a burn injures just the epidermis, or if there are viable cells lining the skin appendages, **epithelial healing** can occur on the surface of a wound. The stimulus for epithelial growth is the presence of an open wound exposing subepithelial tissue to the environment. The intact epithelium attempts to cover an exposed wound through mitosis and the ameboid movement of cells from the basal layer of the surrounding epidermis into the wound. The epithelial cells stop migration when they are completely in contact with other epithelial cells. After this **contact inhibition**, cells can begin to differentiate to form the various epithelial layers. While epidermal cells move about the wound site, they maintain a connection with the normal epithelium at the wound margin. To continue migration and proliferation, a suitable base for the epithelial cells must be provided by adequate nutrition and blood supply, or else the new cells will die.

The process of epithelialization is most evident clinically in the partial-thickness wound that has intact hair follicles and glands. The skin appendages provide a source of epithelial cells from which the wound may heal. The cells migrate outwardly from the appendages and appear as epidermal islands from which they spread peripherally across the wound. Skin growth and coverage from these epithelial islands actually can be visualized over time.

Damage to sebaceous glands may cause dryness and itching of a healing wound. Lubrication can be a problem, and newly healed skin is characteristically dry and may split. Dryness may continue for a long time, because many of the sebaceous glands do not return to their normal function after a wound is epithelialized. Therapists need to educate patients about the type, frequency, and techniques of moisturizing cream application to lubricate newly healed tissue.

Dermal Healing

When an injury involves tissue deeper than the epidermis, **dermal healing**, or scar formation, occurs. Scar formation can be divided into three phases: *inflammatory, proliferative*, and *maturation*. Although these phases will be described separately, they occur on a continuum and one phase often overlaps another.

Inflammatory Phase

The primary reaction of viable tissue to a burn wound is inflammation, which prepares the wound for healing through hemostatic, vascular, and cellular events. Inflammation begins at the time of injury, ends in about 3 to 5 days, and is characterized by redness, edema, warmth, pain, and decreased ROM. Initially, when a blood vessel is ruptured, the wall of the vessel contracts to decrease blood flow. Platelets aggregate, and fibrin is deposited to form a clot over the area. Fibrin serves a threefold function: (1) to partially retain body fluids; (2) to protect the underlying cells from desiccation; and (3) to provide a firm coagulum substance from which cells can infiltrate. Therefore, fibrin can be thought of as forming a lattice network, from which cells can climb and work themselves into the healing structure.

After a transient vasoconstriction of the vasculature, which lasts about 5 to 10 minutes, vessels vasodilate to increase blood flow to the area. There is increased permeability of the blood vessels, with leaking of plasma into the interstitial space and subsequent edema formation. Leukocytes infiltrate the area and begin to rid the site of contamination. Of particular importance is the presence of macrophage cells, which are responsible for attracting fibroblasts into the area.

Proliferative Phase

During this phase, re-epithelialization is occurring at the surface of the wound, while deep within the wound, fibroblasts are migrating and proliferating. **Fibroblasts** are the cells that synthesize scar tissue, which is composed of collagen and protein polysaccharides in the form of a viscous ground substance that surrounds the collagen strands. The collagen is deposited with a random alignment and no true architectural arrangement of fibers. Stress (e.g., a force intended to elongate the scar) applied to the developing tissue during this time causes the fibers to align along the direction of force.[73] During this period of fibroplasia, the tensile strength of the wound increases at a rate proportional to the rate of collagen synthesis.

In conjunction with collagen deposition, granulation tissue is formed during this phase. Granulation tissue consists of macrophages, fibroblasts, collagen, and blood vessels.[72] Newly formed blood vessels bring a rich blood supply to the area and encourage further wound healing. However, granulation tissue formation is not necessary for skin graft adherence, and excess granulation tissue may lead to an increase in hypertrophic scarring.

During the proliferative phase, **wound contraction** occurs. Wound contraction is an active process in which the body attempts to close a wound where a loss of tissue has occurred. The amount of contraction is determined by the amount of available mobile skin around the defect. It involves movement of existing tissue at the wound edge toward the center, not formation of new tissue. Wound contraction ceases when (1) the edges of the wound meet, or (2) tension in the surrounding skin equals or exceeds the force of contraction. Skin grafting may decrease contraction, with thick grafts causing less contraction.

Maturation Phase

A wound is considered closed at the time epithelium covers the surface; however, wound healing involves remodeling of the scar tissue. During the maturation phase, there is a reduction in the number of fibroblasts, a decrease in vascularity due to a lesser metabolic demand, and remodeling of collagen, which becomes more parallel in arrangement and forms stronger bonds. The ratio of collagen breakdown to production determines the type of scar that forms. If the rate of breakdown equals or slightly *exceeds the rate of production*, maturation results in a pale, flat, and pliable scar. If the rate of collagen production *exceeds breakdown*, then a hypertrophic scar may result. This scar is characterized by a red and raised appearance with rigid texture; it stays within the boundary of the original wound. A *keloid* is a large, firm scar that overflows the boundaries of the original wound; it is more common in darkly pigmented individuals. Both of these scars take a prolonged period of time to mature. The presence and contraction of the scar can lead to both functional and cosmetic deformities. The active process of scar contraction during both this maturation phase and the proliferative phase creates a risk of contracture formation. A contracture over a joint will limit ROM and affect joint function.[74]

MEDICAL MANAGEMENT OF BURNS

Advances in the medical management of patients with burn injury have resulted in the survival of thousands of patients who 20 or 30 years ago would have died from their injuries.[75] Research findings and current techniques available at modern burn centers have enabled patients to receive better care through use of more sophisticated interventions for the treatment of major burn injuries. This section addresses the initial treatment of burn injuries and the surgical procedures associated with excision and grafting of new skin onto a burn wound.

Initial Management

The goals in the initial management of a patient with a burn are to address critical life-threatening problems and stabilize the patient through procedures designed to (1) establish and maintain an airway; (2) prevent

cyanosis, shock, and hemorrhage; (3) establish baseline data on the patient, such as extent and depth of burn injury; (4) prevent or reduce fluid losses; (5) clean the patient and wounds; (6) examine injuries; and (7) prevent pulmonary and cardiac complications. Triage (assigning degree of urgency and order of treatment) using these procedures applies to major burn trauma.

Initially, a patient must be transported from the site of injury to a treatment facility. If possible, transportation will be directly to a burn center, rather than to a hospital emergency room. The goals of treatment in transit are to stabilize the patient and maintain an airway. During the initial transportation phase, patient history and personal data are gathered when possible. The type of agent causing the burn is noted, and initial examination of the burn injury takes place. Emergency medical personnel may use the Rule of Nines to estimate the percent of burn injury. In addition, they will prepare the individual for triage at the burn center by removing all burned clothing and jewelry and initiating the administration of fluid through an intravenous line.

One of the major advances in burn care has been in fluid volume replacement initially and throughout a patient's treatment. Research has led to an improved understanding of the physiological changes that occur in a patient after a burn injury and of the fluid volumes necessary to optimize the chance for survival.[60] Information about the physiological changes responsible for the shifts in body fluids and protein has led to the use of intravenous solutions in an amount necessary to replace vital fluids and electrolytes.[76]

After a patient arrives at a burn center and adequate fluid resuscitation (replacement) has been initiated, the burn team determines the extent and depth of injury, and begins initial wound cleansing. Wound cleansing may be performed using a variety of approaches and typically incorporates some form of hydrotherapy.[77-79] The initial wound care allows the team to establish body weight, examine the patient fully, remove hair where necessary, and start the **débridement** process by removing any loose skin. The goals of wound cleansing and debridement are to remove dead tissue, prevent infection, and promote revascularization and/or epithelialization of the area. Depending on the facility, physical therapists may be involved in the initial wound cleaning procedure.[78,80,81]

If used for wound cleansing, a large hydrotherapy tank or whirlpool tub usually will have some form of disinfectant in the water to assist in infection control.[77,82,83] Water temperature should be between 98.6°F and 104°F (37°C and 40°C). While a patient is in the water, adherent clothing or dressings applied during transport are removed. Care must be taken to ensure minimal or no bleeding. *Note*: In general, the removal of adherent material or dressings in the water is less painful than dry removal. Some burn units have converted to the use of showers, spraying, or "bed baths" for the removal of dressings and daily cleaning of wounds.[84] Regardless of the wound cleansing approach, most patients require pain medication before wound care.

Wound Care

After dressings are removed, the wound should be inspected carefully. The appearance, depth, size, exudate, and odor are noted. *Infection* is characterized by thick purulent drainage, odor, fever, a brownish-black discoloration, rapid separation of eschar, boils in adjacent tissue, or conversion of a deep partial-thickness burn to a full-thickness injury.

Wound care is carried out using clean technique and sterile instruments. If **sharp débridement** (the use of surgical scissors or scalpel and forceps to remove eschar) is performed, sloughed epidermis and loose eschar are removed and pockets of pus are drained. The procedure needs to be performed carefully so that bleeding is minimal.

After the wounds have been cleaned, the patient should be kept warm to reduce any further metabolic demand due to additional heat loss. Topical medications and/or dressings are then applied or reapplied. Table 24.3 presents common topical medications used in the treatment of burns. The technique of applying a topical cream or ointment without dressings is called the **open technique** and allows for ongoing inspection of the wound and examination of the healing process. With this technique, the topical medication must be reapplied throughout the day.

The **closed technique** consists of applying dressings over a topical agent. Dressings serve several purposes: (1) they hold topical antimicrobial agents on the wound, (2) they reduce fluid loss from the wound, and (3) they protect the wound. Dressings are changed once or twice a day, depending on the size and type of wound and the type of topical antimicrobial used.

Dressings consist of several layers. The first layer is nonadherent to protect the fragile healing surface from disruption. This may be followed by cotton padding to absorb wound drainage. The final layer consists of roll gauze or elastic bandages, which hold the other layers in place but allow movement.

Surgical Management of the Burn Wound

Primary Excision, Types of Skin Grafts, and Skin Substitutes

Primary excision is surgical removal of eschar. The excision generally includes removal of peripheral layers of eschar until vascular, viable tissue is exposed as the site for skin graft placement.[85] Much of the increased survival rate of patients with extensive burns has been due to the early primary excision of burn wounds.[86] Normally, a patient is taken to surgery after successful resuscitation, usually within 1 week of injury. As much of the eschar is removed at one time as possible. Proponents of early primary excision believe that this approach is easier on the patient than repeated débridement and that it promotes more rapid

Table 24.3 Common Topical Medications Used in Treatment of Burns

Medication	Description	Method of Application
Silver sulfadiazine	Most commonly used topical antibacterial agent; effective against *Pseudomonas* infections.	White cream applied with sterile glove 2–4 mm thick directly to wound or impregnated into fine mesh gauze.
Mafenide acetate (Sulfamylon)	Topical antibacterial agent; effective against gram-negative or gram-positive organisms; diffuses easily through eschar.	White cream applied directly to wound with thin 1–2 mm layer twice daily; may be left undressed or covered with thin layer of gauze.
Mafenide acetate solution (Sulfamylon 5% Solution) Silver nitrate	Topical solution with antimicrobial function against gram-positive and gram-negative organisms. Maintains moist environment. Antiseptic germicide and astringent; will penetrate only 1–2 mm of eschar; useful for surface bacteria; stains black.	50-gram packet of white powder that is mixed with either 1000 mL sterile water or 0.9% sodium chloride–soaked gauze. Dressings or soaks used every 2 hours; also available as small sticks to cauterize small open areas.
Bacitracin/Polysporin	Bland ointment; effective against gram-positive organisms.	Thin layer of ointment applied directly to wound and left open.
Collagenase, Accuzyme	Enzymatic debriding agent selectively debrides necrotic tissue; no antibacterial action.	Ointment applied to eschar and covered with moist occlusive dressing with or without an antimicrobial agent.

healing, reduces infection and scarring, and is more economical in terms of staff and hospital time.[86]

In many burn centers, a burn wound is closed with a skin graft at the time of primary excision. Many types of grafts can be used to close a wound. An **autograft** is a patient's own skin, taken from an unburned area and transplanted to cover a burned area. Autografts are desirable because they provide permanent coverage of the wound. An **allograft (or homograft)** is skin taken from an individual of the same species, usually cadaver skin. The skin can be kept frozen in skin banks for prolonged periods. Allografts are temporary grafts used to cover large burns when there is insufficient autograft available. **Xenograft (or heterograft)** is skin from another species, usually a pig. Allografts or xenografts are used until there is sufficient normal skin available for an autograft.

Perhaps the most progressive advancement in the care of patients with burns in recent years is the use of **skin substitutes** for coverage of an excised wound.[87-94] Skin substitutes consist of cultured autologous skin, which is grown in a laboratory from a biopsy of a patient's own tissue, the use of altered cadaver skin, or other biologically engineered tissues. Skin substitutes are used when large areas of burn exist and coverage is necessary for a patient's survival. Cultured autologous skin takes several weeks to grow and is highly susceptible to infection. Other biologically engineered tissues are more readily available and have demonstrated more reliable adherence than in the past. With the use of most skin substitutes, ROM exercises may be delayed and shearing forces must be avoided. Although skin substitutes are an expensive intervention for wound coverage, they are useful and have proved effective in managing patients with large burn wounds. Examples of skin substitutes include the following:

- *Cultured epidermal autografts (CEAs):* A skin biopsy is obtained from a patient, and only the epidermal cells are cultured.[87,88]
- *Cultured autologous composite grafts:* A skin biopsy is obtained from a patient, and both epidermal and dermal cells are cultured. This forms a bilayer structure.
- *Allogenic skin substitute:* The epidermal layer of skin and all immune cells are removed from cadaver skin. This tissue is applied to the graft bed and once adhered, a thin epidermal autograft or CEA is applied.[95]
- *Cultured dermis (temporary):* Cultured dermal matrix is seeded with human neonatal fibroblasts and used as a temporary covering in place of cadaver skin. This substitute eventually is removed and replaced with an autograft.[92,93]
- *Cultured dermis (definitive):* This skin substitute is composed of cultured bovine collagen with a silicone outer layer. Pores in the material allow for controlled growth of a neodermis. After approximately 14 days, the silicone layer is removed and a very thin skin graft or CEA is applied.[94]

Skin Grafting Procedure

The removal of skin to graft onto a burn wound is done surgically under anesthesia. The skin used for a graft usually is removed with a **dermatome**. This instrument not

only allows the surgeon to obtain a large amount of skin, but a more consistent thickness of skin can be obtained. The dermatome is adjusted to remove a predetermined thickness of skin for a **split-thickness skin graft**. A split-thickness skin graft contains epidermis and a variable amount of dermis, as opposed to a **full-thickness skin graft**, which consists of the full dermal thickness.

The site from which a skin graft is taken is called a **donor site**. Common donor sites include the thighs, buttocks, and back. These wounds heal by re-epithelialization, like a partial-thickness burn, and require appropriate care to prevent additional dermal damage with resultant scar formation. A full-thickness skin graft has the disadvantage of leaving a full-thickness wound at the donor site that will require either primary closure or grafting with a split-thickness skin graft.

Generally, the thinner the skin graft, the better the adherence, and the thicker the graft, the better the cosmetic result. Additionally, a thin graft will contract more than a thick skin graft once it has adhered to the wound bed. Selection of depth depends on many factors, including whether or not the donor site needs to be used again for another skin graft. Taking a thicker graft adversely affects the possibility of taking another graft from the same site for a prolonged period of time. Harvesting from split-thickness skin graft sites may be repeated in 10 to 14 days, depending on the amount of time the donor site takes to heal.

A **sheet graft** is a skin graft applied to a recipient bed without alteration following harvesting from a donor site (Fig. 24.11). The face, neck, and hands are covered with this type of graft for optimal cosmesis and function. When limited donor skin is available, most areas are covered with a **mesh graft** (Fig. 24.12). The meshing of a graft consists of processing the sheet graft through a device that makes tiny parallel incisions in a linear arrangement. This process permits the skin graft to be expanded before it is applied to the wound bed.[96] This technique allows coverage of a larger area, and once the graft adheres, the interstices heal through re-epithelialization.

Figure 24.11 Sheet graft on dorsum of left hand, postoperative day 7. *From Richard and Staley,[4, p. 183] with permission.*

Figure 24.12 Meshed split-thickness skin graft applied to freshly excised wound and secured with staples.

A skin graft usually is held in place with sutures, staples, or Steri-Strip™ skin closures. Once a graft is fixed in position, any blood or serum that might have become located between the graft and the recipient site should be removed. Application of a pressure dressing facilitates contact between the graft and recipient site.

A basic necessity for successful adherence of a graft is sufficient vascularity within the wound bed. Grafts will not adhere to poorly vascularized areas, such as tendon. Once a skin graft has been applied, separation of a graft from its bed must be prevented. Separation may result from shear force, mechanical trauma, or hematoma formation. Initially, an area is immobilized with a dressing that provides firm, even compression on the wound. Other reasons for graft failure include inadequate excision of necrotic tissue and infection.

Survival of a skin graft depends on several factors: (1) circulation, which provides a nutritive supply to the graft; (2) inosculation, or the process by which a direct connection is established between a graft and the host vessels; and (3) penetration of the host vessels into a graft site. Except in darkly pigmented persons, grafts are white in color at the time of transplantation and begin to show a pinkish hue within a matter of hours after their placement on an adequate vascular bed.

The reestablishment of circulation in a skin graft will take place through the formation of direct anastomosis between respective vessels, invasion from the host bed forming new channels, or both. Twenty-four hours after grafting, numerous host vessels will have penetrated the graft.[72] The invasion of new capillaries seems to be the most important consideration in vascularization. Normally, within 72 hours, inosculation has proceeded to the point where the skin graft is secure. Initially, structural connections are fibrous. Collagen is then laid down to secure the attachment of the graft.

Correction of Scar Contracture

If physical therapy interventions are unsuccessful in averting scar contracture formation, and limitations are noted in ROM and function, surgery may be required. In the past, reconstructive surgery usually was postponed while a burn wound was in the active, immature phase of scar formation.[97] More recently, however, successful release of scar contractures before scar maturation has been documented.[98] Each patient's scar will require an individualized evaluation and treatment. Many surgical treatment options are available to eliminate scar contractures; among the more common procedures are skin grafts and Z-plasties.[99]

A schematic diagram of a Z-plasty is shown in Figure 24.13. The Z-plasty serves to lengthen a scar by interposing normal tissue in the line of the scar. Skin grafts are used after surgical release for more severe contractures.

PHYSICAL THERAPY MANAGEMENT

Rehabilitation of a patient with burns begins the moment he or she arrives at the hospital and is an evolving process that may need to be modified daily.[5-7,100] Previous sections of this chapter have discussed the pathophysiological changes and alterations of the skin that occur in the burn wound and the closure of that wound, including various types of skin graft materials. Concurrent with skin healing, is initiation of the physical therapy plan of care (POC). Commonly, physical therapy interventions are directed toward prevention of scar contracture, preservation of normal ROM, prevention or minimization of hypertrophic scar formation and cosmetic deformity, maintenance or improvement in muscular strength and cardiovascular endurance, return to pre-burn function, and performance of activities of daily living (ADL).[4] The physical therapist interacts with other members of the burn team to assist patients in obtaining these outcomes. With adherence to a well-designed treatment plan, a patient can expect to return to a normal, productive life. For many patients, the most difficult phase of rehabilitation occurs after the wounds have healed and the scar tissue begins to contract. At this point, patient education about adherence to strategies designed to prevent or minimize contractures is particularly important. The remainder of this chapter will address the physical therapist's role in the rehabilitation program of a patient who has sustained a burn injury.

Physical Therapy Examination

After the initial examination for depth of burn and percent of TBSA involved, the physical therapist then examines the patient to determine the presence of impairments and activity limitations. The therapist needs to obtain an accurate history from the patient and family members regarding any preexisting limitations or previous injuries that may affect rehabilitation potential. The therapist must also anticipate the potential for development of indirect impairments as the burn wounds heal and mature. For example, active or passive ROM may be limited as a result of edema, restrictive eschar, or pain, and an initial baseline measure should be obtained.

Other tests and measures discussed in this text can be included in the initial examination and reexamination of a patient following burn injury (e.g., gait, functional status). Because healing of a burn wound is a dynamic process and changes may occur daily, the physical therapist needs to examine and monitor patients routinely for changes in skin integrity, ROM, and functional mobility. Frequent evaluation will keep the physical therapist and other members of the burn care team abreast of potential problems so that intervention can occur before a potential problem becomes a real one. Studies addressing assessment of burn scars are presented in Box 24.1 Evidence Summary.

In addition to the physical damage imposed by a burn, there also may be an enormous psychological impact.[101,102] The physical therapist should be cognizant of a potential problem during ongoing evaluations, because psychological trauma may affect the patient's progress and outlook toward his or her future and rehabilitation. Referral to an appropriate professional for intervention may be necessary (see Chapter 26, Psychosocial Disorders).

Box 24.1 Evidence Summary Studies Addressing Assessment of Burn Scar

Reference	Subjects	Methods	Rating Parameters	Results	Comments
Sullivan et al (1990)[a]	73 study subjects Scars less than 1 year old A wide variety of anatomical sites were assessed	Three independent observers rated scars on the following characteristics: • Pigmentation • Vascularity • Pliability • Height	Pigmentation of the scar rated from 0 to 2 (0 = normal, 1 = hypopigmentation, 2 = hyperpigmentation); vascularity of the scar rated from 0 to 3 (0 = normal and increasing numbers represent indicators of increased vascularity). Pliability of scar rated from 0 to 5 (0 = normal and increasing numbers represent indicators of decreased pliability); height of scar was rated from 0 to 3 (0 = normal or flat, 1 = <2 mm, 2 = <5 mm, 3 = >5 mm).	Moderate reliability found between raters; reliability improved with time. No data related to intrarater reliability or validity were reported.	The study suggests the Vancouver Scar Scale (VSS) may have potential as a clinical rating of burn scars.
Baryza and Baryza (1995)[b]	No subject number was reported	Scars were rated by physical and occupational therapists using a modified version of the VSS.	A 2-mm-thick Plexiglas tool and an expanded VSS scale were developed for height measurements (0 = normal or flat, 1 = >0 to 1 mm, 2 = >1 to 2 mm, 3 = >2 to 4 mm, 4 = >4 mm). Modifications of the VSS also included expansion of the pigmentation scale with addition of a "mixed pigmentation" category.	The authors reported good interrater reliability (ICC= 0.81). Cohen's κ values were reported: $\kappa = 0.61$ for pigmentation, $\kappa = 0.73$ for vascularity, $\kappa = 0.71$ for pliability, which reflect good to excellent reliability; reliability for measurement of height was fair with a $\kappa = 0.56$.	Good reliability reported with modifications to the VSS; however, the methodology was lacking in that numbers of subjects, testers, and blinding of testers was not reported.

Yeong et al (1997)[c]	A teaching set of 24 scar photographs used to train evaluators about possible scar characteristics. Ten additional photographs were used to study scar assessment.	Eight trained raters evaluated the 10 color photographs of scars using the teaching set of photographs for comparison. Assessment included the following scar characteristics: • Surface • Border height • Thickness • Pigmentation	The scale included: First, burn scar surface as smooth (-1), normal, (0), and various levels of roughness (1 to 4). Second, burn scar border height as depressed (-1), normal (0), and various levels of raised (1 to 4). Third, burn scar thickness as thinner (-1), normal (0), and various levels of thicker (1 to 4). Fourth, pigmentation of the scar as hypopigmented (-1), normal (0), and various levels of hyperpigmentation (1 to 4).	Interrater reliability was high for all areas: scar surface (0.97), border height (0.95), thickness (0.93), and pigmentation (0.85).	Provides an alternative scale to the VSS; however, the scar variables have a commonality with the VSS.
Crowe et al (1998)[d]	Ten color slide photographs of scars from 10 subjects were assessed using three different scales	Photographs of scars were evaluated by four independent raters (two were experienced clinicians and two were novice clinicians).	Scars were rated on irregularity, apparent depth or height, color, vascularity, pliability, disfigurement clothed and unclothed.	Interrater reliability ranged from 0.66 (vascularity) to 0.90 (color). Test–retest reliability ranged from 0.73 (vascularity) to 0.89 (proportion of irregular scar). Novice therapists were as reliable as expert therapists in use of the scale.	Findings suggest that the rating scale holds potential as a tool for evaluating scar surface, thickness, border height, and color. Subject and evaluator numbers were low.
Martin (2003)[e]	37 scars on 20 initial study subjects were assessed. Follow-up reassessment of scars included 17 scars on 8 subjects. A modified VSS (per Baryza and Baryza[b]) was used for rating scars both initially and on follow-up.	Scars rated were less than 6 months old. For some subjects, the same scars reassessed at approximately 1.5 years after injury. In addition to the modified VSS, a visual analogue scale (VAS) was used to obtain subject responses to two questions.	Scar assessment included pigmentation, vascularity, pliability, and height of scar. The VAS included two questions: (1) "*How would you rate your scar?*" (best possible, most attractive = 0 and worst possible, least attractive = 10); and (2) "*I feel this scar is unattractive to other people*" (completely disagree = 0, completely agree = 10).	Significant improvement in the modified VSS score from early to late assessment. The VAS scores for question 1 did not show a significant change, whereas the scores for question 2 showed significant improvement.	Findings suggest that while subjects might feel their scars improve with time, their feelings about acceptance of the scar by others may be different.

Oliveira (2005)[f]	62 subjects had clinical and photographic evaluation of their scars at hospital discharge and 6, 9, 12, 18, and 24 months after injury. Observers were blinded to the subjects and the time after injury.	Assessment at each time interval included: • Photographic evaluation using VSS • Vascularity using a dermaspectrometer and a chromameter • Pliability using a pneumatonometer and a durometer • Vascularity with a laser Doppler ultrasound flow meter • Thickness with scar biopsy	Scores from the VSS; ratings from measurement instruments based on the specific variable under study. Data from VSS correlated with those from the other measurement instruments.	Photographic evaluation showed increases in scar hypertrophy between 6 and 12 months. Correlations with the VSS: VSS showed best correlation with dermaspectrometer measurements. Good correlation for pliability between VSS and both durometer and pneumatonometer. Scar heights were increased but no correlation was reported between measures. Vascularity showed significant correlation between the VSS and laser Doppler measures and significant increases in vascularity were noted at 6 to 12 months. Hypertrophic scars were associated with more itching than other scars ($p < .05$).	The correlations in this study support the use of quantitative instruments to measure some scar variables. However, the cost of the instruments may not be necessary or justifiable since these variables also appeared to correlate well with the VSS.
Forbes-Duchart et al (2007)[g]	14 pediatric subjects and 32 scars were analyzed using a modified version of the VSS. Three independent raters assessed each scar. The raters were trained together in the use of	The VSS was modified by: • Adding two color scales to address issues of variations in normal skin hue. • Two color scales were used to assist with assessment of vascularity in subjects	Two color scales were designed to assess scar based on a subject's skin tone. The two scales were labeled *"Caucasian"* and *"Aboriginal"* (described as a term used in Canada to describe Native or Indigenous Peoples).	Results indicated poor reliability with the pigmentation assessment. The vascularity subtest showed poor interrater reliability for both the Caucasian and the Aboriginal group. Reasonable reliability was reported for pliability and height.	The interrater reliability for this study was generally lower than other studies examining scar scales. A study limitation was the small sample size.

	the modified VSS.	with different skin tones. • Remainder of scar variables (pigmentation, pliability, and height) assessed using standard VSS scores.			
Nedelec et al (2008a)[h]	Fours skin areas evaluated (3 scar sites; 1 normal skin area) on each of 30 subjects. The four sites included: • The most severe scar • A less severe scar • A donor skin site • A normal skin site	Modified VSS used to assess scar height, pliability, and vascularity. Other measures included: • Cutometer used to assess skin elasticity. • Mexameter used to further assess scar erythema and melanin. • Dermascan used to assess scar thickness.	Each site was evaluated by the same observer using a modified VSS, a cutometer, mexameter, and dermascan. Each site was assessed on three different days within a 2-week period. The observer was blinded to any previous measurements results.	The ICC for the modified VSS for height, pliability, and vascularity subscales was adequate (0.81). The cutometer did not discriminate between normal skin and scar. The mexameter was acceptable for erythema (>0.75) and melanin index (>0.89), as was the dermascan for thickness (>0.82). *Note*: Thresholds were described for some of these measurements.	Variable sensitivity and specificity noted with some measures. Questions raised about intrarater reliability of the modified VSS with hypertrophic scar. The interrater reliabilities for the mexameter and the dermascan were acceptable, allowing consideration of these instruments for measuring the relevant scar.
Nedelec et al (2008b)[i] (*Note:* This is a companion study to the one presented above by the same authors.)	As with study above also by Nedelec et al, four skin areas evaluated (3 scar sites; 1 normal skin area) on each of 30 subjects. The four sites included: • The most severe scar • A less severe scar • A donor skin site • A normal skin site	Modified VSS used to assess scar height, pliability, and vascularity. Other measures included: • Cutometer used to assess skin elasticity. • Mexameter used to further assess scar erythema and melanin. • Dermascan used to assess scar thickness.	Each site was evaluated by the same observer by using a modified VSS, a cutometer, mexameter, and dermascan. Each site was assessed on three different days within a 2-week period. The observer was blinded to any previous measurements results.	Interrater reliabilities of all subscales of the modified VSS were not acceptable (≈0.50). Acceptable reliability was reported for the cutometer (>0.89), the mexameter, and the dermascan (0.82). Concurrent validity was significant with the VSS in every case except with the pliability subscale and the cutometer in cases of severe scar.	The interrater reliabilities of the cutometer, mexameter and dermascan and their concurrent validity with the modified VSS suggests they are objectively measuring the same scar characteristics as the modified VSS.

Simons and Tyack (2011)[j]	Three-phase assessment of rating burn scars from photographs included: • Opinions from 38 health professionals about current practice in scar assessment • Opinions from 36 therapists (PTs and OTs) about what should be included in a photographic scar scale • Opinions of 10 health care consumers about scar evaluation	Opinions were gathered from health professionals using focus groups and questionnaires with instructions for assessment of scars and photographs of scars. Health care consumers received information about burn scar assessment practices, a questionnaire, and photographs of scars.	Responses and answers to open-ended questions were linked for similarity. Linked responses and answers were converted to percentages for descriptive purposes and then analyzed for significance using chi-square analysis.	Some agreement was reached that vascularity, color, contour, height, and overall opinion of the burn scar were parameters that could be assessed using color photography.	The authors suggest that a categorical scale with clear descriptors and strategies may improve photographic evaluation of burn scar.

OT = occupational therapist; PT = physical therapist.

Anticipated Goals and Expected Outcomes

Based on evaluation of examination data with consideration to the severity of burn, and the patient's current health status, age, and physical and mental condition, the patient's prognosis can be estimated. Anticipated goals and expected outcomes are contingent on the patient's prognosis and current medical status. It is difficult to list specific goals and outcomes because of the varied nature of each burn injury; however, the *Guide to Physical Therapist Practice*[21] suggests general goals and outcomes for the physical therapy POC at which specific interventions can be directed (Box 24.2). The optimal outcome of rehabilitation is the return of a patient to normal, preinjury function and lifestyle.

Box 24.2 Suggested Goals and Outcomes for the Physical Therapy Plan of Care for the Patient with Burns

- Wound and soft tissue healing is enhanced.
- Risk of infection and complications is reduced.
- Risk of secondary impairments is reduced.
- Maximal range of motion is achieved.
- Preinjury level of cardiovascular endurance is restored.
- Good to normal strength is achieved.
- Independent ambulation is achieved.
- Independent function in ADL and IADL is increased.
- Scar formation is minimized.
- Patient, family, and caregivers' understanding of expectations and goals and outcomes is increased.
- Aerobic capacity is increased.
- Self-management of symptoms is improved.

ADL = activities of daily living; IADL= instrumental activities of daily living.
From *Guide to Physical Therapist Practice*.[21]

Physical Therapy Intervention

Patients with burns usually begin physical therapy on the day of admission. The initial examination will determine which areas need to be addressed first. Control and resolution of edema and preserving ROM usually are the first priorities of intervention. Edema can be minimized through elevation of the extremities and active movement, especially of the hands and ankles. Prevention of scar contractures can be accomplished through positioning, splinting, exercise, and ambulation. Exercise and ambulation also will help to minimize the deleterious effects of bedrest. Following wound closure, massage and compression therapy will assist with minimizing contracture formation and management of burn scars.

The scar that forms across a joint skin crease while a burn wound is healing is composed of immature collagen. A scar will shorten as a result of the contractile or pulling forces in scar tissue.[103-106] This scar contraction can limit ROM and function unless interventions are taken against this process. Although measures to prevent a contracture are undertaken in expectation of the best result, there will be patients who develop scar contractures. There are several interventions available to address prevention and/or treatment of scar contracture.

As stated, positioning, splinting, exercise, and ambulation are interventions utilized in opposing the scar contracture process. Active exercise and patient participation in functional activities are important strategies to prevent or minimize contractures. However, owing to the relentless forces of scar tissue and pain associated with exercising a burned area, additional interventions may be necessary (e.g., skin grafts and Z-plasty). Early and ongoing patient and/or family education is needed to help these individuals understand the necessity of the burn rehabilitation process.

Positioning and Splinting

A positioning program should begin on the day of admission.[6,7,80,107] The goals of a positioning program are to (1) minimize edema; (2) prevent tissue destruction; (3) maintain soft tissues in an elongated state; and (4) preserve function.[108] Positioning strategies for common deformities are presented in Table 24.4. Examples of proper positioning of different body segments are provided in Figures 24.14 through 24.17. Burned areas should be positioned in an elongated state or neutral position of function.

Splinting can be viewed as an extension of a positioning program. There are certain "anti-deformity" positions in which patients generally are splinted; however, positioning is individualized based on the location of the burn and which movements are difficult for the patient to achieve. With the exception of splints designed to immobilize a skin graft after surgery, splints should be fabricated for patients only if ROM or function would be lost without them. General indications for the use of splints include (1) prevention of contractures, (2) maintenance of ROM achieved during an exercise session or surgical release, (3) reduction of developing contractures, (4) protection of a joint or tendon, and (5) to reduce the overall pain experience.[109,110] Splint design should be kept simple so that it is easy to apply, remove, and clean.[111] Splints are usually worn at night, when a patient is resting, or continuously for several days following skin grafting. Splints should conform to the body part, and care must be taken to ensure that there are no pressure points that may cause a breakdown in healing or normal skin. Splints should be checked routinely for proper fit and revised if necessary. Active motion is important, and splints and positioning are intended to serve as adjuncts to the therapy program until full active motion can be achieved.

Most splints used for burn injuries are static. This type of splint has no moveable parts, and maintains a position or immobilizes an area following skin grafting (Fig. 24.18). Dynamic splints also have been used successfully in the care of patients with a burn injury (Fig. 24.19).[112-114] These splints have moveable parts that allow joint movement. At the same time, dynamic splints apply a low-load, prolonged stress that can be adjusted to a patient's tolerance. They offer great potential for correcting a developing contracture and the early return of active function in areas of extensive burn and grafting.[115] The use of continuous passive motion devices also is appropriate for certain patients with burn injuries.[116-120]

Table 24.4 Positioning Strategies for Common Deformities

Joint	Common Deformity	Motions to Be Stressed	Suggested Approaches
Anterior neck	Flexion	Hyperextension	Use double mattress; position neck in extension (Fig. 24-14); with healing use rigid cervical orthosis
Shoulder-axilla	Adduction and internal rotation	Abduction, flexion, and external rotation	Position with shoulder flexed and abducted (airplane splint)
Elbow	Flexion and pronation	Extension and supination	Splint in extension
Hand	Claw hand (also called intrinsic minus position)	Wrist extension; metacarpophalangeal flexion, proximal interphalangeal and distal interphalangeal extension; thumb abduction	Wrap fingers separately. Elevate to decrease edema. Position in *intrinsic plus* position, wrist in extension, metacarpophalangeal in flexion, proximal interphalangeal and distal interphalangeal in extension, thumb in abduction with large web space
Hip and groin	Flexion and adduction	All motions, especially hip extension and abduction	Hip neutral (zero degrees of flexion/extension), with slight abduction
Knee	Flexion	Extension	Posterior knee splint
Ankle	Plantarflexion	All motions (especially dorsiflexion)	Plastic ankle-foot orthosis with cutout at Achilles tendon and ankle positioned in neutral

Therapeutic Exercise

Active and Passive Exercise

Active exercise begins on the day of admission.[5-7,80,121] Any patient who is alert and able to follow commands is encouraged to perform active exercises of involved body parts frequently throughout the day. A patient should perform active exercise of all extremities and trunk, including unburned areas. Dressing changes are an opportune time for exercise because the burn wound is visible and the therapist can monitor the wound during movement. In the presence of a recent skin graft, active and passive exercise of the area may be discontinued for a period of time to allow the graft to adhere.[100,122,123] After the surgeon determines it is safe to begin exercise again, gentle ROM—first active and then passive, if needed—is reinstituted.[124,125]

Active-assistive and passive exercise should be initiated if a patient cannot fully achieve active ROM.

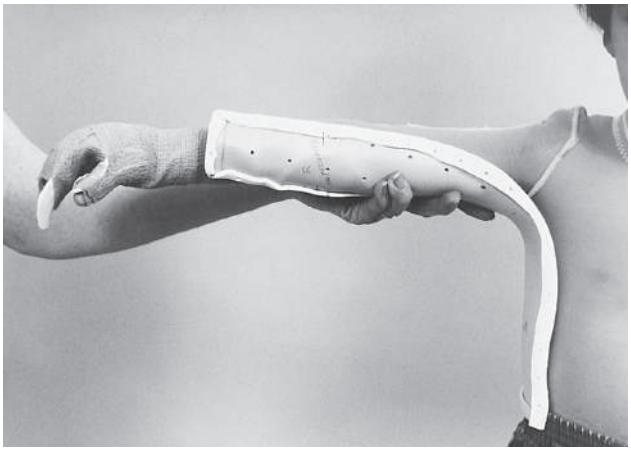

Figure 24.18 Static splint that immobilizes the shoulder in abduction and the elbow in extension.

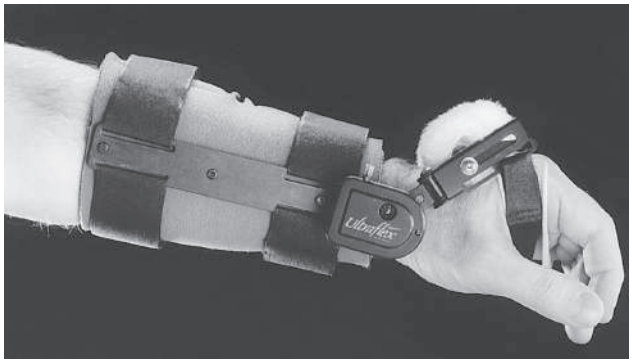

Figure 24.19 Dynamic splint used to provide a low-load, prolonged stress to scar tissue on volar aspect of forearm to gain wrist extension.

To keep the healed burned area moist, it should be lubricated before exercise is initiated. Care should be taken around areas of skin grafts, and stress should be applied in a gentle, prolonged, and gradual fashion. If the burn wounds are well healed, heating modalities (e.g., paraffin, ultrasound) may be used to increase the pliability of the tissue before exercise therapy.[126,127]

Range of motion in the area of unhealed burns can be extremely painful, and patients may voice that they would rather lose their motion than be subjected to the additional pain that occurs with movement. It usually is difficult and mentally draining on the physical therapist to push patients to exercise in and through pain, but it is critical that the therapist be persistent. Coordinating exercise activities with the administration of pain medication can lessen the painful experience for the patient.[98,121] Physical therapists should elicit the assistance of the family and caregivers in keeping the patient motivated and mobile as much as possible.

Resistive and Conditioning Exercise

As a patient continues to recover, the rehabilitation program can be progressed to include strengthening exercises.[5,80,121] Patients with major burns may lose body weight, and lean muscle mass can decrease rapidly.[128] Exercise may consist of isokinetic, isotonic, or other resistive training devices. General principles of exercise training and strength improvement should be followed, but they may need to be modified on the basis of a patient's condition and stage of wound healing. Resistive devices such as free weights and pulleys can be used to prevent loss of strength in areas not burned.

When a patient initially begins strengthening or conditioning (endurance) exercises, the physical therapist should monitor vital signs to assess cardiovascular and respiratory responses to treatment.[129] Overexertion may

occur. Monitoring of pulse, blood pressure, and respiratory rate before, during, and after exercise, particularly in the recovery period after exercise, will yield valuable information as to the status of the cardiovascular and pulmonary systems (see Chapter 2, Examination of Vital Signs).

Patients should be encouraged to participate in exercises that will stress the cardiovascular system, such as walking from the burn unit to the physical therapy department. Cycling or rowing ergometry, treadmill walking, stair climbing, and other forms of aerobic exercise should be encouraged. These activities will not only increase cardiovascular endurance, but can have the added benefit of improving strength and ROM of the extremities. In addition, they introduce variety into the rehabilitation program. The physical therapist needs to be creative and innovative to motivate patients to increase their exercise capacity.

Ambulation

Ambulation activities should be initiated at the earliest appropriate time. If the lower extremities (LEs) are skin grafted, ambulation may be discontinued until it is safe to resume.[130-133] When ambulation is initiated after a skin graft, the LEs should be wrapped in elastic bandages in a figure-of-eight pattern to support the new grafts and promote venous return. If a patient cannot tolerate the upright position because of orthostatic intolerance or pain from the LEs being in a dependent position, gradual increases in tilt-table treatment time will assist in preparing the patient for standing.[134-136] Initially, a patient may require an assistive device to ambulate. However, independent ambulation without an assistive device should be achieved as soon as possible.

The physical therapist will spend a great deal of time with an individual patient during each treatment session. The rewards of a successful POC are tremendous when a patient who has suffered a life-threatening burn is able to walk out of the hospital and return to productive community involvement.

Scar Management

Following wound closure, a skin graft or healed burn wound is vascular, flat, and soft. During the following 3 to 6 months, dramatic changes may occur. The newly healed areas may become raised and firm. Pressure has been used successfully to hasten scar maturation and minimize hypertrophic scar formation.[137] However, no one study validates the mechanism by which pressure alters scar tissue. Pressure may exert control over hypertrophic scarring by (1) thinning the dermis, (2) altering the biochemical structure of scar tissue, (3) decreasing blood flow to the area, (4) reorganizing collagen bundles, or (5) decreasing tissue water content. Constant pressure dressings or garments exerting pressure exceeding 25 mm Hg will decrease the vascularity, decrease the amount of mucopolysaccharides, decrease collagen deposition, and significantly lessen localized edema.[5,137,138] The early hypertrophic scar is readily influenced by compressive forces and thus will respond to pressure therapy. The earlier the scar tissue is exposed to pressure, the better the result.[139,140] Usually, if the scar is less than 6 months old, it will respond to pressure therapy by conforming to the pressure, remaining flat on the surface, and not developing into a hypertrophic scar.[140] If the scar is still active or shows evidence of vascularity (red color), pressure therapy may be successful, even if the scar is as much as 1 year old.

In general, if wounds heal in less than 10 to 14 days, which would be indicative of a superficial partial-thickness burn, pressure may not be needed. If wound healing takes longer than 10 to 14 days (as in a deep partial-thickness burn) or is skin grafted, pressure usually is indicated.[141]

Pressure Dressings

Elastic wraps can be used to provide vascular support of skin grafts and donor sites, as well as to control edema and scarring. Elastic wraps should be used until a patient's skin or scars can tolerate the shearing force of pressure garment application, and open areas are minimal. Elastic wraps are applied in a figure-of-eight pattern on the LEs. A spiral wrap can be used on the upper extremities (UEs) and a circular wrap on the trunk.[137]

A self-adherent elastic bandage can be used for the hand and toes.[137,142,143] This bandage adheres only to itself and can be used over dressings before the wounds have healed. It helps to minimize edema and control scar formation. It may be used before application of a customized pressure glove or as definitive pressure on an infant's hand.

Tubular support bandages come in various circumferences and garment styles. They provide a moderate amount of compression and may be used as interim garments before a custom-made garment is fitted.[137,144] The tubular support bandage is especially useful for small children who grow rapidly and require frequent alterations in garment size.

Several companies manufacture pressure garments. Some are ready made and come in several sizes to fit most patients; others are custom made for the individual patient. For custom-made garments, the physical therapist uses a tape measure to determine the periodic circumference and linear length of each limb and trunk or face so fit of the garment is exact to apply proper pressure. Garments are measured when a patient has only a few remaining open areas. The garments are very tight, and difficult to apply, but the pressure is necessary to prevent scar hypertrophy. Garments can be ordered for any or all body parts,

including the face and head, and they come in many styles, options, and colors (Fig. 24.20).[137] As mentioned, garments can be worn when the skin or scars can tolerate the shearing force of application. Pantyhose may be used under waist-height pressure garments to assist with donning. Garments usually are worn 23 hours a day (removed for bathing) for as long as 12 to 18 months to assist with scar remodeling. Garments should be washed daily to prevent buildup of perspiration and moisturizing cream, which may lead to scar maceration. The patient usually receives two sets of garments, one to wear and one to wash.

Adequate pressure may not be obtained with elastic wraps or pressure garments over concave surfaces, such as the sternum or axilla. In these instances, an insert may be necessary.[145,146] Inserts can be made of many materials, including foam, silicone elastomer, elastomer putty, and gel pads.[137,144,147-149] These items also need to be removed and cleaned regularly to prevent maceration of the underlying tissue.

Early, consistent use of pressure will result in flat, pliable scars, desensitization and protection of scars, and relief of itching. Pressure is necessary until scar maturation, when the scars are pale, flat, and soft.

Silicone Gel

Silicone gel has demonstrated effectiveness in managing hypertrophic scar.[150-152] Sheets of silicone polymer gel may be applied directly over an actively maturing scar. There are varying sizes of these silicone gel sheets. The mechanism of action for the treatment outcome is unknown.[153] The only reported complication with silicone gel sheet use is a local rash with the potential, though rare, for skin breakdown. Rashes that develop are readily reversible by temporarily deferring the use of the gel sheet. Once the site is clear of the rash, the gel sheet can be reapplied.

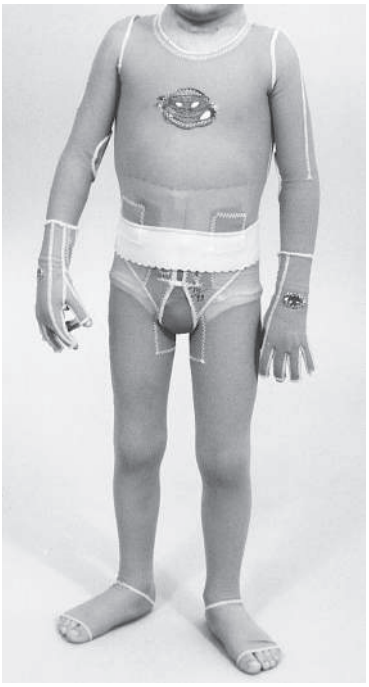

Figure 24.20 Pressure garments such as gloves, vest, and waist-height pants are worn to minimize hypertrophic scar formation.

Massage

Massage is an intervention that clinically appears useful to assist with ROM exercise by making the tissue more pliable. Deep friction massage is thought to loosen scar tissue by mobilizing cutaneous tissue from underlying tissue and acting to break up adhesions.[5,154] When massage is used in conjunction with ROM exercise, the immature scar can be elongated more easily, and a developing contracture can be corrected. Although no study has validated the use of massage for patients with burn injuries,[155] in the long term, skin pliability and texture appear to be improved by the use of massage. Firm scars that are routinely massaged tend to soften. Edges or seams of grafts or any area that is raised and firm may benefit from massage.

Camouflage Make-up

For scars of the face, neck, and hands, camouflage make-up can be used.[7,137] This type of make-up may be useful when a person has either hyperpigmentation or hypopigmentation of the skin due to the burn injury. In addition, make-up can be used before scar maturation, when the scar is still red, and a patient wants to go out in public without his or her pressure garments or devices for short periods of time. The cosmetics are opaque, color-correct burn scars, and are available in multiple shades to accommodate various skin colors. They also are waterproof and can be worn during all activities. These products can be purchased in larger department stores or where theatrical products are sold.

Follow-up Care

Well before patients are discharged from the hospital, the therapist should provide information regarding a home exercise program (HEP), a splinting and positioning program, and skin care.

An HEP should continue to stress frequent ROM exercises in combination with massaging areas involved in the burn injury. In addition, patients should be encouraged to perform as many ADL skills as possible independently. Therapists can videotape the patient's exercise program to provide the patient, family, and outpatient therapist with the actual ROM and movement pattern used in each exercise. Instructional programs (videotape, compact disc) facilitate education of those involved in the patient's rehabilitation program and will help to ensure consistency of treatment after discharge.[156]

The splinting schedule and pressure program that was followed in the hospital just before the patient's discharge should be continued at home. Before discharge,

the patient and/or his or her family members and caregivers should be able to apply and remove all splints and pressure appliances independently.

Proper skin care requires specifying the type of soap and cream a patient is to use. In general, soap should be mild without perfumes or other irritants. A moisturizing soap can be used after all open areas are healed. Moisturizing creams should be applied 2 to 3 times daily and should not contain perfumes or have a significant alcohol content. Patients should be instructed to massage the cream completely into their skin to avoid buildup on the surface. If a patient will be unavoidably exposed to the sun, a sunscreen with a skin protection factor of at least 30 should be used and reapplied frequently.[157] Patients should be cautioned to avoid the sun if at all possible and to use hats or clothing to help protect their skin against the sun's rays.

Small, superficial open areas may plague a patient for many months after wound closure because of the fragility of a healed burn wound. The patient should be instructed to wash these areas twice daily, apply a small amount of antibiotic ointment, and cover the areas with a nonadherent dressing. Avoiding shearing forces, improper fit of clothing, brisk cleansing, and soaking in water too long, or application of too much cream, can help prevent further irritation or maceration.

Itching may intensify when wounds have healed. A patient should be instructed to pat, rather than scratch, the irritated areas. Application of cream may help decrease itching; however, some patients may require oral antihistamine medication to help control this problem.

Some patients with burn injury may require outpatient therapy to supplement the HEP and monitor and adjust their splinting and pressure program. Frequency of outpatient therapy is based on each patient's needs. Regardless of whether or not a patient receives outpatient therapy, he or she should be monitored at regular intervals through an outpatient clinic. This will allow burn team members to evaluate adjustment back into society and alter the rehabilitation program according to the patient's physical abilities and extent of scar maturation. When an adult patient's burns have matured and full ROM is achieved, further follow-up care is unnecessary. However, a child will need to be monitored until he or she is fully grown, because burn scars may not keep pace with a child's growth. In these cases, surgical release of scar tissue may be necessary.[158]

COMMUNITY PROGRAMS

There are various community programs available to individuals who have survived a burn injury. The therapist should be aware of those in the patient's home community so an appropriate referral can be made. If programs are not available, someone in the hospital or community may want to initiate a program. Programs (see Appendix 24.A) include the following:

- Burn Prevention Programs: The American Burn Association (625 N. Michigan Ave., Chicago, IL 60611; 800-548-2876) has a Burn Prevention Committee with a myriad of printed materials.
- School Reentry Programs: Provided by the hospital staff for the students and staff in the child's school.[7,157]
- Burn Camps: Weekend- to week-long camps provide an opportunity for children to interact in a controlled, outdoor environment with peers who have sustained a similar injury.[7,157] The American Burn Association has a Burn Camp Special Interest Group with readily available information about camps throughout the United States and Canada.
- Adult Support Groups: Provide an opportunity for individuals with or without their families to share experiences and gain support from others who have had similar injuries.[157]
- Phoenix Society for Burn Survivors: This is a nonprofit organization dedicated to supporting burn survivors and families in recovery. The Phoenix Society offers many programs and resources that promote return to a meaningful life.[158]

SUMMARY

Burn injuries represent a major health problem in terms of management and care of surviving patients. Specific impairments and complications vary according to the extent and depth of thermal destruction of the skin. The classification of burn injuries is based on the depth of tissue destroyed and includes epidermal burn, superficial partial-thickness burn, deep partial-thickness burn, full-thickness burn, and subdermal burn. The Rule of Nines[30] and the Lund and Browder[31] formula were developed to assist with the initial determination of the extent of burn injury. The specific clinical signs and symptoms that result from a burn injury vary according to the different classifications. Indirect impairments can include infection, pulmonary, metabolic, skeletal, muscular, neurological, and cardiovascular and pulmonary complications. Medical management addresses life-threatening problems and stabilization of the patient. Dressings with topical medications, débridement, surgical excision, and skin grafting are primary treatment measures. Skin substitutes are slowly becoming a practical alternative to skin grafting. Physical therapy management focuses on the prevention of

scar contracture, maintenance of normal ROM, development of muscular strength and endurance, improvement of cardiovascular conditioning, independence in functional activities, and prevention of hypertrophic scarring. Although burn trauma and subsequent recovery can be a devastating life occurrence, there are treatment facilities and medical professionals to assist patients with burn injuries and their families return to as normal a lifestyle as possible.

Questions for Review

1. Identify the two primary layers of skin and two functions of each.
2. Discuss the initial management of a patient with an acute burn injury.
3. Describe the differences between epidermal, superficial partial-thickness, deep partial-thickness, and full-thickness burns.
4. Explain how a deep partial-thickness burn can convert to a full-thickness burn.
5. Compare the treatments for deep partial-thickness and full-thickness burns.
6. Describe the primary involvement of the pulmonary system associated with extensive burns.
7. What is the primary metabolic complication associated with burns and how is it treated?
8. Identify and describe the three phases that occur in dermal healing of a burn wound.
9. Differentiate (1) between a split-thickness and full-thickness skin graft; and (2) between a sheet and a meshed skin graft.
10. Identify three essential factors for successful skin graft adherence.
11. For the patient with a burn injury, identify five general goals and outcomes that may be included in the physical therapy plan of care.
12. What interventions can be used to prevent (1) burn scar contractures and (2) hypertrophic scar formation?

CASE STUDY

A 29-year old male sustained a 30% total body surface area burn 6 weeks before this outpatient examination and evaluation. The patient was burned at home while he was refueling a lawnmower with gasoline, which ignited. Areas of the body affected by the burn include the right upper extremity, portions of the posterior and anterior trunk, lateral neck, right side of face, and thigh. Areas skin grafted included the right dorsal hand, forearm, and arm up to the axillary crease. The remaining wounds healed secondarily. The neck, face, and thigh burns were superficial. The patient was initially treated at a regional burn center and now is referred to the local hospital for follow-up outpatient physical therapy owing to decreased right elbow extension, decreased shoulder flexion, and inability to reach overhead. The right upper extremity lacks 15° of elbow extension (i.e., 15° to 120°) and flexion of the shoulder is limited to 0° to 155°. Scar contracture bands are noted at both locations at the end of available range with movement. The patient states that he has some difficulty donning shirts and his jacket. All other movements are within functional limits. The patient's strength overall is within functional limits. His wounds are all closed. The patient lives with his girlfriend and has medical benefits through his employer.

One week after his discharge from the hospital, the patient presented for his initial outpatient examination wearing interim pressure garments, as instructed. He also brought the static elbow splint that had been issued to him during his acute hospitalization, but which "doesn't fit right anymore." The expected outcome for this patient is to regain full right upper extremity range of motion and function.

GUIDING QUESTIONS

1. Describe how you would approach the clinical problems presented. Your answer should address positioning, splinting, exercise, and scar-management interventions.
2. (A) Identify the impairments and activity limitations you will address in determining the prognosis and the plan of care. (B) Identify the practice pattern(s) consistent with the examination findings (physical therapy diagnosis) using the *Guide to Physical Therapist Practice*.

3. Establish *general* goals (short term) and outcomes (long term) for this case. Develop one goal/outcome that will affect each of the following areas: *impairments, muscle performance, activity limitations,* and *risk reduction/prevention*.
4. Determine the prognosis.
5. Develop a plan of care. Your response should include specific interventions, patient instruction, and required coordination, communication, and/or documentation.
6. Describe the discharge plan.
7. What is the anticipated rehabilitation potential for this patient? Your thought process should include time from burn injury and stage of healing.

Chapter 25

Chronic Pain

Leslie N. Russek, PT, DPT, PhD, OCS

LEARNING OBJECTIVES

1. Assess the importance of chronic pain in terms of its effect on individual activity and participation, as well as the cost to society.
2. Compare and contrast the presentation of acute, persistent, and chronic pain.
3. Apply the International Classification of Function (ICF) model to chronic pain.
4. Explain the physiology of chronic pain, contrasting chronic with acute pain.
5. Classify different types of chronic pain and provide examples of each type.
6. Propose causes and risk factors for chronic pain.
7. Relate psychosocial factors to the presentation, physiology, and risk factors for chronic pain.
8. Contrast various outcome measures for examining chronic pain and its impact on activity and participation.
9. Summarize medical management options for chronic pain.
10. Describe tests and measures appropriate for examining individuals with chronic pain.
11. Identify issues relevant in the evaluation and prognosis of individuals with chronic pain.
12. Describe intervention approaches appropriate for individuals with chronic pain.
13. Discuss complementary and alternative medicine approaches to managing chronic pain.

SUMMARY *1158*

INTRODUCTION

Pain is the most common reason why people visit health care providers and physical therapists. **Chronic pain** affects about 116 million Americans,[1-3] accounting for up to 20% of all primary care visits in the United States;[4,5] low back pain (LBP) is the second most common reason for physician visits.[6] Chronic pain affects more people than diabetes, heart disease, and cancer combined.[2] Up to 26% of American adults have had pain for more than 3 months, and one-third of those report that this pain is disabling.[7] Internationally, chronic pain affects up to 35% of adults and 25% of children; chronic pain is almost twice as prevalent in women compared to men.[8,9] Spinal pain, headache, and arthritis are the most common sources of chronic pain: LBP affects 28%, headache and migraine affect 16%, neck pain affects 15%, and combined peripheral joint pain affects 30% of Americans.[5,10] Other conditions such as stroke, spinal cord injury (SCI), diabetes, multiple sclerosis (MS), HIV/AIDS, amputation, Guillain-Barré

syndrome, cancer, and a variety of other conditions can also lead to chronic pain.[11]

Chronic pain exacts a huge toll in terms of medical care, lost workdays, and compromised quality of life. In the United States, the national economic cost of chronic pain is estimated at $560 billion to $635 billion per year with $261 billion to $300 billion per year of that due to direct medical costs.[1] Lost productivity due to pain costs $297 billion to $336 billion per year.[1] Quality of life is severely compromised for people with chronic pain, often rated even lower than among people dying of cancer.[12]

This chapter will focus on chronic neuromuscular and musculoskeletal pain most likely to present for physical therapy intervention. It is not the goal of this chapter to address cancer or visceral pain, even though those are growing specialty areas within physical therapy. Recent advances in pain physiology are presented as a foundation for understanding common chronic pain conditions and the appropriate interventions for those conditions.

Definitions of Pain

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.[13] Pain is thus more than merely the firing of **nociceptive** neurons, but also includes the *perception of pain*, the *experience of suffering*, and *pain behavior*.[14] The perception of pain may depend on the situation or mental state, such as when soldiers on the battlefield or athletes on the playing field do not feel pain when injured. In contrast, a person with posttraumatic stress disorder (PTSD) may experience significant pain without any physical stimulus. Some people experience suffering, or the affective experience of distress, with minimal tissue damage, whereas other people may have significant tissue damage and pain with minimal experience of suffering.

Acute, Persistent, and Chronic Pain

Acute pain is associated with tissue damage or the threat of such damage and typically resolves once the tissue heals or the threat resolves. Acute pain is often associated with physiological signs of distress, such as sweating, pallor, nausea, and heart rate changes. Acute pain may become persistent pain if the cause of the pain is unresolved. For example, chronic diseases such as osteoarthritis (OA) or diabetic neuropathy are associated with pain; as long as the disease remains, the pain remains. Alternatively, *pain triggers* may occur and recur, such as in a cervicogenic headache due to poor posture or LBP due to segmental instability. Although the causes of persistent pain may be difficult to resolve, the pain is nonetheless proportional to tissue damage or potential tissue damage and the nociceptive input and would resolve if the nociceptive causes could be addressed. **Recurrent pain** includes repeated episodes of acute pain, such as recurrent low back strain, or chronic pain in which the symptoms are intermittent, such as a migraine headache.

Chronic pain has been defined in a variety of ways. The simplest is to define it as any pain persisting more than a specified length of time, such as 3 or 6 months. While this definition is simple to apply, it does not reflect the psychosocial and physiological changes that occur in chronic pain.[6,15] A second definition of chronic pain is pain that is long-lasting, persistent, and of sufficient duration and intensity to adversely affect a patient's well-being, function, and quality of life.[16] While this second definition recognizes the psychosocial aspects of long-lasting pain, it still does not reflect the unique physiology that differentiates chronic pain from persistent acute pain. A third definition of chronic pain is pain that persists past the healing phase following an injury with impairment greater than anticipated based on the physical findings or injury, and occurs in the absence of observed tissue injury or damage.[6,15,17,18] Other definitions related to pain are presented in Box 25.1.[13,17,19]

The Biopsychosocial Model of Pain

The traditional biomedical model of pain correlates tissue damage to pain sensations; according to the biomedical model, if you fix the tissue damage the pain will resolve. This model works well for many types of acute pain; however, it is unable to explain many other examples of pain where no physical damage could be found.[15] Historically, pain whose physiological source could not be found was called *nonorganic pain* and was traditionally considered **psychogenic**; research now shows that chronic pain, in the absence of peripheral tissue damage, has a physiological basis and is not merely a psychological manifestation.[6,20-22] In contrast to the biomedical model, the *biopsychosocial model* of pain recognizes that physical factors interact with personal and environmental factors to affect body function and structure, activity, and participation in life activities. The biopsychosocial model provides a better framework for recent advances in the understanding of pain physiology and effective pain management.

The World Health Organization's (WHO's) *International Classification of Functioning, Disability and Health* (ICF)[23] was developed to create a consistent terminology and framework for describing, classifying, and assessing function and health. The ICF model replaces the Nagi model of disability used in early versions of the *Guide to Physical Therapist Practice*.[24] Figure 1.1 in Chapter 1, Clinical Decision Making, illustrates the interaction among different aspects of the ICF model. (*Note*: ICF terminology is defined in Chapter 1 and in the Glossary.) Within the ICF model, pain is considered an abnormal body function classified under the designation *Sensory Function and Pain*. The physiological changes observed in chronic pain may also be associated with changes in the *Structure of the Nervous System*, at the level of body structure.[25] Table 25.1 identifies the various classifications for **Body Function**, **Body Structure**, **Activities**, and **Participation** that are most relevant to patients with

Box 25.1 Pain Terminology

- **Acute pain**: Pain associated with tissue damage or the threat of such damage and typically resolves once the tissue heals or the threat resolves.[13]
- **Adjuvant medication**: Medications whose primary indication is a condition other than pain, but which have demonstrated benefit in pain management.
- **Allodynia**: Pain due to a stimulus that does not normally provoke pain.[13]
- **Analgesia**: Absence of pain in response to stimulation that would normally be painful.[13]
- **Causalgia**: A syndrome of sustained burning pain, allodynia, and hyperpathia after a traumatic nerve lesion, often combined with vasomotor and sudomotor dysfunction (such as diabetic autonomic neuropathy) and later trophic changes.[13]
- **Central pain**: Pain initiated or caused by a primary lesion or dysfunction in the central nervous system.[13]
- **Chronic pain**: Pain that persists past the healing phase following an injury; impairment is greater than anticipated based on the physical findings or injury and it occurs in the absence of observed tissue injury or damage.[19]
- **Chronic pain syndrome**: Pain that exists when individuals have developed extensive pain behaviors such as preoccupation with pain, passive approach to health care, significant life disruption, feelings of isolation, demanding, angry, or doctor-shopping.
- **Dysesthesia**: An unpleasant abnormal sensation, whether spontaneous or evoked.[13]
- **Hyperalgesia**: An increased response to a stimulus that is normally painful. Hyperalgesia reflects increased pain on suprathreshold stimulation.[13]
- **Hyperesthesia**: Increased sensitivity to stimulation, excluding the special senses. Allodynia is suggested for pain after stimulation that is not normally painful. Hyperesthesia includes both allodynia and hyperalgesia, but the more specific terms should be used wherever they are applicable.[13]
- **Hyperpathia**: A painful syndrome characterized by an abnormally painful reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold.[13]
- **Malignant pain**: Pain associated with cancer.
- **Nociceptive pain**: Pain that arises from actual or threatened damage to non-neural tissue and is due to the activation of pain receptors, nociceptors.[13]
- **Nocebo (nocebo effect)**: The opposite of a placebo or the placebo effect. A nocebo is an inert treatment or event that increases symptoms because the patient believes it will increase symptoms. The expectation of pain can result in both increased pain from painful stimuli and allodynia, pain from a normally nonpainful stimulus.
- **Pain**: An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.[13]
- **Pain neuromatrix**: A complex network of synaptic links within the central nervous system, initially determined by genetics but modified by psychological and sensory inputs both before and during the pain experience.
- **Paresthesia**: An abnormal sensation, whether spontaneous or evoked.
- **Persistent pain**: Pain related to tissue damage or the threat of such damage that persists because the causative factors persist.
- **Placebo (placebo effect)**: A placebo is an inert treatment, such as a sugar pill or fake treatment, that is beneficial because the patient believes it will be beneficial.
- **Psychogenic pain**: An older term for pain believed to be caused by psychological factors when organic factors were absent or not severe enough to explain the pain complaint.[19]
- **Recurrent pain**: Repeated episodes of acute pain.
- **Referred pain**: Spontaneous pain outside the area of injury or source of pain.[17]
- **Suffering**: Refers to the affective component of pain. Suffering includes both emotional (e.g., anxiety and anger) and cognitive (e.g., thoughts of helplessness) components, and may be due to a combination of unpleasantness and catastrophizing (making a "catastrophe" out of minor issues).

chronic pain.[23,25-28] The multidirectional nature of the ICF model is particularly pertinent to chronic pain where structure, function, activity, and participation are interrelated and can all affect one another.

Suffering refers to the affective component of pain. Suffering includes both emotional (e.g., anxiety and anger) and cognitive (e.g., thoughts of helplessness) components, and may be due to a combination of unpleasantness and *catastrophizing* (making a "catastrophe" out of minor issues).[29] Pain behavior includes verbal and nonverbal expressions of pain, activity and participation changes, fear avoidance, and treatment-seeking behavior in response to the perception of pain. As with suffering, the extent of pain behavior can be quite independent of tissue damage. **Chronic pain syndrome** exists when individuals have developed extensive pain behaviors

Table 25.1 Core Set of World Health Organization's International Classification of Functioning, Disability and Health Classifications Relevant to Patients with Chronic Pain[23,25-28]

ICF Code	Description	ICF Code	Description
	Body Function		***Body Structure***
B122	Global psychosocial functions	S110	Structure of the brain
B126	Temperament and personality functions	S120	Spinal cord and related structures
B152	Emotional functions	S140	Structure of the sympathetic nervous system
B130	Energy and drive functions		
B134	Sleep functions	S199	Structure of the nervous system, unspecified
B147	Psychomotor function	S770	Additional musculoskeletal structures related to movement (bones, joints, muscles, ligaments, fascia, and so forth)
B260	Proprioceptive function		
B280	Sensation of pain		
B455	Exercise tolerance	#Needed	Structures specific to the given pathology
B710	Mobility of joint function		
B730	Muscle power functions		
B735	Muscle tone functions		
B740	Muscle endurance functions		
B760	Sensations related to muscles and motor function		
B770	Gait pattern functions		
	Activities		***Participation***
D160	Focusing attention	D230	Carrying out daily routine
D240	Difficulty handling stress and other psychological demands	D560	Unable to travel
		D620	Acquisition of goods and services
D410/5	Changing/maintaining body position	D760	Family relationships
D430	Lifting and carrying objects	D770	Intimate relationships
D450/5	Walking/moving around	D850	Remunerative employment
D530	Toileting	D910	Community life
D630	Preparing meals	D920	Recreation and leisure
D640	Doing housework		

(Box 25.2).[3] Psychosocial aspects of pain will be addressed later in this chapter.

Chronic pain can be considered a disease rather than a symptom. Just as a myocardial infarction may have many contributing factors and causes, chronic pain has multiple contributing factors and causes and has its own pathology, signs, and symptoms.[30-33] Using the disease model, treatment of chronic pain should address the secondary pathology and perpetuating factors rather than focus on a presumed initial pathology, which might no longer be present. Treatment of the disease of chronic pain should address peripheral and central sensitization, disinhibition, anxiety, catastrophizing, fear-avoidance, and so forth, as well as contributing psychosocial and behavioral factors.[30] Chronic pain affects all aspects of life just as would a chronic disease; chronic pain also needs to be managed, because it often cannot be cured.[15]

Box 25.2 Characteristic Behaviors in Chronic Pain Syndrome[3]

- Doctor-shopping
- Dependency on the health care system for multiple medical problems
- Preoccupation with pain, significant pain behavior
- Passive-dependent personality traits
- Denial of emotional or family conflicts
- Significant life disruption in many areas
- Feelings of isolation and loneliness
- Being demanding, angry, or skeptical
- Lack of insight into self-defeating behaviors
- Use of pain as a symbolic means of communication

PAIN PHYSIOLOGY

While a thorough discussion of pain physiology is beyond the scope of this chapter, an overview is essential to understanding how chronic and acute pain differ, both in presentation and in management. Readers can find more extensive coverage of pain physiology in one of the textbooks on pain: *Mechanisms and Management of Pain for the Physical Therapist*[34] or *Chronic Pain: An*

Integrated Biobehavioral Approach.[35] Acute pain is primarily nociceptive (peripheral nerves responding to high-intensity or harmful stimuli) including inflammatory peripheral sensitization. Mechanical, thermal, chemical, and free nociceptive nerve endings in the periphery transmit information about noxious stimuli via afferent nerves through the dorsal root into the dorsal horn.

The lightly myelinated A-δ and unmyelinated C fibers have very different features, summarized in Table 25.2. Generally, the A-δ fibers transmit detailed somatosensory information allowing localization of pain, whereas C fibers transmit more diffuse information driving the affective response to pain. The unmyelinated C fibers are approximately 10 times slower than the A-δ fibers, which are 5 to 10 times slower than other sensory receptors for touch, pressure, proprioception, muscle spindles, and Golgi tendon organs (A-γ, A-β, and A-α). Since most deep tissues such as muscles, joints, and viscera are innervated by C fibers whereas cutaneous structures are more likely innervated by A-δ fibers, pain from deep structures is perceived as slow, dull, aching, or **referred pain** whereas cutaneous structures are more likely to produce sharp, localized pain.[17] Although A-β sensory neurons do not normally transmit pain, they can produce **paresthesias** and **dysesthesias** when provoked.

Figure 25.1 shows the primary anatomical structures related to pain transmission.[33,36] Once axons enter the dorsal horn, A-δ fibers synapse with interneurons in laminae I, II, and V. Primary sensory afferents from skin, muscle, joints, and viscera may also converge on wide-dynamic-range interneurons; convergence of nociceptive and non-nociceptive input provides a mechanism for referred pain.[37] Projection fibers from A-δ and some C afferents retain a somatotopic organization, cross and ascend through the lateral spinothalamic tract to the ventral posterior lateral thalamus, then to the primary and secondary somatosensory cortex. These fibers transmit information about pain localization, intensity, duration, and quality.[37] In contrast, projection fibers from most C afferents ascend through the medial spinothalamic, spinoreticular, and spinomesencephalic tracts to the medial thalamus, reticular formation, hypothalamus, limbic system, autonomic centers, and cingulate gyrus. Pain from C fibers tends to be poorly localized and associated with affective responses to pain.

Current research suggests that different components of the brain process different aspects of the pain experience. The SI somatosensory cortex mediates the sensory-discriminatory aspect of pain whereas the SII somatosensory cortex is involved in recognition, learning, and memory of painful events. The anterior cingulate cortex processes pain unpleasantness and contributes to affect, cognition, and response selection. The insula mediates autonomic responses to noxious stimuli and the affective components of pain-related memory and learning.[29,386] Extensive crosstalk among the various pain pathways creates what Melzack called the **pain neuromatrix**, a complex network of synaptic links initially determined by genetics, but modified by psychological and sensory inputs both before and during the pain experience.[39-41] Pain is therefore not a simple cause-and-effect process, but a complex web of

Table 25.2 Features of Fast and Slow Nociceptive Pain

Features	Fast	Slow
Nerves	A-delta (myelinated)	C (unmyelinated)
Stimulus	Pinprick, heat	Tissue damage
Sensation	Sharp, pricking, burning, dermatomal	Slow, dull, crawling, sclerotomal
Diameter	1–4 μm	0.1–1 μm
Conduction velocity	5–30 m/sec	0.4–1.4 m/sec
Distribution	Body surface	All tissues except CNS
Reflex response	Withdrawal	Muscle spasm or tone
Biological value	Avoidance of tissue damage	Enforced rest
Effect of morphine	Very little	Suppresses pain
CNS target	Thalamus, cortex	Limbic, hypothalamic
Affective response	No	Yes
Autonomic signs	No	Yes
Localized receptor field	Yes	No
Dorsal horn connection	Laminae I and V	Laminae II and III

μm = micrometer; m/sec = meters per second; CNS = central nervous system.

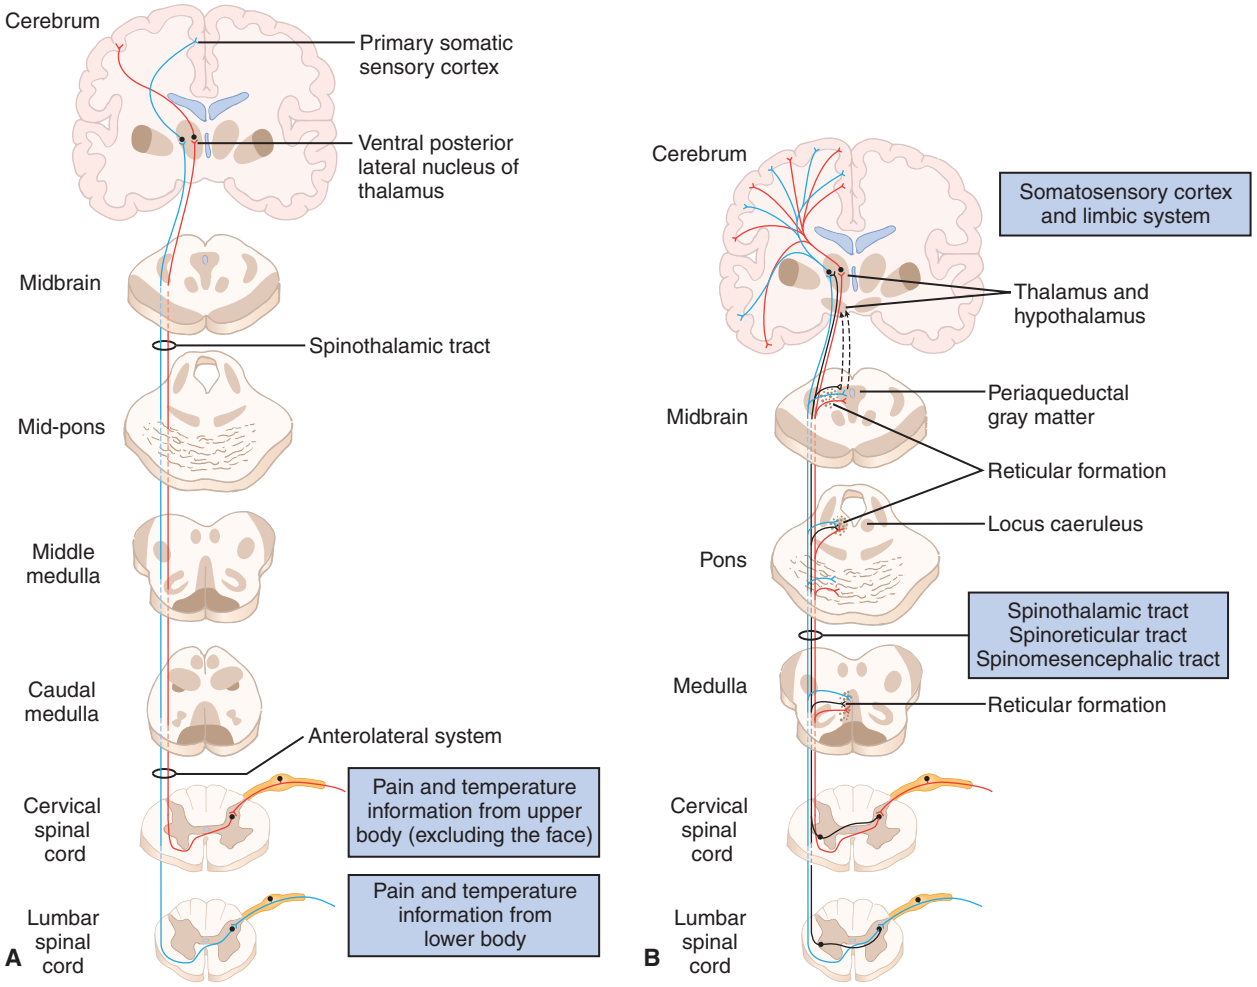

Figure 25.1 Central pain pathways. **(A)** Projection fibers from A-δ afferents retain a somatotopic organization, cross and ascend through the lateral spinothalamic tract to the ventral posterior lateral thalamus, then to the primary and secondary somatosensory cortex. These fibers transmit information about pain localization, intensity, duration, and quality. **(B)** Projection fibers from C afferents ascend through the medial spinothalamic, spinoreticular, and spinomesencephalic tracts to the medial thalamus, reticular formation, hypothalamus, limbic system, autonomic centers, and cingulate gyrus. The medial pain pathways contribute to the affective, autonomic, and cognitive experience of pain. *Based on diagrams from: (1) Argoff, CE, et al: Multimodal analgesia for chronic pain: Rationale and future directions. Pain Med 10(Suppl 2):S53, 2009. (2) Ford, B: Pain in Parkinson's disease. Mov Disord 25(Suppl 1):S98, 2010.*

interactions modulated by both current and previous physical and psychological states.

Pain Processing and the Evolving Gate Control Theory

Superimposed on these neuroanatomical tracts, numerous regulatory influences affect the ascending information. The Gate Control Theory, first proposed by Melzack and Wall[42] in 1965, explains a key aspect of pain regulation: how nonpainful sensory stimuli can decrease the perception of pain. Figure 25.2 shows how pain fibers synapse with an inhibitory interneuron and a secondary neuron that transmits the pain signal to the brain. Sensory nerves, such as Aα and Aβ, also provide input into the inhibitory interneuron. With sufficient stimulus to the Aα or Aβ nerves, the inhibitory interneuron "closes the gate" on the secondary neuron and prevents pain stimuli from being transmitted to the brain. The gate control process is the basis for conventional transcutaneous electroneural stimulation (TENS).

Melzack subsequently added descending control to the model to explain how noxious stimuli might not result in pain, as when severely wounded soldiers or athletes can perceive no pain from their injuries.[39] Descending pain inhibition appears to be modulated by norepinephrine and descending noradrenergic connections.[43] Simple descending inhibition, however, fails to explain other observations such as gender differences, chronic pain in the absence of

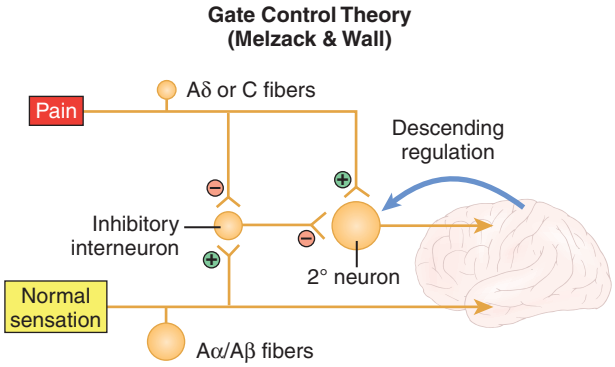

Figure 25.2 The Gate Control Theory. Pain fibers (A-δ or C fibers) synapse with both an inhibitory interneuron and a secondary neuron, which transmits the pain signal to the brain. Sensory nerves, such as Aα and Aβ, also provide input into the inhibitory interneuron. With sufficient stimulus to the Aα or Aβ nerves, the inhibitory interneuron "closes the gate" on the secondary neuron and prevents pain stimuli from being transmitted to the brain. Descending regulation also modifies output of the secondary neuron.

noxious stimuli, and the impact of psychological factors such as stress and previous experiences.[44] As mentioned, Melzack[39] proposed the pain neuromatrix to explain how the pain experience is modulated by multiple factors and not always proportional to tissue damage.

Descending inhibitory factors modify activity of the pain pathways at all levels of the nervous system. Descending control is opioid sensitive, and can be reversed by naloxone, the opiate antagonist. *Placebo* (use of fake treatment, especially sugar pills), antidepressants, and anticonvulsants all modulate pain through enhancing descending inhibition.[33] Descending control involves the hypothalamus, amygdala, rostral anterior cingulate cortex, periaqueductal gray (PAG) matter, rostral ventromedial medulla (RVM), projecting to the dorsal horn.[6,43] Descending inhibitory pathways travel through the dorsolateral funiculus resulting in secretion of noradrenalin, acetylcholine, serotonin, and glycine in the dorsal horn.[37,45]

Descending modulation can facilitate pain as well as inhibit it; facilitation is called the **nocebo effect**, in contrast to the placebo effect. The expectation of pain can result in both increased pain from painful stimuli but also **allodynia**, pain from normally nonpainful stimuli. Imaging studies show that the nocebo effect is mediated by a complex interplay among the ipsilateral caudal anterior cingulate cortex, the head of the caudate, the cerebellum, and the contralateral cuneiform nucleus.[43] Descending facilitation passes through the ventrolateral funiculus and is mediated in the dorsal horn by serotonin, norepinephrine, opioids, and cholecystokinin.[37,45]

Peripheral and Central Sensitization

Descending modulation of pain is a normal process. However, the facilitation process can result in abnormal peripheral or central sensitization, both of which are integrally linked with chronic pain. Abnormal facilitation can be the result of damage to or disease of neural tissue or abnormal function of neural or supporting tissues. Peripheral or central sensitization can occur through neuronal death, ectopic activity, abnormal sprouting and cellular connections, disinhibition, and altered gene expression.[20,30,31]

In *peripheral sensitization*, the afferent nociceptive input is increased through decreased threshold, increased responsiveness, and/or increased receptive field.[46] Inflammation of either peripheral tissues or neural connective tissue results in decreased nociceptor threshold as a protective response aiming to decrease further injury. The inflammatory mediators of peripheral sensitization include cytokines, prostaglandins, and serotonin; injured nerve terminals become hypersensitive to circulating norepinephine.[11] In some cases, antidromic impulses go from spinal cord to the afferent's receptive field, releasing peptides (substance P, CGRP, somatostatin) and cytokines leading to peripheral flare, edema, and stimulation of a local and neurogenic inflammatory response, further sensitizing nociceptors.[31,47] Injury sensitizes the nerve through either inflammation within the neural connective tissue or direct compromise to the axons.[20,47] Long-term peripheral sensitization occurs through modifications of the second messenger system as well as excess and abnormal branching and hypersensitivity of free nerve ending.[33,47]

Wind-up and long-term potentiations are forms of *central sensitization*. In wind-up, repeated low-frequency nociceptor stimulation results in progressively increased action potential in the dorsal horn cells.[20] Summation of C fiber action potentials causes concurrent release of substance P and glutamate, which increases postsynaptic calcium release; *N*-methyl-D-aspartate (NMDA) and other receptors are up-regulated causing a feedback loop resulting in further increased intracellular calcium.[45] Wind-up can result in long-term potentiation, in which the neural response is strengthened through increased neurogenic inflammation and altered gene expression resulting in altered nerve phenotype, with different receptors and transmitters.[45]

Central sensitization occurs through many similar mechanisms as peripheral sensitization, including changes in microglia, astrocytes, and gap junctions.[20] Glia appear to perpetuate sensitization by releasing growth hormone that stimulates an immune response.[31,48] Inflammation in the central nervous system (CNS) causes central sensitization by increasing excitability in the dorsal horn and inflammatory chemical mediators up-regulate expression of genes affecting synaptic transmission.[15] These processes result in hyperalgesia, allodynia, after-sensations, summation, and receptive field expansion.[20] **Hyperalgesia** occurs when the pain fiber synapse with the secondary neuron in the dorsal horn (see Fig. 25.1) is amplified, resulting in firing of the secondary neuron with lower peripheral

stimulus. Short-term allodynia may be caused by decreased firing threshold or decreased inhibition; long-term allodynia includes sprouting of A-α and A-β fibers to synapse with nociceptor fibers in the spinal cord, causing normal sensory input to be perceived as pain. Central sensitization can be maintained by ongoing nociceptive input or may be independent of nociceptive input.[37] Central sensitization can occur in the spinal cord, rostroventral medulla, amygdala, anterior cingulate cortex, and trigeminal brainstem complex.[11]

Central sensitivity occurs in conditions such as fibromyalgia, widespread myofascial pain, chronic headache, temporomandibular joint (TMJ) disorder, and neuropathic pain. Stimulation of visceral nociceptors creates sensitization of both visceral hypersensitivity and viscera-somatic pain (i.e., hypersensitivity of musculoskeletal tissues in the referral region), leading to conditions such as irritable bowel and interstitial cystitis.[20,31] Peripheral injury can permanently alter central pain processes that can, in turn, modulate peripheral signaling mechanisms.[33] Any peripheral nociceptive stimulus can perpetuate centrally mediated pain, with joint and muscle nociceptors resulting in longer-lasting sensitization than cutaneous nociceptor stimulation. For example, muscle trigger points can generate widespread central sensitization. Chronic osteoarthritis pain may have a centrally mediated component, explaining the mismatch between radiographic signs of OA and pain. However, it appears that central sensitization does not require continued peripheral input.[20]

Peripheral and central components of the autonomic system can also abnormally perpetuate pain through a variety of mechanisms. First, sympathetic efferents can sprout synapses with nociceptors, which develop adrenergic receptors; autonomic activation then directly activates nociceptors in the spinal cord. This process is particularly important where the sympathetic efferents connect to deep somatic afferents; sympathetic stimulation can then result in somatic pain.[49] Another mechanism for autonomic amplification of pain occurs through the hypothalamic-pituitary-adrenal (HPA) axis. Physical or emotional stress activates the HPA axis, leading to a self-perpetuating cascade of events resulting in chronic sympathetic activation in chronic pain.[14,48,50] The processes are complicated, however, and some chronic pain diagnoses (e.g., fibromyalgia) actually present with elevated autonomic activity at rest but blunted responses to autonomic challenges (e.g., orthostatic).[51]

Central sensitization provides a physiological basis for pain in the absence of identifiable injury or tissue damage. It also provides a physical mechanism for pain to be exacerbated by stress or psychological state. Consequently, some or much of what used to be considered psychologically based pain (e.g., nonorganic, somatoform, psychosomatic, hysteric) may be a manifestation of central sensitization.[20,21]

Physiological Changes Occurring with Chronic Pain: Neuroplasticity and Learning

The above discussion clearly demonstrates that the nervous system is plastic and can undergo both short- and long-term changes in response to pain. Recurrent pain sensations can activate receptors, create new synapses, and alter neurotransmitter production, as well as receptor types and prevalence.[3,30,33,52] Plastic changes appear to occur at all levels of pain processing: peripheral, spinal, and central.[52] Peripheral and central sensitization may persist even when the causative factors have been removed. Within the CNS, abnormal central reorganization may include expansion of the painful area representation in the primary somatosensory cortex, S1.[53] There is also evidence of gray matter atrophy and gross changes in brain morphology with chronic pain; gray matter atrophy appears to reverse if the chronic pain resolves.[6,54] Studies show that learning related to pain is quite powerful as chronic pain provides constant reinforcement.[6]

Since prolonged pain leads to sensitization, some suggest that preemptive **analgesia** eliminating nociceptive input may prevent wind-up, peripheral, and central sensitization; however, research findings have been inconsistent for preventing acute pain and poor for preventing the transformation from acute to chronic pain.[55,56] Psychosocial factors are also critical in the transformation from acute to chronic pain. This will be discussed later in the chapter, together with other risk factors for the development of chronic pain.

Classification of Pain

Pain can be classified in several different ways and often several different classification systems can apply to a given patient. The distinction among acute, persistent, and chronic pain is described earlier in this chapter. Pain can be divided by body region affected, such as LBP or headache, or classified by pathology, such as phantom limb pain, MS, or **malignant** if cancer related. The physiological processes involved, such as nociceptive, inflammatory, neurogenic, or maladaptive, may also categorize pain.[17,57-59] The term *psychogenic pain*, once commonly used for medically unexplained pain, has been challenged with better understanding of pain physiology. Pain may also be described as having three dimensions: sensory-discriminative, motivational-discriminative, and cognitive-evaluative;[17] or four dimensions: nociception, pain cognition, suffering, and pain behavior. This section will contrast several of these classification systems. Later sections will describe special cases of chronic pain pathologies.

The three dimensions of sensory-discriminative, motivational-discriminative, and cognitive-evaluative reflect the multidimensional International Association for the Study of Pain (IASP) definition of pain as sensory, emotional, or cognitive. The *sensory-discriminative dimension* refers to localization, intensity, duration, and the

nature of the pain (burning, sharp, and so forth). The *motivational-affective dimension* refers to the emotional response a person has, including physiological manifestations of that emotional response, such as nausea. The *cognitive-affective dimension* relates to how pain is interpreted in the context of past and present experience, culture, and so forth.[17]

One physiological classification system is to divide pain into nociceptive, inflammatory, and maladaptive.[57] *Nociceptive pain* is a response to an immediate noxious stimulus (mechanical, thermal, or chemical), signaling impending tissue damage; nociceptive pain typically leads to a protective withdrawal response and is therefore beneficial.[57,58] *Inflammatory pain* increases sensory sensitivity after tissue damage, discouraging use and further damage, allowing for tissue repair; the pain is due to hypersensitivity resulting from peripheral injury, pathology, or other inflammatory process. Inflammatory pain is generally a beneficial mechanism for encouraging rest of the involved tissues; however, it becomes counterproductive when severe or ongoing.[57] *Maladaptive pain* results from an abnormally functioning nervous system relaying pain signals unrelated or disproportional to tissue damage.[31] Maladaptive pain represents altered neural processing; decreased physical activity resulting from maladaptive pain does not contribute to healing and may exacerbate pain and lead to secondary problems. Examples of maladaptive pain include tension headache, TMJ disorder, fibromyalgia, and irritable bowel syndrome.[57] Maladaptive pain is a manifestation of chronic pain that occurs in the absence of identified tissue damage.[17] A slightly different classification system could include inflammation as a type of nociceptive pain mediated by chemical stimuli or inflammation could lead to both peripheral and central neurogenic pain.

Some classification systems consider "muscle pain" distinct from nociceptive pain whereas other systems include muscle pain as a type of nociception.[16] Muscle pain is often dull, deep, aching, cramping, and difficult to localize.[60] Muscle trigger points can refer pain to other sites, as well as cause other symptoms such as tinnitus, paresthesias, and blurry vision. Trigger points may be idiopathic or associated with another disorder such as OA or rheumatoid arthritis (RA), fibromyalgia, TMJ disorder, or chronic tension-type headaches.[61] Widespread myofascial pain syndrome appears to involve central sensitization as well as peripheral nociception.[62,63]

Pain can also be divided into the following categories: nociceptive, peripheral neuropathic/neurogenic, and central neuropathic/neurogenic; some older classification systems include a category of psychogenic. Nociceptive pain can be further subdivided into superficial, deep somatic, and visceral through the different presentations; non-neurogenic inflammation, described above, is also nociceptive. Table 25.3 contrasts the different types of pain.[44,58,64]

Table 25.3 Subjective and Objective Characteristics Associated with Different Types of Pain and Tissue Sources[44,58,64]

Type of Pain	Tissue Source	Subjective	Objective
Nociceptive: Cutaneous or superficial	Skin and subcutaneous tissues (predominantly A-δ fibers)	Well-localized, stabbing, burning, cutting	Clear, consistent, proportional pain reproduced through movement or mechanical testing of target tissues
Nociceptive: Deep somatic	Bone, muscle, blood vessels, connective tissues (predominantly C fibers)	Often referred to other locations; tearing, cramping, pressing, aching	Vague, sometimes referred pain reproduced through movement or mechanical testing of deeper tissues; spasm, trigger points common
Nociceptive: Visceral	Organs and the linings of the body cavities (predominantly C fibers)	Often referred to other locations; poorly localized, diffuse, deep cramping or splitting, sharp, stabbing	Vague pain reproduction on movement or mechanical testing of visceral tissues
Peripheral neurogenic	Nerve fibers (axons or neural connective tissue)	Pain variously described as burning, shooting, sharp, aching or "electric-shock-like"	Pain or symptom provocation with movement or mechanical tests that move, load, or compress neural tissues
Central	Spinal cord and central nervous system	Disproportionate, nonmechanical, unpredictable pattern of pain provocation in response to multiple, nonspecific aggravating or easing factors	Disproportionate, inconsistent, nonmechanical or nonanatomical pattern of pain provocation in response to movement or mechanical testing

Peripheral neurogenic pain stems from mechanical or chemical damage to peripheral nerves, including inflammation of peripheral nerves. In addition to negative symptoms of hypoesthesia, anesthesia, or weakness, neurogenic pain may include positive symptoms of **paresthesia**, dysesthesia, and pain.[15,65] Peripheral neurogenic pain can be further subdivided into axonal effects versus those due to neural connective tissue. Nerves, themselves, can be the source of pain due to nociceptors and nervi nervorum in the neural connective tissue. This type of pain tends to be deep, aching, and localized with discomfort generally proportional to stimulus.[65] Pain produced by injury to the axons results in dysesthesias such as burning, prickling, tingling, searing, or crawling sensations from hyperexcitable afferents being triggered at the site of axonal injury rather than at the receptor site. Axonal pain can be quite variable and may be spontaneous or cumulative.[65] Peripheral neurogenic pain may become prolonged beyond the initial nerve injury through processes of peripheral sensitization and because of glia releasing growth factors and other substances acting on the immune system.[48] Neurogenic pain sometimes evolves into **causalgia** where vasomotor, sudomotor, or trophic changes can also occur.

Central neurogenic pain can be due to injury or disease affecting the CNS such as stroke, traumatic brain injury (TBI), MS, or fibromyalgia. Pain is often burning, aching, lancing, pricking, or pressing.[44] Both hyperalgesia and allodynia may exist. Some conditions may generate pain without any nociceptive input, whereas others appear to be mediated by centrally amplified and perpetuated peripheral nociceptive pain.[61] The HPA axis plays a central role in mediating stress-related pain syndromes, such as fibromyalgia, irritable bowel syndrome, PTSD, and burnout.[48] Central neurogenic pain appears to be mediated by glia and astrocytes altering synaptic activity[33] and synaptic connections forming between general sensory afferents and pain fibers (allodynia).[20] These various mechanisms result in descending facilitation.[43] Imaging studies show changes in both the brainstem and somatosensory cortex in response to central sensitization.[20]

CAUSES AND RISK FACTORS FOR CHRONIC PAIN

Chronic pain is not just a symptom; it should be considered a disease with a variety of causes and risk factors. While injury or disease often trigger the development of pain, additional risk factors include genetic predisposition, gender, psychosocial history, psychological state at the time of initial injury, and lifestyle.

Up to 50% of the variability in prevalence and severity of pain appears to be due to genetic factors. In fact, twin studies show that many chronic conditions involving central sensitization have a hereditary component.[20,66-70] This genetic predisposition may account for the high prevalence of co-morbidities among conditions involving central sensitization; the presence of any one disorder increases the likelihood of other central sensitization related conditions, with odds ratios up to 29. Common comorbid conditions include migraine, fibromyalgia, complex regional pain syndrome (CRPS), low back pain, irritable bowel syndrome, chronic tension-type headache, TMJ disorder, interstitial cystitis, depression, panic disorder, PTSD, pelvic pain, and chronic widespread pain.[20,66-68,70]

Women are more likely than men to experience most chronic pain conditions, including migraine with aura, tension headache, TMJ pain, CRPS, fibromyalgia, MS, and RA.[71-73] Munce and Stewart[73] report that in a community sample, 38.4% of women reported chronic pain compared to 27.1% of men. Women are also more likely than men to see a physician for management of pain syndromes[71] and are more likely to have co-morbid depression.[73] Increased prevalence of chronic pain in women is likely due to a combination of influences including physiological, sociocultural, and psychological factors.[72]

Psychosocial history can be a strong contributing factor in the development of chronic pain. Extensive research demonstrates relationships between past trauma and chronic pain or other central sensitization conditions. Post-traumatic stress disorder is highly correlated with chronic pain conditions. Childhood abuse and other forms of PTSD are as high as 58% among people with chronic pain conditions.[74-78] Consequently, the probability of having multiple chronic pain conditions is increased among survivors of childhood or adult abuse[70,74,77,79-85] and other psychosocial stressors.[81] There are likely to be several mechanisms by which emotional trauma leads to chronic pain. Several studies have shown physiological changes in functional magnetic resonance imaging (fMRI) patterns within the brain,[86] diurnal cortisol patterns, gene transcription, and hypothalamic-pituitary regulation.[74]

Numerous other psychosocial factors increase risk of chronic pain through both psychosocial and physiological mechanisms. These include poor social support, poor coping skills, low job security, low socioeconomic status, limited access to preventative care, external locus of control, marital/family discord, cultural background, and beliefs.[33] Work environment also affects the likelihood that acute pain will become chronic. Whether patients like their job or get along with their supervisor is highly correlated to levels of both pain and disability.[16]

Depression, psychological distress, passive coping strategies, and fear-avoidance beliefs are independently linked with poor outcome among people with chronic pain.[87,88] Recent research suggests that individuals with high levels of fear-avoidance are more likely to have successful outcomes when the intervention specifically addresses those fears.[89] Kinesiophobia, or fear of movement, is also associated with poor outcomes.[90] Maladaptive and passive coping strategies,[91,92] depression, and

traumatic life events[92] all increase the likelihood of developing future chronic pain and disability due to pain.

The Effect of Lifestyle Factors

Some health habits are also risk factors for chronic pain. Smoking has a complex relationship with chronic pain; smoking has immediate analgesic effects through both central and peripheral pain receptors.[93] However, smoking is associated with greater prevalence of chronic pain disorders such as LBP,[94,95] pelvic pain,[96] and other chronic pain disorders once socioeconomic factors have been controlled.[93,97] Pain and activity restriction are also greater among smokers.[98] A high correlation exists between chronic pain and opiate or alcohol addiction, though it is difficult to determine the direction of causality.[97] Obesity and overweight are also correlated with chronic LBP[94,99] and a variety of other chronic pain conditions,[69] but it is unclear whether obesity increases the risk of chronic pain or whether chronic pain contributes to obesity.

Sleep disorders are highly correlated to chronic pain, increased disability, and suffering due to pain, and increased health care utilization.[100-102] Studies have shown that poor-quality sleep predicts onset of chronic pain 15 months later,[101] and experimental sleep deprivation can result in diffuse musculoskeletal pain.[103] The relationship between sleep disorder and chronic pain appears to be reciprocal, with each exacerbating the other,[102,104,105] and restorative sleep seems to be associated with decreases in pain.[106] Sleep disorders can be screened using the *Pittsburgh Sleep Quality Index (PSQI).*[107]

Although there are no nutritional cures for chronic pain, nutritional deficits may exacerbate pain conditions. Research suggests that vitamin D deficiency causes dull, persistent, generalized musculoskeletal aches and pains and muscle weakness,[108,109] and may be associated with fibromyalgia, rheumatic disorders, OA, and migraine.[109,110] Studies have found vitamin D deficits in 26% to 93% of patients with diffuse bone and muscle pain responding poorly to medication.[108,111] However, studies assessing vitamin D supplements for treating chronic pain have provided inconsistent results.[112]

PSYCHOSOCIAL FACTORS ASSOCIATED WITH CHRONIC PAIN

The Mind-Body Relationship

The definition of pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage,[13] incorporates the cognitive, emotional, and social context in which pain occurs. The Cartesian concept of mind-body duality in which a problem was either in the body or in the mind is now known to be incorrect.[33,50,113-116] The spatial discrimination and affective components of pain are equally physiological; they simply occur in different portions of the brain.[6,29,38] Autonomic and endocrine pathways relay affective, autonomic, hormonal, and immune information bidirectionally between the CNS and periphery. Pain is clearly more than somatic information transmitted from the body to the brain.[50]

Psychosocial factors have a strong impact on distress and disability outcomes, independent of chronic pain intensity. For example, catastrophization and poor coping skills are associated with increased pain intensity and greater disability.[115,117-120] Some psychosocial variables have been shown to be predictive, such as depression and past life trauma predict the transition from acute to chronic low back pain, while depression and negative pain beliefs predict greater disability.[92] Many psychosocial factors lead to vicious cycles because they both contribute to and are aggravated by chronic pain. For example, depression both contributes to chronic pain and is caused or aggravated by chronic pain. Some socioeconomic variables are also vulnerable to such cycles: for example, poverty is a risk factor for chronic pain, while chronic pain leads to disability, which contributes to poverty. Sullivan et al[117] provide a comprehensive review of the interaction between mental health and chronic pain. Jensen et al[119] review measurement tools for assessing psychosocial factors relevant to disability and chronic pain. A few tools for assessing psychosocial factors are listed in Table 25.4.[89,107,121-143]

Yellow flags have been defined as psychosocial factors that increase the likelihood that acute pain will progress into chronic pain and disability.[144-146] Although most sources combine all psychosocial factors into the concept of yellow alert flags, Table 25.5 outlines a terminology proposed by Nicholas et al.[144] In this terminology *yellow flags* include beliefs, emotional responses, and pain behavior; *orange flags* represent frank psychiatric symptoms; and *blue flags* reflect the interaction between work and health perceptions. The yellow flags with greatest impact appear to be (1) the belief that pain and activity are harmful, (2) a depressed mood and social withdrawal, (3) the expectation that passive treatment will help more than active treatment, and (4) low self-efficacy.[147] Other important factors include sickness behavior (e.g., excessive rest), history of pain or disability, poor job satisfaction, overprotective family or lack of support, and problems with claims or compensation.[146] Psychosocial issues should not be reduced into a single factor affecting pain. Each person is different and each psychosocial factor reflects a complex interaction among all components of the ICF model: environmental and personal factors affect activity, participation, and even body function and the health condition.[145] Psychosocial issues should be considered individually for each patient, because interventions addressing specific psychosocial factors are more successful than interventions that do not.[145] However, the presence of psychological factors should not invalidate the patient's pain complaint and

Table 25.4 Psychosocial Assessment Tools by Construct

Construct	Tool	Description	References/Websites*
Catastrophizing	Pain Catastrophizing Scale (see Appendix 25.A)	13 items on 3 subscales: rumination, magnification, helplessness; norms available	Sullivan and Pivik [131] http://sullivan-painresearch.mcgill.ca/pcs.php [online access; Appendix in User's Manual]
Coping	Chronic Pain Coping Inventory™ (CPCI™)	Short form has 8 or 16 questions with 8 categories	Hadjistavropoulos et al[133] www4.parinc.com/Products/ [fee required for access] Available in Jensen et al[136]
Coping	Coping Strategies Questionnaire (CSQ) for Pain-Related Coping	Short form has 7 or 14 items with 7 categories: 6 cognitive and one behavioral	Hadjistavropoulos et al[133] http://parqol.com/ Available in Jensen et al[136]
Depression	Center for Epidemiologic Studies Depression Scale (CES-D)	20 items validated for use in chronic pain	Radloff et al[124] www.chcr.brown.edu/pcoc/cesdscale.pdf [online access]

Table 25.5 Alert Flags for Chronic Pain[144]

Flag Color	Type of Problem	Examples
Red	Serious physical pathology	Cauda equina syndrome, fracture, tumor.
Orange	Psychiatric symptoms	Clinical depression, post-traumatic stress disorder, personality disorder.
Yellow	Beliefs, appraisals, and judgments	Negative pain beliefs. Expectation of poor outcome.
	Emotional responses	Fear, anxiety, catastrophization, distress.
	Pain behavior, including pain coping strategies	Fear-avoidance behavior, dependence on passive interventions.
Blue	Perceptions about relationship between work and pain	Belief that work will cause further injury and pain. Belief that supervisor and co-workers are unsupportive.
Black	System or contextual obstacles	No modified duty options at work. Legislation restricting return to work options. Lack of insurance coverage. Overly solicitous family or health providers.

should not interfere with attempts to identify and address physical sources that cause or exacerbate pain.[16]

Pain Beliefs and Coping

Pain-related beliefs include people's understanding about what is causing their pain, the meaning of their pain, and expectations regarding the impact pain has on their present and future lives. Beliefs associated with better outcomes include having control over pain, global self-efficacy, pain self-efficacy, control over life, and internal pain control. Beliefs associated with poor outcomes include the following: pain indicates injury/damage and should be avoided, pain will be constant, pain is disabling, emotions influence pain, and that other people should be solicitous because of the pain, helplessness, and external locus of control (the belief that pain is controlled by someone other than the individual in pain).[119] Some people with chronic pain believe that someone is to blame for their pain and that their pain is unfair; such feelings of injustice can interfere with rehabilitation.[132]

Coping is the way in which people manage stress. Some coping mechanisms are beneficial, or adaptive, whereas others are destructive, or maladaptive. Beneficial coping responses include activities to distract oneself from the pain, task persistence, exercise, ignoring pain, coping self-statements, and acceptance of the condition. Detrimental coping responses include guarding, resting, venting emotions, passive coping (avoidance), and asking for assistance.[119,148]

Anxiety and Fear Avoidance

Anxiety is a normal response to acute pain and can be an adaptive response encouraging people to stop activities causing tissue damage. However, if the cause of pain cannot be found, anxiety is replaced by frustration that the cause cannot be found, hostility that other people do not believe the pain is real, fear that the pain will not go away, and discouragement because nothing helps.[149] Anxiety is a common co-morbidity with chronic pain,[150] and evidence suggests that anxiety may be a risk factor for acute pain becoming chronic.[16,150] Anxiety is more highly correlated with chronic pain than depression. Post-traumatic stress disorder, a special case of anxiety disorder, is particularly common in chronic pain.[150]

An adaptive anxiety response in acute pain can become a maladaptive fear response in chronic pain. The *Fear-Avoidance Model* of pain proposes that some people have an exaggerated fear that movement will cause reinjury and/or increase pain.[151,152] Fear of pain can even become more disabling than the actual pain. People with pain either confront or avoid these fears; those who confront will increase activity and will generally have improved functional outcomes and decreased pain. Fear-induced avoidance of activity leads to hypervigilance, inaccurate predictions about pain, misinterpretation of body sensations, muscular reactivity, and physical deconditioning.[151,152] Figure 25.3 shows how these factors result in increased pain and increased disability for a given level of pain. Maladaptive beliefs are reinforced as people expect activity to increase pain and expect pain to lead to disability.[16,120,151] Decreased activity due to fear results in deconditioning impaired motor control due to disuse, both of which increase likelihood of increased pain.[16,151,153]

Catastrophizing

Catastrophizing includes pessimism, helplessness to control symptoms, magnification (threat exaggeration), and rumination (excessive focus on pain sensations).

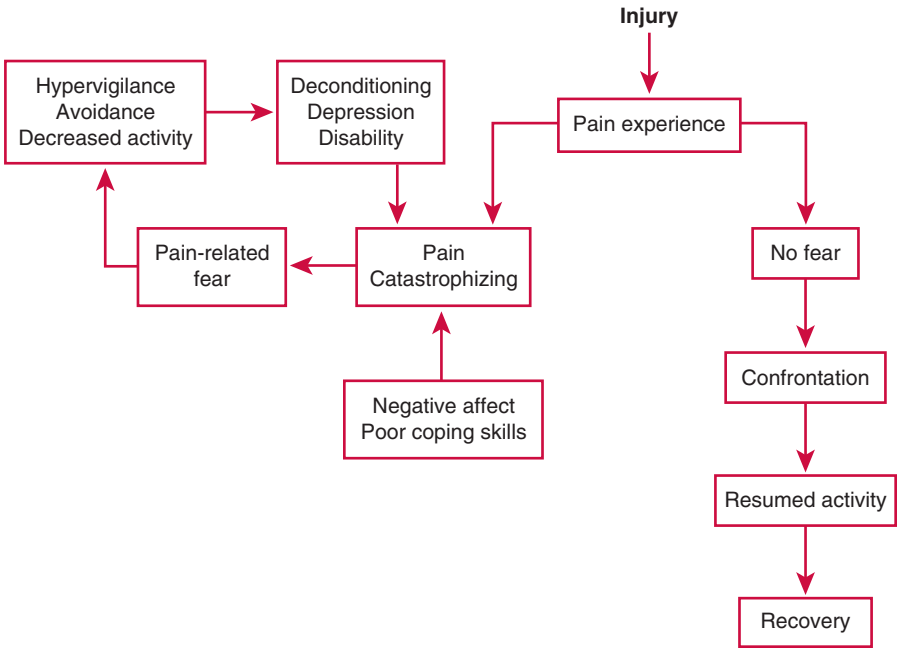

Figure 25.3 The fear-avoidance model shows how the pain experience can resolve in the absence of fear or become a vicious cycle in the presence of pain-related fear. Negative affect and poor coping skills cause the pain experience to be perceived as a threat; pain catastrophizing increases pain-related fear, hypervigilance, and avoidance. Activity avoidance leads to secondary problems such as deconditioning, depression, and additional disability, which further exacerbate the negative aspects of the pain experience. On the other hand, individuals who do not perceive pain as a threat are more likely to progress back into activities that had been painful, leading to recovery.

Catastrophizing involves both cognitive appraisal and beliefs or attitudes; however, it can also be described as a (maladaptive) coping mechanism.[29,31,117,119,154] It appears to be an interaction between inherited temperament and personal history and experience.[29] Examples of catastrophizing self-statements might include the following: "this pain has destroyed my life," "I know there is something terribly wrong with me," "I can't stop thinking about how much it hurts," or "I can't stand this anymore." Appendix 25.A contains the *Pain Catastrophizing Scale*.[131] Catastrophizing is the strongest and most consistent psychosocial factor affecting both pain intensity and function.[119,120,154] Interestingly, catastrophizing activates the same portions of the brain activated with suffering.[29]

Depression and Grieving

Depression is a very common co-morbidity with chronic pain, ranging between 13% and 85% of patients depending on the population,[16,73,155,156] suggesting that depression can both cause and be caused by pain.[31] Depression is associated with increased catastrophizing, fear of pain, and perceived disability,[157] as well as increased pain complaints and poorer rehabilitation outcomes.[155] Depression is a strong predictor for the development of chronic pain and disability following acute LBP.[6,92] Physiologically, depression is associated with increased activity in portions of the brain that mediate the affective component of pain.[158]

People in severe pain are unable to fulfill social roles such as maintain a job, sustain family relationships, or satisfy personal needs for growth and recreation. As a result, people with chronic pain may suffer and grieve for their loss of identity, job, relationships, or hobbies. They may feel guilt for their failure to perform life roles. Family and friends may also feel loss.[159-161] These experiences may lead to depression or grieving. The traditional model of grief proposed by Kübler-Ross posits that people go through five stages in the grieving process: *denial, anger, bargaining, depression*, and *acceptance*.[162] However, the stages of grieving model has been challenged when applied to chronic illness as an oversimplification of a more complex narrative.[163] A recent model of grieving associated with chronic pain proposes a process of adaptation and relearning the world, associated with four processes occurring along a continuum: despair to hope, lack of understanding to insight, meaning disruption to meaning, bodily discomfort to reintegrated body.[160,164]

Stress

The body's short-term response to acute stress allows the organism to respond to the threat. Acute stress may produce analgesia, as is sometimes seen in soldiers or athletes. Stress-induced analgesia works through both opiate- and non–opiate-mediated mechanisms via descending inhibition.[48] Prolonged psychological or physiological stress, however, leads to a dysfunctional response with excessive immune system suppression, muscle atrophy, compromised tissue growth and repair, autonomic dysfunction, cognitive changes, and structural changes in the brain.[48,50,149] Stress-related mechanisms appear to be important in a number of chronic pain syndromes such as chronic headaches, fibromyalgia, and TMJ disorders, as well as other central sensitization conditions such as chronic fatigue and irritable bowel, PTSD, anxiety, and depression.[48,50] Appendix 25.B includes the four-question *Primary Care Post-Traumatic Stress Disorder Screen*.[130] Stress-mediated peripheral and central sensitization involves activation of the autonomic nervous system and the HPA axis.[48,50,165] Chronic pain also aggravates stress when patients feel blamed or labeled as complainers, when multiple tests do not identify a source of the pain, when treatment is ineffective, and when they are unable to work or perform activities of daily living (ADL), sleep, or maintain relationships.[149]

Nonorganic Findings

Waddell et al[166] first presented the concept of nonorganic findings to identify patients who would benefit from further psychological testing. The original implication was that these patients had findings not consistent with an organic basis for their pain, hence psychological sources needed to be considered. The five components of Waddell and colleagues' nonorganic testing are superficial or nonanatomical tenderness, pain in response to simulation tests, inconsistent responses to distraction, regional sensory and strength impairments, and overreaction (sometimes referred to as *Waddell signs*). Positive findings in three or more of these categories are considered a *positive nonorganic test*.[166,167]

Research confirms that having multiple positive Waddell signs is correlated with increased psychological distress, pain severity, and perceived disability.[144,168] Although Waddell signs appear to have value in identifying people at risk for poor response to treatment, they should not be considered as truly "nonorganic." Research indicates there is an organic basis for at least some of them; for example, overreaction and superficial tenderness are consistent with allodynia due to central sensitization.[21,168] Although Waddell signs are commonly misinterpreted to indicate malingering, this was not their intended use: evidence does not show an association between Waddell signs and malingering or secondary gain.[169] In summary, assessment of nonorganic findings can be constructive as long as the findings are considered within the context of current knowledge about chronic pain. Chronic pain may exist in the absence of peripheral tissue damage, central sensitization amplifies the pain response, and it is common for people with chronic pain to have psychosocial factors affect their pain.[21,144]

Personality Disorders

Some evidence suggests that personality disorders, such as borderline, histrionic, or obsessive compulsive, are not

risk factors for developing chronic pain, but are associated with poorer prognosis. Other research suggests increased prevalence of personality disorders among people who have chronic pain.[19,170] In either case, it does appear that chronic pain may exacerbate personality disorders.[19] The reader is referred to Dersh et al[19] for further discussion of issues and evidence related to personality disorders.

Social Support

Social factors operate at a societal level, at the level of workplace or school, or microlevel of interpersonal relationships and informal help.[171] General social support is one of the ICF environmental factors relevant to chronic pain,[26] and lack of social support is identified as one of many potential barriers to treatment that are difficult to overcome.[16] General or global social support and social reinforcers for wellness behavior tend to be beneficial.[118,119,172] However, the impact of social responses to pain behaviors depends on the nature of the behavior and whether the response is solicitous or punishing. Solicitous behaviors are pain-contingent responses such as sympathy, encouragement to avoid pain and do less, and allowing people to avoid tasks due to pain. Solicitous responses lead to increased pain and decreased function.[119,173] Punishing or negative responses to pain behaviors also lead to increased pain and depression.[154]

EXAMINATION OF PAIN

Pain is a purely subjective phenomenon. Unlike range of motion (ROM), strength, or tissue extensibility, pain has no objective or specific measurement tool. However, the measurement of pain has become a vital part of patient examination. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has emphasized the importance of pain assessment and treatment by calling pain "the fifth vital sign." Effective examination of chronic pain is more complex than the visual analog or numeric rating scales typically used for acute pain. The psychosocial aspects of chronic pain should be examined and evaluated to better identify psychosocial factors and guide intervention within a biopsychosocial model of care.

A thorough patient examination allows the physical therapist to hypothesize potential sources of the pain (i.e., nociceptive due to peripheral tissue damage, peripheral neurogenic, central neurogenic). Patients with chronic pain disorders may also have acute or subacute conditions superimposed on chronic pain: that is, a person with fibromyalgia may still have rotator cuff impingement, lumbar instability, or carpal tunnel syndrome. Since conditions associated with peripheral tissue injury may exacerbate peripheral or central sensitization, physical therapists need to consider whether to treat the superimposed musculoskeletal conditions and/or the underlying chronic pain.

Pain should be examined both at rest and with movement.[174] Several mnemonics can be used to guide the examination of pain; *PQRST* and *SOCRATES* are shown in Box 25.3.[175-177] The standard tools for quantifying pain severity are the *visual analogue scale (VAS)* and the more commonly used *numeric rating scale (NRS)*. The VAS and NRS correlate well with one another and are equally sensitive whereas the *verbal (categorical) rating scale (VRS)* of mild, moderate, severe is not as accurate. The NRS is easier to understand, faster to score, and more practical than VAS. A variety of *Faces scales* are used for children over 3 years old.[174,178] While severity is the most commonly measured parameter, clinical guidelines for chronic pain management emphasize that single-dimension pain examination such as the VAS or NRS are inadequate for chronic pain and that it is essential to use a multidimensional tool that examines the emotional and cognitive aspects of pain as well. Furthermore, emphasis on pain rating scales encourages attention to and preoccupation with pain, which interferes with effective pain management.[3] Consequently, de-emphasis of pain quantification in chronic pain management may clash with the JCAHO focus on pain measurement.

Body diagrams provide information about pain location, radiation, and character. Pain diagrams require more patient instruction than pain quantification, hence are more time consuming to administer. Patients are instructed to distinguish between aching, burning, stabbing, pins and needles, and numbness; and sometimes sensations such as heaviness, swelling, or other autonomic symptoms. Information about the location and nature of the pain

Box 25.3 Mnemonics for Pain Assessment[175-177]

PQRST

- **P**rovoking/precipitating factors
- **Q**uality of pain
- **R**egion and radiation
- **S**everity or associated symptoms
- **T**emporal factors/timing

SOCRATES

- **S**ite: Where is the pain?
- **O**nset: When and how did it start? Sudden or gradual? Trauma, illness, or other possible cause?
- **C**haracter: How does the pain feel? Sharp? Stabbing? Burning? Aching? Other?
- **R**adiation: Does the pain radiate? Where? What causes radiation?
- **A**ssociations: Other symptoms, such as numbness, paresthesias, heaviness, other?
- **T**ime course: How does the pain vary over the day?
- **E**xacerbating/relieving: What aggravates or relieves the pain?
- **S**everity: Intensity rating

can be used to hypothesize about the source of the pain: sclerotomes, referred pain, dermatomes, and peripheral nerve patterns all implicate specific structures whereas symmetrical patterns of autonomic symptoms implicate central neurogenic involvement. Data obtained from body diagrams is more difficult to analyze objectively than data obtained from VAS or other pain tools and observer bias may influence analysis of body diagram data.[179]

Pain Questionnaires and Outcome Measures

A multitude of pain questionnaires and outcome measures exist to measure both nonspecific and disease-specific aspects of pain from a biopsychosocial perspective. For a more comprehensive discussion of pain examination, interested readers are referred to several excellent review articles;[174,180-183] in addition, the website *Pain Treatment Topics* includes brief summaries of many examination tools, as well as links to those tools (see Appendix 25.E). Table 25.6 provides a short list of practical examination instruments appropriate for chronic pain.[178,180,184-198]

The *McGill Pain Questionnaire (MPQ)* and the *Short Form MPQ (SF-MPQ)* examine sensory, affective-emotional, evaluative, and temporal aspects of pain.[174,195,199] The original MPQ was intended to indicate the possible source of pain through descriptors the patient selected. Word category 1 (e.g., "quivering," "beating," or "pounding") suggested vascular origin; categories 2 through 8 suggested neurogenic origin; category 9 suggested musculoskeletal origin; and categories 10 through 20 reflected the emotional content of pain.[195] The SF-MPQ includes fewer verbal descriptors.[199] Other tools also help distinguish the source of the pain. For example, the *Leads Assessment of Neuropathic Symptoms and Signs* (LANSS) distinguishes between neurogenic and nociceptive pain with sensitivity of 80% to 85% and specificity of 80% to 94%.[200] The *Neuropathic Pain Scale* (NPS) also distinguishes between neuropathic and non-neuropathic pain.[201]

Ideally, a comprehensive outcome measure should examine each of the domains within the ICF: body structure or function, activity, and participation.[202]

Table 25.6 Pain Assessment Tools Appropriate for Chronic Pain*

Pain Scale	Properties	Items	References/Websites/ Description
Body Map	Able to monitor location of pain and other symptoms	Body chart	Margolis et al[184] www.aapmr.org/patients/conditions/pain/Documents/paindrawing.pdf [online access]

Self-report Leeds Assessment of Neuropathic Symptoms and Signs (S-LANSS)	Distinguishes between neuropathic and non-neuropathic pain; S-LANSS is the LANSS without the 2 objective testing questions	7 self-report questions	Bennett et al[189] http://clahrc-gm.nihr.ac.uk/cms/wp-content/uploads/GM-SAT_SLANNS.pdf [online access]
Visual Analog Scale (VAS), Numeric Rating Scale (NRS)	10 cm line or 0–10 scale for pain severity	1 item	Burckhardt[180] Measures pain across a continuum of values (often from *No Pain* to *Worst Possible Pain*)

*Many of these and other pain scales can be found at http://pain-topics.org/clinical_concepts/assess.php.
ICF = International Classification of Functioning, Disability and Health.

The *Brief Pain Inventory (BPI)* examines pain now, worst, least, and average over 24 hours. It rates pain interference with functional activities such as general activity, walking, normal work, relations with other people, mood, sleep, and enjoyment of life. The BPI was initially designed for cancer-related pain, but has since been validated with other sources of pain. [114,174] The *Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT)* is a multimodal examination tool that includes the domains of (1) pain, (2) physical functioning, (3) emotional functioning, (4) patient ratings of improvement and satisfaction with treatment, (5) other symptoms and adverse events during treatment, and (6) patient demographics.[203]

Some tools have been developed to examine specific types of pain. For example, Jensen et al[181] review several tools specific for neuropathic pain. Some pain assessment tools are condition-specific: for example, the *Western Ontario and McMaster University Osteoarthritis Index (WOMAC)* for osteoarthritis of the knee, the *Oswestry Low Back Pain Disability Questionnaire* for LBP, the *Revised Fibromyalgia Impact Questionnaire (FIQR),* and the *Headache Impact Test*. Some disease- or condition-specific tools (such as the FIQR) examine both pain and other symptoms or activity restrictions relevant to those conditions. Inclusion of nonpain symptoms such as anxiety, depression, sleep quality, balance, and memory provides a more comprehensive picture of the patient's complaints, but may obscure examination of pain.

Because pain is an integration of physical, emotional, and cognitive processes, physical measurements of chronic pain are of limited value. While people experiencing acute pain usually demonstrate physiological arousal (e.g., increased heart rate), such arousal is not typically associated with chronic pain. Box 25.4 lists verbal and nonverbal forms of pain expression that may be useful in acute pain; however, such pain expressions can be misleading in patients with chronic pain owing to multiple factors influencing the pain.[175] Some potential physical measurements of allodynia and central sensitization include *von Frey filaments* for pain threshold, temperature discrimination using test tubes filled with cold and hot (40°C) water for thermal allodynia; cotton, wool, or an artist's brush for mechanical allodynia, and a blunt needle for hyperalgesia; and temporal summation.[174] The LANSS also includes physical assessment of allodynia (brushing the skin) and hyperalgesia (hypersensitivity to pinprick in the locations of pain).[181,190]

Box 25.4 Pain Expression and Factors Affecting Pain Expression[175]

Forms of Pain Expression

- Vocalizations: Verbal pain report, crying, moaning, sighing, screaming.
- Movement and mobility: Decreased motion, rubbing, guarding, splinting, muscle spasm, limping.
- Facial expression: Wincing, grimacing, frowning.
- Mood and behavior: Distress, anxiety, depression, irritability, aggression, quietness, withdrawal, decreased cognition, decreased appetite, sleep deprivation, confusion.

Factors Affecting Pain Expression

- Nature of the pain: Type, intensity, location.
- Cognitive status, mood, sedation.
- Meaning of pain to the individual, learned pain behaviors from family or culture.
- Expectations regarding pain and pain relief, perceived consequences of the pain.
- Acceptable behaviors within the family or culture, other people's responses.
- Situation and environment.

Examination of Pain in Special Populations

Children, the elderly, and people with dementia or limited cognitive function pose special challenges to examination of pain. Historically, it was believed that infants had immature nervous systems that were not able to experience pain. This is now known to be incorrect; the necessary neural pathways for pain experience are present and functioning starting at 24 weeks of gestation. Pain experiences in infants or children can cause permanent changes in neural structure and function, leading to increased pain perception later in life. Children experience a range of common pain conditions, including headaches and migraines, back pain, and muscle and joint pain.[44] In some cases, the conditions may present differently than in adults; for example, migraines in children often present as abdominal symptoms without actual headache.[204]

A variety of *faces scales* exist for use with children who are able to articulate their pain, typically used with children over 4 years old. The various faces scales may include from 5 to 10 options of facial expressions representing different severities of pain.[178] Younger children can use the *Pieces of Hurt Scale*, in which they indicate how many poker chips of pain they have, from one to four.[183] For infants and children who are nonverbal, several observational pain assessment tools exist for acute pain; for example, ***C**rying, **R**equires increased oxygen administration, **I**ncreased vital signs, **E**xpression, **S**leeplessness (CRIES)* Pain Scale for infants 0 to 6 months; ***F**ace, **L**egs, **A**ctivity, **C**ry, **C**onsolability Scale* (*FLACC)* for infants and children 2 months to 7 years; *COMFORT Pain Scale* for unconscious or ventilated infants, children, or adolescents.[174,205,206] Since behavioral signs are different for acute and chronic pain, these observational scales are probably not valid for chronic pain.[207]

There is no indication that pain sensation diminishes with age as do vision, hearing, and the other special

senses.[44,208] However, research suggests that with advancing age there are a higher proportion of C fibers relative to A-δ fibers, resulting in more diffuse, burning pain rather than localized prickling pain among the elderly. Older individuals may report "discomfort" or "aches" rather than "pain," so clinicians should be alert to changes in pain descriptors with age.[209] Several reports review pain assessment tools for elderly individuals with dementia or who are nonverbal; the *Pain Thermometer* is more accurate than the NPS or VAS for elderly persons with cognitive deficits.[188,198] As with the pain assessment tools for infants, these tools were developed for acute pain and it is not clear that these observational tools accurately reflect chronic pain. Bruckenthal et al[209] present a useful summary of issues related to pain assessment in the elderly.

Narrative Examination of Pain

The current emphasis on objective measurement should not overshadow the importance of narrative reasoning approaches to examining patients with chronic pain. During the history taking, narrative reasoning strives to understand the patient's story, illness experience, beliefs, fears, and expectations. The emphasis of narrative reasoning is therefore to understand the patient's experience, beliefs, and feelings rather than to quantify or objectify pain. Narrative information is often obtained verbally during history taking or while talking during interventions; nonverbal information such as weeping or avoidance of eye contact also conveys narrative information. Edwards et al[210] present a comprehensive approach to applying narrative reasoning throughout the patient care process. Given the importance of psychosocial issues in chronic pain, the narrative approach may be particularly valuable in this patient population.[211,212]

MEDICAL MANAGEMENT OF CHRONIC PAIN

Medical Diagnostic Testing

There are no general imaging or laboratory tests diagnostic for chronic pain. Furthermore, positive findings on imaging tests do not prove that the identified pathology is related to the patient's pain, as indicated in multiple studies showing positive lumbar imaging findings in people without LBP,[16,213,214] and the mismatch between radiographic findings of OA and pain.[215] Repeated diagnostic testing to search for an undefined physical abnormality is generally not indicated because it encourages patients to focus on physical abnormalities that might not exist (adhering to a biomedical model) rather than looking for strategies to manage the pain using a biopsychosocial model.[216]

Laboratory tests, such as thyroid hormone levels, sedimentation rates, Lyme titers, or general blood screening, can be appropriate to rule out conditions that are treatable. Electrodiagnostic testing, such as needle electromyogram (EMG), is not indicated unless there is suggestion of specific neuropathy. Diagnostic nerve blocks (peripheral or sympathetic), joint blocks (facet or sacroiliac), and provocative discography can help determine whether a given structure is involved; see any of the clinical guidelines on chronic pain for more information on interventional testing.[15,16,18,216] Ultimately, excessive or repeated tests foster patients' obsession with obtaining a pathophysiological diagnosis and may interfere with chronic pain management.[15,16,216]

Pharmacological Management of Chronic Pain

Medications are typically staged, starting with those least likely to cause adverse side effects to those with greatest risk. The various classes of medication are shown in Table 25.7, along with primary indication(s) and adverse effects.[16,217-219] In general, treatment starts with acetaminophen and proceeds to nonsteroidal anti-inflammatory drugs (NSAIDs) and topical medications. NSAIDS are generally beneficial for arthritic pain and LBP, but are believed to be ineffective for neuropathic pain.[220] *Adjuvant medications* (medications whose primary indication is a condition other than pain, but which have demonstrated benefit in pain management) are added next. Muscle relaxants and weak opiates are added if prior medications, physical therapy, and cognitive therapy are unsuccessful. Kroenke et al[218] and Turk et al[220] provide good overviews of the mechanisms and efficacy of various classes of medications for chronic pain.[218,220]

Adjuvant medications include antidepressant, antiseizure, muscle relaxant, and sleep medications. Antidepressants for pain are typically used at much lower dosages than when used to treat depression because the mechanism of action is distinct from treatment of depression. Tricyclic antidepressants (TCAs) have demonstrated benefit for neurogenic pain, fibromyalgia, LBP, headaches, and irritable bowel.[220] Results for selective serotonin reuptake inhibitors (SSRIs) for chronic pain are inconsistent. Serotonin-norepinephrine reuptake inhibitors (SNRIs) appear to have the benefits of TCAs for managing neuropathic pain with fewer side effects.[220] Overall, TCAs and SNRIs are more effective than SSRIs for managing chronic pain.[16,219] Evidence is also strong for some anticonvulsant medications in managing neuropathic pain, including fibromyalgia and lumbar radiculopathy.[220] Medications to treat sleep disturbance can also be beneficial because sleep disturbance frequently exacerbates chronic pain.[219] Benzodiazepines and muscle relaxant medications are generally not recommended for prolonged use in chronic pain because risks are relatively high and there is little evidence of benefit.[16] Cyclobenzaprine, however, has been shown to be effective for fibromyalgia and conditions involving chronic muscle spasm.[220]

Topical medications for chronic pain fall into three broad categories: those creating cooling sensations, those

Table 25.7 Medications for Chronic Pain[218]

Class	Medication	Type of pain	Possible Adverse Effects
Para-aminophenols	Acetaminophen	Most	Liver toxicity
NSAIDs	Naproxen, salsalate, etodolac, ibuprofen, diclofenac	Nociceptive, inflammatory	GI bleeding, nausea, cardiac risk
Topical	Capsaicin, lidocaine, salsalate, NSAID, menthol	Nociceptive, peripheral neurogenic	Skin irritation
Adjuvant: antidepressants (tricyclics, SNRIs)	Amitriptyline, nortriptyline (Tramadol has SNRI effects)	Peripheral or central neurogenic; some nociceptive pain	Hypertension, orthostatic hypotension, arrhythmias, falls in the elderly, dry mouth, constipation, blurry vision, sedation, insomnia; risk of serotonin syndrome
Adjuvant: anticonvulsants	Gabapentin, duloxetine, pregabalin, topiramate	Peripheral or central neurogenic	Dizziness, fatigue, ataxia, peripheral edema, dry mouth, weight gain or loss, liver damage
Muscle relaxant	For spasticity: baclofen, dantrolene, and tizanidine For musculoskeletal conditions: carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, and orphenadrine	Muscle spasm or trigger points: FMS, MPS	Dizziness, drowsiness, fatigue, weakness
Weak opiate	Tramadol	Peripheral or central neurogenic	Nausea, constipation, sedation, dizziness, vomiting, pruritus, sexual dysfunction, sleep disturbance, hyperalgesia, tolerance, addiction; risk of serotonin syndrome
Strong opiate	Codeine, hydrocodone, morphine, oxycodone, methadone, fentanyl patch	Peripheral or central neurogenic, cancer pain	Nausea, constipation, sedation, dizziness, vomiting, pruritus, sexual dysfunction, sleep disturbance and hyperalgesia, tolerance, addiction; risk of serotonin syndrome

FMS = fibromyalgia syndrome; MPS = myofascial pain syndrome; NSAID= Nonsteroidal anti-inflammatory; SNRI = serotonin and norepinephrine reuptake inhibitor.

creating warmth sensations, and those with bioactive agents. Those creating cooling sensation, generally menthol-based, work as a counterirritant probably via the gate control mechanism. Those creating the sensation of warmth are generally capsaicin-based. An important aspect of capsaicin-based topical medications is that the counterirritant effect begins immediately after application but the neurogenic effect requires daily use for 6 to 8 weeks. One proposed explanation for the time required is that repeated use of capsaicin depletes nerve endings of substance P; the actual physiology appears to be more complex.[221,222] A variety of NSAIDs can be administered via topical rubs. Research shows that medication can be absorbed through the skin into muscle, synovium, and joint tissue.[223] Lidocaine cream or patch can be beneficial for peripheral neurogenic pain.[224] Opiates can also be administered topically, but are less commonly used this way.

The benefits and risks of opiate use in managing nonmalignant (i.e., noncancer) chronic pain remain controversial.[15,16,216,218,220,225,226] Although opiates are frequently prescribed for nonmalignant chronic pain, evidence suggests that decreases in pain are small and improvements in quality of life are limited with less

functional improvements than with other analgesic medications.[218,220] Furthermore, evidence suggests that opiate use may encourage focus on pain and illness behavior.[226] The potential for both physiological tolerance and addiction makes opiates even more controversial, and careful screening for addictive history or personality is indicated before initiating opiate medication.[15,16,224] Concern is often raised about the safety of people taking opiate medications while performing tasks such as driving; research suggests that risk of car accidents increases when opiates are initiated or when the dose is increased, but not when doses are stable and appropriate.[216] Opiate-induced hyperalgesia, due to changes in receptors or neural circuits, may undermine pain management.[220,226] The incidence of opiate abuse also remains controversial, with current estimates of abuse among patients receiving opiates between 18% and 41%.[226]

An important consideration with all medications is the potential *placebo effect*, the benefit resulting from the patient's belief that the treatment will be successful. The placebo effect appears to be mediated by the brain's reward system, which also mediates some components of chronic pain. The placebo effect is as high as 20% to 40%, depending on the condition for which the medication is given.[227] Interestingly, placebos are more likely to result in decreased pain if they cause side effects.[220] Recent research suggests that the placebo effect can be effective in managing irritable bowel syndrome (another central sensitization condition) even when the subject knows that the medication is a placebo.[228]

Serotonin syndrome (serotonin toxicity) is a potentially dangerous consequence of polypharmacy (use of multiple drugs to treat the same condition) with medications often used to manage chronic pain. The most likely medications involved are SSRIs, SNRIs, TCAs, some opiates, and triptans (used as an abortive medication for migraines) and less obvious medications such as antibiotics.[15,229] Because the condition is potentially lethal, the physical therapist should remain alert for symptoms of serotonin syndrome: agitation, anxiety, confusion, hypomania, hyperthermia, tachycardia, diaphoresis, flushing, mydriasis (prolonged pupil dilation), hyperreflexia, clonus, myoclonus, shivering, tremor, and hypertonia.[229,230]

Interventional Medicine

Interventional medicine includes injections, surgical procedures, and implantable devices (Table 25.8). Several

Table 25.8 Interventional Procedures for Chronic Pain[18]

Procedure	Description	Indication
Joint block	Injection of anesthetic with our without steroids into facets or sacroiliac (SI) joint	Facet or SI pain
Trigger point injection	Botulinum toxin A (botox) injections into trigger points	Myofascial pain syndrome, which may be associate with various other pain syndromes
Nerve block	Injection of anesthetic with our without steroids into peripheral nerve, celiac plexus, paravertebral sympathectomy, medial branch block, stellate ganglion block, cervical paravertebral sympathectomy	Low back pain (LBP) Complex regional pain syndrome (CRPS)
Epidural, intrathecal injections	Steroid injections with or without local anesthetics; opioid injections into intrathecal space	Neck pain, LBP, radiculopathy, postherpetic neuralgia (PHN)
Ablative techniques	Chemical denervation, cryoneurolysis, cryoablation, thermal intradiscal procedures, radiofrequency ablation	Neuropathic, facet, or musculoskeletal pain
Implanted electrical stimulator	Subcutaneous peripheral nerve stimulation and spinal cord stimulation	Peripheral nerve injuries, neuropathic pain, CRPS, failed low back surgery, phantom limb pain, cauda equina injury, radiculopathy, peripheral vascular disease, visceral pain, multiple sclerosis
Implantable drug delivery	Infusion of medication into spinal cord or specific arteries serving involved structures	Cancer, refractory spasticity due to cerebral or spinal cord injury, intractable pain with objective pathology
Minimally invasive spinal procedure	Vertebroplasty, kyphoplasty, percutaneous disc decompression, nucleoplasty	Osteoporotic compression fracture, radiculopathy

CRPS = complex regional pain syndrome; LBP = low back pain; PHN = postherpetic neuralgia; SI = sacroiliac.

reviews of interventional procedures for chronic pain are available and the evidence for effectiveness is summarized in Appendix 25.C.[15,16,18,216,220,231-238]

Injections are most often to the epidural space, nerves, facet joints, or muscles. Joint and nerve blocks are sometimes used diagnostically, to confirm involvement of specific structures. Surgical options are considered only when all other efforts at pain management have failed and there is ongoing, observed pathology perpetuating the pain. Patients need to be carefully selected for permanent surgical procedures. Psychological evaluation should confirm that pain is not perpetuated by psychosocial factors, because these would persist after surgery and result in failed intervention. When possible, a temporary version of the intervention should be implemented first to determine that the surgery would be successful (e.g., guidelines recommend a 1-week trial before permanent implantation of epidural or intrathecal infusion pumps or spinal cord stimulators).[15,18] Injections into nerve, joint, or muscle should be followed with active rehabilitation to take advantage of the time in which pain is reduced or eliminated.[15,16]

PHYSICAL THERAPY EXAMINATION

The Therapeutic Relationship

Patient-centered care requires assessing both the illness and the patient's experience of the illness, understanding the patient as a person, and engaging in shared decision making.[212] Patient-centered care therefore requires effective communication and an effective patient–provider relationship. However, the difficulty of managing chronic pain can place significant strain on both patient and provider.

There is a perception among some clinicians that patients with chronic pain are difficult. Indeed, patients with chronic pain may be angry, abusive, demanding, deceitful, or nonadherent or engage in doctor-shopping.[212,239,240] See Box 25.2 for additional chronic pain syndrome behaviors.[3] Understanding the source of these patient behaviors helps clinicians empathize and improves communication. For example, patients may be defensive or hostile because of previous negative interactions with unsupportive medical professionals.[240] Since chronic pain can lack objective findings of a physical cause for the pain, many patients have struggled with not being believed by health care providers.[212,241] The biomedical model divides conditions into exclusively physical or exclusively psychological; since psychosocial factors often exacerbate chronic pain, prior health care providers may have treated patients as though their pain was not real.[242] In the absence of observable pathology, many people with chronic pain have been considered malingerers, liars, hysterics, drug-seekers, or considered to have a purely psychiatric problem.[20] Having struggled to be believed by past providers, patients may arrive in the physical therapy clinic prepared for another fight. Accepting that the patient's pain experience is real can accomplish a great deal in establishing rapport.

Psychological or socioeconomic challenges, sometimes beyond the patient's immediate control, compound difficulties. For example, depression makes it difficult for patients to adhere to their home program. Anxiety or catastrophization leads them to overreact, appearing to "symptom-magnify." Patients may be in the anger phase of the grieving process, grieving for the past life they have lost. Patients who believe in a purely biomedical model may arrive wanting the problem to be "fixed"; such patients may be passive about their care and unwilling to take an active role in pain management.

The effective clinician develops strategies for identifying and dealing with difficult behavior to enhance patient adherence and reduce the chance of frustration and burnout. Strategies to diffuse anger, relieve anxiety, eliminate ambiguity, and maintain appropriate professional boundaries are as important to clinical practice as the skillful application of any treatment technique.[212,239,240,243] Klyman et al[240] provide a useful mnemonic for working effectively with difficult patients, called *GUT REACTIONS*, described in Box 25.5.

Since a high proportion of people with chronic pain have experienced some form of abuse, physical therapists need to be sensitive to the needs of this population, especially given the importance of touch to physical therapy. Survivors of abuse may have difficulty distinguishing symptoms such as fatigue or hunger from distress or

Box 25.5 Mnemonic for Managing Difficult Patients: GUT REACTIONS[240]

- **G**: What is your *Gut reaction* to this patient?
- **U**: What can you *Understand* about the patient's feelings?
- **T**: How can your feelings and understanding guide your *Treatment*?
- **R**: Patients often *Regress* when facing illness, pain, and loss.
- **E**: How does the patient's *Environment* affect the condition or situation?
- **A**: *Anxiety* is important and often contagious to caregivers.
- **C**: *Consistency* and *Continuity* are important for effective care.
- **T**: *Tolerant* means listening to the patient's emotions, with their ambiguity, ambivalence, and conflicts.
- **I**: Attentive listening has an important *Influence* on the patient.
- **O**: The *Original* parent–child relationship may influence the patient–provider relationship.
- **N**: The caregiver's *Needs* should not be neglected.
- **S**: *Symptoms* serve a purpose and may have both physical and psychological causes.

pain; they also may have difficulty distinguishing between physical and emotional pain.[82-85,244] Physical therapists working with this population should know how to ask about and respond to revelations of past or present abuse.[82] An appropriate question would be: "Many people with chronic pain have had frightening or painful experiences, sometimes as a child. Has anything like this ever happened to you?" Since patients expect physical therapists to be asking about physical trauma, it may be necessary to clarify that physical, sexual, or emotional trauma in childhood can all contribute to chronic pain as an adult. The physical therapist's response to a revelation is critical to developing a trusting relationship. It should include an acknowledgement that those traumatic experiences are very difficult and can be stressful to live with, even as an adult, and that it takes great courage to talk about such experiences.

Survivors of sexual abuse often become stressed by physical contact needed in physical therapy and clinicians should be sensitive to their special needs. Physical therapists should be aware of strategies for working with survivors of childhood sexual abuse who may present with hypervigilance, anxiety, disempowerment, distrust, somatization, transference, or dissociative reactions.[82-85] Strategies include the following: ensure two-way communication; observe body language; establish positive rapport and a trusting therapeutic relationship; give the patient control and respect boundaries; obtain consent frequently; keep the patient an active participant; pay attention to physical stressors; recognize and respond to triggers; check in with the patient; and try alternative treatment approaches if the patient is uncomfortable.

Health care providers should also take care of their own emotional well-being. Chronic pain is difficult to treat, often leaving both patients and providers unsatisfied with the results. Clinicians may feel frustrated and inadequate, leading to stress and burnout.[212] Even when patient–provider interactions are constructive, the emotional needs of patients with chronic pain can lead to *empathy fatigue* for the clinician, a state of emotional, mental, and physical exhaustion.[245] Stebnicki[245] offers strategies for avoiding empathy fatigue: provide a support system within the facility where clinicians can discuss the stress of working with difficult patients, provide mentoring for new clinicians, encourage support networks outside the workplace, avoid having one clinician treat many difficult patients at one time, and promote education and wellness programs within the clinic or organization.

Subjective Examination

The subjective examination for a patient with chronic pain is based on the nature of the patient's complaints and presentation. A thorough subjective interview is critical for developing a physical therapy diagnosis, understanding the patient's narrative, and developing rapport with the patient.[210] Box 25.6 outlines the examination elements recommended in the *Guide to Physical Therapist Practice*. Questions about the pain should include a description of the pain (e.g., using the SOCRATES mnemonic described in Box 25.3) as well as addressing the emotional and functional consequences of the pain. Multidimensional pain assessment tools provide quantitative baseline data regarding pain severity and impact. The interview should also ask about nonpain signs and symptoms, including motor, sensory, and autonomic changes.[18] Follow-up questions should address psychosocial issues described above, such as abuse history, anxiety, depression, and so forth. Even if using a depression or anxiety assessment tool, verbal questions about these topics may help the patient appreciate the relevance to pain. Questions about the patient's use or abuse of medications, alcohol, or other drugs are also relevant.

Systems Review

The complex nature of chronic pain means that the systems review component of the patient examination is extremely important. Systems review in the *Guide to Physical Therapist Practice* includes cardiovascular/pulmonary, integumentary, musculoskeletal, neuromuscular, and communication components. Cardiovascular screening of vital signs examines whether there are cardiovascular restrictions to aerobic exercise. While measuring respiratory rate, clinicians should observe the breathing pattern, because overuse of accessory breathing muscles can aggravate pain. The integumentary system should be examined, particularly for old injuries or surgeries that could compromise fascial mobility or lymphatic flow. For patients presenting with widespread musculoskeletal pain, musculoskeletal screening should include the *Brighton Score as part of the Brighton Criteria* (Box 25.7) for hypermobility syndrome (also known as Ehlers-Danlos syndrome, hypermobility type).[246,247] Patients with hypermobility syndrome may present with diagnoses of fibromyalgia, myofascial pain syndrome, chronic headaches, or spinal pain; if the underlying hypermobility is not identified and addressed, treatment is more likely to fail.[248] Neuromuscular screening should include balance, locomotion, and transfers. Testing for clonus, hyperreflexia, and hypertonicity is important if there is any suspicion of serotonin syndrome (see section titled Pharmacological Management of Chronic Pain).[230] The communication, affect, cognition, and learning style component of the systems review is particularly important given the psychosocial aspects of chronic pain. Evidence shows that physical therapists are not accurate in determining the presence of depression[143] or fear avoidance[249] based on observation; consequently, screening tools are appropriate components of the systems review.[126-128]

Chronic pain often involves multiple body systems, such as the gastrointestinal system with irritable bowel syndrome or the urinary tract with chronic pelvic pain.[216] Goodman and Snyder[250] provide a comprehensive discussion of review of systems.

Box 25.6 Examination Elements Relevant to Chronic Pain[24]

Documentation of history may include the following:

- General demographics
- Social history
  - Abuse history
  - Other traumatic experience
- Employment/work (job/school/play)
- Growth and development
- Living environment
  - Support system
- General health status (self-report, family report, caregiver report)
  - Psychological health status may include screening tool for:
    - Anxiety disorder
    - Depression
    - Post-traumatic stress disorder
  - Symptoms other than pain, such as dizziness, fatigue, loss of balance, and so forth
  - Sleep disturbance
- Social/health habits (past and current)
  - Exercise habits
  - Use of alcohol or nonprescription drugs
- Family history
- Medical/surgical history
- Current condition(s)/chief complaint(s)
  - Pain assessment addressing all aspects of the pain experience
- Functional status and activity level
  - Self-report of activity or performance restriction
- Medications
- Other clinical tests

Systems Review

- Cardiovascular/pulmonary
  - Breathing pattern: diaphragmatic or chest breathing
- Integumentary
- Musculoskeletal
  - May include Brighton Criteria for hypermobility syndrome
- Neuromuscular
  - Gross mobility and coordination
- Communication, affect, cognition, learning style
  - Current emotional state

Tests and Measures

(Will vary depending on specific presentation and diagnosis)

- Aerobic capacity and endurance:
  - Physical performance measures such as 6-minute walk, 30 second sit-stand
- Anthropometric characteristics
- Arousal, mentation, and cognition
  - Pain beliefs, fear-avoidance beliefs, pain-related readiness to change
- Assistive and adaptive devices
- Circulation (arterial, venous, lymphatic)
  - Lymphedema
- Cranial and peripheral nerve integrity
  - Nerve tests for neurogenic pain, vestibular tests, sensation, including hyperalgesia and allodynia
- Environmental, home, and work (job/school/play) barriers
- Ergonomics and body mechanics
- Gait, locomotion, and balance
  - Balance, balance confidence, Timed Up and Go
- Integumentary integrity
  - Skin temperature, texture or turgor (for autonomic involvement)
- Joint integrity and mobility
  - Any joint disorder contributing nociceptive input
- Motor function
- Muscle performance
  - Including trigger point assessment
- Neuromotor development and sensory integration
  - Proprioception
- Orthotic, protective, and supportive devices
- Pain
  - Pressure point threshold (using an algometer)
  - Trigger point palpation
- Posture
- Prosthetic requirements
- Range of motion
- Reflex integrity
  - Upper motor neuron screens such as Babinski and Hoffmann
- Self-care and home management
- Sensory integrity
  - Proprioception
- Ventilation, respiration, and gas exchange
  - Respiratory pattern
- Work, community, and leisure integration or reintegration

Box 25.7 The 1998 Brighton Criteria for Hypermobility Syndrome, or Ehlers-Danlos Syndrome, Hypermobility Type[247]

The nine points of the Brighton score are assessed if the:

- Elbows hyperextend past 10° (1 point each side)
- Knees hyperextend past 10° (1 point each side)
- The 5th finger metacarpophalangeal joint extends past 90° (1 point each side)
- Thumb apposes to the forearm (1 point each side)
- Hands can be placed flat on the floor while standing with knees straight

Major Criteria

- Brighton score of 4 or more
- Joint pain in 4 or more joints for longer than 3 months

Minor Criteria

- Brighton score of 1–3 (or even 0 if age over 50)
- Pain in 1–3 joints, or back pain, for longer than 3 months
- Joint dislocation
- 3 or more instances of damage to the soft tissues (lesions)
- Exceptionally tall, slim build with unusually long, slender fingers ("Marfanoid habitus")
- Thin or unusually stretchy skin, stretch marks or scarring from minor cuts
- Drooping eyelids, short-sightedness or slanting eyes
- Varicose veins, hernia, or prolapse of the womb (uterus) or rectum

For a diagnosis of hypermobility syndrome to be confirmed, an individual should have:

- 2 major criteria **or**
- 1 major + 2 minor criteria **or**
- 4 minor criteria **or**
- 2 minor criteria + a first-degree relative (parent, child, brother or sister) with confirmed hypermobility.

Tests and Measurements

Body Structure and Function Measures

The specific body structure and function measures needed will be determined by how the patient presents, because each patient with chronic pain has different structural and functional involvement. If the clinician hypothesizes that a specific neuromusculoskeletal condition may be the cause of nociceptive, inflammatory, or peripheral neurogenic pain, the examination should include specific tests and measures for those conditions. For example, a patient with stroke-related pain may have shoulder instability, a patient with diabetic neuropathy may have carpal tunnel syndrome, or a patient with postconcussion headaches may have cervical instability. Patients with systemic pain conditions, such as MS, could have an acute musculoskeletal injury superimposed on the underlying chronic pain. Therefore, standard musculoskeletal and neurological tests may be appropriate.

On the other hand, not all positive findings indicate tissue damage relevant to that patient's chronic pain. Diagnostic imaging of the lumbar spine, for example, frequently identifies pathological structures even when no pain is present. Multiple computed tomography (CT) and magnetic resonance imaging (MRI) studies show high rates of disk herniation and spinal stenosis in persons without symptoms.[16,213,214] Furthermore, patients with central sensitization may have a positive response to many pain provocation tests due to hyperalgesia and allodynia. The current discussion will not address all the tests and measurements that could be performed, but will outline how testing might be modified for patients with chronic pain.

Palpation for tenderness may be useful for identifying tissue damage, muscle spasm, trigger points, or hyperalgesia and allodynia. Palpation can be quantified through use of an *algometer*, which measures palpation pressure. *Pressure pain threshold (PPT)* is the point at which pressure changes from comfortable pressure to slightly unpleasant pain.[251] The amount of pressure needed to create slightly unpleasant pain is decreased in involved structures. Changes in PPT may also be noted in remote sites, such as over the tibialis anterior in patients with neck pain. Decreased PPT at remote sites is an indication of hyperalgesia, providing evidence of central sensitization and predicting a poorer outcome.[252,253] Allodynia can be examined with light brushing or by using test tubes filled with cold and hot (40°C) water for thermal allodynia. Mechanical hyperalgesia or temporal summation can be examined with a dull needle or von Frey filaments.[174,181,189]

Many widespread pain complaints are associated with myofascial trigger points.[16,61,254] *Trigger points (TrPs)* are defined as ropelike taut bands within a muscle fiber. Palpation may elicit local tenderness or referral along the pattern specific for that muscle. To elicit the referred pain pattern associated with trigger points, pressure needs to be maintained for at least 10 seconds or only local tenderness will be detected.[255] Palpation of a TrP may elicit a local twitch response, a transient contraction of the muscle fiber, or a *jump response*, which is patient vocalization or withdrawal from the palpation. An *active TrP* exists when the patient reports spontaneous local or referred pain for that TrP. A *latent TrP* exists when local or referred pain is only elicited with palpation.[255,256]

An examination of balance and proprioception is often indicated because the primary injury or disease, deconditioning, and/or fear of movement may compromise balance.[257-265] Chronic pain has been associated with balance impairments and increased risk of falls among the elderly and even near-falls can exacerbate pain conditions by straining muscles. The specific choice of balance test depends on the patient (see Chapter 6, Examination of Coordination and Balance, for a discussion of balance tests). Some patients will have difficulty with a basic Romberg test, whereas others will have no

difficulty completing the Berg Balance Scale. Proprioception and motor control deficits perpetuate microtrauma and macrotrauma and pain. For example, post-stroke shoulder pain is associated with impaired proprioception,[261] and cervical joint position sense is compromised in patients with chronic neck pain.[262,263,265] Joint position sense can be examined using traditional tests for proprioceptive awareness (see Chapter 3, Examination of Sensory Function), a goniometer, or a laser pointer.[266,267]

Activity and Participation Measures

Activity limitations can be examined through either self-report or performance measures. Self-report of activity limitations may be nonspecific, disease specific, or customized for the patient. Activities commonly affected by chronic pain include physical functions such as walking, mobility, changing or maintaining body position, toileting, preparing meals, and doing housework. Activity limitation due to chronic pain may also include difficulty focusing attention or handling stress and other psychological demands (see Table 25.1).[23,25-28] Quantification of activity limitations or participation restrictions, independent of symptoms, allows the therapist to develop appropriate goals and outcomes when pain and other symptoms are not likely to resolve with intervention.[16] These tools may also be used to gather information about the impact that secondary problems, such as deconditioning, fatigue, sleep disturbance, or fear of movement, have on a patient's ability to participate in life situations. Many tools include separate sections for symptoms, activity, and participation components. For example, the *Revised Fibromyalgia Impact Questionnaire* (FIQR) has one section for symptoms, one section for activity restrictions, and one for the affective consequences of the illness.[268] Activity and quality-of-life tools should be culturally appropriate; the FIQR, for example, emphasizes housekeeping tasks that are generally less relevant for men. Ideally, tools should examine ability to perform activities without reference to pain, because the belief that activity should be discontinued with increased pain is counterproductive for people with chronic pain. The *Oswestry Low Back Pain Disability Questionnaire,* for example, asks how much each activity is restricted by pain, resulting in an examination of pain more than an examination of function or activity level. The *Patient-Specific Functional Scale (PSFS)* allows patients to identify specific functional activities of personal importance affected by their pain condition.[269] The PSFS is particularly helpful in identifying several key outcomes for a patient whose presentation may otherwise be somewhat overwhelming to the clinician. In some patients, symptoms other than pain can limit activity. For example, impaired balance is common among people with fibromyalgia; the *Activity-Specific Balance Confidence Scale (ABC)* can be used as a self-report tool for balance confidence.[270]

For patients with widespread pain, physical activity measures can assess multiple body regions with one test. For example, the *30-Second Sit-to-Stand Test*, *Timed Up and Go*, and *10-Meter Walk Test* are efficient ways to assess functional lower extremity (LE) strength and balance. Combined performance tests such as the *Short Physical Performance Battery* (SPPB), which combines sit-to-stand transitions, balance, and walking velocity, reflect activity and predict participation restrictions.[271,272] Although the SPPB was designed for the elderly, it provides an appropriate level of challenge for many adults with chronic pain. Formal functional capacity evaluations can be useful for establishing a person's physical work capability.[215] Chronic pain is often associated with deconditioning, which exacerbates activity and participation restrictions.[273] A 2- or 6-minute walk test can provide valuable information about endurance and willingness to exercise, as well as activity tolerance.

Chronic pain leads to participation restrictions such as impaired family relationships, inability to engage in employment, and compromised intimate relationships.[26] Participation restrictions are often included in self-assessment tools, either the multifactorial pain assessment or the activity assessment tools described above.

PHYSICAL THERAPY EVALUATION, DIAGNOSIS, AND PROGNOSIS

Evaluation

According to the *Guide to Physical Therapist Practice*, evaluation is a dynamic process integrating subjective and objective examination data to make clinical judgments.[24] One of the first clinical judgments in the evaluation of a patient with chronic pain is the identification of factors leading to, perpetuating, or exacerbating the pain. The ICF model identifies personal and environmental contextual factors that can affect body function or structure, activity, or participation. Personal factors contributing to chronic pain include age, gender, heredity, past and present experience, occupation, education, personality, coping strategies, and social or cultural background. Personal factors include such traits as anxiety, fear-avoidance, catastrophizing, depression, and low patient motivation. These traits may also be characterized as body function involvement (global psychosocial functions) in the ICF model (see Table 25.1).

Many contributing factors, such as age, gender, and heredity, are nonmodifiable. Personal history factors may also contribute to the patient's complaints; for example, PTSD or a history of childhood abuse is common among people with chronic pain conditions. It is important to realize that traumatic personal history not only contributes to psychological distress and maladaptive behaviors that exacerbate pain, but also changes the CNS to perpetuate chronic pain.[74,78,86,274,275] Just as a myocardial infarction caused by stress is just as real as any other myocardial infarction, chronic pain caused by distress or prior traumatic experiences is just as real as any other chronic pain. Whatever factors may contribute to a given patients' chronic pain, it is important for

health care providers to acknowledge that chronic pain has multiple contributing factors and affects the whole patient.[16]

Possible outcomes of the evaluation process may be referral to or consultation with another practitioner either instead of or in combination with physical therapy intervention. Yellow flags, suggesting psychosocial factors, were discussed under Psychosocial Factors Associated with Chronic Pain in a previous section of this chapter. Examples of red flags suggesting systemic involvement include personal or family history of cancer, recent infection, significant weight change without effort, pain unrelieved by rest or change in position, inability to relieve or provoke symptoms during the examination, night pain, pain in a visceral referral pattern, and certain associated signs and symptoms.[250] Readers are referred to Goodman and Snyder's *Differential Diagnosis for Physical Therapists* for an extensive discussion of how to screen for red flags.[250] Each patient's situation should be examined individually because many people with chronic pain have one or more red or yellow flags that may be readily explained, do not require referral, and do not interfere with physical therapy. However, multiple yellow or red flags should lead the physical therapist to consider whether referral to another health care provider is indicated, and whether that referral should occur at the same time as or instead of physical therapy intervention.[250] The judgment about who needs to be referred can be difficult with patients who have chronic pain, because they may have many yellow and red flags. When in doubt, the referring physician should be contacted to discuss these findings.

Chronic pain is often poorly correlated to physical findings; therefore, body structure and function findings are often consequences of chronic pain rather than causes. For example, CRPS is often associated with edema, autonomic signs, atrophy, and weakness resulting from the pain. Edema, in this case, would not be an indicator of local inflammation but related to disuse and sympathetic dysfunction. The physical therapist may therefore identify patient-nonspecific problems such as generalized weakness, decreased ROM, poor cardiovascular fitness, decreased function, and so forth.

Diagnosis

According to the *Guide to Physical Therapist Practice*, diagnosis is the process of integrating examination and evaluation information to develop a prognosis, plan of care, and intervention strategies. There are several different ways in which the physical therapist may need to categorize patients with pain. First, is the pain acute, persistent, or chronic? Is the pain nociceptive, inflammatory, peripheral neurogenic, or central neurogenic? Is the patient's presentation consistent with a defined syndrome? Identifying pathological or anatomical causes for the chronic pain is occasionally helpful, but often is not possible, and should not be the overriding emphasis of the diagnostic process. Acute conditions superimposed on and aggravating underlying chronic pain can and should be identified.[216]

Chronic pain often occurs in the absence of observed tissue injury or damage or when the amount of pain is not proportional to the observed tissue injury or damage. Acute or persistent pain may become chronic if peripheral or central sensitization occurs. In the case of patients with a 3-month or more history of pain, the physical therapist needs to decide whether the pain is truly chronic in the sense that it occurs in the absence of observed tissue injury or damage, or whether it is persistent but the causes have not been identified or addressed.[216] Persistent causes for acute and subacute pain must therefore be sought and identified. For example, a patient may have daily pain due to lumbar segmental instability, myofascial trigger points, or OA. In cases of persistent peripheral pain without central or peripheral sensitization, evaluation should identify the factors contributing to tissue damage and impeding healing. In lumbar instability, poor motor control is a modifiable contributing factor. The causes of isolated myofascial trigger points may be eliminated through patient education regarding body mechanics and the existing trigger points resolved through exercise or manual therapy. Although the underlying OA cannot be modified by physical therapy, the pain and activity limitations can be managed to minimize the patient's activity and participation restrictions. Persistent pain can be resolved or managed to the extent that the physiological, personal, and environmental contributing factors can be addressed and the tissue can heal.

Neurogenic pain can also be persistent or chronic. In cases where the nerve damage is reversible, neurogenic pain is similar to other forms of persistent pain. For example, mild carpal tunnel syndrome (with neuropraxia) can be managed to the extent that the contributing factors can be addressed and healing facilitated. Other forms of neurogenic pain, such as diabetic neuropathy or that associated with MS, involve permanent damage to neural tissue and, like the example of OA, can be managed to minimize the patient's activity limitations and participation restrictions. In cases where persistent musculoskeletal or neurogenic pain cannot be resolved, many of the intervention strategies for chronic pain can be beneficial.

A second decision the physical therapist needs to make in the diagnostic process is categorization of the type or types of pain: nociceptive, inflammatory, peripheral neurogenic, or central. Knowing the type of pain assists in determining prognosis, plan of care (POC), and intervention. For example, central pain generally has a poorer prognosis because the changes in the CNS are difficult or impossible to reverse and central sensitization is more likely to be self-perpetuated through psychosocial factors that lie outside the physical therapist's control. Patients may have multiple types of pain and the relative intensity of different types of pain may vary from day to day. For example, people with a central pain condition such as migraine often also have myofascial trigger

points provoking nociceptive pain. A flare of nociceptive myofascial pain may trigger a migraine and amplify central sensitization, which will further amplify nociceptive pain. Recognizing both components of pain improves the likelihood that intervention will be successful.[16,216] The discussion of common forms of chronic pain, earlier in the chapter, describes the types of pain occurring in various common conditions.

Prognosis

Prognosis determines "the level of optimal improvement that may be attained through intervention and the required amount of time required to reach that level" [24, p S682] Prognosis depends on personal and environmental factors identified in the evaluation process. Table 25.9 shows a variety of factors relevant for chronic pain that affect prognosis.[26-28] For example, yellow flags are associated with poorer prognosis in chronic LBP. Although some of these personal factors will compromise prognosis, others may be beneficial to the patient. For example, medical co-morbidities, anxiety, or a history of sexual abuse compromise prognosis, whereas a record of regular exercise, adequate stress management strategies, and good emotional function lead to an improved prognosis.

Pain readiness to change is a personal characteristic that is also related to prognosis. As with other forms of readiness to change based on the *Transtheoretical Model of Behavior Change*, individuals who are ready to change are more likely to incorporate pain management strategies into their lives, hence their prognosis is better. Patients resistant to change are unlikely to be compliant with rehabilitation and are less likely to benefit.[139,140,276]

Table 25.9 Environmental Contextual Factors Affecting Prognosis, Using ICF Terminology[25-27]

ICF Code	ICF Category Title
E355	Health professionals
E410, E425, E430	Attitudes of family, friends, colleagues, community
E450, E455	Attitudes of health and health-related professionals
E460, E570,	Social attitudes, services, and policies
E575	General social support services, systems, and policies
E580	Health services, systems, and policies
E590	Labor and employment services, systems, and policies
E540	Transportation services, systems, and policies
E135	Products and technology for employment
E155	Design and construction of buildings

Two tools for examining pain-related readiness to change are described in Table 25.4. Environmental factors such as having a support system, attitudes of friends and family, or access to comprehensive health care all affect prognosis. Table 25.9 lists a number of environmental factors relevant to chronic pain.[26-28]

Treatment goals for patients with chronic pain should deemphasize pain reduction and instead focus on restoration of activity and participation through self-management. Box 25.8 includes a range of general anticipated goals and expected outcomes for the patient with chronic pain. Studies show that activity and participation restrictions are often related more to fear-avoidance and deconditioning than to pain.[15,16] Functional restoration requires a biopsychosocial treatment approach emphasizing a supportive process for transferring to the patient primary responsibility for his or her physical and emotional well-being; independent long-term management is the primary desired outcome.[15] The Institute for Clinical Systems Improvement (ICSI) Chronic Pain Guidelines recommend five components to the goals: increased function, increased physical activity, stress management, improved sleep, and decreased pain.[16]

PHYSICAL THERAPY MANAGEMENT OF CHRONIC PAIN

The Multidisciplinary Pain Management Team

The principles of chronic pain management include a range of physical, psychological, vocational, and medical objectives (Box 25.9). The physical therapist's role in management of chronic pain depends on both the patient and the environment in which the therapist practices. Figure 25.4 shows the general progression of interventions from least invasive (e.g., independent exercise and over-the-counter medications) to most invasive (e.g., surgical interventions such as neuroablation, implanted spinal analgesia or stimulator). The specific order of implementation may vary based on patient preference; for example, some patients may prefer cognitive approaches to physical therapy or may prefer both physical therapy and cognitive-behavioral therapy (CBT) over medication use. A multidisciplinary pain management team may include any of the following health professionals: primary care physician, pain specialist, physiatrist, anesthesiologist, psychiatrist, psychologist, pharmacist, social worker, caseworker, physical therapist, occupational therapist, sleep specialist, or nurse.[2,277] Although multidisciplinary care has been shown to be more effective than monotherapy or standard medical care, the optimal components of multidisciplinary care have not been identified,[277] and the cost-effectiveness has been questioned.[278]

A physical therapist working within a multidisciplinary pain clinic may be able to refer psychological issues

Box 25.8 Anticipated Goals and Expected Outcomes

Impact of pathology/pathophysiology is reduced.

- Patient/client, family, and caregiver knowledge and awareness of the disease, prognosis, and plan of care are enhanced.
- Symptom management is enhanced.
- Risk of secondary impairment is reduced.
- Intensity of care is reduced.

Impact of restrictions due to body structure and function is reduced.

- Balance is improved.
- Endurance is increased.
- Joint integrity and mobility are improved.
- Motor function is improved.
- Muscle performance (strength, power, and endurance) is increased.
- Postural control is improved.
- Quality and quantity of movement between and across body segments are improved.
- Range of motion is improved.
- Relaxation is increased.
- Sensory awareness is increased.
- Pain is decreased.

Activity and participation restrictions are reduced.

- Functional independence in activities of daily living (ADL) and instrumental activities of daily living (IADL) is increased.
- Physical function is improved.
- Disability associated with chronic illnesses is reduced.
- Performance levels in self-care, home management, work (job/school/play), community, or leisure actions, tasks, or activities are improved.

Decision making regarding self-management is enhanced.

- Decision making is enhanced regarding health, wellness, and fitness needs.
- Decision making is enhanced regarding patient/client health and the use of health care resources by patient/client, family, significant others, and caregivers.
- Awareness and use of community resources are improved.
- Behaviors that foster healthy habits, wellness, and prevention are acquired.
- Decision making is enhanced regarding patient/client health and the use of health care resources by patient/client, family, significant others, and caregivers.
- Patient/client knowledge of personal and environmental factors associated with the condition is increased.
- Self-management of symptoms is improved.
- Utilization and cost of health care services are decreased.

Health status and quality of life are improved.

- Health status is improved.
- Risk of recurrence of condition is reduced.
- Safety of patient/client, family, significant others, and caregivers is improved.

Patient/client satisfaction is enhanced.

- Access to and availability of services are acceptable to patient/client and family.
- Quality of rehabilitation services is acceptable to patient/client and family.
- Care is coordinated with patient/client, family, caregivers, and other professionals.
- Patient/client and family feel care is compassionate.

Box 25.9 General Principles of Chronic Pain Management[3]

- Improve ability to cope with pain
- Teach nonpharmacological pain management techniques
- Increase physical strength, endurance, and cardiovascular fitness
- Increase mobility, independence, and functional activity
- Improve sleep
- Teach proper body mechanics
- Increase social and recreational activities
- Improve mood and cognitive function
- Decrease or eliminate dependence on medications
- Decrease overutilization of the health care system
- Improve psychological and emotional well-being
- Enhance vocational potential
- Provide vocational rehabilitation for paid work, volunteer work, and hobbies
- Enhance family communication and function

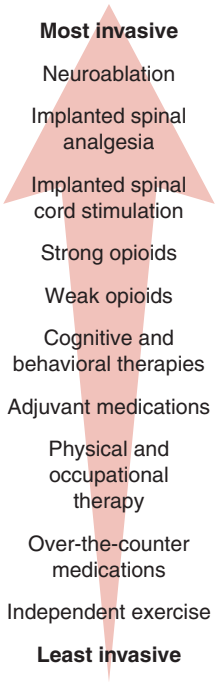

Figure 25.4 The pain management continuum starts with independent exercise, progresses to over-the-counter medications, physical or occupational therapy, cognitive-behavioral therapy, prescription medications, and medical (interventional) procedures. The order of intervention may change based on the patient's preference.

to the team psychologist and coping skills to the occupational therapist.[35] However, a therapist working in an isolated outpatient clinic might not have access to such collaborations and may need to integrate a broader range of components into the POC while remaining within his or her scope of practice. The following discussion emphasizes what may benefit patients with chronic pain; who provides a given service will depend on the context. In cases when multidisciplinary or specialist care is not available or practical, motivated patients may be able to pursue some aspects of their care independently. Appendix 25.D provides a sample personal care plan for chronic pain self-management.[16] Appendices 25.E and 25.F provide a list of resources for patients interested in taking responsibility for some aspects of their pain management program.

Note that some aspects of pain management, such as relaxation, are applicable to most patients with chronic pain, whereas other approaches are most appropriate for certain pain problems; for example, thermal biofeedback is well suited for migraines whereas stretching is appropriate for myofascial pain. The general principles of chronic pain management need to be adapted to the needs, preferences, and restrictions of any given patient. Appendix 25.C presents a summary of reviews of various chronic pain interventions.

Collaboration, Communication, and Documentation

Patients with chronic pain often have involvement of multiple body systems and may be working with several health care providers. Coordination of care and communication with other providers is essential to a comprehensive, patient-centered approach. It is especially important that the patient receive consistent information from providers regarding such things as the fact that there might not be current tissue damage other than that due to deconditioning, and the need to maintain activity in spite of pain. All providers should be consistent about encouraging functional goals rather than using pain ratings as a guide of treatment success.[216] Patients may need to be referred for consultation with other providers. Some referrals, such as to a psychologist or pain specialist, are obvious. Other potential referrals include a sleep clinic for patients suspected of having a sleep disturbance; occupational therapy for patients with trouble problem solving or managing their medical appointments; relationship counseling for patients whose relationships are stressed by chronic pain; and nutritional counseling, especially for patients whose obesity exacerbates their pain.

Patient/Client-Related Instruction

Patient/client-related instruction is critical when considering chronic pain as a chronic disease that the patient must learn to manage. For the current discussion, the *Guide to Physical Therapist Practice* categories of Functional Training in Self-Care and Home Management

and in Work, Community, and Leisure are combined with Patient-Related Instruction because so much of the content overlaps. The physical therapist should identify potential learning barriers such as difficulty concentrating, depression, or refusal to accept a biopsychosocial model of pain, or lack of readiness to change. The family may also require education about chronic pain to both recognize chronic pain as a real disease and to avoid fostering illness behavior in the patient. Box 25.10 identifies several components of patient and family education.

Patients need to understand what types of pain they have to most effectively manage their pain. For example, persistent pain due to OA requires joint protection strategies such as limiting painful activity whereas central sensitization pain requires that patients be encouraged to push through pain. An understanding of the nature of chronic pain and the dissociation between pain and tissue injury or damage helps patients appreciate that (1) hurt does not always mean harm; and (2) there may be no physical damage that surgery or medication can fix.[22,279] Patients need to understand the relationship between mind and body so they do not become defensive about suggestions of psychological management approaches.[216] While some patients will have qualified health providers helping them through the many psychosocial factors associated with chronic pain, many patients will benefit from the many excellent educational resources available.

Box 25.10 Goals of Educational Components of Chronic Pain Management[16]

The goals of patient education are for the patient to:

- Acknowledge that chronic pain is real
- Recognize the complex, biopsychosocial nature of pain, and need for multifaceted management program in which the patient is an active participant
- Understand the impact of pain on sleep, mood, energy, fitness, ability to work, family life, and stress
- Avoid letting pain guide activity or medication use because pain-based treatment encourages pain behavior
- Recognize and utilize wellness behaviors
- Recognize the role of poor posture and body mechanics in perpetuating pain
- Overcome fear of movement through gradual exposure to feared activities
- Learn relaxation strategies
- Actively participate in own management program
- Enlist family support and participation in management program
- Participate in an exercise program, either through physical therapy, independently, or using community resources
- Minimize fear of movement and activity reduction due to fear of movement

Appendix 25.F provides a selected list of books to educate patients about issues ranging from pain physiology to maintaining intimacy in the presence of chronic pain. Web-based resources for clinicians, families, and patients with chronic pain can be found in Appendix 25.E.

Self-care training in all environments is critical to effective management of chronic pain (Fig. 25.5).[280] A sample personal care plan is shown in Appendix 25.D. This personal care plan combines goals with patient responsibilities for self-care, including physical therapy, independent exercise, stress management, and sleep hygiene; medications may be included as part of the self-care program. All patients should recognize the role of poor posture and body mechanics in perpetuating pain syndromes.

Since focus on pain and pain reduction causes individuals to become hypervigilant, patients, families, and health care providers need to deemphasize pain severity as a measure of status. Patients should therefore set functional goals that emphasize coping skills and wellness behavior rather than pain-based goals.[35] Graded activity should be performance rather than pain based, reassuring patients that "hurt" does not always lead to "harm" to overcome the fear-avoidance belief.[3,16,22,279] The *Patient-Specific Functional Score* encourages patients to identify and track personally relevant functional goals.[281]

People with chronic pain often need to be encouraged to return to previously enjoyable recreational activities. Some patients feel that they hurt too much to participate in leisure activity or that they should not indulge in pleasurable activities if they are unable to perform "necessary" tasks such as work or home care. Losing pleasurable activities, however, aggravates depression, loss of social life associated with those activities, and deconditioning. Consequently, people with chronic pain may need to schedule leisure and recreational activities and set specific goals including such activities.

Since sleep disturbance is a common occurrence in chronic pain, patients should be educated in proper sleep hygiene. Basic sleep hygiene involves avoiding caffeine, nicotine, alcohol, and medications containing stimulants, especially before bedtime. Sleep hours should be consistent; environmental distractions such as light, noise, and cold should be minimized; stress should be minimized through relaxation or meditation activities. Exercise generally improves quality of sleep, as long as vigorous exercise is avoided within 4 hours of bedtime. Gentle exercises such as stretching, yoga, Qigong, or Tai Chi may improve quality of sleep.[3,50,282-286]

Patients need to understand that stress contributes directly to pain; some patients will be relieved to realize that sympathetic efferents connect directly to nociceptive afferents and the pain-amplifying effects of stress are not all "in their minds."[49] Relaxation can thus decrease pain through reducing nervous system tone, muscle activity, and neuroendocrine reactivity.[14,50] Relaxation techniques include diaphragmatic breathing, biofeedback, progressive

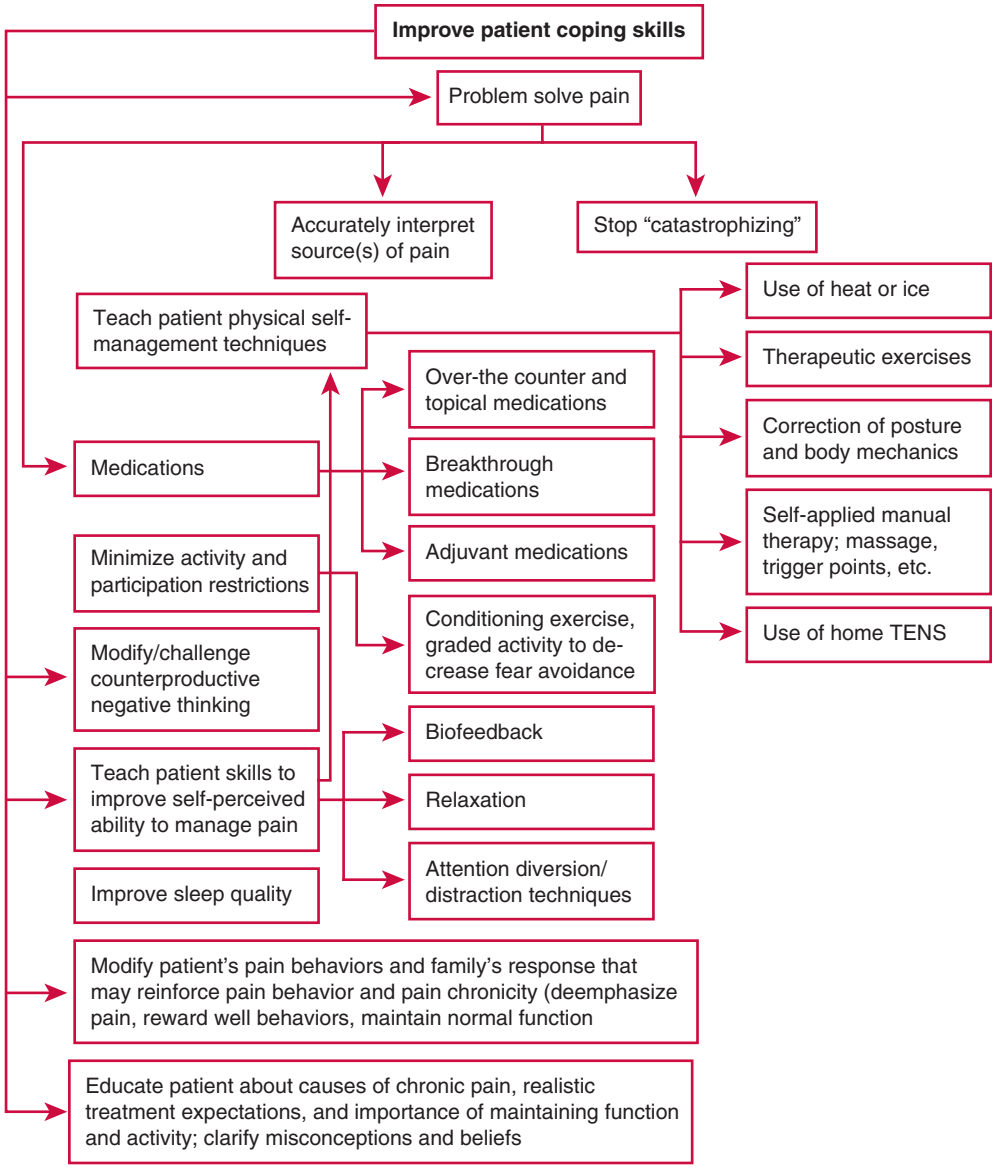

Figure 25.5 Behavioral management of chronic pain. Patients should be educated so that they recognize the various cognitive and behavioral strategies they can use to manage their pain. *Adapted from Mueller, 2000, who proposed a similar model for behavioral management of chronic headaches. Mueller, L: Psychologic aspects of chronic headache. J Am Osteopath Assoc 100(9 Suppl):S14, 2000.*

relaxation, stretching, aerobic exercise, imagery, autogenic training (imagining warmth or heaviness of the limbs), yoga, and meditation.[16] Biofeedback will be discussed below in the section titled Neuromuscular Reeducation under Procedural Interventions. Mindfulness meditation has been successful for managing stress-related diseases such as heart disease and chronic pain. Mindfulness and acceptance-based meditation uses focus on the present moment, attending to thoughts, emotions, sensations, and perceptions without judgment.[16,287-289] The acceptance aspect of mindfulness meditation helps patients differentiate between pain sensations and suffering, hence improves coping. Appendix 25.E includes several patient resources for learning mindfulness meditation.

Physiological quieting and self-regulation use relaxation training for both physiological and psychological regulation to correct some of the autonomic and neural dysfunctions associated with chronic pain. Although developed for TMJ pain, the principles are generally applicable to other forms of stress-related pain. Self-regulation training includes (1) education and reassurance, (2) strategies to monitor and reduce abnormal muscle function, (3) proprioceptive awareness training, (4) postural relaxation training, (5) diaphragmatic breathing, (6) methods of

improving sleep onset, and (7) instruction regarding physical activity, diet, and fluid intake.[14] Hulme[290] recommends a similar self-regulating program for fibromyalgia, emphasizing sleep routine, physiological quieting, nutrition, exercise, medication, positive self-talk, rest/work cycles, pacing/prioritizing, dressing, modalities, and journaling. Hulme's compact disc (CD) guiding individuals through physiological quieting is included in the Resources for Patients in Appendix 25.F.

Patients may benefit from *cognitive-behavioral therapy (CBT)* in which beliefs, attitudes, and behaviors are modified to alter the experience of pain, overcome fear-avoidance, improve function, and minimize disability.[16,35,232,233,291] Beissner et al[291] propose that some CBT techniques lie within the scope of physical therapy practice because therapists already educate patients about relaxation strategies, graded activity, pacing, and identification of counterproductive thought patterns.[14] For therapists working with children, von Baeyer and Tupper[292] present behavioral approaches specifically for working with children. Components of CBT include the following:[14,16,35,291,293]

- Education about the nature of chronic pain, that it might not be associated with damaged tissue, and the importance of self-management.
- Education regarding the impact that cognition (thoughts, beliefs, and behaviors), emotions (fear of pain), and behaviors (activity avoidance due to fear of pain) have on the pain experience. Patients need to accept that self-management includes psychological as well as physical aspects of pain and this does not mean the pain is purely psychological.
- Behavioral activities to improve function, such as activity pacing, pleasurable activity scheduling, relaxation training, diversion, biofeedback, functional restoration, graded activity, and goal setting.
- Cognitive activities to improve responses to pain, such as cognitive restructuring and problem solving. For example, patients could identify and challenge spontaneous thoughts leading to negative emotions and substitute positive coping strategies. Problem solving can overcome barriers such as those associated with regular exercise. Building new narratives based on healthy perceptions can modify abnormal cognitive processes seen in chronic pain and some associated disorders, such as PTSD.[78]
- Development of maintenance strategies to manage pain flares, anticipate future problems, ensure adherence, and progression of exercises and self-care.

Many aspects of CBT are naturally integrated into the POC, such as graded exercise, pacing, problem solving, and functional restoration.[294] For physical therapists unfamiliar with CBT, Rundell and Davenport[293] provide a case report demonstrating the integration of CBT into management of a patient with chronic LBP. Evidence suggests that CBT strategies can modify several yellow flags associated with disability in chronic pain such as pain beliefs, self-efficacy, and psychological distress.[147,294] Although formal instruction in CBT strategies is preferred, patients may also learn many strategies independently using one of the self-help resources listed in Appendix 25.E. Figure 25.5 shows how a variety of behavioral tools can be integrated into self-management of pain.

Self-care strategies may include a variety of self-applied techniques such as heat, ice, massage, topical rubs, or TENS. Although research into the benefit of TENS for chronic pain remains inconclusive, practice guidelines recommend use of TENS if it increases patient function and activity or decreases need for medications.[15,16,295] Other self-care devices may include home lumbar or cervical traction units, paraffin, or hot tubs. Patients with trigger points may benefit from a trigger point cane or tennis balls in a sock to treat persistent trigger points. Several books listed in Appendix 25.F can be helpful for patients managing multiple and variable trigger points. Patients should understand that the purpose of decreasing pain is to increase function; they should not develop a passive approach limited to pain reduction.

Family and/or caregiver education can be just as important as patient education. Chronic pain affects the whole family through changes in family roles due to the patient's activity and participation restrictions. The family may reinforce the patient's "sick role" in an attempt to be supportive. Both the patient and the family need to understand the importance of maintaining normal activities and participation to minimize disability; patients must not perceive lack of physical assistance as lack of support or concern from family. In contrast, the family may be completely unsupportive, often owing to lack of objective evidence that the pain is real. Family members may be angry with the individual with pain and may blame that individual for financial, personal, or family problems.[3,296]

Personal intimacy is often very difficult with chronic pain, just as it is for other chronic injuries or diseases. Problems may be due to the pain, deconditioning and fatigue, depression, decreased sense of self-worth, or adverse reactions of medications. Distress is often greater for survivors of childhood sexual abuse.[297] It is important that both partners learn about chronic pain so that they understand the reasons for challenges faced. Both partners need to accept that the nature of the intimate relationship can change and not harbor anger, frustration, blame, or guilt. Individuals with chronic pain can improve their self-image through daily exercise, grooming, and cognitive strategies of CBT. Communication is critical so that both partners can contribute suggestions for problem solving. For example, select a time of day with the least amount of pain and fatigue and find positions that minimize stress

to the body. Appendix 25.E includes several patient resources for working through the challenges of intimacy with chronic pain.

Procedural Interventions

Therapeutic Exercise

Therapeutic exercise is a key part of chronic pain management.[3,15,16,216] Exercise is associated with decreased pain complaints and protection from future development of pain among individuals with PTSD.[78] Graded exercise directed at decreasing fear-avoidance can overcome the poor prognosis associated with the behavior.[89] Postural exercises to improve posture and body mechanics, as well as to decrease muscular imbalances, help decrease chronic stress on musculoskeletal structures. Aerobic conditioning improves function through counteracting deconditioning that typically occurs as people with chronic pain become sedentary.[3,15,16] Function-based exercises improve tolerance for functional activity. Overall, no one type of exercise (e.g., aerobic, strengthening, stretching, balance, aquatic) is superior to others. Individual patients may tolerate and respond to some forms of exercise better than others. For example, individuals with OA or fibromyalgia are likely to respond well to aquatic therapy in a (warm) therapeutic pool.[15,16]

Since falls and sensory motor problems are more common among individuals with chronic pain,[257-265] balance and proprioceptive training are often important components of the exercise program. A great variety of balance-improving exercises can be integrated into the program. Joint position sense can be both tested and trained using a goniometer or laser pointer.[265-267] For example, in the cervical spine, a laser pointer attached to the patient's eyeglasses or to a plastic hair band can be aimed at a target; patients may practice accurate repositioning or fine motor coordination while tracking shapes. Since proprioceptive information from the cervical spine is integrated with visual and vestibular input, eye and vestibular exercises can be beneficial in conditions involving the cervical spine.[263]

Graded exercise should begin at a level the patient can perform and then gradually increased. Patients need to recognize that some soreness and discomfort is typical and to be expected when beginning an exercise program. They should be reminded that hurt does not always indicate harm or tissue damage. People with chronic pain often have trouble distinguishing psychological distress from physical pain, so they need guidance distinguishing fear of movement from actual pain. Proprioceptive and motor control impairments can affect the ability of people with chronic pain to perform exercises correctly, so repeated feedback during exercise instruction can maximize safety and success. Kinesiophobia can be reduced if early efforts at exercise are successful.[89] Specific performance-based targets can prevent overly enthusiastic patients from overdoing their exercise.

Patients will be most motivated if exercises relate directly to functional goals. For example, a patient who wants to go to the movies with his wife could follow an exercise program designed to overcome his specific obstacles, such as walking from the car to the theater and sitting comfortably through the movie. Exercises with a social component help address isolation often experienced by people with chronic pain; for example, group exercise programs, active family involvement, or dancing can make exercise more enjoyable.

Certain chronic pain conditions respond to specific types of exercise or neuromuscular reeducation. For example, phantom limb, CRPS, dystonia, and stroke are typically associated with changes in sensory and motor mapping in the sensorimotor cortex. In these cases, sensory input through use of a myoelectric prosthesis, virtual reality or mirror training, or sensory discrimination training stimulates cortical reorganization that is generally associated with decreased pain.[216,298,299]

Manual Therapy

Manual therapy may be beneficial in the case of persistent pain with ongoing nociceptive input or in cases where central sensitization is perpetuated by peripheral nociceptive input.[15,16,300] Manual therapy may resolve a transient flare of central sensitization, and thus decrease other symptoms of central sensitization such as hyperalgesia and anxiety.[301] A recent systematic review concluded that manual therapy including manipulation and muscle energy techniques appears to be effective for chronic LBP and knee pain; however, the evidence was weak for other manual therapies (Swedish massage, Feldenkrais, and reflexology) and other sources of chronic pain (fibromyalgia and neck pain).[302] However, this does not confirm that manual therapy is ineffective in other forms of pain.[236] Because manual therapy is unlikely to alleviate the pain completely and there is a risk of patients becoming dependent on it, use of passive manual therapy modalities should be limited. Using massage and trigger point management as maintenance therapy may be part of the patient's self-care program.[15,16]

Neuromuscular Reeducation

Neuromuscular reeducation using EMG biofeedback can teach patients to relax overactive muscles and isolate functional muscles without widespread over-recruitment. Diaphragmatic breathing can also stimulate a relaxation response. Yoga, Tai Chi, or Qigong may be beneficial both through their relaxation effect, proprioceptive training, alleviation of fear-avoidance behavior, and perhaps sleep enhancement, and alleviation of depression and anxiety.[3,50,282-286]

Biofeedback, which uses feedback to the patient to teach modified neural control, can also stimulate a relaxation response and decrease autonomic function associated with stress.[231] A variety of biofeedback devices can be used with chronic pain. Electromyogram works

by measuring the intensity of muscle activation. It can be used to teach patients how to relax specific muscles by teaching them to decrease muscle activity. For example, patients with TMJ pain can learn to relax the masseter. Once patients learn to relax the target muscle, they are progressed to maintain or restore that relaxation after adding physical activity such as standing and walking or after visualizing stressful images. Electromyography works well with conditions involving excessive muscle tension or trigger points.[14,282] In some cases, research has identified subgroups more or less likely to benefit; for example, people with cramping phantom limb pain are more likely to benefit from EMG than those with burning pain.[282] Galvanic skin response (GSR) works through controlling the autonomic nervous system and decreasing the stress response. Heart rate variability is a newer form of biofeedback in which autonomic balance is restored by synchronizing breathing with low-frequency patterns.[231,303] Skin temperature can be an effective way to stimulate parasympathetic activity by placing the thermistor (temperature sensor) on the hand and imagining the hands becoming very warm. Temperature biofeedback is also used for migraines, by placing the thermistor directly on the patient's forehead. Respiration rate and heart rate can also be used as biofeedback measures.

Assistive Devices

Patients with persistent activity limitations due to defined physical impairments may benefit from assistive devices to improve function. Patients with joint disorders, such as OA or RA, should consider devices that decrease stress to affected joints. For example, shoe orthotics and knee braces have strong evidence for modest improvements for OA of the knee.[304] Other devices that decrease stress to joints include items such as jar openers and carts for transporting groceries. Conditions associated with focal weakness, such as stroke or MS, may benefit from braces or splints to support weakened structures and decrease muscle length and strength imbalances. Each patient's specific situation needs to be examined and evaluated, because over-reliance on splints and appliances to protect painful regions in the absence of specific pathology can be counterproductive if it reinforces pain and illness behavior.[216]

Physical and Electrotherapeutic Modalities

Evidence for passive physical modalities such as heat, cold, ultrasound, laser, traction, or TENS in the treatment of chronic pain is controversial with weak evidence.[234,305-307] For patients who appear to benefit from such a modality, consideration should be given to whether it can be provided as a self-care strategy such as a home TENS[216] or home traction unit. When instructing a patient in use of a home TENS unit, consideration should be given to use of acupuncture-like parameters (low frequency), which stimulate an endorphin response, rather than traditional TENS, which stimulates a gate control mechanism.[308]

COMPLEMENTARY AND ALTERNATIVE APPROACHES

Complementary and alternative approaches include active therapies such as yoga and Tai Chi, mental therapies such as hypnosis and meditation, manual therapies such as acupuncture and Reiki, devices such as magnets, and herbal and nutritional supplements. Magnets, herbal medicines, and supplements are beyond the scope of this chapter. Since 35% to 63% of people with chronic pain use these approaches,[50,282] physical therapists should be familiar with how they may be integrated into a comprehensive POC.

Movement therapies such as yoga, Tai Chi, and Qigong now have substantial support as forms of exercise for improving flexibility, strength, balance, and proprioception, and decreasing fear of movement.[3,50,282-286] Not only do these activities have physical benefits, they also foster relaxation and independence, both of which are important components of self-management. Furthermore, many of these activities are practiced in a community-based group setting, which addresses issues of isolation and loss of recreational activities.

Manual techniques include acupuncture, chiropractic, massage, Reiki, and therapeutic touch. Insofar as chiropractic includes manual therapy of the spine, it is a potentially effective component of management for spinal pain.[15,16,282] Acupuncture is now practiced in both nontraditional and traditional health settings. Extensive research shows that it can be a beneficial component of pain management, especially when pharmacological options are limited due to co-morbidities or adverse reactions. Various forms of massage have shown temporary benefit for chronic musculoskeletal pain conditions, but long-term benefit occurs only when combined with exercise and patient education.[282] Some of the less common manual approaches, such as Reiki, therapeutic touch, and craniosacral therapy, have inconclusive evidence regarding benefit for chronic pain. It is likely that patients experience a relaxation response with most of these manual approaches; while relaxation is beneficial, active self-directed methods of relaxation are preferable to passive approaches in which patients depend on health care providers.

Mind-body therapies include meditation, mindfulness-based stress reduction, and hypnosis. Biofeedback, CBT, and relaxation training, which were once considered alternative approaches, have now become standard components of pain management. Mindfulness meditation has the longest history of research supporting its beneficial effects for a variety of chronic health conditions.[282,288,289] Hypnosis has been found to be at least as effective as other cognitive and physical interventions for pain; patients are often taught self-hypnosis to facilitate self-management.[173,282,309,310] Mind-body practices

appear to work through decreasing stress, anxiety, and dysfunctional thought processes that subsequently decrease autonomic and central arousal, as well as diminish the perception of suffering.[50]

In summary, several complementary and alternative approaches have documented benefit for patients with chronic pain while others do not. In general, side effects are minimal, especially compared to some of the pharmacological and surgical interventions. A few, such as acupuncture or chiropractic manipulation, have specific physical benefits while others, such as the movement and mind-body activities, enhance overall physical fitness and relaxation. Those approaches that foster independent self-management and functional improvements can be appropriate components of a chronic pain self-management plan.

SUMMARY

Chronic pain is a disease process affecting all aspects of the patient's life. The biopsychosocial model integrates physiological, psychological, and social factors, each contributing to the development and experience of chronic pain. Pain may be classified in various ways and the classification can guide selection of interventions. Nociceptive, peripheral neurogenic, and central neurogenic pain each require different intervention approaches, though many chronic pain conditions include a combination of these pain mechanisms. Chronic pain differs from acute pain in that it is not always associated with tissue damage. Peripheral and central sensitization allow pain to be perpetuated even in the absence of peripheral tissue involvement. Intervention therefore needs to address contributing factors and sequelae of chronic pain, such as fear-avoidance, deconditioning, and illness behavior.

Effective management of chronic pain needs to address the whole patient and often also the patient's family. While many interventions can benefit people with chronic pain, the ultimate goal is to help the patient develop a self-management program that maximizes functional activity and minimizes participation restrictions. Although chronic pain is best managed in a multidisciplinary environment, physical therapy can provide significant benefits with or without a pain management team. Physical therapists provide patient education, neuromuscular reeducation, graded exercise, and functional training that are critical to minimize activity and participation restrictions. Although the disease chronic pain cannot be "cured," physical therapy can offer patients hope for an improved quality of life.

Questions for Review

1. Where in the nervous system is pain interpreted?
   a. Substantia gelatinosa
   b. Nociceptors
   c. Limbic system
   d. Cerebral cortex
2. According to the Gate Control Theory, modulation of painful input is achieved through:
   a. Presynaptic inhibition of the transmission cell
   b. Postsynaptic inhibition of the transmission cell
   c. Presynaptic excitation of the transmission cell
   d. Postsynaptic excitation of the transmission cell
3. The Gate Control Theory may explain the analgesic properties of all of the following treatments except:
   a. Conventional transcutaneous electrical nerve stimulation
   b. Acupuncture
   c. Massage
   d. Vibration
4. Contrast the physiology and presentation of acute versus chronic pain.
5. Contrast the biomedical and biopsychosocial models applied to pain.
6. List and propose the mechanism for five risk factors contributing to chronic pain.
7. Explain central sensitization.
8. Outline the components of a physical therapy examination for a patient with chronic pain.
9. Describe several educational and behavioral principles that physical therapists can integrate into the plan of care for patients with chronic pain.

CASE STUDY

HISTORY

The patient is a 28-year-old married female. During the interview, she avoids eye contact, bites her nails, and provides minimal answers to your questions. She does not work outside the home because she has been unable to keep a job as a result of her headaches (HA) and other pain complaints. Her current primary complaint is of HA, neck pain, and jaw pain, though she also reports low back and left (L) shoulder pain. She has had severe HA since age 12, but they became constant after a motor vehicle accident last year. She is sensitive to light, sound, and perfumes. Her HA are over the forehead, behind her right (R) eye, and over the back of her head. She also has dizziness when she stands up or turns suddenly. She has ringing in her R ear and the sensation that both ears are "stopped up." She reports grinding her teeth at night.

PAST MEDICAL HISTORY

Diagnosed with migraines since age 15 and chronic daily headache after her whiplash injury last year. She reports irritable bowel symptoms of abdominal cramps and frequent diarrhea since age 14. She notes that she does not sleep well and has not since she was a child. She has been diagnosed with depression and post-traumatic stress disorder (PTSD).

DEMOGRAPHICS (INCLUDING PSYCHOLOGICAL, SOCIAL, AND ENVIRONMENTAL FACTORS)

Her husband works construction and does not have work for winter months; consequently, money is always tight and is a source of stress between her and her husband. She is on Medicaid; she has applied for disability but been rejected. She reports that her husband is not supportive of her medical complaints and he tells her she is lazy. During follow-up questioning regarding her PTSD she reluctantly reveals that she was repeatedly sexually abused by neighborhood boys when she was a child (ages 11 to 13); that abuse included both vaginal and oral sex. She has had flashbacks and nightmares about the abuse since she was 11 and continues to be afraid of going to sleep for this reason. She states that she does not have a counselor because she is on Medicaid and there are no available counselors; she has been on a waiting list for psychological services for 2 years. She considers her life very high stress; her only stress management strategy is to watch TV and smoke. She reports smoking one-half pack of cigarettes per day; she denies drinking alcohol or using recreational drugs.

MEDICATIONS

Zoloft 50 mg daily (for depression, anxiety, and PTSD), tramadol 50 mg 3 times/day (for pain), Maxalt nasal spray 5 mg (for migraines) PRN, which she uses 1 or 2 times/day because she has migraines daily.

SYSTEMS REVIEW

- *Cardiovascular/pulmonary*: HR 84, BP 95/68, RR 18/min.
- *Integumentary*: No gross abnormality noted.
- *Musculoskeletal*: Brighton score: B elbow and knee hyperextension, B thumb apposition to forearm; standing trunk flexion: hands flat on floor. No gross asymmetry or weakness. Height 5 ft 4 in, weight 145 lb, endomorphic build.
- *Neuromuscular*: Locomotion and transfers normal; resting tremor in the hands.
- *Communication, affect, cognition, learning style*: Flat affect, withdrawn, anxious. Unable to determine learning style.

TESTS AND MEASURES

Self-Care and Activities of Daily Living

Headache Impact Test HIT-6 score of 72/78 (36 = minimum participation restriction, 78 = maximal participation restriction). Patient-Specific Functional Scale: work 10 hours/week outside the home, current ability to perform = 0/10 (0 = unable, 10 = able to perform normally); able to do 2 hours/day of housework and cooking meals 5 days/week, current ability to perform = 3/10.

Posture

Severe forward head, forward shoulders, flat mid-thoracic spine, increased upper thoracic kyphosis and upper cervical lordosis.

Range of Motion

Neck ROM excessive in all directions, with exacerbation of HA on flexion and extension. Cervical extension demonstrates poor motor control with excessive jutting of the chin. Temporomandibular joint opening restricted to about 50%.

Cranial and Peripheral Nerve Integrity

Upper quadrant neurological screen: Normal myotomes and reflexes. Dermatomes normal for light touch except for hypersensitivity and allodynia to light touch over the posterior scalp.

Cranial nerve testing: Normal except for (1) dizziness and increased HA with eye movement for cranial nerve (CN) III, CN IV, CN VI; (2) hypersensitive with allodynia to light touch over the CN V distribution; (3) increased temporal pain with strength testing of the masseter and temporalis.

Joint Integrity and Mobility

Mild ligamentous laxity noted in the transverse ligament. Unable to assess segmental mobility of cervical vertebrae due to patient guarding. Tender over OA, AA, C2/3, T3–5 facets B.

Cervical joint position error excessive for all cervical motions (normal is less than 4.5°).

Muscle Performance

Deep neck flexor strength decreased with poor motor control and limited endurance. Patient unable to correct motion with cueing.

Muscle palpation: Active trigger points B sternocleidomastoid (SCM), masseter, suboccipitals. Pressure to SCM aggravates frontal and retro-orbital HA and increases tinnitus; pressure to masseter increases pain over the temporomandibular joint and tinnitus. Diffuse spasm and tenderness throughout neck and upper back.

Ventilation, Respiration, and Gas Exchange: Breathing Pattern

Excessive use of accessory breathing muscles, which protrude visibly; patient is unable to perform diaphragmatic breathing even when cued to do so.

Circulation

Vertebral artery test: No symptoms at end range for 15 sec; increased dizziness on return to neutral.

GUIDING QUESTIONS

1. Are the sources of this patient's pain nociceptive, peripheral neurogenic, or central neurogenic?
2. How do psychosocial factors in this case contribute to chronic pain?
3. What psychosocial assessment or screening tools might be appropriate to perform with this patient? How might you apply the results of these tools, recognizing that she currently has limited access to psychology or counseling services?
4. What are the symptoms of serotonin syndrome? What physical tests should you perform if you suspect serotonin syndrome, and what results would raise concern?
5. Does this patient have hypermobility syndrome? If so, how does that contribute to her pain?
6. Identify three anticipated goals and three expected outcomes for this patient.
7. What are three interventions you can do in the clinic to reduce central sensitization? What are three community-based activities you can encourage her to participate in to reduce central sensitization?

Pain Catastrophizing Scale

appendix 25.A

Everyone experiences painful situations at some point in their lives. Such experiences may include headaches, tooth pain, joint or muscle pain. People are often exposed to situations that may cause pain such as illness, injury, dental procedures or surgery.

Instructions: We are interested in the types of thoughts and feelings that you have when you are in pain. Listed below are thirteen statements describing different thoughts and feelings that may be associated with pain. Using the following scale, please indicate the degree to which you have these thoughts and feelings when you are experiencing pain

RATING	0	1	2	3	4
MEANING	Not at all	To a slight degree	To a moderate degree	To a great degree	All the time

E

When I'm in pain ...

Number	Statement	Rating
1	I worry all the time about whether the pain will end.	
2	I feel I can't go on.	
3	It's terrible and I think it's never going to get any better	
4	It's awful and I feel that it overwhelms me.	
5	I feel I can't stand it anymore	
6	I become afraid that the pain will get worse.	
7	I keep thinking of other painful events	
8	I anxiously want the pain to go away	
9	I can't seem to keep it out of my mind	
10	I keep thinking about how much it hurts.	
11	I keep thinking about how badly I want the pain to stop	
12	There's nothing I can do to reduce the intensity of the pain	
13	I wonder whether something serious may happen.

Primary Care Post-Traumatic Stress Disorder Screen

In your life, have you ever had any experience that was so frightening, horrible, or upsetting that, **in the past month**, you:

1. **Have had nightmares about it or thought about it when you did not want to?**
   YES / NO

2. **Tried hard not to think about it or went out of your way to avoid situations that reminded you of it?**
   YES / NO

3. **Were constantly on guard, watchful, or easily startled?**
   YES / NO

4. **Felt numb or detached from others, activities, or your surroundings?**
   YES / NO

Current research suggests that the results of the PC-PTSD should be considered "positive" if a patient answers "yes" to any three items.

A positive response to the screen does not necessarily indicate that a patient has Posttraumatic Stress Disorder. However, a positive response does indicate that a patient *may* have PTSD or trauma-related problems and further investigation of trauma symptoms by a mental-health professional may be warranted.

Appendix D - Personal Care Plan for Chronic Pain

This tool has not been validated for research; however, work group consensus was to include it as an example of a patient tool for establishing a plan of care.

1. Set Personal Goals

- ☐ Improve Functional Ability Score by _____ points by: Date _____
- ☐ Return to specific activities, tasks, hobbies, sports...by: Date _____
  1. _____
  2. _____
  3. _____
- ☐ Return to ☐ limited work/or ☐ normal work by: Date _____

2. Improve Sleep (Goal: ____ hours/night, Current: ____ hours/night)

- ☐ Follow basic sleep plan
  1. Eliminate caffeine and naps, relaxation before bed, go to bed at target bedtime _____
- ☐ Take nighttime medications
  1. _____
  2. _____
  3. _____

3. Increase Physical Activity

- ☐ Attend physical therapy (days/week _____)
- ☐ Complete daily stretching (_____ times/day, for _____ minutes)
- ☐ Complete aerobic exercise/endurance exercise
  1. Walking (_____ times/day, for _____ minutes) or pedometer (_____ steps/day)
  2. Treadmill, bike, rower, elliptical trainer (_____ times/week, for _____ minutes)
  3. Target heart rate goal with exercise _____ bpm

  Strengthening
  1. Elastic, hand weights, weight machines (_____ minutes/day, _____ days/week)

4. Manage Stress – list main stressors _____

- ☐ Formal interventions (counseling or classes, support group or therapy group)
  1. _____
- ☐ Daily practice of relaxation techniques, meditation, yoga, creative activity, service activity, etc.
  1. _____
  2. _____
- ☐ Medications
  1. _____
  2. _____

5. Decrease Pain (best pain level in past week: ____ /10, worst pain level in past week: ____ /10)

- ☐ Non-medication treatments
  1. Ice Heat _____
  2. _____
- ☐ Medication
  1. _____
  2. _____
  3. _____
  4. _____
- ☐ Other treatments _____

Physician name: _____ Date: _____

Psychosocial Disorders

Pat Precin, MS, OTR/L, LP

Chapter 26

LEARNING OBJECTIVES

1. Discuss the psychosocial factors that influence rehabilitation.
2. Explain the impact of psychological functioning and social interaction on health, disease, accident proneness, and adjustment to illness and physical trauma.
3. Recognize the psychological impact of disability on the patient.
4. Differentiate the various professionals (and their roles) to which physical therapists can refer patients with psychosocial issues.
5. Apply the interventions used to handle challenging behavior—how to deescalate an agitated patient, manage violent patients, and identify signs of hypersexuality.
6. Describe the stages of psychosocial adaptation to loss and disability and apply them to treatment.
7. Differentiate between psychosocial adaptation and psychosocial adjustment.
8. Analyze different coping strategies that have been found to be important in psychosocial adaptation and adjustment to chronic disability and illness.
9. Analyze common defensive reactions to disability.
10. Understand how body image may be affected by disability and what a physical therapist can do to address body image issues.
11. Recognize the warning signs of possible post-traumatic stress disorder.
12. Describe the general adaptation syndrome, its aims, uses, and potential dangerous outcomes.
13. Determine crisis points in the rehabilitation process and use clinical reasoning to problem solve solutions.
14. Apply psychosocial techniques to facilitate patient/client-centered intervention.
15. Compare strategies and resources for prevention, wellness, and psychosocial education.

SUGGESTIONS FOR REHABILITATIVE INTERVENTION *1205*
- Optimizing Patient Involvement *1206*

SUMMARY *1210*

Psychosocial factors pertain to the psychological development of an individual in relation to his or her social environment.[1] Psychosocial factors are numerous, as a person's psyche is affected by countless events in the internal and external environments. This chapter focuses on the psychosocial factors that may influence the direction of physical therapy intervention. Some examples of psychosocial factors include premorbid status or mental illnesses, personality styles, **coping strategies**, defense mechanisms, and emotional reactions to disability. Others include spirituality, values, environment, adjustment, cognitive abilities, **motivation**, family, social supports, **life roles**, and educational level. All of these factors can affect patients and treatment outcomes.

This chapter (1) identifies and describes how psychosocial factors can influence rehabilitation; (2) demonstrates how to address such factors during physical therapy intervention; and (3) provides indications for referral to psychosocial rehabilitation specialists. Psychosocial factors profoundly affect a patient's ability to recover. Patients who are emotionally upset will have difficulty concentrating on physical therapy goals until emotional issues are addressed. If a patient is motivated to participate in rehabilitation, but his or her family members do not support the patient's rehabilitation goals, the patient will be unlikely to progress on returning home. Mental health status has been shown to be one of the most important predictors of physical health.[2] Wickramasekera et al[3] found that more than 50% of all visits to primary care doctors involved somatic complaints resulting from psychosocial problems. Patients with physical disabilities may fail to respond to treatment if a prominent psychosocial issue is affecting them as well.

Treatment outcomes will be influenced by patients' perceptions of their role in the rehabilitation process. Patients who believe that they possess control regarding their treatment and feel respected by staff tend to experience better **health** outcomes.[4,5] Empowerment, education, inclusion in goal setting, and a high level of engagement are important factors that positively influence **recovery**.

The mind and the body are highly connected.[6] Because of their reciprocal influence, psychosocial and physical issues should be addressed simultaneously to best facilitate recovery. A slow recovery may cause or prolong **depression**, which may in turn further delay the rehabilitation period. Watts[7] believes that mental health interventions should be provided to all rehabilitation patients, because health outcomes tend to be poor and prolonged when psychosocial problems remain unaddressed.

Physical therapists regularly encounter patients who have psychiatric illnesses. Psychiatric conditions occur with some frequency in the general population (Table 26.1), but occur at an even higher rate in rehabilitation settings.[8] For instance, **panic disorder** occurs in 10% to 30% of patients treated in cardiovascular, respiratory, and neurological rehabilitation units, and in 60% of those treated in cardiology clinics (compared to 1% to 2% in the general population).[9] **Conversion disorder** has been reported to occur at a rate of up to 14% in general medical or surgical inpatient units (compared to 0.5% in the general population).[10] Friedland and McColl[11] found the prevalence of depression and substance abuse to be significantly higher among people with disabilities than in the general population, as did Turner and Beiser,[12] who documented the rate to be three times higher regardless of gender and age. Seventeen percent of senior adults with disabilities also had a diagnosis of major depression, and 14% had mild depression that interfered with daily activities.[13] Twenty-seven percent of patients with stroke were found to be depressed—a finding that correlated with poorer rehabilitation outcomes.[14] Patients with traumatic brain injury (TBI), spinal cord injury (SCI), and Parkinson's disease also reported higher levels of depression compared to the general public.[15,16]

Table 26.1 Lifetime World Prevalence of the Most Common Psychiatric and Personality Disorders[9]

Major Psychiatric or Personality Disorder	Lifetime World Prevalence (%)
Alzheimer's (85+ years old)	16–25
Alcohol abuse or dependence	15
Major depression	10
Marijuana abuse or dependence	5
Schizotypal personality disorder	3
Dependent personality disorder	3
Obsessive-compulsive disorder	2.5
Histrionic personality disorder	2.3
Borderline personality disorder	2
Antisocial personality disorder	2
Panic disorder	1–2
Schizophrenia	1

If a patient does not have a preexisting psychosocial illness, he or she is more likely to develop one after the onset of physical illness. Anxiety disorders can result from endocrine (e.g., hyperthyroidism and hypothyroidism, pheochromocytoma, hypoglycemia, and hyperadrenocorticism), cardiovascular (e.g., congestive heart failure, pulmonary embolism, and arrhythmia), respiratory (e.g., chronic obstructive pulmonary disease, pneumonia, and **hyperventilation**), metabolic (e.g., vitamin B_{12} deficiency and porphyria), and neurological conditions (e.g., vestibular dysfunctions, encephalitis, and neoplasm).[9] The onset of depression has also been linked to the presence of an existing physical disability.[11,12] There is evidence for the converse as well; the longer one

possesses some form of mental health concern, the greater the risk for developing a physical illness. Depression is a risk factor for heart disease and post-stroke mortality.[17,18] Heinemann et al[19] found that alcohol-related automobile accidents are responsible for a significant number of SCIs, and Zegans[20] reported that psychological problems could be exacerbated by physical illness or injuries. Anxiety can also increase the risk of cardiovascular disease and **hypertension**.[21]

Although the co-occurrence of physical disabilities and mental illness is high, the rate of treatment for mental illness among people with disabilities is low. In 1997, only 23% of adults with depression, 38% with **anxiety** disorders, and 47% with serious mental illness received treatment.[13]

A thorough examination of the patient's **psychological** and **social functioning** can contribute significantly to a better understanding of needs, fears, anxieties, and capabilities, as well as furnish essential information about the patient's emotional adjustment to disability, assets and liabilities, personality structure, and cognitive functioning. These can then be used to better understand the patient's emotional barriers and behavioral difficulties that can impede recovery. Although not inclusive, Box 26.1 highlights the major areas of consideration in a mental health examination.

Whether physical therapists should address psychosocial issues during treatment or refer psychologically impaired patients to other professionals depends on several variables: (1) the severity of the patient's psychosocial

Box 26.1 Elements of a Mental Health Examination

Client Demographics

- Gender, age, culture, ethnicity, education, economic status, primary (and secondary) language(s)
- Living environment (past, present, and projected future) and environmental supports
- Family history of psychiatric diagnoses/interventions
- Current complaints
- Psychiatric medication (past and current)
- Roles (past, present, and projected future)
- Occupation (past, present, and projected future)
- Social supports (past, present, and projected future)
- Leisure interests (past, present, and projected future)
- Goals (past, present, and projected future)
- Values (past, present, and projected future)
- History of psychiatric hospitalizations, substance abuse detoxifications, and/or rehabilitation stays

Systems Review

- Psychosocial

Examination

Chosen to measure or identify the following:

- Cognitive status (orientation, memory [short-term, long-term, working memory], executive functioning, judgment, calculations, attention, processing, meta-cognition, use of cognitive strategies), volition, self-awareness, mental status, degree of organicity and cognitive disability and its relationship to the patient's rehabilitative capacity. *Primary impairments*: disorientation, amnesia, word-finding difficulty, impaired memory, poor judgment, executive functioning deficits, thought blocking, poor use of cognitive strategies and/or meta-cognition, lack of motivation, impaired self-awareness of limitations, impairments in mental status.
- Emotional status. *Primary impairments*: anxiety, depression, mania, hypomania, grief, mourning, shock, anger, suicidal ideation, emotional numbness, overwhelmed, paranoia, agitated, low self-esteem, regression, delusions, poor reality testing, inappropriate affect, blunted affect, hypervigilance or hypovigilance, anhedonia (inability to experience pleasure), mood swings.
- Defense mechanisms. *Primary impairments*: The use of predominantly primitive defense mechanisms (such as splitting, acting out, denial, devaluation, dissociation, idealization, isolation of affect, projection) as opposed to more mature defenses (sublimation, humor, rationalization, omnipotence, altruism, autistic fantasy). Defense mechanisms are rigid enough to impair ego functioning.
- Personality types. *Primary impairments*: personality disorders (paranoid, antisocial, dependent, borderline, histrionic, narcissistic, avoidant, obsessive-compulsive, schizoid, schizotypal).
- Coping styles. *Primary impairments*: external locus of control, self-blame, substance abuse, and non-direct passive and escape/avoidance modes of coping.

Box 26.1 Elements of a Mental Health Examination—cont'd

- Determination of suicidal tendencies, decompensation, and other risks. *Primary impairments*: history of suicide attempts in self or family members, current suicidal ideation, suicide note, plan for suicide, emotional and/or behavioral regression, substance abuse, feelings of hopelessness and/or helplessness, birthdays or anniversaries of deaths of loved ones, holidays, anniversaries of traumatic events.
- Symbolic meaning of the disability and loss, and the compensatory reserves that can be elicited. *Primary impairments*: Poor compensatory reserves or use of compensatory strategies. The meaning of the disability is both negative and fixed/rigid (e.g., the disability is karmic or a curse that is deserved).
- Levels of pain, stress, tolerance, and secondary gain. *Primary impairments*: Low frustration tolerance coupled with high levels of pain and/or stress. The secondary gain of the impairment is high (important) enough to cause a fixation at a lower than expected level of functioning, result in malingering, or interfere with rehabilitation.
- Sexual practices. *Primary impairments*: sexual dysfunction, impotence secondary to psychiatric medication, unprotected sex, impulsive sexual behavior, sexual abuse, perversions, hypersexuality, sexual addictions.
- Current functional capacities. *Primary impairments*: Problems with basic activities of daily living or instrumental activities of daily living, inability to perform in current roles and occupations, decreased community mobility, inability to live independently.

issue; (2) the level of comfort with which the physical therapist can address psychosocial problems; and (3) the patient's ability to progress in rehabilitation if existing psychosocial issues are not addressed. Professionals to whom referrals may be made for additional psychosocial intervention include but are not limited to psychiatrists, **psychologists**, **psychiatric nurses**, **occupational therapists**, social workers, creative arts therapists, vocational counselors, **rehabilitation counselors**, **substance abuse professionals**, and **pastoral counselors**.

PSYCHOSOCIAL ADAPTATION

The combination of intense psychological stress, uncertain prognosis, prolonged treatment, and interference with daily activities can greatly affect the rehabilitation of patients with disabilities and chronic illnesses. **Disability** is loss of or diminished ability to perform specific social roles normally expected of the patient. **Psychosocial adaptation** to disability and chronic illness is an ongoing, dynamic, evolving process through which a patient strives to attain an optimal state of function within his or her environment.[22] Successful psychosocial adaptation may be characterized by (1) a sense of personal mastery; (2) participation in social, recreational, or vocational pursuits; (3) successful negotiation of the environment; and (4) a realistic awareness of one's current strengths, deficits, and functional capacities.[23] Adjustment is the final phase in adaptation and includes striving to achieve life goals, feeling self-confident and having positive self-esteem, possessing a positive attitude toward one's disability, forming emotional connections to others, and establishing a community member role.[24]

The processes of **adaptation** and adjustment are influenced by whether or not a chronic illness or disability is congenital or adventitious, of sudden onset or gradually progressive, and stable or unstable. Patients born with a physical disability and those who acquire them as a result of accident or disease later in life have substantial psychological differences.[25] Children born with a physical disability have only experienced life with their impairment; the development of their self-identity commonly mirrors that of children without disabilities.

In contrast, patients with adventitious disabilities often experience acute loss and grief. Patients with gradually progressive diseases or disabilities of sudden onset often experience anxiety and **shock** when first becoming aware of their condition. Such anxiety and shock is often followed by anger and depression, as patients realize the magnitude and consequences of their diagnosis.[22] Disabilities of sudden onset (e.g., injuries or accidents) are usually experienced as crises that will change the lives of patients and their families for all time.

Grief, Mourning, and Sorrow

Grief is a psychological state of distress resulting from a significant loss. In reaction to a disability, grief may emerge from lost function, broken relationships, the loss of one's familiar self-identity, and disrupted roles. Grief is characterized by preoccupation with loss and feelings of worthlessness or helplessness. Specific symptoms include feelings of tightness of the throat, muscular weakness, emptiness in the abdomen, anxiety that is described as painful, shortness of breath and choking, and periodic waves of physical distress lasting up to an hour. Other symptoms may include forgetfulness, poor concentration, dissociation, insomnia, loss of appetite, compulsive behavior, an inability to manage time in a productive manner, disorganized cognitive functioning, social **withdrawal**, guilt, decreased ability to make decisions, excessive speech, and hostility.[26] Severe, prolonged cases of grief can compromise the immune system.[27] The grief–mourning period is unpredictable, lasting anywhere from 6 months to 2 or more years. According to Donatelle and Davis, the grieving process consists of

10 stages: (1) frozen feelings; (2) emotional release; (3) loneliness; (4) physical symptoms; (5) guilt; (6) panic; (7) hostility; (8) selective memory; (9) struggle for a new life pattern; and (10) a sense that life is okay.[26] It is important to note that such stages do not always occur in a progressive linear fashion, and some stages may occur simultaneously.

Grief is a natural experience necessary to regain or adapt to one's losses and construct a new self-concept. New coping skills are learned as patients adjust to unfamiliar challenges. There may be a difference between people grieving over loss from a disability and those grieving over other types of losses.[27] When grief occurs as a result of disability, it may become prolonged, as the patient must continuously strive to accept the disability and his or her altered self. Burke et al[28] described the grief of people with disabilities as "chronic sorrow," or a grief regarding the loss of normality. Lindgren et al[29] defined chronic sorrow as (1) progressive sadness that often increases after the initial loss; (2) prolonged periods of sorrow with no predictable end; and (3) recurrent or cyclic in nature as the sadness is continuously triggered by internal or external events that reawaken loss. Patients with chronic sorrow can eventually experience adaptation to their losses if they are highly motivated to rebuild their lives and find meaning in their experience. Conversely, patients with pathological grief often experience prolonged feelings of guilt, anger, and sadness that inhibit function and adaptation.

It is important to recognize that grief can be an all-encompassing experience that can take time and energy away from rehabilitation, thereby affecting the process of rehabilitation and its outcomes. Physical therapists must understand grieving, mourning, and sorrow so that a patient's lack of progress or motivation is not misinterpreted as **malingering**.

Phase Models of Psychosocial Adaptation

The literature regarding psychosocial adaptation to chronic disability and illness falls into two opposing theories of adaptation—one in which adaptation occurs as a set of nonsequential and independent patterns of behavior, and the other in which adaptation occurs progressively through a series of phases.

Phase models suggest that a patient's reaction to chronic disability or illness follows a stable sequence of phases, or stages, that are hierarchically and temporally ordered. This progression is gradual, linear, and involves the psychological assimilation of changes to one's body image and self-concept. The most frequently identified phases in the adaptation to chronic disability and disease are shock, anxiety, denial, depression, internalized anger, externalized hostility, acknowledgment, and final adjustment.[22]

Shock

Shock usually occurs as the initial reaction to a psychological trauma or severe and sudden physical injury. It results from an overwhelming experience and may include the inability to move or speak, psychic numbness, decreased cognitive skills, disorganization, and depersonalization.

During a traumatic event, an individual will respond primarily at the physiological level; emotional reactions are commonly delayed until the event is over and the individual is medically stable. Likewise, the medical emergency team will first implement immediate lifesaving attempts before addressing accompanying psychological issues.

During a perceived or real catastrophic event, an organism would most likely respond with what Selye termed the **general adaptation syndrome** (GAS).[30] Selye described GAS as an organism's defensive adaptation attempt, which expresses itself through physiological and emotional responses aimed at dealing with such emergencies. During GAS, there is a physiochemical chain reaction, whereby a peptide called corticotropin-releasing factor (CRF) is secreted to stimulate the release of adrenocorticotropic hormone (ACTH). ACTH sets into motion an increase of specific physiological activity designed to maximize the body's defense capacity while minimizing the utilization of nonessential physiological activities. Although an increase in CRF serves the person's self-defensive strategies, its inhibitory effect on other body functions—such as the production of insulin and calcium—is undesirable in the long run.

Studies have shown that injection of a CRF antagonist reduces anxiety in stressful situations.[31] When the inhibitory effects of CRF are prolonged, however, the additional undesirable effects of hypertension, digestive problems, and interference with the immune system result. Selye[30] documented the devastating effect that a prolonged GAS response has on human mental and physical functioning.[30] Theorell et al[32] documented the occurrence of resultant illnesses long after the stress-producing event had ended.

Anxiety

Once the magnitude of the traumatic event is comprehended, anxiety in the form of a panic-stricken reaction commonly occurs and is marked by compulsive activity, confusion, elevated pulse rate, difficulty breathing, and cognitive flooding (e.g., when emotions such as anxiety preclude logical thought). Situations that activate the sympathetic nervous system through repeated alarm or chronic stress may alter synaptic transmission and lead to depression and malfunction of normal body systems.

It should be noted that the physiological and psychological reactions to stress are not limited to catastrophic conditions. An extensive body of research shows **stress reactions** to be present in individuals under conditions that may not be traumatic but nevertheless persistent and disruptive. Everyday life frustrations, internal and external conflicts, and changes in life conditions are major causes of the stress reaction that, over time, have

a deleterious effect on a person's function and health. Physical therapists should be cognizant that even though a patient's emergency situation is over, a stress reaction may continue to be present.

Denial

Denial is often used as a defense mechanism to alleviate the anxiety and pain associated with a disability or illness. Denial occurs as a specific phase early in the adaptation process and protects the person from having to confront the overwhelming implications of illness or injury all at once. Instead, denial allows a gradual assimilation of one's altered reality. Breznitz[33] identified seven types of denial:

1. Denial of threatening information (using selective inattention and partial awareness)
2. Denial of vulnerability (exerting control and maximizing personal strengths)
3. Denial of urgency (using methods to see the situation as less pressing than it is)
4. Denial of affect (reduction of emotional impact)
5. Denial of affect relevance (diverting attention to other issues and believing that an emotion is coming from an unrelated cause)
6. Denial of personal relevance (attributing difficulties to a benign cause and blaming others when involvement was one's own)
7. Denial of all information (creating a barrier between external reality and one's psyche resulting in total disbelief of having an illness or disability)

Patients in the stage of denial may selectively attend to the environment, choose facts that support their beliefs about themselves and their condition, and ignore facts that remind them of their new challenges. They may have unrealistic and wishful goals for recovery and may be seen as indifferent and aloof.

Depression

The phase of depression occurs as denial lessens, allowing a greater awareness of one's losses. **Depression** is a reactive response of bereavement for impending death, suffering, or the loss of body function. Neurochemical and biological changes resulting from disability or disease, **premorbid** personality and family history, and reactions to stress have all been identified as risk factors for depression.[34,35]

Internalized Anger

Anger occurs in reaction to anxiety, misperception, threats of abandonment, feelings of helplessness, or fear of losing control. Characteristics of anger include hostility, resentment, or hatred. **Anger** is a response to loss and if not expressed is termed **internalized anger**. Internalized anger is associated with self-blame and is a manifestation of self-directed bitterness and resentment. Signs of internalized anger include manipulation, sabotage, and passive-aggressive behavior. Sometimes anger emerges when a patient attributes his or her own behaviors to the onset of disability or disease. In such cases, internalized anger can result in depression, suicidal tendencies, or **psychosomatic** complaints—particularly in people who have a chronic condition.[36]

There are many reasons why patients may not express anger: fear of losing loved ones or social isolation, **cultural restraints**, lack of awareness, fear of losing control, or belief that expressing anger is inappropriate or dangerous. Repressed anger not only affects a patient's psychological well-being, but may also slow rehabilitation. It is important for physical therapists to encourage expression of angry feelings by providing a safe environment for patients to verbalize their anger in appropriate ways. Therapists might state that anger is a normal emotion—especially under the patient's circumstances—offer reasons why it is important to express anger, and provide anger management techniques (e.g., effective coping strategies). It is equally important for therapists to understand that although a patient's anger may be directed at the therapist, such anger more often reflects the patient's own projected feelings regarding his or her disability.

Externalized Hostility

Externalized hostility is anger directed toward other people or objects in the environment and is an attempt to retaliate against activity limitations. Challenges encountered during rehabilitation may trigger externalized hostility. As time from the onset of the disability passes, externalized hostility tends to become more apparent.[37] Signs include passive-aggressive behaviors that obstruct rehabilitation, aggressive acts, hypercriticism, demanding or antagonistic behaviors, falsely blaming others, and abusive accusations. Patients who express anger aggressively through physical or verbal abuse, sarcasm, or controlling behaviors need the help of the entire team to redirect their anger into productive therapeutic activities that further their rehabilitation goals.

Acknowledgment

Acknowledgment is the first sign that the patient has accepted or recognized the permanency of the condition and its future implications. The patient begins to integrate activity limitations into his or her self-concept. During this phase, the patient accepts himself or herself as a person with a disability, develops a new self-concept, reassesses values, and searches for new goals and meaning.

Adjustment

Adjustment is the final phase in adaptation and involves the development of new ways of interacting successfully with others and one's environment. The person is now adjusted to the outside world after having fully assimilated his or her activity limitations from disability into a new, cohesive self. In this phase, the person regains

self-worth, understands that new potentials are possible, pursues vocational and social goals, and overcomes obstacles that arise in the attainment of goals.

There is evidence that the phase model of adjustment to chronic disability or illness is nonlinear, multidimensional, and progressive. Phase models tend to have 10 common assumptions:[22]

1. People may skip one or more phases or may **regress** to an earlier phase, but adaptation is not usually reversible.
2. The pace and structure of adaptation can be influenced by external events or interventions (e.g., environmental changes or counseling) yet are mainly determined by internal processes.
3. Not everyone achieves adjustment; some fixate at earlier phases.
4. Adaptation is an unfolding, dynamic process that gradually shifts from initial experiences of distress to assimilation of loss and reconciliation.
5. The adaptation process is initiated by significant and permanent changes in the body's functional capacities and appearance, which are usually followed by alteration of self-concept and body image.
6. The amount of time spent in each phase varies and may be determined by a combination of the following factors: social support, financial and human resources, past exposure to crises, age at onset, severity, nature of the disability or illness, and premorbid personality.
7. Psychological maturity and growth occur as the patient progresses through the phases.
8. Psychological re-equilibrium occurs through gradual adaptation and integration of the perceived misfortune.
9. Human variability and uniqueness have a strong influence on the temporal ordering of phases—the sequence of phases is not universal.
10. Occasionally, phases may overlap, be nondiscrete, or fluctuate, causing patients to experience more than one reaction at a time.

Chronic Illness and Disability: Differences in Adaptation

There are marked differences in the way that people adapt psychosocially to a disability associated with a traumatic event—such as TBI—versus a chronic illness—such as multiple sclerosis (MS). The onset of disability in a traumatic event is sudden, and medical stability may be achieved shortly after. The onset of a chronic illness is usually insidious and gradual; its course is often uncertain and marked by states of remission and deterioration.[38] In chronic illness each onset of symptoms can be experienced as a new illness.

Shock may not be experienced by people with gradually deteriorating medical conditions (e.g., Parkinson's disease, rheumatoid arthritis, or diabetes mellitus), but is usually experienced following a trauma (e.g., TBI, myocardial infarction, amputation, or SCI). The phases of anxiety and depression relate more to the past, such as grieving over the loss of premorbid functioning. Shock may be present but not as strong in people with life-threatening or end-stage diseases (e.g., AIDS, cancer, or amyotrophic lateral sclerosis). In a chronic illness, anxiety and depression relate more to the future (e.g., fear of death, feelings of hopelessness, and fear of the unknown).[39] The acknowledgment and adjustment phases may be more difficult to achieve in chronic, life-threatening conditions that require the internalization of and acceptance that the condition may worsen and result in death.

Post-traumatic Rehabilitation

The post-traumatic period may include phases of anxiety, depression, denial, internalized anger, and externalized hostility mentioned earlier, and is usually the time during which much, if not most, of the rehabilitative intervention takes place. It is also the period during which the psychological effects of the traumatic experience are more strongly felt by the patient. It seems as if the psychological defenses and reactions that became secondary during the initial traumatic period (shock phase) begin emerging as the physical injury is dealt with. These repressed reactions seem to interact with a growing awareness of the effects of the disability creating fears, anxieties, and behaviors that the rehabilitation team must address.

Regardless of which phase the patient is in, physical therapists need to be aware of each patient's **psychological needs**. During the initial phases of adaptation, patients may experience an awareness of their injuries that facilitates panic and fear of total dependence. Patients may also experience anxiety as a result of anticipating painful medical treatment. Some patients react to these feelings by desperately seeking control over their rehabilitation. Others experience shock regarding their losses and become overly dependent. Patients may idealize the past and have unrealistic expectations about the duration of their recovery.

During these early stages, physical therapists should praise small gains and work with caregivers so they can offer hope and support to the patient. Therapists should be supportive but careful not to make unrealistic predictions about the expected degree of recovery, because this may lead to disappointment, resentment, and depression.[40] One of the first approaches physical therapists can use to help patients regain self-control is **diaphragmatic breathing**, which may decrease pain and anxiety through the **relaxation response**.[41]

During the middle stages, physical therapists may need to educate patients about medical precautions, contraindicated movements or activities, how the patient's body has adapted to disability, and how to reformulate expectations. Psychosocial instruction should be integrated with information about activities of daily living

(ADL), mobility, strengthening, and endurance. The transition from the patient role to an independent adult member of society is a difficult adjustment and can result in anxiety, depression, and poor social integration.[22,42] Physical therapists should help patients prepare psychologically for discharge and reintegration into society. Some of the issues that patients may fear include negative reactions to their disability, feelings of inadequacy, having to identify new social supports, receiving help in the home environment, and adjusting to a new body image.

Body image includes judgment about one's appearance, an awareness of boundaries and personal space, judgment about one's bodily responses, perception of one's body parts and their movement, and an awareness of physical pleasure and pain. Body image is intimately related to self-concept and self-esteem. It affects a person's functional abilities, cognition, perceptions, attitudes, and emotions, as well as the reactions of others to oneself. Because body image changes throughout life, it is thought to be both dynamic and developmentally based. Difficulties brought on by a disability—such as activity limitations and pain and disfigurement—alter body image and threaten its stability. Patients must then reconstruct their body image and self-perception to adapt to this physical change.[22]

Biordi[43] has identified the following patterns in patients who experienced shifts in body image after disability: (1) denying the existence of one's body; (2) fantasizing about a lost or damaged body part being magically replaced or healthy; (3) concentrating solely on noninjured body parts in order to deny impairment of the affected area; and (4) experiencing a period of defensiveness followed by gradual acceptance and assimilation of their altered body.[43] The physical therapist's comfort level with the patient's physical disability and the therapist's attention to the affected body part may help the patient feel less ashamed about body changes.

PERSONALITY AND COPING STYLES

The more a patient has evolved socially and psychologically, the better he or she will be at using adaptive methods to deal with crises. Hence, a patient with a healthy premorbid personality but a severe physical disability may do better in rehabilitation than one with a less severe disability and a pathological premorbid personality.[44] When aware of their patients' personality styles, physical therapists will be more adept at strategizing interventions, developing a plan of care (POC), and motivating and guiding patients through rehabilitation.

Personality Types

Although each personality is unique, personalities have been categorized into different types, such as *type A, perfectionistic, authoritative,* and *passive-aggressive*. These personality types are nonpathological and develop in response to one's environment when young.

Individuals with type A personalities have a compulsive need to be achievers in all aspects of life. They are extremely independent and productive. These qualities also serve as defenses against low self-esteem and interpersonal conflicts. These people usually derive satisfaction from being strong individuals who can help others. If they can no longer participate in this role, they may become depressed because of a perceived inability to confirm their worth through altruistic activities. Physical therapists can use these qualities in patients with type A personalities to motivate their interest in rehabilitation. Because they are often self-starters and take initiative for their own learning, they can usually be depended on to independently practice home exercise programs (HEPs).

Individuals with perfectionistic personalities uphold high standards in order to maintain self-esteem. These individuals judge themselves by inflexible and possibly unachievable criteria and may not be able to tolerate slow progress during rehabilitation. Physical therapists may aid these patients by helping them derive pleasure from simple things, such as a meal, a sunset, a new shirt, or interesting information. Helping them discover value in these things offers them sources of self-esteem other than meeting impossibly high standards.

Individuals with authoritative personalities need to be in control and need things to be done in a particular way because of rigid perceptions regarding values, rules, and the manner in which others should behave. They are often concerned with status, tend to be judgmental, and have difficulty empathizing with others. During rehabilitation, these patients may try to dictate their treatment and engage in a power struggle with their physical therapists. Patients with authoritative personalities have difficulty adapting to disability, which often requires acceptance and compromise. They may require alternative strategies to solve what may have been perceived as an unsolvable problem. Physical therapists should engage patients in problem solving to generate strategies to meet their goals.

Individuals with passive-aggressive personalities express hostility by using passive techniques such as procrastination, **resistance**, stubbornness, and intentional inefficiency. These personalities react to authority negatively and have difficulty working with others. Physical therapists may work more efficiently with passive-aggressive patients by placing the responsibility for progress onto them. Patients can be instructed to make decisions about their treatment whenever possible and then summarize their progress after each session. This deemphasizes the physical therapist's **role** as an authority figure, and therefore the need for a passive-aggressive response.

Personality Disorders

When an individual's personality style deviates from cultural norms over a long period of time, is inflexible

or pervasive, causes **distress** to oneself and others, and leads to activity limitations, that personality style is considered to be dysfunctional.[9] Personality disorders have been thoroughly classified. They include paranoid, antisocial (also referred to as sociopath or psychopath), borderline, histrionic, narcissistic, avoidant, dependent, obsessive-compulsive, schizoid, and schizotypal personalities. Freidman and Booth-Kewley[45] state that disability exacerbates preexisting pathology, meaning that the stress of dealing with a physical illness can make personality disorders even more pronounced.

Patients with paranoid personality disorder interpret the motives of others as malevolent when they may not be. This results from a pattern of suspiciousness and distrust. These patients believe that others are trying to exploit, deceive, or harm them. Because of such mistrust, they may discharge themselves from treatment. Physical therapists should look for behaviors that indicate paranoid thoughts such as hostile reactions, guardedness, argumentation, and stubbornness, and encourage patients to express their thoughts at that moment. If the patient seems paranoid, the physical therapist should help him or her to better understand the reality of a specific situation. For instance, if the patient complains about being forced to participate in an elaborate intervention so that, in his or her view, the therapist can make more money, the therapist should review the pros and cons of various treatments and discuss the clinical reasoning involved. Literature can be very convincing since it does not come directly from the therapist.

Patients with antisocial personality frequently engage in deceit and manipulation. In rehabilitation, they may use an alias, lie to the staff, or malinger. They are irresponsible and often fail to comply with self-care procedures such as hygiene and home maintenance. They seek out and take advantage of weaker staff members, often using wit and charm. When they do not receive what they want, they commonly become irritable and violent, especially when staff members attempt to impose restrictions. They frequently cause disruption to others in rehabilitation. These patients require a cohesive **team approach** with immediate and strong intercommunication to minimize disruptive behaviors and refocus on rehabilitation goals.

Patients with borderline personality disorder have instability in emotions, relationships, and self-image; are impulsive; use primitive defense mechanisms such as splitting (Box 26.2) and devaluation; and tend to engage in self-destructive behaviors such as abusing drugs or **self-mutilation**. On the surface, they may appear critical of others but these are signs of deep vulnerability and should be treated as such. Therapists should respond with understanding and empathy instead of anger, and should emphasize strengths and strategies for ongoing work. Self-mutilating behaviors, such as repetitive cutting with razor blades, pinpricking, or cigarette burning, should be immediately reported to a doctor and referral made to a **psychiatrist**.

Box 26.2 Common Defense Mechanisms

Acting Out

Instead of expressing feelings verbally, the patient uses actions to release stress. For example, a patient is angry with the insurance company for not funding an athletic wheelchair, so refuses to use the standard wheelchair. Acting out occurs because certain feelings such as anger and hurt are too difficult to express verbally. Unexpressed feelings build anxiety until they are released through action.

The therapist should identify the feeling behind the acting out behavior by asking the patient why he or she behaved in that way. For instance, the therapist would ask the patient above about using the wheelchair. The patient's responses will eventually trace back to the original unexpressed feeling. Through questioning, the therapist brings to the patient's awareness the link between the feeling and the action. The patient can now verbalize and discuss the feeling. In the case above, the patient may be more willing to use the wheelchair. A patient who does not have difficulty verbalizing feelings tends not to act out.

Altruism

The patient becomes dedicated to helping others in order to manage his or her own stress. An altruistic patient may stop treatment to help everyone else in the treatment room, including the therapist. Such a patient receives gratification through these actions, and hence decreases his or her stress.

Autistic Fantasy

The patient engages in excessive daydreaming instead of pursuing human relationships in order to decrease stress. The patient may have difficulty following directions, may appear to be in another world, but happily so, and may become emotional and tense when returned to reality. If asked what he or she is thinking about, the patient may describe his or her fantasies, which can be a rich source of wishes and desires that can be used by the therapist to motivate the patient to work on short-term goals. For instance, a male patient relates a fantasy of dating his favorite teen idol. However, in order to engage in dating, he must first develop interpersonal skills and practice them in simulated and real-life settings.

Box 26.2 Common Defense Mechanisms—cont'd

Denial

Denial protects the ego from being overwhelmed by pain through an unrelenting process of disbelief. In the case of disability, denial may be used to protect the patient from reminders of an altered external reality and the resultant sense of loss. Therefore, the patient may refuse to acknowledge an emotionally painful condition or situation that is apparent to others. The patient often denies the severity of a new disability, believing he or she can return to previous jobs or roles, despite reality testing from the therapist. The patient may refuse rehabilitation, claiming that he or she just wants to leave the hospital in order to care for his or her children.

It is important to help the patient work through denial slowly in order to avoid depression, which may occur if the patient becomes aware of his or her reality before psychologically ready to accept it. If the patient's denial is so great that treatment cannot proceed, he or she should be referred to a psychologist to explore what disability means to his or her future life.

Devaluation

The patient is overly critical of others and of himself or herself and may insult therapists and other personnel. The therapist should not take such insults personally, but should offer empathy and kindness, which usually decrease devaluation and build rapport. Once a patient trusts the therapist, he or she may discuss insecurities and fears instead of defending against them through criticism. If the therapist becomes angry with the patient, the insults usually become worse and a power struggle may ensue.

Displacement

The patient transfers a response to, or feeling about, one object onto a less threatening object to minimize stress. For example, a patient may be angry with a spouse for driving the car recklessly and having an accident but takes the anger out on the physical therapist. In this situation, it may not be safe or helpful for the patient to express anger directly to the spouse, who may be the patient's only emotional support.

The therapist should help the patient transfer the misplaced feeling back to the object for which it was originally intended. The therapist might accomplish this by asking the patient a series of questions concerning the origin of the anger.

Dissociation

The patient deals with stress through a breakdown in memory, perception, consciousness, or sensorimotor behavior. The patient becomes detached from what is happening in the moment because it is too painful. The patient may stop speaking or participating in therapy and stare blankly into space for up to several minutes without responding to the environment. Afterward, the patient may not be aware of his or her dissociated state, or if he or she is, the patient may state that he or she "just spaced out." The patient who uses dissociation usually relies on it often; a physical therapist may note its occurrence several times during a session. It is important to notice what happened just before the dissociation to identify the painful thoughts, feelings, or actions that upset the patient.

Help-Rejecting

The patient deals with the stress of having covert hostile feelings toward caregivers by frequently asking for help and then rejecting every suggestion. Working with a patient who uses help-rejecting as a defense mechanism can be very frustrating. Such patients seem to sincerely seek help but reject all advice as ineffectual. In these cases, it may be helpful to point out to the patient that efforts to help have been thwarted. The patient is usually not aware that he or she has rejected all solutions and may then come up with a solution or be more open to one that has already been proposed.

Humor

Humor can be used to minimize stress by highlighting the ironic or amusing aspects of a stressful situation. For instance, a patient states that he is going to open up a hardware store since he has so much hardware (meaning surgically placed pins and plates) in his leg. A patient who uses humor as a defense mechanism usually feels better if the physical therapist laughs at his or her jokes and participates in joking behavior. It is a safe way for the patient to recognize the difficulty of his or her situation.

Idealization

A patient endows another individual with overly positive attributes to enhance an otherwise negative situation. This other individual may be the therapist, in which case the therapeutic relationship is often strengthened. Or it could be a spouse, in which case problems could arise if he or she is not such a positive support to the patient. It is important to uncover the reality of the situation so necessary treatment and discharge plans can be made.

Box 26.2 Common Defense Mechanisms—cont'd

Intellectualization

A patient uses intellectual reasoning rather than expressing emotions in order to avoid painful feelings. For example, the patient describes neurotransmitters and synapses when asked about a head injury. Therapists can relate to such patients by intellectualizing with them. For example, the therapist may speak about the patient's head injury in terms of science and facts instead of emotions.

Isolation of Affect

A patient separates feelings from ideas when thinking about and discussing an upsetting event to minimize negative feelings associated with it. He or she speaks of the details regarding the recent accident that caused a disability without mentioning any feelings associated with the event to avoid reexperiencing them. Therapists should help the patient integrate feelings about an event into his or her memory of it. This can be achieved by asking the patient how he or she feels about certain aspects of the event while talking about it.

Omnipotence

A patient feels or acts as if he or she is better than others to guard against feelings of inadequacy. For instance, a patient looks down on other patients with disabilities because he does not want to see himself as disabled. A therapist might observe criticism and devaluation of external objects, bragging about accomplishments or skills, conceit, and grandiosity. The therapist could use this defense mechanism to motivate the patient to get better in order to avoid feeling inferior.

Projection

A patient transfers his or her own unacceptable feelings, thoughts, and beliefs onto another person and becomes certain that the other person really feels, thinks, and believes that way. A patient cannot tolerate the idea of having unacceptable feelings such as anger, but expresses them by projecting them onto another person, remaining relatively guilt free. For example, a patient says that his therapist is annoyed with him when in fact the patient is annoyed with his therapist.

Rationalization

A patient uses elaborate explanations to reassure him or her that personal actions are driven by sound motives, when he or she may truly be unsure. A family member caring for a relative with congestive heart failure asks for a do not resuscitate (DNR) status, citing extensive research studies. The family member states that the relative will die soon anyway, thereby concealing the real and less acceptable reason for seeking the DNR status—to relieve himself or herself from caregiving responsibilities.

Repression

A patient unconsciously erases negative experiences, wishes, or thoughts from consciousness in order to decrease stress. For example, a patient finds an endearing letter to a spouse from a student and forgets to mention it because the possibility of the spouse having an affair is painful. Repressed material can be dangerous because it remains in the unconscious. Encouraging the patient to express his or her feelings, both good and bad, helps free him or her of these feelings and any possible negative urges to act on them.

Splitting

A patient views a person or event through a positive or negative lens at any given point in time. Later, the patient may flip his or her feelings to the opposite end of the spectrum regarding the same person or situation, acting in this manner because he or she has difficulty integrating ambivalent feelings. Some patients will often attempt to split staff, identifying one staff member with unrealistic positive attributes, while identifying another staff member with unrealistic negative qualities. The staff member who has been identified as negative has usually denied some desire the patient requested. The patient may approach the positively identified therapist and complain that the first therapist is insensitive and does not understand his or her needs. The patient may express that only the positively identified therapist understands his or her problems. However, when the positively identified therapist also denies the patient's request, the patient then vilifies that therapist as well. The therapist may help the patient to integrate the opposite poles of his or her emotions by bringing both positive and negative emotions into consciousness. The patient then may be able to see the reality of his or her situation.

Sublimation

Sublimation occurs when patients transform unacceptable emotions or desires into socially acceptable actions. For example, a patient who is angry about a recent divorce may be unable to consciously express those feelings for fear of losing the affection of his or her children. Instead of expressing the anger he or she may sublimate those emotions into a more socially acceptable action, such as working out in the gym and eventually training for marathons. By participating in an activity that is valued and admired in the society, he or she gains the positive support of others.

Box 26.2 Common Defense Mechanisms—cont'd

Suppression

A patient intentionally avoids thoughts of disturbing feelings, situations, experiences, or problems in order to reduce stress. When refusing to talk to his or her therapist about the accident that brought him or her to rehabilitation, the patient suppresses disturbing thoughts. Therapists can refer patients to creative arts therapists (e.g., dance, music, art, drama, or poetry therapists) to facilitate the expression of disturbing thoughts, because such emotions accrue over time if not expressed.

Undoing

A patient uses behavior or words to negate unacceptable actions, thoughts, or feelings. For example, one who is frequently bullied by another patient during rehabilitation feels rage against the aggressor, but invites him or her to lunch.

Note: In both undoing and suppression, disturbing feelings are intentionally avoided. In suppression, the feelings are avoided and nothing else happens. Feelings are avoided and concealed through opposing words or actions. Both undoing and suppression differ from repression in that repression is an unconscious act.

Patients with histrionic personality disorder seek attention via excessive emotionality. Since these patients respond well to audiences, therapists should provide situations in which patients can gain positive attention from doing well in rehabilitation. Physical therapists should set boundaries to help patients achieve a balance between their need to express themselves and their need to focus on therapeutic interventions. A calm and logical approach to rehabilitation helps settle intense emotions. Patients who have difficulty verbalizing their feelings can be referred to a **creative arts therapist** to facilitate expression through nonverbal means—such as music, dance or art.

Patients with narcissistic personality disorder are condescending and have a need for admiration and feelings of superiority. If an illness causes a reduction in this image, they will require help from their physical therapists to identify strengths and feel acceptable.

Patients with schizoid personality disorder have a **flat affect**, or limited range of emotional expression, and are detached from social interactions. The therapist should attend to the patient's rehabilitation without trying to engage him or her in a great deal of social interaction. If the disorder has been long-standing, the patient will likely feel uncomfortable socializing.

Patients with schizotypal personality disorder have eccentric behavior, perceptual or **cognitive distortions**, and marked distress in social relationships. The social intimacy and physical restriction of a rehabilitation environment may cause anxiety. Slow, unforced integration into the therapeutic setting may be required. Asking patients whether their views of reality are accurate may help them remain focused on achieving rehabilitation goals.

Patients with avoidant personality disorder suffer from social inhibition, feelings of inadequacy, and hypersensitivity to criticism. Physical therapists should reassure these patients that they are doing well and emphasize their strengths.

Patients with dependent personality disorder exhibit clinging behavior, need others to care for them, and are submissive. They may fail to function independently in their life roles even after physical functioning has returned, continuing the pattern of dependency. They fear abandonment and require constant reassurances that staff members understand their condition and care about them. Some respond to clear explanations and feedback about their progress and treatment plans. The therapist should reinforce independent behavior through attention and positive feedback while extinguishing dependent behavior by ignoring or redirecting it.

Patients with obsessive-compulsive personality disorder have a long-standing preoccupation with control and order and are often perfectionists. Their self-esteem may suffer if they perceive a loss of control, and they may react by becoming more obstinate, demanding, and inflexible. Those who publicly express their anger may become ashamed. These patients require greater predictability in treatment than usual, dislike change, and do well when given an established routine to follow. The therapist should provide rehabilitative activities that promote a sense of control and predictability, and consider allowing patients to set treatment goals, and then monitor their daily progress.

Coping Styles

Coping styles are ways that people deal with stress and include behavioral, emotional, and cognitive efforts to cope with internal and external challenges that strain ordinary resources.[46] Theories of coping suggest that it is not what happens to people that is important, but rather how they react.[47] Various coping strategies have been identified in the literature and summarized by Livneh and Antonak.[22] They include planning, problem solving, wishful thinking, avoiding, minimizing, seeking social support, searching for meaning, emoting feelings, blaming, accepting, negotiating, disengaging, and turning to religion. These and others can be categorized into three

different types of coping: (1) seeking versus avoiding control and information; (2) expressing versus repressing emotional reactions; and (3) seeking versus withdrawing from social interactions and networks.

Coping strategies have been found to be of great importance in rehabilitation. Patients with higher-level coping skills can more easily identify and report symptoms, make treatment decisions, comply with intervention, and accept support. Patients with good problem solving skills and positive attitudes have been found to make more positive adjustments to their disabilities than patients with low self-esteem and poor self-concept.[48] Coping styles often determine whether or not patients seek medical help and follow advice.[46]

Social influences, psychological characteristics, and health beliefs have been shown to modify the impact of disability and disease on an individual. Social activism, positive self-acceptance, and information seeking have predicted better ability to cope with a disability.[49] Krause and Rohe[50] studied the relationship between adjustment and personality following SCI and found that positive values, emotions, actions, and warmth correlated with superior outcomes. Adaptive coping styles that result in positive outcomes for people with disabilities utilize positive, direct, and active problem solving, social support seeking, and information seeking. Maladaptive coping styles that lead to unfavorable adaptation outcomes include self-blame; non-direct, passive, and escape/avoidance modes of coping; and substance abuse.

Locus of control is a belief about one's ability to control life conditions and events.[51] Patients with an *external locus of control* believe that other people or outside factors determine outcomes. Patients with an *internal locus of control* take responsibility for change because they believe they can affect their own circumstances. The latter leads to goal-directed activity and active coping.

The ability to intentionally change the relative importance of events that occur in one's life requires constant practice.[52] It has been shown that patients with external loci of control experience stress and anxiety in rehabilitation, whereas patients with internal loci of control have quicker recoveries, better motivation, more hope, and more energy.

Coping styles can be examined through interviews, observations, self-report surveys, checklists, and information from the family. Treatment considerations based on these findings should include emphasis on previous ways of successfully coping and expanding the range of coping strategies, such as maintaining a journal to increase self-expression. Taking care of a pet or using animal assistance can lend help, comfort, and companionship, as well as increase motivation. Group treatment can also be used to increase social networks.[53,54]

Many people with disabilities who have risk factors for emotional problems, such as lower education, less income, and social isolation, still do well in life because of a certain resilience defined as successful adaptation to stressful situations or events.[55] Researchers of resilience identify protective factors that safeguard people from adverse consequences. Protective factors can arise from the individual, family, and society and are concerned with how these strengths and supports provide security, safety, and positive opportunities.

Turning points are important experiences and realizations that enable people to find new direction, purpose, or meaning in life. King et al[56] reported four protective factors: determination, perseverance, spiritual beliefs, and social support. Seven protective processes were also identified: transcending, self-understanding, accommodating, receiving a diagnosis that helps explain a patient's experiences, believing in oneself, using anger as motivation, and setting goals. These protective factors and processes help people with disabilities during turning points in their lives. Analysis of turning points revealed three major ways that patients maintained meaning in their lives: through doing, belonging, and understanding themselves in relationship to the world. Doing involves participating in activities that are fulfilling and facilitate competency. Belonging involves perceived acceptance by others or membership in a valued group. Understanding oneself in relationship to the larger world provides a sense of identity and sometimes purpose.

COMMON DEFENSE REACTIONS TO DISABILITY

Defense mechanisms are coping styles that people use to defend against internal and external stressors. They happen automatically and unconsciously. Some individuals use many different defense mechanisms throughout their lives, but most tend to utilize only one or two. The goal is not to change or modify these defense mechanisms, but to identify them in order to understand the patient's psychological processes that underlie certain behaviors and resistance. Understanding these behaviors can help physical therapists to motivate or redirect patients during difficult times in their rehabilitation. The defense mechanisms described in Box 26.2 are common reactions to disability and can be further explored in the *Diagnostic and Statistical Manual of Mental Disorders*.[9]

Anxiety

Anxiety is the apprehensive anticipation of future danger or misfortune accompanied by feelings of tension and agitation. The anticipated danger may be real or imagined, but is experienced both psychologically and physiologically.[57] The experience of **anxiety** varies in different patients. When someone is nervous (indicating a moderate level of anxiety), he or she may experience an upset stomach or headache. When someone is experiencing a panic attack (indicating a high level of anxiety), he or she may feel impending doom and terror. A symptom of anxiety in one patient may be heart palpitations, while in another it may be shortness of breath. What is anxiety

producing to one patient may cause little to no anxiety in another. Given these variables, the following definitions may facilitate physical therapists' understanding of their patients' conditions.

A **panic attack** is a sudden onset of intense, overwhelming fear that may include feelings of imminent danger or impending doom. These attacks are marked by symptoms of palpitations, chest pain, smothering or choking sensations, shortness of breath, and fear of losing control, dying, or going crazy. Panic attacks may be unexpected (occurring without an internal or external trigger) or situational. It is unclear what kind of physiological change in the brain may trigger such a severe response. A **phobia** is an anxiety disorder characterized by intense anxiety resulting from thoughts of, or exposure to, a specific feared situation or object (such as heights, spiders, or elevators) leading to avoidance of that object or situation. **Generalized anxiety disorder** is defined as excessive worry and anxiety without an apparent source persisting for at least 6 months.[9]

Causes of Anxiety

Twenty to 30 million Americans suffer from anxiety.[26] Some signs and symptoms of anxiety are listed in Table 26.2, and behaviors that may result from anxiety are provided in Table 26.3. Much of the literature on stress and coping has identified major life events as stressors. Life events refer to major changes in lifestyle, status, role, or situation. This view is consistent with the notion that stress, though individually mediated, is to some degree environmentally based and/or exacerbated by environmental and social conditions. Various life event measures have been developed and are used in examining potential environmental stress. One of the more well-known and used instruments is the **Holmes-Rahe Social Readjustment Rating Scale** (Appendix 26.A), which quantifies the effects of life changes on stress and health.[58] Such measures of life events assume a relatively global impact, and take into account only those items listed. Although there is justified validity in such an approach, there exist potentially more sensitive and valid measures, one of which is the Hassles Scale.

The **Hassles Scale** (Appendix 26.B), developed by Kanner et al,[59] requires subjects to identify the irritating and frustrating demands of everyday transactions with the environment. This approach takes into account the individual's perception of events believed to pose a threat. It is consistent with the theoretical assumption that chronic struggle may tax coping abilities and lead to greater difficulty in the management of daily life events. Considering the enormous changes in a person's function when disability occurs, patients are more likely to expect an increase in daily hassles and stressors. Dealing with life becomes more taxing when disabling circumstances block one's coping style, causing a gap between the person and his or her fit within the world. Repeat occurrences of stress and the continual need to adjust to new situations can result in repetition of the fight-or-flight response, which can, over time, result in high blood pressure leading to heart attack or stroke.[21]

Anxiety and Rehabilitation

Different levels of anxiety have different effects on patients. If anxiety is completely absent, patients may

Table 26.2 Signs and Symptoms Associated with Low, Moderate, and High Levels of Anxiety

Low-Level Anxiety	Moderate-Level Anxiety	High-Level Anxiety
Agitation	Abdominal distress	Chest pains
Apprehension	Aches	Depersonalization
Distress	Chills	De-realization (feeling unreal)
Irritability	Decreased concentration	Difficulty sleeping
Motor restlessness	Diarrhea	Dizziness
Muscle tension	Fear	Dread
Nervousness	Feeling light-headed, unsteady, or faint	Helplessness
Worry	Fever	Horror
	Heart palpitations	Hypervigilance
	Hot flashes	Increased sensitivity to pain
	Increased heart rate	Nausea
	Misperception	Paresthesia
	Shaking or trembling	
	Shortness of breath	
	Sweating	

Table 26.3 Behaviors Associated with Low, Moderate, and High Levels of Anxiety

Low-Level Anxiety	Moderate-Level Anxiety	High-Level Anxiety
Avoiding stressful situations	Going to the bathroom frequently	Holding hand over heart
Biting lips	Incessant talking	Reacting to irrelevant cues
Drumming fingers on a tabletop	Mumbling	Throwing up
Fidgeting	Overactivity	
Nail biting	Staring blankly	
Pacing	Verbalizing somatic preoccupations	
Pulling or twirling hair		
Rubbing an object such as worry beads		
Shaking legs		
Sighing heavily		
Tapping feet		

not be motivated to achieve treatment goals. Mild anxiety can be motivating if directed toward rehabilitation. Severe anxiety can escalate quickly and impair all aspects of the patient's life, including rehabilitation outcomes, by intensifying the perception of pain, inhibiting immunosuppression, and prolonging recovery time.[60,61] Patients who had difficulty managing anxiety before physical illness will probably have more difficulty managing stress brought on by disability.

When a patient is anxious, thought and energy often become focused on the anxiety instead of physical therapy, resulting in decreased concentration. Decreased learning may be observed when a patient is unable to concentrate on the therapist's instructions. The patient may be unable to perform motor tasks that require multiple-step directions. Poor concentration can also result in safety risks as the patient's attention may be alternating between the anxiety and the demands of rehabilitation. To appear functional, the patient may try to perform a task having heard only part of the therapist's instructions. Such a patient may fail to understand directions given by the therapist and may not realize that he or she missed important information. Steps may be skipped and a patient may jump ahead too quickly, resulting in injuries to the patient or others.

If patients become fearful because of anxiety, they may avoid certain behaviors in an attempt to decrease their fear. Fearful, anxious patients are reluctant to try new things. They may refuse treatment, remain in their rooms, request a bedpan when they are capable of using the commode, or be reluctant to progress to the next step in therapy. Such patients will commonly make statements such as, "I can't. I don't feel well. I'm too tired. Leave me alone. Not now, I'll do it later. I'm afraid. You can't help me. You don't look strong enough. I'm going to fall."

Patients who express anxiety through overactivity may attempt to progress too quickly through rehabilitation. They often want to achieve everything at once and appear impatient. They tend to rush through a treatment activity without mastering each step. Such patients frequently talk of discharge before it is an option. They may make rash decisions regarding major life changes, such as purchasing new cars or planning vacations when neither would be in their best interest. Such behaviors may provide immediate relief from anxiety for both patients and their families yet cause more distress in the long run.

When anxiety causes misperception, patients may perceive their level of dysfunction and improvement differently than do their therapists. They often leave therapy sessions with an unrealistic opinion concerning any progress or gains made. Such patients may believe they performed at a higher level than they actually did.

Watching a patient experience a panic attack for the first time can be frightening. It may not be immediately evident to either the patient or physical therapist if the patient has never experienced one before. Patients experiencing a panic attack usually report fear of immediate death. They may start to hyperventilate, then suffer shortness of breath. Sometimes they believe they are having a heart attack as a result of chest pain, heart palpitations, and increased heart rate. Terror and panic ensue, and the therapist may call a code or, if in an outpatient setting, initiate emergency transport of the patient to the hospital.

How to Address Anxiety

Physical therapists need to help patients control anxiety so they can proceed with treatment. Some patients may find it beneficial to discuss their fears and concerns with their physical therapists. In such cases the therapist should initiate a dialogue with the patient, asking, "How are you feeling?" "What is your greatest concern?" "What is the worst thing you believe may happen?" and

so forth. Physical therapists can work with patients to help defuse anxiety by using **cognitive restructuring**—or the reshaping of the patient's thoughts and beliefs regarding the feared event. For example, a therapist might help the patient to engage in reality testing by assisting the patient to understand that the occurrence of the feared event is unlikely.

Patients with real and imminent crises may benefit from assistance with problem solving, should their worst-case scenario occur. Such problem solving can help patients to believe that they can survive and live meaningful lives despite the occurrence of feared events. After patients have expressed their feelings, therapists can help them segue into treatment and redirect their emotion into physical activity.

It should be noted that patients who are verbose and cannot stop talking about their fears should not be encouraged to dwell on them during physical therapy sessions. Encouraging patients to verbalize their anxieties is also contraindicated with patients whose psychosomatic complaints are fueled by conversation regarding their anxieties. For patients who are very anxious, it may help to conduct treatment in a setting that is familiar, calm, and comfortable. An unfamiliar setting, too much stimulation in the environment, too many people, or too much noise can increase anxiety levels. It may be helpful to reorient patients to the therapy room and to treatment expectations—each session—to allow them to feel a greater sense of control.

Physical therapists should choose a purposeful activity with the patient's anxiety in mind. Some anxious patients have been known to respond to activities that consist of one repetitive motor action, as rhythmic motion helps to calm them.[62] Gross motor movements help decrease the physical symptoms of anxiety such as muscle aches, agitation, and restlessness. Therapists should begin by involving patients in a therapeutic activity that is easily performed and then increase the complexity of the task once the patient has gained confidence.

Anxious patients who may interrupt the physical therapist while he or she is with other patients may be reassured that they will be seen on a certain date and time. Physical therapists should ignore, without anger, all subsequent intrusions. Setting limits in this fashion helps patients improve their frustration tolerance. Very anxious people often welcome clear boundaries set by therapists because they have difficulty setting limits for themselves.

Stress management techniques are useful before and after a session. Techniques such as meditation, **imagery**, relaxation, stretching, stress management diaries, identifying stressors, biofeedback, nutrition, prioritizing, problem solving, decision making, anger management, Reiki (a Japanese technique for decreasing stress that involves the transfer of healing energy from the practitioner to the patient), music therapy, therapeutic massage, and prayer have been shown to improve both physical and emotional wellbeing.[63-65] Some of these techniques work more effectively for some patients than others. Choosing one depends on the patient's preference, amount of time available, and materials required.

Relaxation Response

Whichever stress management technique is selected, the overall goal is to teach patients how to experience the **relaxation response** and replicate it independently during stressful situations.[66] After studying the relaxation response for 20 years, Dr. Herbert Benson identified two essential components that elicit the response: (1) repetition of a sound, word, phrase, prayer, or muscular activity; and (2) disregarding distracting thoughts and returning to the repetition. Benson[21] suggests that patients use the following techniques:

1. Choose a phrase, word, or prayer that is part of your belief system.
2. Sit comfortably and quietly.
3. Close your eyes.
4. Relax your muscles beginning with your feet and working your way up your body.
5. Breathe naturally and slowly. Say your phrase, word, or prayer silently as you exhale.
6. Rid yourself of all distracting thoughts by letting them flow in and out of your mind like waves on the ocean, always returning to your phrase, word, or prayer.
7. Continue for up to 20 minutes.
8. Sit quietly for a minute, allowing your thoughts to return before opening your eyes. Sit for another minute before standing.
9. Practice this technique daily on an empty stomach if possible.

The relaxation response has proven to be effective in treating headaches, hypertension, anxiety, cardiac rhythm irregularities, mild and moderate depression, and premenstrual syndrome. The relaxation response works by decreasing heart rate, rate of breathing, metabolism rate, oxygen consumption, and carbon dioxide elimination, and returning the body to a healthier balance.[21,66,67] When within-subject comparisons were made between blood pressure before and after meditation using the nine aforementioned steps above for several weeks, the average systolic blood pressure for the 36 subjects dropped from 146 to 137 mm Hg, and diastolic pressure dropped from 93.5 to 88.9 mm Hg; both are statistically significant changes.[21] The relaxation response seems to decrease blood pressure through counteracting the activity of the sympathetic nervous system—the same mechanism underlying the action of antihypertensive drugs. Lower blood pressure leads to lower risk for atherosclerosis and related diseases.

Guided Imagery

Another intervention is guided imagery, frequently used as a standard of care to improve rehabilitation through relaxation. Guided imagery is said to work by decreasing

the levels of cortisol that can inhibit the immune system and slow tissue repair.[68] As in eliciting the relaxation response, the patient should be guided to a state in which the mind is silent and calm. Through use of an audiotape, videotape, or therapy guide, the patient is asked to imagine a special place (e.g., the ocean, a forest, a sunset) and focus on vivid details using the five senses. By focusing on this location for increasing lengths of time, patients learn to gain relief from constant worry by releasing concerns for a period of time and returning to a place of relaxation and peace. Guided imagery enhances the mind–body–spirit connection through the induction of an altered state in which the mind communicates more effectively with the body.[60]

The use of guided imagery has achieved improved outcomes of care through significant reductions in pain, blood pressure, stress, side effects of treatments, headaches, uncertainty, depression, insomnia, blood glucose levels, and histamine response to allergies. Significant enhancement of the immune system and wound and bone healing has also been noted.[69] Because music may trigger emotional responses by influencing the limbic system when used with imagery, music used with guided imagery has been shown to decrease pain through increasing endorphin release.[70,71] Guided imagery with music has also been found to reduce the need for large doses of medication and reduce recovery time.[60]

Desensitization

Phobias severe enough to interfere with daily functioning have been reported by one out of every eight American adults.[26] Patients suffering from phobias that interfere with treatment may require desensitization techniques, also called **situational exposure exercises**. For example, wheelchair users with a fear of elevators who always used stairs before injury now require help in coping with their fears. In a comfortable, calm treatment environment far from an elevator, the physical therapist can have the patient begin to talk about benign aspects of elevators (e.g., what they look like, where they are located, and how many floors are in the building). While the patient is answering these questions, the physical therapist should determine the patient's level of anxiety. What specific issue regarding the elevator is the patient discussing when his or her anxiety increases? If the patient has not as yet become too anxious, the therapist may ask more anxiety-producing questions, such as, "How high is the elevator's ceiling?" "Is there an emergency phone?" "Are you more fearful of taking an elevator by yourself or with a crowd of people and why?" "Have you ever taken an elevator before and if so, what happened?" The therapist should continue to examine the patient's level of anxiety during questioning, stopping just before the patient's anxiety reaches a point at which the patient cannot easily be calmed.

This process, called desensitization, allows the patient to discuss his or her fear in a safe environment where he or she does not feel overwhelmingly anxious. The physical therapist slowly increases the level of anxiety by asking more difficult questions, but only to a tolerable degree. The patient is then asked to visually imagine that he or she is in an elevator, while practicing relaxation techniques. The patient continues to practice this visualization, over time, until he or she can do so without experiencing fear. When the patient can visualize himself or herself in an elevator without experiencing fear, therapy progresses to the real-life experience of riding in an elevator with the therapist. Relaxation techniques continue to be used during such real-life practice. The activity of riding in an elevator with the therapist using relaxation techniques continues until the patient can do so without fear. The final step would be for the patient to practice riding in an elevator alone while using self-induced relaxation techniques. Desensitization therapy has a high rate of effectiveness in the treatment of phobias.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (or **cognitive restructuring**) can help decrease anxiety by changing **maladaptive thought patterns** and modifying unhealthy behaviors.[72] Before unhealthy behaviors can be modified, they must first be identified and classified. Because many patients are not conscious of their anxiety, an initial step when using cognitive-behavioral therapy is to help patients recognize anxiety. Determine what the patient's first signs of stress tend to be. Many will reply that they react severely to stress, stating "I throw up," or "I cannot breathe." In these cases, therapists should ask about the existence of less severe signs, such as nail biting or leg shaking.

Next, patients should count how many times a day they experience stress, recording these in a journal. Physical therapists should help patients look for patterns in their anxiety. Are patients more anxious in the morning or evening, when they attend therapy, or when family members visit? The more patients can identify patterns of anxiety, the more they can anticipate it and prepare for anxiety before it occurs. Therapists should encourage patients to use stress management techniques as soon as they experience the first sign of stress so that their anxiety does not escalate. Keeping a stress management journal can give patients insight into how their thoughts affect their behavior. Research has shown that cognitive-behavioral therapy can be as effective as medication.[73-77] Box 26.3 Evidence Summary presents a summary of research data examining the effects of cognitive therapy versus use of antidepressants for depression.

Treatment for Panic Attacks

If the therapist knows that a patient has a history of panic attacks, the following techniques can be helpful.

Box 26.3 Evidence Summary Research Examining the Effects of Cognitive Therapy versus Antidepressants for Depression—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Blackburn and Moorhead[73] (2000)	Depressed (non-bipolar and nonpsychotic) or dysthymic outpatients 64% female; mean age = 43.7	Randomized treatment-outcome study comparing two groups: cognitive therapy ($N = 22$) and antidepressant treatment (amitriptyline or clomipramine) ($N = 20$)	12.9 weeks of therapy or medication in a hospital.	21% of the cognitive group became depressed again during a 2-year period following intervention vs. 78% of the antidepressant group, a significant ($p < .05$) difference.	Cognitive therapy for patients with mild to moderate depression should be considered before referral to a psychiatrist for antidepressants.
Butler et al[74] (2006)	Subjects came from different studies and had a variety of psychiatric diagnoses: unipolar depression, generalized anxiety disorder, panic disorder, social phobia, post-traumatic stress disorder, childhood depressive and anxiety disorders, childhood somatic disorders, adult depression, obsessive-compulsive disorder, bulimia nervosa, schizophrenia, and chronic pain	Meta-analysis of 16 meta-analytic studies examining the efficacy of cognitive behavioral treatment vs. psychopharmacology on psychiatric clients	Duration varied with studies.	Effect sizes for cognitive behavioral therapy in the treatment of generalized anxiety disorder, unipolar depression, panic disorder, post-traumatic stress disorder, panic disorder, and childhood anxiety and depressive disorders were large. Moderate effect sizes were reported for cognitive behavioral therapy in the treatment of chronic pain, marital distress, childhood somatic disorders, and anger. For adults with depression, cognitive-behavioral therapy was more effective than antidepressants. Venlafaxine (Effexor) demonstrated the highest rates of remission compared to SSRIs but other therapies such as cognitive were also necessary for a high percentage of patients to achieve full remission from depression.	Limitations due to a meta-analysis are present in this study; it is difficult to compare studies that use different lengths of treatment and assessments. However, the findings in this review of meta-analytic studies support other studies on the effectiveness of cognitive-behavioral therapy.

Box 26.3 Evidence Summary Research Examining the Effects of Cognitive Therapy versus Antidepressants for Depression—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Lam and Sidney[75] (2004)	A total of 31,368 depressed subjects throughout different studies	Meta-analysis of 16 meta-analyses (227 RCTs and 19 studies of other rigor) examining the efficacy of antidepressants vs. psychotherapies in achieving and sustaining remission from depression	Longitudinal studies	MANOVAs revealed no significant difference between different types of psychotherapy and their effect on decreasing depression regardless of the disorder; however, clients (regardless of disorder) treated with psychotherapy (regardless of the type) showed significant improvement at the end of therapy and at follow-up compared to those in the control group.	The combination of antidepressants and psychological therapy resulted in 70% of the patients sustaining remission from depression over extended periods of time.
Leichsenring et al[76] (2004)	Major depression, maternal depression, post-traumatic stress disorder, bulimia nervosa, anorexia nervosa, opiate dependence, cocaine dependence, cluster C personality disorders, somatoform pain disorder, borderline personality disorder, social phobia, and chronic functional dyspepsia	Meta-analysis of 17 RCTs that examined the effects of various short-term psychotherapies (including cognitive) on depression	Intervention ranged from 7 to 40 sessions. Mean length of follow-up was 1 year.	Patients who received combined intervention made significantly greater improvements than those who received antidepressants alone (OR, 1.86; 95% CI, 1.38–2.52). Medication nonresponders and dropout rates were not significantly different between the two groups (OR, 0.86; 95% CI, 0.60–1.24). Combined intervention was significantly more effective than drug intervention alone in studies where intervention lasted longer than 12 weeks (OR, 2.21; 95% CI, 1.22–4.03), with a significant decrease in dropouts when compared with nonresponders (OR, 0.59; 95% CI, 0.39–0.88).	Not all of the studies in this meta-analysis used cognitive therapy, nor did the meta-analysis identify which elements of the different short-term psychotherapies were effective in reducing depression and preventing relapse.

Box 26.3 Evidence Summary Research Examining the Effects of Cognitive Therapy versus Antidepressants for Depression—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Pampallona et al[77] (2004)	Control group consisted of wait-listed patients, 16 trials of 910 depressed patients randomized to pharmacotherapy combined with psychotherapy and 932 to pharmacotherapy alone	Systematic review of RCTs that examined the relationships between efficacy of and adherence with psychological intervention plus antidepressant drugs vs. psychopharmacology alone	Duration of intervention varied according to the particular study.		Antidepressants combined with psychotherapy was more effective in the treatment of depression than antidepressants alone.

CI = confidence interval; MANOVAs = multivariate analyses of variance; OR = odds ratio; RCTs = randomized controlled trials; SSRIs = selective serotonin reuptake inhibitors.

Have the patient describe the first signs of discomfort during the attack. Immediately help him or her to breathe long, deep, and slow breaths. This may require the use of a brown paper bag held by the patient over the mouth while breathing into it to slow the inhalation rate. It is beneficial to acknowledge that a panic attack is occurring and that the patient will be all right if he or she continues to focus on breathing slowly and deeply. The panic attack can become severe within minutes and pass just as quickly. The patient most likely will be seated or lying down throughout the panic attack, as it may render him or her incapable of doing anything else.

Patients are usually embarrassed after an attack and may avoid all situations in which they believe one may occur. They may sit on the end of the aisle while watching a movie, may avoid crowds, or, in extreme cases, stop leaving their homes entirely (referred to as **agoraphobia**). Therapists can help patients who experience panic attacks to achieve a more productive life by teaching them techniques to control the attacks before they become severe. Families and patients should be educated to understand that panic attacks involve a real physiological reaction, tend to last only several minutes, and often recur without further intervention. Patients with severe, continuous panic attacks should be referred to a psychiatrist for possible medication management.

When to Make a Referral for Anxiety

Multiple referrals may be necessary. Patients who have panic attacks should be referred to a psychiatrist for a medication consultation. Generalized anxiety can be treated with medication; hence, a referral to a psychiatrist would be appropriate if the anxiety lasts more than a week and interferes with the patient's performance in rehabilitation. Those who continue to experience anxiety from phobias despite desensitization therapy and medication should be referred to a psychologist for a more in-depth exploration of their fears. A referral to a psychologist is indicated if the anxiety seems to be a deeply rooted characteristic of the patient's personality. A social work referral can be helpful if the patient's anxiety results from a lack of necessary resources or involves family members.

In many cases, medication does not fully alleviate patients' anxiety. However, it may decrease it sufficiently enough for patients to begin expressing their fears and implementing strategies to decrease stress. Sometimes a patient may not be forthcoming about his or her anxiety and a formal diagnosis may not be present in the chart. If this is the case, the physical therapist may become aware of an anxiety disorder through the type of medication prescribed. By becoming familiar with the names of different antianxiety medications, physical therapists can identify patients suffering from anxiety. The names, effects, and adverse side effects of commonly prescribed antianxiety medications are presented in Table 26.4.

ACUTE STRESS DISORDER AND POST-TRAUMATIC STRESS DISORDER

People who were disabled as a result of a traumatic event (e.g., a violent crime, abuse, an accident, a natural disaster, or war) or individuals who have witnessed such are

Table 26.4 Effects and Adverse Side Effects of Commonly Prescribed Antianxiety Medications

Medication	Summary of Effects	Adverse Side Effects
Alprazolam (Xanax)	Decrease anxiety, seizures, sleep disorders, alcohol abuse, catatonic schizophrenia	Sedation, potential for abuse, difficult to taper (gradual dose reduction)
Buspirone hydrochloride (BuSpar)	Decrease depression, anxiety, addictions, ADHD	Tremors, decreased appetite, insomnia, restlessness
Chlordiazepoxide (Librium, Mitran, Reposans-10)	Decrease anxiety, seizures, sleep disorders, alcohol abuse, catatonic schizophrenia	Sedation, potential for abuse, difficult to taper
Clorazepate dipotassium (Tranxene, Gen-Xene)	Decrease anxiety, seizures, sleep disorders, alcohol abuse, catatonic schizophrenia	Sedation, potential for abuse, difficult to taper
Diazepam (Diastat, Valium)	Decrease anxiety, seizures, sleep disorders, alcohol abuse, catatonic schizophrenia	Sedation, potential for abuse, difficult to taper
Estazolam (Prosom)	Decrease insomnia	Cognitive impairments, dizziness, daytime sleepiness, anxiety, uncoordinated motor movements, intoxication, drug accumulation
Flurazepam hydrochloride (Dalmane)	Decrease insomnia	Cognitive impairments, dizziness, daytime sleepiness, anxiety, uncoordinated motor movements, intoxication, drug accumulation
Hydroxyzine hydrochloride (Vistaril)	Decrease insomnia, tremors, weight gain, anxiety	Dizziness, sedation, constipation, cotton mouth, weight gain, urinary retention, blurred vision, hypotension, confusion
Lithium carbonate (Eskalith, Lithobid)	Decrease mania and suicidal ideation, stabilizes mood	Toxicity can be lethal, increase weight, nausea, acne, sedation, psoriasis, diarrhea, polydipsia, tremors, edema, uncoordinated motor movements
Lorazepam (Ativan)	Decrease anxiety, seizures, sleep disorders, alcohol abuse, catatonic schizophrenia	Sedation, potential for abuse, difficult to taper
Oxazepam (Serax)	Decrease anxiety, seizures, sleep disorders, alcohol abuse, catatonic schizophrenia	Sedation, potential for abuse, difficult to taper
Temazepam (Restoril)	Decrease insomnia	Cognitive impairments, dizziness, daytime sleepiness, anxiety, uncoordinated motor movements, intoxication, drug accumulation
Triazolam (Halcion)	Decrease insomnia	Cognitive impairments, dizziness, daytime sleepiness, anxiety, uncoordinated motor movements, intoxication, drug accumulation
Zaleplon (Sonata)	Decrease insomnia	Dizziness, drowsiness
Zolpidem tartrate (Ambien)	Decrease insomnia	Dizziness, drowsiness

Note: Brand names are shown in parentheses.
ADHD = attention deficit–hyperactivity disorder.

at risk for **post-traumatic stress disorder** (PTSD) or **acute stress disorder** (ASD). Both are specific forms or subsets of anxiety disorders. The *Diagnostic and Statistical Manual of Mental Disorders* differentiates between both disorders in terms of the duration of the disorder and its symptoms.[9] ASD involves symptoms that must range in duration between 2 days to a maximum of 4 weeks. If symptoms of ASD persist longer than 4 weeks, the diagnosis of ASD is discontinued and changed to PTSD. Post-traumatic stress disorder is differentiated as *acute* PTSD if symptoms last more than 4 weeks but less than 3 months and as *chronic* PTSD if symptoms last 3 months or longer. Both ASD and PTSD, however, must result from exposure to a traumatic event, and PTSD can be qualified with the term "with delayed onset" if symptoms first occur at least half a year after the traumatic event. Research notes that PTSD is an expected outcome for a certain percentage of patients experiencing even mild traumas.[78,79]

Among the symptoms exhibited are one or more of the following: reexperiencing the traumatic event; **numbing** of responsiveness to, or reduced involvement with, the external world; and/or a variety of autonomic, dysphoric, or cognitive symptoms. The reexperiencing of the event is described as recurrent, painful, and consisting of intrusive recollections, dreams and nightmares, and, on rare occasions, dissociative states during which the individual may act as if reliving the actual traumatic event. This may last only several minutes or occur for hours or even days. The numbing of responsiveness, also called *psychic numbing* or *emotional anesthesia*, is expressed by complaints of feeling detached or estranged from others, a loss of ability or interest in previously enjoyable activities, or the lack of any emotions or feelings. Cognitive symptoms may include impairment of memory, concentration, and task completion ability. Patients may experience excessive autonomic arousal resulting in hyperalertness, anticipatory anxiety, an exaggerated startle response, constant scanning of the environment, the perception of people and objects that are not real (i.e., **hallucinations**), or difficulty falling and remaining asleep.[80] Following this state of hypervigilance, the patient may experience a denial reaction marked by a diminution of responsiveness to the environment. Survival guilt may be present in those cases in which others were harmed or killed during a catastrophic event.

Additional associated features that should alert the physical therapist to the presence of PTSD are increased irritability, hostile behavior, constant tension, chronic **free-floating anxiety**, muscle tension, sexual and social difficulties, and somatic stress symptoms. Box 26.4 summarizes some of the prominent behavioral features of PTSD.

Box 26.4 Behavioral Features (Warning Signs) of Possible Post-Traumatic Stress Disorder (PTSD)

Any one of the following behaviors:

- Recurrent, intrusive recollection of traumatic event
- Intrusive and distressing dreams of event
- Dissociative states (behaving as if reliving event; can last for several seconds or minutes)
- Amnesia of events

More than one of the following behaviors:

- Psychic numbing (lack of interest in social or physical environment or activities; significantly lowered participation in social or physical environment)
- Unable to feel emotions (e.g., intimacy, love, sexuality, anger)
- Disturbed sleep patterns
- Hypervigilance
- Exaggerated startle response
- Ongoing level of irritability
- Heightened difficulty with concentration

Not everyone who experiences trauma develops PTSD. The triple vulnerability model postulates that three vulnerabilities need to be present to develop an anxiety disorder: (1) a biological vulnerability; (2) a generalized psychological vulnerability (existing from past experiences of lost control over unpredictable events); and (3) a specific psychological vulnerability that links anxiety to specific situations.[81] Keane and Barlow[82] have proposed an explanation for how PTSD develops based on the triple vulnerability model. They suggest that during a traumatic event, a person experiences alarm and other intense emotions. The person is more likely to develop PTSD if the event and resultant emotions are perceived to be unpredictable and beyond the person's control. If the event is perceived to be predictable and within the person's control, it is less likely that PTSD will occur.

Chronic pain frequently occurs concurrently with PTSD, and the occurrence of both disorders tends to negatively affect the treatment outcome for each.[83] Similar processes, such as avoidance, fear, anxiety, oversensitivity, and catastrophizing (i.e., interpreting an experience as overly threatening), may act to maintain both conditions. Given the high co-morbidity of PTSD and chronic pain, physical therapists should examine patients with PTSD for the existence of chronic pain. The Yale Multidimensional Pain Inventory or the McGill Pain Questionnaire can be administered.[84,85] PTSD may be examined using the Clinician Administered PTSD Scale Revised or the

Posttraumatic Stress Disorder Checklist.[86,87] Examination should also include the patient's beliefs, self-efficacy, level of anxiety, sensitivity, coping style, expectations, and degree of behavioral and cognitive avoidance in order to understand the mechanisms that may maintain these conditions. See Chapter 25, Chronic Pain, for a more detailed discussion of instruments designed to measure pain.

The main desired outcome of treatment for PTSD should be engagement in healthy, satisfying, necessary activities. The physical therapist can help patients to build positive self-efficacy through **cognitive restructuring**, development of healthy coping skills, and learning to use the relaxation response—all in a predictable, safe environment. Techniques used to help decrease catastrophizing and avoidance include situational exposure exercises (mentioned earlier) and **interoceptive exposure exercises** (such as running in place or spinning in a chair).[88] Interoceptive exposure exercises help patients cope with uncomfortable physiological sensations that may prevent participation in activities. Finally, the therapist should provide the patient education regarding how PTSD and pain can facilitate each other and result in avoidance. As participation in healthy activities increases, co-occurring disorders—such as depression, anxiety, panic, and substance abuse—may decrease, and a higher quality of life may ensue for the patient with PTSD.

Depression

Depression refers to feelings of despair and hopelessness, negative shifts in perception, and decreased interest in activities that once provided pleasure. A person may have a depressed personality (referred to as *dysthymia*) and therefore experience sadness throughout his or her entire life. As in most cases of depression, a person may have one or more episodes of depression, before and after which a normal mood exists. A certain degree of depression is normal in response to life's events, but when depression lasts 2 or more weeks and affects occupational and social functioning, it is considered to be **major depression**. Depression may occur as a biochemical imbalance in the brain, which may be triggered by stress, or in response to internal conflicts or life events. For example, the rate of depression in people with SCI is five times higher than that of the general population.[89]

Women with disabilities are more prone to depression (30%)[90] than women without disabilities (10% to 25%),[9] men with disabilities (26%),[90] and the general population (10%).[9] Other researchers support the finding that women with disabilities tend to experience depression more commonly than their male counterparts. In their analysis of 443 women with disabilities, Hughes et al[91] found depression to be a frequently occurring secondary condition (51% of the sample scored in the mildly depressed range or higher on the Beck Depression Inventory–II [BDI-II]). Fifty-nine percent of women with SCI were found to be clinically depressed, compared to a rate of 4.5% to 9.3% of women in the United States at any given time.[92] This high rate of depression among disabled women may be due to the combination of being a woman and having a disability, since both are risk factors for depression. Women are more than twice as likely to have a depressive episode than men due to economic, social, psychological, and biological factors.[93] Female socialization experiences and gender-based roles may also increase their vulnerability to depression. Depression in women has been linked to experiences of abuse and poverty, lack of social support, reduced mobility, chronic pain, lower educational levels, and lower levels of perceived control.[94]

If untreated, depression can spiral into greater severity and may result in suicide; 15% of people who are depressed commit suicide each year.[18] Depression may begin with loss, such as the onset of a physical disability, divorce, death, or the departure of a close friend. As a result of such losses, patients may become appropriately sad and mournful. If patients reach out to friends and express their feelings, they can alleviate feelings of loneliness and isolation that commonly occur in response to loss. However, if patients do not take steps to express their feelings, the downward spiral of depression may continue. Over time, patients may lose interest in activities and remain at home. They may lack the energy or motivation to attend to their responsibilities, and feelings of guilt may ensue. A decrease in role participation usually leads to diminished self-esteem and feelings of worthlessness. Eventually, people stop caring about their hygiene. They may avoid social contact and become increasingly lonely. At this point, staying in bed becomes a welcome alternative to dealing with the outside world and the painful feelings it may incur.

Depression and Rehabilitation

Given the signs and symptoms of depression (Table 26.5) and its associated behaviors (Table 26.6), depression may negatively affect the outcome of treatment. Depressed patients may have difficulty getting out of bed and may not be motivated to attend therapy. If they do attend treatment, they may display **psychomotor retardation** and lack energy and interest; they may also verbalize self-deprecating remarks, feel criticized, and believe that they are progressing inadequately. It may be difficult for physical therapists to leave depressed patients unattended while working with others because the depressed patient may not engage in the prescribed exercises. Patients may feel guilty that they are in the hospital instead of taking care of their children, working to earn money for their family, or engaging in other life roles.

Table 26.5 Signs and Symptoms Associated with Mild, Moderate, and Severe Depression

Mild Depression	Moderate Depression	Severe Depression
Anger	Decreased self-esteem	Anguish
Anxiety	Despair	Change in appetite and weight
Decreased concentration	Despondence	Decreased sex drive
Depressed mood	Excessive guilt	Desperation
Indecisiveness	Fearfulness	Feeling overwhelmed
Intrusive thoughts	Inadequacy	Helplessness
Irritability	Sensitivity	Hopelessness
Lethargy		Insomnia or excessive sleep
Loneliness		Recurrent thoughts of suicide
Neediness		Worthlessness
Sadness		

Table 26.6 Behaviors Associated with Mild, Moderate, and Severe Depression

Mild Depression	Moderate Depression	Severe Depression
Being easily frustrated	Crying	Decreased interest in all activities
Difficulty planning ahead	Feeling pessimistic about the future	Lack of personal hygiene
Obsessing about tasks	Having difficulty making decisions	Staying in bed all day
Sitting alone	Making frequent self-deprecating remarks	Suicide (or suicide attempt)
	Overdependence	
	Reacting strongly to criticism	
	Reporting psychosomatic symptoms	
	Ruminating about problems	
	Ruminating about the past	
	Social withdrawal	

Depression usually affects performance negatively. Depressed patients may not want to make gains in rehabilitation because of decreased motivation and lack of pleasure in life. They may believe that they are unable to progress in rehabilitation as a result of low self-esteem or feelings of hopelessness. Such patients may also have difficulty asserting themselves because of feelings of worthlessness and an inability to express anger. When people feel worthless or have low self-esteem, they may feel unworthy of having or voicing an opinion. Depression may result from anger turned inward. Instead of expressing anger in the moment, depressed patients may turn their anger against themselves or repress it. People who experience this type of depression may not have been allowed to express hostility in the past.

Depressed patients often become immobilized because they have difficulty making decisions. They may weigh the pros and cons of each choice and become overwhelmed. They may be unable to concentrate on one thought long enough to make decisions. Sometimes depressed patients experience the opposite; when they attempt to execute a decision they may have no thoughts at all (referred to as **thought blocking**). Consequently, they may need 1 to 2 minutes to think about and answer questions.

Treating Patients with Depression

Depressed patients require assistance with motivation. Physical therapists can facilitate motivation by providing encouragement, emphasizing strengths, offering positive feedback, addressing values, and mobilizing guilt into goal acquisition. Empowering patients by providing activities that offer opportunities for self-control and success have been shown to decrease depression.[95,96]

Depressed patients experience a narrowing of perception. They have difficulty seeing alternate solutions to problems or simple tasks and often feel there is no solution to obstacles. They may perceive their condition as terminal when there is no justification for such a belief. Because of these distortions, it is important to offer reality checks—such as pointing out their strengths when they feel worthless. Cognitive therapy can be used to correct ongoing pessimism by challenging negative thought patterns.

If given choices about their treatment, depressed patients may become ambivalent and unable to decide on a course of action. As a result, they may do nothing. Physical therapists should choose treatment that provides the patient with opportunities for progressive success experiences, avoiding feelings of failure. When reluctant patients perceive that they can succeed in therapy instead of giving up, their chances of continuing treatment increase. Progress made in physical rehabilitation can alleviate depression, as patients report feeling better after having succeeded in an activity they believed they could not accomplish.

Perhaps the most valuable information that a physical therapist can offer depressed patients is that depression will not last forever. Patients will eventually become better through the combination of therapy and possible medication management. Depression can cause an activity or life role that once seemed effortless—such as being a partner in a relationship—to become arduous. It is important for the patient to understand that this does not mean that the relationship caused the depression; more likely, the role of partner has become more difficult to carry out because of depression.

Families often experience a depressed family member as lazy, obstinate, or uncaring, and may not recognize that he or she is suffering from an illness. Depression can be just as disabling as a physical illness. Families need to be educated that depression, like physical disability, causes decreased functioning and requires treatment. Recovery from depression does not have a specific timeline. Each patient's situation is unique, as is the recovery period. Most patients cannot "snap out of it" as many family members desire.

When to Make a Referral for Depression

If depression is suspected, the physical therapist should determine if the patient is currently being treated for depression or has received treatment in the past. If the patient has never been treated for depression and is experiencing suicidal ideation (see section on Suicide below) or symptoms of depression that markedly impair life roles, the therapist should refer the patient to a psychiatrist for possible medication management. Medication can enable patients to attend therapy, more readily discuss problems, and express repressed feelings. However, some patients are reluctant to inform their physical therapist of their depression out of stoicism or shame. (There is often a negative stigma attached to being depressed because, to the uninformed, it may imply weakness or feeling sorry for one's self.) A diagnosis of depression may not be in the chart and the symptoms may be misinterpreted as fatigue. In these cases, knowledge of the names of medications used to treat depression may help therapists identify patients with depression. The names, effects, and adverse side effects of frequently prescribed antidepressant medications are presented in Table 26.7.

Patients with less severe symptoms who are not suicidal can be referred to a psychologist for verbal therapy. If a patient's depression seems to be caused by family turmoil, a referral to a social worker for family intervention can be made. Patients who have difficulty verbalizing their feelings can be referred to a creative arts therapist to facilitate expression through nonverbal means such as music, dance or art. A referral to an occupational therapist can be made to help patients regain function in daily life roles that have been disrupted by depression.

Suicide

Each year more than 35,000 cases of suicide are reported in the United States, and 65,000 additional cases may go unreported due to complications regarding the cause of death.[26] More people lose their lives to suicide than to any other cause, with the exception of cancer and cardiovascular disease. Suicide is often a result of poor social support, low self-esteem, ineffective coping skills, and the inability to see a solution to difficult situations. Risk factors include serious illness, previous suicide attempts, family history of suicide, alcohol and substance abuse/dependence, loss of a loved one through rejection or death, prolonged depression, and financial difficulties.

Recognizing the warning signs of possible suicide risk is important for its prevention. The most frequent signs of suicide risk include the following:

- Direct comments about suicide, such as, "I just want to die"
- Indirect comments about suicide, such as, "My mother will not have to worry about me anymore"
- A plan to commit suicide
- Writing a suicide note
- Preoccupation with death
- A sudden flight into happiness or relief after a long depression
- Excessive risk taking (e.g., driving while inebriated) and a careless attitude
- Final preparations (e.g., composing a will, giving away personal possessions, repairing broken relationships, or writing revealing letters)
- Self-hatred

Table 26.7 Effects and Adverse Side Effects of Commonly Prescribed Antidepressant Medications

Medication	Summary of Effects	Adverse Side Effects
Amitriptyline hydrochloride (Elavil)	Decrease depression, manage anxiety, insomnia, migraines, and chronic pain.	Adverse side effects: dry mouth, urinary retention, constipation, hypotension, dizziness, tachycardia, blurred vision, impaired memory, and weight gain.
Amoxapine (Asendin)	Decrease depression, manage anxiety, insomnia, migraines, and chronic pain.	Dry mouth, urinary retention, constipation, hypotension, dizziness, tachycardia, blurred vision, impaired memory, and weight gain.
Bupropion (Wellbutrin)	Decrease depression, anxiety, addictions, and ADHD.	Tremors, decreased appetite, insomnia, and restlessness.
Celexa (Lexapro)	Decrease depression and anxiety.	Adverse side effects: nervousness, nausea, headache, diarrhea, sexual dysfunction, insomnia, apathy, sweating, hyponatremia, fatigue, and may cause suicidal ideation in children and teens.
Desipramine hydrochloride (Norpramin)	Decrease depression, manage anxiety, insomnia, migraines, and chronic pain.	Adverse side effects: dry mouth, urinary retention, constipation, hypotension, dizziness, tachycardia, blurred vision, impaired memory, and weight gain.
Doxepin hydrochloride (Sinequan, Zonalon)	Decrease depression, manage anxiety, insomnia, migraines, and chronic pain.	Adverse side effects: dry mouth, urinary retention, constipation, hypotension, dizziness, tachycardia, blurred vision, impaired memory, and weight gain.
Fluoxetine (Prozac, Sarafem)	Decrease depression and anxiety.	Nervousness, nausea, headache, diarrhea, sexual dysfunction, insomnia, apathy, sweating, hyponatremia, fatigue, and may cause suicidal ideation in children and teens.
Fluvoxamine (Luvox)	Decrease depression and anxiety.	Nervousness, nausea, headache, diarrhea, sexual dysfunction, insomnia, apathy, sweating, hyponatremia, fatigue, and may cause suicidal ideation in children and teens.
Imipramine hydrochloride (Tofranil)	Decrease depression, manage anxiety, insomnia, migraines, and chronic pain.	Dry mouth, urinary retention, constipation, hypotension, dizziness, tachycardia, blurred vision, impaired memory, weight gain.
Isocurboxazid (Marplan)	Decrease depression and anxiety; used to treat bipolar depression and treatment-resistant depression.	Dizziness, hypotension, weight gain, sedation, cotton mouth, insomnia, and sexual dysfunction.
Maprotiline (Ludiomil)	Decrease depression and manage anxiety, insomnia, migraines, and chronic pain.	Dry mouth, urinary retention, constipation, hypotension, dizziness, tachycardia, blurred vision, impaired memory, and weight gain.

ADHD = attention deficit–hyperactivity disorder.

- Changes in personal appearance, eating habits, sexual drive, sleep patterns, menstrual cycle, behavior (e.g., inability to concentrate or disinterest in activities), or personality (e.g., withdrawal, anxiousness, sadness, irritability, apathy, indecisiveness, or fatigue)
- A recent loss accompanied by an inability to stop grieving

The most important thing for a physical therapist to do when suspecting that a patient is suicidal is to prevent him or her from carrying out the act. This usually involves obtaining help from a mental health professional, preferably a physician with the knowledge and ability to admit the person to a hospital if needed. It is important not to leave the patient alone while

waiting for help. During this period, the following should take place:

- Ask patients if they are thinking of hurting or killing themselves.
- Listen to patients without expressing shock, without discrediting what they say, and without devaluing their feelings; take all suicide threats seriously even if you do not believe them at the time.
- Respond to patients with empathy and understanding; tell them how much you care about them and that you will be available to help them.
- Help patients think of alternatives; offer choices based on your knowledge about the patient's life, rather than generic answers that are easy to offer when under pressure.
- Alert family members, friends, and significant others to the patient's suicide risk; all of these individuals may help prevent the patient from trying to commit suicide; suicidal ideation does not go away in a day; additional help is required from all possible sources over time.

SUBSTANCE ABUSE

Substance abuse occurs when an individual demonstrates a dysfunctional pattern of drug and/or alcohol use characterized by recurrent and significant adverse consequences. Substances may include, but are not limited to, alcohol, amphetamines, caffeine, marijuana, cocaine, hallucinogens, inhalants, opioids, or sedatives.[9]

Substance Abuse and Rehabilitation

If clients come to the clinic under the influence of drugs or alcohol, they may be inappropriate, argumentative, irritable, disinhibited, stubborn, illogical, or angry and will have difficulty following treatment plans. They may also disturb other clients, some of who may be in their own substance abuse recovery. For these reasons, intoxicated clients should be escorted out of the treatment area and referred back to their substance abuse programs, with a call to their substance abuse program provider describing the incident that occurred. If they are not currently engaged in a substance abuse program, a referral should be made. Although many drugs have unique and specific consequences, Table 26.8 presents an overview of common physiological, psychological, and behavioral manifestations associated with substance abuse.

If patients are not under the influence during treatment, but are using drugs or alcohol at home, they may miss treatment sessions or may come to rehabilitation tired, hungry, or late. They may have poor concentration and irritable moods resulting from hangovers. They may experience recurring injuries from falls. Often, patients will not comply with treatment and fail to complete their home exercises or forget to take their prescribed medications. When prescribed medications are ingested along with illegal substances, adverse drug reactions can occur. Patients may lack insight about the extent of their abuse and the trouble that it produces in their lives. They may mask feelings such as anger, guilt, anxiety, or depression through the numbing effect of the substance, but try to present themselves as though they are fine.

Patients in denial commonly do not perceive their need for physical rehabilitation, often neglect to follow precautions, and frequently attempt to obtain discharge before completing rehabilitation goals. Their low frustration tolerance causes them to quit treatment easily. Whether they are actively using substances or not, patients who have abused substances may have **cognitive deficits** that inhibit their ability to follow or remember instructions. They may experience family discord and lose family support, thus finding themselves homeless. Patients with a history of chronic alcohol abuse tend to have poor balance resulting from changes in the cerebellum and peripheral nerves.[97] To maintain balance, they develop a stereotypic, wide-based gait. Such factors should be considered during gait examination and training. Despite their gruff demeanor, patients who abuse substances can be overly sensitive, easily hurt, suffer from low self-esteem, and easily stressed once they are no longer abusing substances. These patients tend to have poor boundaries. They can be intrusive, flirtatious, or deal seeking in order to obtain what they want, such as alcohol, cigarettes, or extra medication.

Treating Patients Who Abuse Substances

Physical therapists can help patients in recovery by providing opportunities that allow them to gain control over their lives again. Such assistance may include opportunities to practice setting boundaries, regulating emotions, and tolerating frustration. Physical therapists can emphasize healthy activities that provide pleasure and decrease cravings. Stress management, time management, ADL, and social skills are usually necessary skills to promote recovery.

Education on Substance Abuse

Physical therapists, patients, and patients' family members should be aware that substance abuse is an illness. Like physical or mental illness, it causes a decrease in function, requires skilled intervention for recovery, results in decreased **role performance**, and can affect anyone. Patients with a diagnosis of substance abuse usually cannot stop using drugs and alcohol on their own. They need help, and recovery is a lifelong process that includes developing skills to manage cravings, dealing with stress in healthy ways, expressing feelings, participating in 12-step programs, and engaging in drug-free activities.

Table 26.8 Common Physiological, Psychological, and Behavioral Manifestations Associated with Substance Abuse

Physiological

- Abnormal blood pressure
- Abnormal pupillary response
- Altered appetite
- Constipation
- Cravings
- Dizziness
- Drowsiness
- Enlarged heart
- Gastrointestinal bleeding
- Hallucinations
- Impaired liver function
- Irregular or increased heartbeat
- Loss of consciousness
- Malnutrition
- Peripheral neuropathy
- Perspiration
- Psychomotor disturbances
- Red nose or eyes
- Reduced perception of pain
- Sensory impairments
- Shiny ears
- Sleep disturbances
- Tremors (shakiness)
- Unexplained weight loss or gain
- Visible needle marks (if injecting)

Psychological

- Confusion
- Delusions
- Denial
- Depression
- Disturbances in interpersonal behavior
- Disturbances of perception
- Easily frustrated
- Emotional lability
- Grandiosity
- Intense emotions
- Loneliness
- Low self-esteem
- Paranoia
- Poor concentration
- Poor memory
- Reduced inhibitions
- Thought disturbances

Behavioral

- Anger
- Associating only with other substance abusers
- Belligerence
- Cheating
- Compulsive use of drugs
- Decreased ability to manage stress
- Decreased ability to manage time
- Difficulty holding a job
- Discontinuation of usual activities
- Drug-seeking and drug-using behaviors
- Falling
- Financial irresponsibility
- Hyperactivity (restlessness)
- Impaired judgment
- Impaired or inability to fulfill major life roles
- Impulsivity
- Inability to control drug use
- Irritability
- Isolation
- Lack of interest in favorite sport or activity
- Lying
- Mood swings
- Nervousness
- Poor hygiene
- Possession of drug paraphernalia
- Spending money on drugs
- Staying up all night (insomnia)
- Stealing
- Violence
- Withdrawal

When to Make a Referral for Substance Abuse

If the patient is going through withdrawal, the physical therapist should immediately refer the patient to a physician. Signs of withdrawal can include sweating, impaired sleep, seizures, impaired motor coordination, faulty judgment, anxiety, shaking, slurred speech, fluctuating levels of consciousness, and visual and tactile hallucinations. After stabilizing the patient, the physician may transfer him or her to a **detoxification unit**. If the patient is not experiencing withdrawal and is not already in a substance abuse treatment program, physical therapists can make a referral to an appropriate treatment center. Such treatment centers include **28-day inpatient rehabilitation** programs, long-term (1 to 1.5 years) inpatient therapeutic communities, 12-step programs for community-dwelling outpatients, and **dual diagnosis programs** for patients who have also been diagnosed with mental illness.

Patients who have been abusing substances for long periods of time should be referred to a **nutritionist** for proper dietary regulation. Physical therapy patients who have been abusing substances can be referred to occupational therapists to address regulating emotions, setting and maintaining appropriate boundaries, tolerating frustration, managing time, obtaining social skills, and regaining necessary ADL. Occupational therapists also can help patients learn that healthy activities can be pleasurable, through task groups in which patients choose, engage in, and discuss healthy activities. A social work referral can be made if the patient requires **community integration**, family intervention, or social supports.

AGITATION AND VIOLENCE

Physical therapists may not expect patients to demonstrate sexual, aggressive, or violent behaviors, yet most have witnessed such behaviors at least once. Therapists

should learn how to predict violence, identify signs of escalation, manage aggressive patients, and verbally respond to threats. Violence is not always predictable, but the more therapists understand its signs, the better equipped they will be to handle a dangerous situation.

An initial step involves recognizing the early signs of agitation. Agitation usually does not diminish by itself. Instead, it may build to a verbal altercation or physical act. Some signs of agitation may include clenching fists, pacing back and forth, making angry facial expressions, grunting, groaning, swearing, tapping a foot, spitting, refusing to engage in therapy, throwing objects, and banging weights or other therapeutic equipment.

After observing signs of agitation, physical therapists should identify the source of the agitation in order to better control it. While many situations can cause agitation, it is important to remember that events that agitate one person may have no effect on another; levels of frustration vary from person to person. People with Alzheimer's disease may become agitated because they cannot recall the names of familiar objects or remember familiar motor plans. They may believe that family members are lying to them, deceiving them, or attempting to place them in a nursing home. People can become agitated as a result of physical pain, memory failure, hunger, fatigue, and dependency on others. Temporal lobe injury, psychosis, and the side effects of certain medications can cause agitation. People with personality disorders who have difficulty managing anger and who have experienced an upsetting event can easily become agitated.

Addressing the underlying circumstance causing the agitation may help to defuse it. If the source of agitation is unknown, the physical therapist should acknowledge to the patient, in a non-accusatory manner, that he or she seems upset. Many people are unaware of their agitation and calm down once it is brought to their attention. The therapist can then encourage the patient to verbally express why he or she feels upset. Therapists can also attempt to redirect patient anger into more productive channels and help alter their perspective regarding the disturbing issue.

Violence also can happen without warning. Many therapists working on inpatient TBI units have been bitten, kicked, punched, or scratched. Patients may feel that they are being forced to participate in therapy they do not need, or that they are being treated like children. They may believe that staff members have assumed control over their lives. To avoid humiliating the patient, therapists can use a client-centered therapy approach in which patients are offered respect and included in goal setting and treatment planning.

If efforts to defuse the patient's agitation do not work and he or she becomes violent, the physical therapist should remove all other patients from the area, then leave and call for help. After an act of violence, members of the rehabilitation team should examine what occurred to learn from the incident, prevent a future recurrence, and provide support and education to those involved. In reviewing the incident, the physical therapist should address the following questions:

- What was the patient's potential for aggression?
- What were the signs of escalating anger?
- Did the patient have a history of violence? If yes, under what circumstances did it occur?
- How did therapists and patients respond to the aggressor before, during, and after the act?
- What could have been done differently during the incident?

In addition to managing an agitated or violent patient, physical therapists need to recognize when a patient is undergoing abuse. It is estimated that 10% of women with disabilities experience sexual, physical, or disability-related violence.[98] Abuse has been related to decreased social support, increased social isolation, and elevated levels of depression and stress.[97] Women with disabilities may be even more susceptible to abuse, due to their dual minority status as people with disabilities and as women. As compared to women without disabilities, women having disabilities experienced longer periods of abuse and abuse from a greater number of perpetrators.[99] Nosek et al[100] have identified several factors that predict with 80% accuracy whether or not a woman has experienced abuse within the past year. These include decreased mobility, social isolation, depression, and a lack of education. Examination for abuse should be considered for women with disabilities.[100] Nosek et al developed a four-item screening tool, the Abuse Assessment Screen—Disability (AAS-D), that examines sexual, physical, and disability-related abuse in the past year.

HYPERSEXUALITY

Hypersexuality is a state of heightened sexual arousal that may be accompanied by verbal or physical aggression. These behaviors can be caused by mania, childhood sexual abuse, or brain damage. Patients may desire attention, or want to provoke or exert power over others, to impress others, or to show off. Verbal signs of hypersexuality can include whistling; verbalizing sexual desires; or asking for physical closeness, phone numbers, or dates. Physical behaviors include staring, pinching, brushing up against another's body, touching, kissing, exposing genitalia, masturbating, and blocking another's exit from a room.

There are several ways to proceed when a patient exhibits hypersexual behavior. If the therapist feels threatened, he or she should leave the area and obtain assistance. If the patient's hypersexual behavior is a newly observed behavior, the therapist can describe

the behavior to the patient and firmly state that it is inappropriate and will not be tolerated. If the therapist believes that the patient is exhibiting symptoms of mania or hypomania, referral should be immediately made to a psychiatrist. Holding a **multidisciplinary team conference** may help the patient understand that hypersexual behaviors are not tolerated in the clinic.

PSYCHOSOCIAL WELLNESS

According to Jacobs and Jacobs[101] and Donatelle and Davis,[26] wellness is a dynamic process in which people attempt to fully develop their emotional, social, environmental, physical, spiritual, and intellectual health. Donatelle and Davis describe a well individual as someone who can forgive himself or herself and others, learn from mistakes, appreciate all things both grand and small, develop a realistic sense of self and the environment, achieve a balance in life roles and daily activities, respect others and maintain healthy relationships, feel a sense of life satisfaction, understand one's needs and express emotions appropriately, and function in his or her community. Achieving this definition of wellness may require substantial effort for someone with a disability who may experience multiple barriers to wellness.

Barriers to Wellness for People with Disabilities

Healthy People 2020 identified gaps and disparities in the health and wellness of Americans with disabilities.[90] It reported that people with disabilities exhibited more symptoms of psychological distress and tended to not engage in as many physical activities as people without disabilities. Objectives to overcome these barriers included to "Increase the proportion of people with disabilities who participate in social, spiritual, recreational, community and civic activities to the degree that they wish" (DH-13) and "Reduce the proportion of people with disabilities who report serious psychological distress" (DH-18).

More specifically, research has found that women with disabilities experience higher levels of stress than do males with disabilities, possibly owing to higher incidences of poverty, violence, abuse, chronic health problems, and social isolation.[93] Economic disadvantage may be due to stress-inducing factors such as earning a lower income, having less access to disability benefits from public programs, having less education than their male counterparts with disabilities, and having a higher likelihood of being unemployed or unmarried.[102] People with SCI report a higher level of perceived stress than the general population, and women with SCI tend to have a higher level of perceived stress than men with SCI.[103]

Social Support

Social support is critical in maintaining or achieving psychosocial wellness. **Social support** is defined as the availability of other persons in the environment who can offer emotional support, financial or material help, a listening ear, guidance, or encouragement. Social support has been associated with increased self-esteem, coping, and adjustment for individuals with disabilities. Evidence suggests that social support plays a strong preventative and palliative role in a wide range of physical and medical conditions. Rintala et al[104] found that the amount of social support was directly related to a sense of life satisfaction and well-being in patients with SCI. Hardy et al[105] and Kaplan[106] found that high social support was predictive of a return to vocational functioning after rehabilitation.

Researchers have suggested that failure to recover from depression stemming from disability may correlate to a lack of adequate social support. Social isolation is a frequently encountered condition associated with disability. Physical restrictions such as pain and mobility limitations may discourage connections with others. The combination of diminished social opportunities, negative societal perceptions, and multiple environmental barriers may result in isolation and a lack of emotional intimacy.

Social support can be used to enhance treatment and promote patient adherence. The physical therapist plays an important role in guiding patient education, including access to resources and instruction in use of adaptive equipment and environmental devices designed to improve a patient's access to social networks and socialization. Appendix 26.C provides Web-based resources for patients, families, and caregivers. It provides resources for improving community accessibility (independent living centers), depression, substance abuse, anxiety, and PTSD.

WELLNESS IN REHABILITATION

Psychosocial wellness requires that patients experience success in both rehabilitation activities and long-term relationships and roles. Rehabilitation activities focus on improving functional outcomes, involvement in meaningful events that foster socialization (e.g., playing wheelchair basketball with other patients), and community reintegration. Long-term relationships and roles include being a spouse, parent, worker, and friend. Psychologists, **social workers**, and occupational therapists can facilitate readjustment to these long-term roles. Both rehabilitation activities and long-term relationships and roles should provide a sense of contentment, happiness, and well-being. Physical therapists can promote and provide opportunities for patients to choose and engage in meaningful activities that promote psychosocial wellness.

Patients who spend a great deal of time dwelling on the past and worrying about the future are unable to be fully cognizant of the present moment. The ability to become absorbed in the present moment can decrease anxiety concerning the past or future—the patient's emotional energy is focused on his or her immediate activities. Each instance in which a patient can focus on the present offers him or her the power to change, to break through old habits, to view circumstances differently, and to recognize available choices. Physical therapists can help patients remain focused on the present moment by selecting activities that are both meaningful to and congruent with the patient's goals for rehabilitation.

Having a daily balance of work, leisure, and social activities is important to sustain psychosocial wellness. Any psychological or physical impairment can disrupt this balance. In a study of the relationship between depression and leisure participation in people with SCI, Loy et al[107] found that patients without depression had wider repertoires and higher levels of leisure activity than patients with depression. Therapists can help patients engage in leisure activities through the use of activity interest surveys and schedules. Activity interest surveys are used to gather information about the types of leisure pursuits patients previously engaged in, which leisure pursuits they currently hold interest in, and which leisure activities they would like to pursue in the future.

A negative outlook inhibits psychosocial wellness. Physical therapists can help patients with negative perspectives to positively alter their expectations through goal setting, identifying optimistic options, using cognitive-behavioral techniques that challenge the validity of negative perceptions, or referring the patient to a psychologist for longer-term intervention.

INTEGRATING PSYCHOSOCIAL FACTORS INTO REHABILITATION: CASE EXAMPLE

Bill, a 19-year-old who was training to be an Olympic gymnast, sustained an SCI in a motorcycle accident. Bill had developed a strong social support system and participated in a variety of extracurricular activities. He was engaged and planning to be married, participated on his college's gymnastic team, and worked as an athletic counselor in the summer camp he had attended since age 7. The SCI he sustained caused a loss of function from his chest down.

All of Bill's energy is now focused on getting through each day. He does not view himself as able to work or attend school. The accident has changed his expectations for the future, his outlook on life, his environmental challenges, and his social support system. His depression was compounded by his broken marriage engagement, and Bill no longer meets his friends for social events; in fact, he rarely leaves his home other than to attend rehabilitation. Just when he was becoming independent of his parents, Bill has now become dependent on them again. He observes his younger sisters and brothers progressing in their lives and feels stagnant, angry, depressed, and ashamed. His self-esteem, which was once high, is now severely diminished and he has lost his familiar identity.

As part of his rehabilitation, the therapist should provide a safe way for Bill to express his anger; referral to a psychologist is also warranted. The therapist can help him to better understand his physical limitations and capabilities. Based on Bill's strengths and limitations, the therapist should help him to redefine interests that could emerge into new roles and a new identity. For instance, it might be helpful if Bill could identify a meaningful activity that could take the place of his athletic training (such as coaching a children's gymnastic team). Information about college and distance learning could also be beneficial. The therapist also can assist Bill and his family in the understanding of SCI and reasonable expectations for the future.

SUGGESTIONS FOR REHABILITATIVE INTERVENTION

Table 26.9 offers a list of behaviors that suggest inappropriate and pathological response patterns to disability. This list is not meant to be fully inclusive, but rather indicates areas requiring further consideration. It is important to understand that even mild expressions of pathological response patterns can become chronic and worsen in severity over time. Table 26.10 identifies patient behaviors that warrant a mental health consultation.

Box 26.5[108] gives examples of general goals and outcomes for patients with psychosocial issues, and Box 26.6 provides instruments typically used to measure these outcomes organized by the *International Classification of Functioning, Disability, and Health* (ICF) Categories.[109] However, human reactions, response patterns, and the adaptation process are variable and individualistic. Each patient must be approached uniquely and treatment goals should incorporate the patient's individual personality characteristics, responses, and needs. An important component of rehabilitation is the patient–practitioner relationship. Physical therapists can establish a therapeutic atmosphere of communication, understanding, and cooperation with patients, which can serve as the foundation necessary to produce positive rehabilitation outcomes. Therapists can sometimes forget the powerful influence they have in setting the tone of this interaction. The very structure and atmosphere of service delivery and the personality and type of communication provided by the practitioner

Table 26.9 Behaviors Suggesting Pathological Response Patterns

Grieving	Depression	Damaged Self-Esteem	Heightened Possibility for Suicide	Heightened Possibility for Violence
Grieving for actual or perceived impairment of functioning or actual loss is normal and expected, but the following might serve as clues to a more severe reaction:	Flat affect (showing little emotion)	Isolation from social sphere	Depression	Low threshold for anger
Denial of problem or its severity	Very low energy levels	Self-destructive behavior	Giving away possessions	Depression
Exaggeration or idealizing the loss	Manic energy and behavior	Inability to sustain eye contact	Hoarding/hiding medications or potential weapons	High-anxiety state
Obsession with the past or the pre-loss state	Psychomotor retardation (slowing down of movement and action)	Inability to accept praise	Writing suicide note	Motoric agitation
Obsession with guilt related to loss	Ruminating about negative thoughts	Judgmental attitude	Updating will	Self-mutilation
Regression	Change in eating and sleeping patterns (insomnia or hypersomnia)	Self-deprecating and self-critical	Verbalizing loneliness or hopelessness	Oversensitive
Difficulty with concentration	Regression	Unwarranted pessimism	Statements regarding benefit of release of pain, absence, and so forth	Argumentative
Loss of interest in activities and events	Social withdrawal	Unconcern for appearance	Intrusiveness of such thoughts	Inability to express feelings
Lability of mood	Self-destructive behaviors	Unconcern for personal safety		Fears of abandonment
Inability to discuss loss	Loss of interest in environment, people, and events			Highly dependent
Fear of being left alone	Self-blame and self-criticism			Dissociative states
Acting out behaviors (tantrums, suicidal gestures, promiscuity)				
Angry stance				

exert a strong influence on patient participation and response to rehabilitation efforts.

Optimizing Patient Involvement

Patients should be involved as fully as possible in their own treatment. This includes involvement in goal setting and treatment planning, as well as in the ongoing evaluation of progress. Patient cooperation is also dependent on the therapist's clear explanation of the patient's situation, anticipated goals and expected outcomes, and interventions. Relating to the patient as a partner in therapy can engender cooperation and trust in the therapeutic relationship. When patients feel a heightened sense of control and ability (i.e., locus of control), feelings of despair and helplessness can be mitigated.

Therapists should also maintain a receptive ear to patient concerns and encourage communication. Listening carefully to patients in a nonjudgmental manner will allow them to reveal concerns and issues they may otherwise feel uncomfortable discussing. Clear and articulate communication, however, can be disrupted by emotion, uncertainty, or power discrepancies that exist when patients become passive recipients of service. Although it may sometimes appear easier to do for patients than to witness their struggle—particularly when patients assume a passive role in rehabilitation—promoting self-reliance andindependence fosters patients' engagement and responsibility in their recovery. Allowing patients to maintain a passive role fosters helplessness, encourages dependency, and slows progress in the long term.

Use of Jargon and Labels

Patient–therapist communication should be characterized by simple and easy to understand language that matches the cognitive level of the patient. The use of scientific jargon and labels should be avoided when speaking with patients, because it impedes patient understanding and emotionally distances patients from therapists. Similarly, when patients hear therapists referring to fellow patients by their diagnosis, they receive the message that patients are nothing more than disabilities. Such practice should be avoided and, instead, therapists should use language

Table 26.10 Patient Behaviors Warranting a Mental Health Consultation

Regression	Regression involves reverting to earlier, more immature patterns of functioning. This may be more commonly observed in children but might be observed in adults as well. For example, children may revert back to sucking their thumb, or may appear to have lost their toilet training skills. Regression in adults may generally be seen in lost skills and abilities and/or even in the extreme behavior of reverting to taking a fetal position.
Disorientation	Disorientation is confusion as to time, place, activity, self-identity, or identity of others. Occasional, transient disorientation is not wholly uncommon in the average person, yet persistence in frequency or duration of occurrence is cause for examination and intervention. Any more extreme confused behaviors and thought processes need to be carefully examined.
Delusional thinking	Delusional thinking refers to faulty and mistaken beliefs and, although related to inaccurate interpretation of environment, is distinguished by the persistence of this belief system. This can run the gamut from delusions of grandeur or of persecution, to delusions about the nature and scope of a disability. These delusions hold up and persist in the face of contrary information.
Inaccurate interpretation of environment	This is the broadest category in this list, but fortunately is also the most readily understood category. Clearly, when a patient significantly misinterprets and misunderstands the objective situation and reality about him or her, it is probably most readily noted by non–mental health practitioners in its many expressions. This should draw attention and intervention, not only in its extreme form of a psychotic break, but also in its minor form of small, repeated episodes of misinterpretations.
Inappropriate affect	Affect refers to the mood state displayed by the patient, where feelings such as joy, sadness, fear, and so forth are reflected in body language, facial expression, and verbalizations. Inappropriate affect can be seen in an affective expression alien to the situation; for example, demonstrating and expressing joy on hearing bad news. It also refers to a split between displayed affect and verbalization; for example, the verbal expression of mourning and condolence offered while smiling brightly and jumping for joy.
Hypovigilance or hypervigilance	Hypovigilance can be noted in a patient being oblivious to his or her surroundings and the events around the patient, socially, as well as physically. Hypervigilance refers to an intense focus and alertness to social and physical surrounds. Each of these has different ramifications and meaning to the mental health team. A consultation is suggested as either extreme is approached.
Mood swings	We all experience changes in mood, yet most of the time these changes are relatively appropriate reactions to external determinants, such as the receipt of news and information or to changing occurrences and circumstances in our environment. Although changeable, moods are generally persistent and stable. When mood shifts either to extremes and/or with some frequency, it suggests either instability or that mood is being driven predominantly by internal rather than external factors.
Self-destructive behaviors	Any self-destructive behavior, particularly ones that persist, are cause for serious concern. Self-destructive behaviors can run the gamut from subtle, difficult to detect signs to very clear and frightening overt signs. Subtle signs can include non-adherence with treatment regimen, poor self-maintenance activities such as not eating, overeating, diminishment of personal care and hygiene, or carelessness in negotiating the environment. Clearer signs can include self-inflicted wounds and suicidal ideation and expressions.
Normal behaviors taken to extremes	Normal human behavior enjoys a wide latitude of response repertoire before drawing attention as being out of expected bounds. This latitude must usually be extended further when dealing with someone undergoing a more extreme, traumatic, or stressful experience. Individuals confronted with a disability would be expected to naturally focus their attention, concerns, and anxiety around this issue. The level of focus on a left leg given by someone preparing to have that leg amputated would be considered obsessive in a healthy ambulatory person, yet normal here. Care in judgment is required by the clinician when determining behavior expressions. That said, issues such as obsessiveness, extreme distractibility, immobilization in the face of routine decisions, and unexpected egocentricity or self-denigration may require a consultation. An overly adherent patient, an extremely calm patient, as well as an overly contentious, argumentative, or extremely anxious or hysterical patient also promotes concern. Any response (verbal or behavioral) that appears unwarranted to the stimuli should draw attention. Overreactions in opposite directions or any behavior that appears to be at an extreme, using reasonable judgment, deserves attention.

Box 26.5 Examples of General Goals and Outcomes for Patients with Psychosocial Issues Adapted from the *Guide to Physical Therapist Practice*[108]

Impact of pathology is reduced.
- Patient/client, family, and caregiver knowledge and awareness of the disease, prognosis, and plan of care is enhanced.
- Symptom management is enhanced.
- Changes associated with recovery are monitored.
- Risk of secondary impairments and reoccurrence of condition is reduced.
- Intensity of care is decreased.

Impact of impairments is reduced.
- Cognitive function is improved.
- Communication is improved.
- Ability to participate in rehabilitation is improved.

Ability to perform physical actions, tasks, or activities is improved.
- Independence in ADL is increased.
- Problem solving and decision making skills are improved.
- Safety of client, family, and caregivers is intact.

Disability associated with chronic illness is reduced.
- Ability to assume/resume self-care and home management is improved.
- Ability to assume roles such as participation in work activities (job/school/play) and community leisure roles is improved.
- Awareness and use of community resources are improved.

Health status and quality of life are improved.
- Sense of well-being is enhanced.
- Stressors are reduced and/or the ability to manage them is improved.
- Insight, self-confidence, and self-management skills are improved.
- Health and wellness are improved.

Client satisfaction is enhanced.
- Access to and availability of services are acceptable to client and family.
- Quality of rehabilitation services is acceptable to client and family.
- Care is coordinated with client, family, caregivers, and other professionals.
- Discharge placement needs are determined.

that reflects respect for the patient's dignity and unique life circumstances.

Rehabilitation Team Members' Self-Awareness

Finally, and perhaps most important, therapists need to be aware of their own feelings, motivations, and responses. Such self-awareness is critical for therapists to understand their own reactions to patients. It is normal for people to respond to others based on conscious or unconscious memories. Sometimes patients can remind therapists of significant others, such as siblings, parents, spouses, or employers. However, when therapists react to patients based on unconscious associations to others, they can misperceive patient needs and respond inappropriately. For example, unconscious reactions to patients can cause therapists to become overprotective or, at the other extreme, become frustrated with patients without recognizing that their own reactions have more to do with other relationships than with the patient at hand.

Generally, when therapists feel a heightened sense of emotion in response to a particular patient it may often serve as a cue that such emotions stem from unconscious associations to others. When this occurs, it is important for therapists to step back and evaluate their own feelings in order to discern the connection between their reactions to the patient and how the patient may be triggering unconscious emotions.

The converse is also true; patients will respond to therapists based on their own unconscious associations with significant others who have similar personality characteristics to those of the therapist. Therapists must be aware of this normal phenomenon and refrain from responding emotionally to the patient's unconscious associations. Rather, the therapist should continue to build a respectful relationship with the patient that, in time, will demonstrate to the patient that his or her first impressions were misperceptions.

SUMMARY

It is important for physical therapists to identify and understand the individual psychosocial factors that enhance or inhibit the rehabilitation of their patients, and intervene accordingly. Successful intervention depends on the following:

- Understanding the psychosocial aspects of each patient, including personality styles and coping skills
- Recognizing and interpreting the common defense mechanisms that patients use in rehabilitation
- Distinguishing the stages of psychosocial adaptation to disability and helping patients' progress in their own adjustment
- Understanding how to identify anxiety, depression, and substance abuse; determining how to address these problems; and recognizing when referral to other team members is warranted
- Integrating a patient/client-centered approach that emphasizes respect, empathy, and compassion
- Empowering patients and families through psychosocial education, and wellness and prevention strategies
- Working together with patients to develop anticipated goals and expected outcomes congruent with their needs, values, and level of functioning
- Collaborating with patients and team members to establish and implement appropriate interventions
- Developing a team approach and providing referrals as necessary

Questions for Review

1. Identify five psychosocial factors and state how each factor may influence rehabilitation.
2. Give examples of interventions for each psychosocial factor identified in question 1.
3. Differentiate among the different mental health professionals who can treat patients with psychosocial issues by describing their roles.
4. What should therapists do to calm an agitated patient?
5. Describe an approach for managing a violent patient and how to analyze an act of violence after it has occurred.
6. What are the manifestations of hypersexuality and how should it be addressed?
7. Identify and describe the phases of psychosocial adaptation to disability.
8. Discuss three coping strategies that have been found to be effective in the psychosocial adaptation to chronic disability and illness.

9. Describe five common defense mechanisms that patients use in response to disability.
10. What are the signs and symptoms of post-traumatic stress disorder?
11. Differentiate between typical reactions to grieving and pathological reactions.
12. Explain several ways to optimize patient involvement in the rehabilitation process and promote self-reliance.
13. Why is patient/client-centered intervention important? What strategies can be used to achieve this type of interaction?
14. Describe the general adaptation syndrome.

CASE STUDY

The patient is a 68-year-old female, admitted to an inpatient unit 2 days after sustaining a right femoral neck fracture from falling down her basement stairs. Hip replacement surgery (arthroplasty) was performed on the same day as the fall. The referring documentation indicates "weight-bearing as tolerated." The patient complains that she "can't do anything" for herself owing to the fall.

Before her fall, she was in fair health but was experiencing declining eyesight, poor short-term memory, and osteoporosis. Her hip fracture has placed her at high risk for further deconditioning and loss of function. The patient's husband had suffered a prolonged illness; the patient cared for him during the last 5 years until he passed away. She has a son whom she rarely sees, because he is married with children and living in another part of the country. A close friend lives several miles from her and the rest of her friends have died. The patient is embarrassed to be seen in public in a wheelchair.

Given the deaths of her husband and friends, and given her recent accident, the patient is now very anxious about her own mortality for the first time in her life. She is preoccupied with her husband's death since he was so much a part of her life. She feels that she has no future and nothing to look forward to. She no longer knows who she is and longs to "be reunited with" her husband.

GUIDING QUESTIONS

1. Identify the psychosocial factors apparent in this case study.
2. What relevant questions about the patient remain unanswered (i.e., what relevant information is missing)?
3. How might the patient's emotional condition affect rehabilitation?
4. Develop a problem list for the patient.
5. Identify the patient's assets.
6. Identify the general goals of physical therapy intervention on which specific anticipated goals and expected outcomes will be based.
7. Identify the general categories of procedural interventions appropriate for this patient.
8. Identify referrals to other professionals or resources.

For additional resources, including answers to the questions for review and case study guiding questions, please visit **http://davisplus.fadavis.com**

Holmes-Rahe Social Readjustment Scale

appendix
26.A

Rank	Life Event	Mean Value
1	Death of spouse	100
2	Divorce	73
3	Marital separation	65
4	Jail term	63
5	Death of close family member	63
6	Personal injury or illness	53
7	Marriage	50
8	Fired at work	47
9	Marital reconciliation	45
10	Retirement	45
11	Change in health of family member	44
12	Pregnancy	40
13	Sex difficulties	39
14	Gain of new family member	39
15	Business readjustment	39
16	Change in financial state	38
17	Death of close friend	37
18	Change to different line of work	36
19	Change in number of arguments with spouse	35
20	Mortgage over $10,000	31
21	Foreclosure of mortgage or loan	30
22	Change in responsibilities at work	29
23	Son or daughter leaving home	29
24	Trouble with in-laws	29
25	Outstanding personal achievement	28
26	Wife begin or stop work	26
27	Begin or end school	26
28	Change in living conditions	25
29	Revision of personal habits	24
30	Trouble with boss	23
31	Change in work hours or conditions	20
32	Change in residence	20
33	Change in schools	20

Continued

Rank	Life Event	Mean Value
34	Change in recreation	19
35	Change in church activities	19
36	Change in social activities	18
37	Mortgage or loan less than $10,000	17
38	Change in sleeping habits	16
39	Change in number of family get-togethers	15
40	Change in eating habits	15
41	Vacation	13
42	Christmas	12
43	Minor violations of the law	11

26.B The Hassles Scale

Directions: Hassles are irritants that can range from minor annoyances to fairly major pressures, problems, or difficulties. They can occur few or many times.

Listed on the following pages are a number of ways in which a person can feel hassled. First, circle the hassles that have happened to you *in the past month.* Then look at the numbers on the right of the items you circled. Indicate by circling a 1, 2, or 3 how *severe* each of the *circled* hassles has been for you in the past month. If a hassle did not occur in the last month, do *not* circle it.

Hassles		Severity		
		1. Somewhat Severe	2. Moderately Severe	3. Extremely Severe
(1)	Misplacing or losing things	1	2	3
(2)	Troublesome neighbors	1	2	3
(3)	Social obligations	1	2	3
(4)	Inconsiderate smokers	1	2	3
(5)	Troubling thoughts about your future	1	2	3
(6)	Thoughts about death	1	2	3
(7)	Health of a family member	1	2	3
(8)	Not enough money for clothing	1	2	3
(9)	Not enough money for housing	1	2	3
(10)	Concerns about owing money	1	2	3
(11)	Concerns about getting credit	1	2	3
(12)	Concerns about money for emergencies	1	2	3
(13)	Someone owes you money	1	2	3
(14)	Financial responsibility for someone who does not live with you	1	2	3
(15)	Cutting down on electricity, water, and so forth	1	2	3
(16)	Smoking too much	1	2	3
(17)	Use of alcohol	1	2	3
(18)	Personal use of drugs	1	2	3
(19)	Too many responsibilities	1	2	3
(20)	Decisions about having children	1	2	3
(21)	Non-family members living in your house	1	2	3
(22)	Care for pet	1	2	3
(23)	Planning meals	1	2	3
(24)	Concerned about the meaning of life	1	2	3

Continued

Hassles		Severity		
		1. Somewhat Severe	2. Moderately Severe	3. Extremely Severe
(25)	Trouble relaxing	1	2	3
(26)	Trouble making decisions	1	2	3
(27)	Problems getting along with fellow workers	1	2	3
(28)	Customers or clients give you a hard time	1	2	3
(29)	Home maintenance (inside)	1	2	3
(30)	Concerns about job security	1	2	3
(31)	Concerns about retirement	1	2	3
(32)	Laid-off or out of work	1	2	3
(33)	Do not like current work duties	1	2	3
(34)	Do not like fellow workers	1	2	3
(35)	Not enough money for basic necessities	1	2	3
(36)	Not enough money for food	1	2	3
(37)	Too many interruptions	1	2	3
(38)	Unexpected company	1	2	3
(39)	Too much time on hands	1	2	3
(40)	Having to wait	1	2	3
(41)	Concerns about accidents	1	2	3
(42)	Being lonely	1	2	3
(43)	Not enough money for health care	1	2	3
(44)	Fear of confrontation	1	2	3
(45)	Financial security	1	2	3
(46)	Silly practical mistakes	1	2	3
(47)	Inability to express yourself	1	2	3
(48)	Physical illness	1	2	3
(49)	Side effects of medication	1	2	3
(50)	Concerns about medical treatment	1	2	3
(51)	Physical appearance	1	2	3
(52)	Fear of rejection	1	2	3
(53)	Difficulties with getting pregnant	1	2	3

Chapter 27

Cognitive and Perceptual Dysfunction

Carolyn A. Unsworth, OTR, PhD

LEARNING OBJECTIVES

1. Identify the signs of cognitive and perceptual deficits.
2. Describe how cognitive and perceptual deficits affect a patient's ability to participate in rehabilitation.
3. Explain how a patient can be assisted to compensate for body scheme and/or body image disorders.
4. Describe how spatial relations impairments can affect the patient's ability to follow directions.
5. Compare and contrast the effect of the various agnosias on the patient's ability to recognize stimuli in the environment.
6. Differentiate between ideomotor and ideational apraxia. Describe how a patient with apraxia might behave in response to different instructional sets commonly employed in rehabilitation.
7. Identify how the psychological and emotional status of a patient with cognitive and perceptual deficits may affect participation in rehabilitation.
8. Analyze and interpret patient data, formulate realistic anticipated goals and expected outcomes, and identify appropriate interventions when presented with a clinical case study.

SUMMARY *1259*

Cognitive and perceptual deficits are among the chief causes of poor rehabilitation progress for patients who have sustained brain damage, even among those whose motor skills have returned. Cognitive and perceptual deficits are some of the most puzzling and disabling difficulties that a person can experience. Thinking, remembering, reasoning, and making sense of the world around us is fundamental to carrying out daily living activities. When individuals experience problems with these capacities, it can have a devastating effect on their lives and the lives of their family. These people may not be able to live alone, fulfill the responsibilities of paid employment, or sustain a family life and relationships.[1] Thus, effective treatment of many patients with brain damage depends on understanding perception and cognition.

The brain may be damaged through several mechanisms, including infections, such as encephalitis; anoxia, as may occur following near-drowning, cardiopulmonary arrest, or carbon monoxide poisoning; tumors that are benign or malignant; trauma resulting from motor vehicle accidents, falls, or violent incidents (e.g., traumatic sports-related injury, gunshot wound); toxins such as alcohol or substance abuse; and vascular disease, which may produce an infarct or hemorrhagic stroke. The largest two groups of people who acquire cognitive and perceptual impairments following brain damage are persons who experienced stroke and traumatic brain injury (TBI).[1] The physical rehabilitation of these patient groups is addressed in Chapter 15, Stroke, and Chapter 19, Traumatic Brain Injury.

The patient who has sustained an initial cerebral vascular accident (CVA) is thought to have focal or localized damage to discrete areas of the brain, often resulting in discrete cognitive or perceptual deficits. In contrast, patients who have sustained a TBI are presumed to have generalized brain damage resulting in cognitive impairment with generalized deficits in attention, memory, learning, and so forth, rather than specific difficulties in discrete cognitive or perceptual functions. However, elements of both perceptual and cognitive dysfunction may occur in brain damage owing to either CVA or trauma. The distinctions between the two groups of patients become particularly blurred when one considers the patient who has suffered multiple strokes; this patient may in fact present with combined elements of both focal and generalized brain damage. Throughout this chapter, the patient with hemiplegia in whom brain damage has occurred as a result of a stroke will be the focus. The overriding goal of this chapter is to introduce the reader to concepts relating to cognitive and perceptual dysfunction following brain damage.

An important focus for the physical therapist should be an understanding of how a particular cognitive or perceptual impairment might be manifested clinically, and how examination and treatment of movement disorders might be adjusted to capitalize on the abilities and minimize the cognitive or perceptual limitations of the patient. Deficits in the cognitive or perceptual domain must be considered to accurately determine the patient's true residual abilities. Using sets of directions that would confuse a patient with apraxia during a specific examination procedure may paint a picture of a greater or different motor disability than that which actually exists. Often the first clue to a cognitive or perceptual problem appears during initial sensorimotor testing. Awareness of the possibility and nature of cognitive or perceptual deficits will signal the therapist to redirect the method of testing, particularly the instructional sets and cues.

COGNITION AND PERCEPTION

The perceptual–motor process is a chain of events through which the individual selects, integrates, and interprets stimuli from the body and the surrounding environment. Cognition can be conceived of as the method used by the central nervous system (CNS) to process information. Cognitive processes include knowing, understanding, awareness, judgment, and decision making.[2] The difficulty of separating perceptual and cognitive deficits is readily apparent, both in patient behavior and in contradictory conceptualizations of these two domains of function. In a review of the literature, Katz[3] found that to some authors, *cognition* is conceived of as a general term that includes perception, attention, thinking, and memory; to other authors, *perception* is an umbrella term that encompasses both cognition and visual perception as subcomponents. At this time, there is insufficient evidence to suggest which approach most accurately reflects the way we think about and perceive information. What is clear is that normally functioning perceptual and cognitive systems are a necessary key to successful interaction with the environment. Because the majority of work in this field does distinguish between cognition and perception[1] and because it is probably easier to learn about these processes individually, they are defined and addressed separately in this chapter.

Cognitive and perceptual capacities are clearly prerequisites for learning,[4] and rehabilitation is largely a learning process.[2] Thus, it is not surprising that patients with cognitive and perceptual disorders are limited in their ability to learn self-care and activities of daily living (ADL) skills; hence, as a group, they are more limited in their potential for achieving independence.[5] In any rehabilitation program geared toward achievement of maximum independence, there is a compelling need for therapists to learn to recognize behavior related to perceptual deficits. The therapist's modification of examination and treatment approaches in light of these deficits will ensure that patients receive the full benefit of these services.

Cognition and Higher-Order Cognition

Cognition is the act or process of knowing, including awareness, reasoning, judgment, intuition, and memory. **Executive functions** are sometimes included under this heading as well. Executive functions include the capacity to plan, manipulate information, initiate and terminate activities, recognize errors, problem solve, and think abstractly. Commonly, executive functions are categorized as *higher-order cognitive functions*[6] or *metacognitive functions*.[7,8]

Perception

Lezak[4] defines **perception** as the integration of sensory impressions into information that is psychologically meaningful. Thus, perception is the ability to select those stimuli that require attention and action, to integrate those stimuli with each other and with prior information, and finally to interpret them. The resulting awareness of objects and experiences within the environment enables the individual to make sense out of a complex and constantly changing internal and external sensory environment.[9]

The terms *perception* and **sensation** are often confused with each other. Sensation may be defined as the appreciation (awareness) of stimuli through the organs of special sense (e.g., eyes, ears, nose, and so forth), the peripheral cutaneous sensory system (e.g., temperature, taste, touch, and so forth), or internal receptors (e.g., deep receptors in muscles and joints).[9] Perception cannot be viewed as independent of sensation. However, the quality of perception is far more complex than the recognition of the individual sensation.[9] Perceptual deficits do not lie in the sensory ability itself, but rather with the individual's ability to interpret the sensation accurately, and therefore respond appropriately.[1]

RESPONSIBILITIES OF THE PHYSICAL THERAPIST AND THE OCCUPATIONAL THERAPIST

Occupational therapists are the members of the rehabilitation team who are specially trained to examine and treat cognitive and perceptual deficits in relation to functional adaptation. They are responsible for the selection and administration of an appropriate constellation of tests and measures, accurate interpretation of results, and formulation of an overall plan of care (POC) for cognitive and perceptual rehabilitation. If appropriate, the occupational therapist may refer a patient to a neuropsychologist for specific intellectual testing.

In the hospital setting, the physical therapist is often the first member of the rehabilitation team to see a patient with brain injury. The physical therapist must understand the nature of cognitive and perceptual dysfunction and recognize that individuals in certain diagnostic categories, such as those with stroke or TBI, are likely to behave in ways that indicate the presence of particular cognitive or perceptual deficits.[10] When this occurs, the physical therapist should refer the patient to occupational therapy for evaluation and treatment.

The tests and measures described in this chapter are included to assist the reader in understanding the nature of the different cognitive and perceptual disabilities and to guide decision making about referral to another practitioner. They are not a substitute for an intensive evaluation by a trained occupational therapist when referral is deemed necessary.

An understanding of cognitive and perceptual dysfunction may go a long way toward alleviating much of the potential frustration that often accompanies treatment of a patient with brain damage, most of which is the result of inappropriate expectations on the part of team members, the patient, and the family. By collaborating with the occupational therapist, other members of the rehabilitation team, and the family, consistent treatment strategies may be developed and carried out, with obvious benefits to the patient.

CLINICAL INDICATORS

Cognitive and perceptual deficits ought to be ruled out as a cause of diminished functioning in all patients who have experienced brain damage. Such problems are particularly likely culprits in cases in which the patient seems unable to participate fully in self-care tasks and has difficulty participating in physical therapy for reasons that cannot be accounted for by lack of motor ability, sensation, comprehension, or motivation. Cognitive and perceptual dysfunction resulting from acquired brain damage must be differentiated from premorbid cognitive perceptual deficits (from previous trauma, illness, congenital abnormality, or dementing process) and from the general confusion and emotional sequelae that often accompany stroke and brain injury.[4]

Often, patients with cognitive and perceptual difficulties may display the following characteristics: inability to do simple tasks independently or safely, difficulty in initiating or completing a task, difficulty in switching from one task to the next, and a diminished capacity to locate visually or to identify objects that seem obviously necessary for task completion. In addition, they may be unable to follow simple one-step commands, despite apparently good comprehension. They may make the same mistakes over and over. Activities may take an inordinately long time to complete, or they may be done impulsively. Patients may hesitate many times, appear distracted and frustrated, and exhibit poor planning. They are frequently inattentive to one side of the body and extrapersonal space, and may deny the presence or extent of their disability. These characteristics, all or some of which may be present, often make participation in daily living activities and therapy seem an insurmountable problem. These clinical features are explained and expanded on throughout this chapter.

Two typical scenarios are presented to give the reader an idea of when to suspect perceptual dysfunction. The first case involves a patient with a right hemisphere stroke who presents clinically with a left hemiparesis and good speech. Upon observation in the nursing unit, the patient appears to have functional strength in the unaffected right extremities and fair return on the affected left side. Yet the patient seems to have difficulty with simple range of motion (ROM) activities, even in the intact extremities, appearing confused and unable to move the arm up or down on command. The patient cannot seem to follow instructions for walking with a quad cane, constantly confuses the proper step sequence, and is unable to maneuver a wheelchair around the corner without crashing into the wall.

This patient should not be dismissed as uncooperative, intellectually inferior, or confused. In this instance, the patient is likely experiencing difficulty in spatial relations, right–left discrimination, and vertical disorientation, or perhaps left-sided unilateral neglect. Further observation and examination should reveal the precise cause of the difficulties.

The second case involves a patient with left hemisphere damage and a resulting right hemiparesis and mild **aphasia**. The patient can respond reliably to "yes/no" questions and is able to follow simple one-step commands such as, "Put the pencil on the table," or "Give me the cup." However, if asked to point to the arm, or asked to imitate the therapist's movements during an active ROM test even with the unaffected limbs, the patient does not respond and appears totally uncooperative. During therapy, the same patient is on a mat table. The therapist explains and then demonstrates the proper techniques for rolling to one side. The patient does not move. However, a moment later when his wife arrives, the patient quickly initiates rolling in an attempt to sit up to greet his wife. The astute therapist will realize

that this patient may not be confused, stubborn, or uncooperative, as indeed he may appear. Rather, he may be suffering from a lack of awareness of body structure and relationship of body parts (somatagnosia), as evidenced by the ROM test incident, and an inability to perform a task on command or to imitate gestures (**ideomotor apraxia**), as demonstrated in the rolling episode.

HOSPITALIZATION FOLLOWING BRAIN DAMAGE

The brain that has been damaged functions as a whole, just as it does in individuals without brain damage. When one part is damaged, the behavior observed is not merely the result of the brain operating precisely as in the intact individual minus the function of the area that was subject to anoxia. Rather, it is an outward manifestation of the reorganization of the entire CNS, at multiple levels, working to compensate for the loss.[11]

Because of the brain damage, the patient must cope with a nervous system operating without normal sensory input at all levels, both cortical and subcortical.[11] Normal responses to environmental stimuli are difficult to obtain when the input on which they have to act is deranged or incomplete. Recovery of function can be attributed to structural reorganization of the CNS into a new dynamic system widely dispersed within the cerebral cortex and lower segments.[12,13]

A significant contributor to the clinical picture of a patient after a CVA is the response to hospitalization. From a cognitive and perceptual perspective, when a patient is hospitalized (with or without brain damage), the inputs imposed on that patient's nervous system are radically different from the ones normally received. On the one hand, the environment is sensorially impoverished. There is no variation in temperature and lighting, and familiar background noises (e.g., telephones, airplanes, dogs, buses, and so forth) are missing. On the other hand, an enormous array of unfamiliar noise is present: nurses talking, loudspeakers, and the whir of machines. Strange and different smells, and unfamiliar, unavoidable, and unpleasant sights abound. Often, because of motor impairment, the patient cannot move around to seek or to escape inputs; therefore, a multiplicity of sensory inputs bombards the nervous system. Even if orienting responses are preserved, there is a profound sense of loss of control. This sensory derangement compounds the problems faced by the patient with brain damage, because those very abilities that enable the individual to select, filter out, and integrate incoming sensations to organize the self for appropriate action often fail in this sensorially bizarre environment.

To gain insight into the experience of the patient under such circumstances, it is enlightening to browse through the biographical and autographical reports of some noted neurologists and neuropsychologists, themselves victims or relatives of victims of CVAs. Particularly instructive are the reports of Bach-y-Rita,[14] Brodal,[15] and Gardner.[16]

THEORETICAL FRAMEWORKS

The theoretical bases of five approaches to therapy are examined in this section together with the examination procedures and treatment approaches consistent with the theoretical model. It is important to note that treatment approaches are not mutually exclusive. Many therapists use a combination of approaches, guiding selection by their clinical expertise and the patient's response to the interventions. Specific applications of these approaches will be presented following the description of individual cognitive and perceptual deficits in the final section of this chapter. Further information on a variety of theoretical approaches used by occupational therapists when working with patients who have cognitive and perceptual problems can be found in Averbuch and Katz[17] and Unsworth.[1]

The Retraining Approach

Averbuch and Katz[17] described this approach, which focuses on the remediation of underlying skills the patient has lost. Sometimes this approach is referred to as the *transfer-of-training approach*. The approach is based on the assumption that a disruption in one brain region can have a negative impact on brain functioning as a whole. An underlying assumption is that skills learned for one task can generalize to others. In other words, transfer-of-training is assumed. The premise is that practice in one task with particular cognitive or perceptual requirements will enhance performance in other tasks with similar perceptual demands.[1,18,19] Thus, doing specifically selected perceptual exercises, such as pegboard (a board with a regular pattern of small holes for pegs) activities, or parquetry blocks (inlaid blocks of different woods arranged in a geometric pattern) and puzzles, will result in improving the perceptual skills required to perform those functional tasks. For example, Young et al[20] demonstrated that training patients with left hemiplegia in block design (constructing shapes using blocks to match a two-dimensional pattern), in addition to *visual scanning* (using the eyes to follow a target) and *visual cancellation tasks* (placing a line through a specific number, letter, or word embedded randomly among other numbers, letters, or words), resulted in improvements in reading and writing, although no specific training in these areas was offered. Because all tasks require the use of multiple perceptual skills, it is difficult to ascertain precisely which perceptual skills are being trained during any one session.[21]

To date, research has not unequivocally demonstrated a generalization from perceptual–motor training to functional skills.[18,21] Neistadt[19] suggests that the patient's capacity to learn must be evaluated and that learning capacity is the key to a patient's ability to generalize material learned in one situation to others.

If transfer-of-training does occur, then strategies to enhance this can be incorporated into other components of the treatment program such as those aimed at maintaining sitting or standing balance, weight-bearing exercises, or functional use of the more involved extremities.

The Sensory Integrative Approach

Ayres developed the theory of **sensory integration** (SI) in an effort to explain the relationship between neural functioning and the behavior of children with sensorimotor or learning problems.[22] The theory, strongly influenced by the neurobehavioral literature, describes normal sensory integrative development and functioning, defines patterns of sensory integrative dysfunction, and suggests treatment techniques.[22] *Sensory integration* can be defined as the organization of sensation for use.[23,24]

Integration of basic sensorimotor functions (tactile, proprioceptive, and vestibular) proceeds in a developmental sequence in the normal child within the context of goal-directed, meaningful activity. It is assumed that the production of an adaptive response (desired motor response) facilitates sensory integration, which in turn enhances the ability to produce higher-level adaptive behaviors. Sensory integration is thought to occur at all levels of the nervous system.

The underlying assumption for treatment is that, by offering opportunities for controlled sensory input, the therapist can promote normal CNS processing of sensory information and thus elicit specific desired motor responses.[25] The performance of these adaptive responses, in turn, influences the way in which the brain organizes and processes sensation, thus enhancing the ability to learn.

Some of the treatment modalities employed include rubbing or icing to provide sensory input, resistance and weight-bearing to impart proprioceptive input, and the use of spinning or rocking to provide vestibular input. Following the controlled sensory input, an adaptive motor response is required by the patient to integrate the sensations provided by the therapist. In young children, the use of compensatory or **splinter skills** (skills acquired in a manner inconsistent with, or incapable of being integrated with, those already present) is avoided in favor of remediating underlying deficits. For more detailed information the reader is referred to the work of Ayres.[23,24]

Zoltan[2] argues that elderly patients, who comprise the majority of the stroke population, experience sensory integrative dysfunction similar to that of children with learning disabilities because of age-related physiological changes together with environmentally induced sensory deprivation. The limitations in mobility caused by a stroke further prevent the patient from receiving and thus processing adequate sensory input.

The application of this theory to the adult post-stroke population, however, is open to serious debate. Bundy et al[22] argue that the theory explains mild to moderate learning and behavioral problems resulting from a central deficit in processing sensations but are not specifically associated with frank brain damage. Further, there are a number of problems with the application of this approach to adult populations, even if it is theoretically tenable.

The treatment process is ordinarily quite lengthy. In addition, specific tests and measures and treatment approaches have been developed for and standardized on children, who presumably have sufficiently plastic nervous systems to be influenced by this form of therapy. The neurophysiological literature is replete with examples of skills that children can gain using this approach that would not be possible with mature individuals with similar lesions.[26-28] Furthermore, a mature adult with diffuse cerebral damage may have other complicating medical concerns and deficits in mobility that actually contraindicate the use of the equipment that is essential to the treatment process.[22] It is likely that many of the treatment regimens described as sensory integration are best described as a *sensorimotor approach*, which utilizes handling or directed sensory stimulation to elicit a specific motor response.[22]

The Neurofunctional Approach

The *neurofunctional approach* was first described by Giles and Wilson in 1992[29] and is based on learning theory. In contrast to the retraining approach, which assumes that transfer-of-training can occur, the authors of the neurofunctional approach assume that patients with acquired brain injury must practice every activity in its true context in order to recover function. Hence, the focus of this approach is on retraining real-world skills rather than on retraining specific cognitive and perceptual processes.[30] Giles[30] argues that remediation approaches (which include the idea of transfer-of-training) are largely unproven, and thus may result in little functional improvement for the patient. He also suggests that compensatory skills or techniques are taught to a patient without considering if the gains made in terms of quality of life justify the considerable effort required.

The Rehabilitative/Compensatory (Functional) Approach

Probably the most widely used approach in treating perceptual deficits is the *rehabilitative/compensatory approach*[31-33] (also referred to as the *functional approach*), which offers a great deal of practical support for the physical therapist. The basic assumptions underlying this approach are that adults with brain trauma will have difficulty generalizing and learning from dissimilar tasks.[34] Direct repetitive practice of specific functional skills that are impaired is an efficient means of enhancing the patient's independence in those specific tasks. More recently, Fisher[35] extended the work of Trombly[31] by

(1) articulating more explicitly assumptions made about people within the rehabilitative/compensatory model; (2) generalizing this model beyond persons with physical disabilities to those with developmental, cognitive, or psychosocial disabilities; and (3) adding collaborative consultation to education and adaptation as strategies used to effect change.

The proponents of this approach favor addressing the functional problem over and above the treatment of its underlying cause when working with an adult post-stroke population. For example, a patient with difficulty in depth and distance perception, who is therefore unable to navigate a flight of stairs, would be made aware of the deficit, would be provided with external cues to compensate for the perceptual disorder, and would repetitively practice adapted techniques for safe stair climbing. The more closely the therapeutic practice situation resembles the home situation in terms of stair depth and height, amount of traffic, lighting, and so forth, the less generalizing is required and the more success the patient is likely to have when he or she returns home. However, problems might still be displayed in depth and distance perception in other areas of daily function.

In this functional approach, therapy is viewed as learning that takes into consideration the unique strengths and limitations of the individual patient. It is composed of two complementary components: compensation and adaptation.[1] *Compensation* refers to the changes that need to be made in the patient's approach to tasks. *Adaptation* refers to the alterations that need to be made in the human/social and physical environment in order to facilitate relearning of skills. In relation to the human/social environment, the therapist is concerned with altering the actions of others' functioning in the environment to enhance the patient's performance.

To compensate for the disability, the patient first has to be made aware of deficiencies (*cognitive awareness*) and must then be taught how to circumvent them using intact sensations and perceptual skills. The patient should be instructed in specific techniques and assisted in developing successful functional habits. The patient will need to be taught to attend to cues from the environment to enhance skill performance. The therapist helps the patient identify and then call on these new cues. For example, if the patient has a visual field cut, the therapist should explain that because of a visual problem, the patient is seeing only one half of the environment. The patient should then be shown how to turn the head to compensate for the deficit. Environmental scanning (moving head, and therefore eyes, from side-to-side to view surroundings) could be incorporated into general therapy sessions as well.

General suggestions when teaching compensatory techniques include the following: (1) use simple directions; (2) establish and carry out a routine; (3) do each activity in a consistent manner; and (4) employ repetition as much as necessary.

Adaptation refers to the alteration not of the patient's strategy, but of the environment. For example, if the patient cannot differentiate between right and left, or tends to neglect the left side of the body, a piece of red tape on the left shoe during gait training will allow the patient to attend more easily to the left side and thus to follow the therapist's instructions more accurately. The therapist can use this functional approach to assist patients in improving specific motor skills related to treatment goals.

There are several inherent benefits to the rehabilitation/compensatory (functional) approach. First, in the current managed care environment there is a limited amount of time for inpatient rehabilitation.[36] Therefore, therapists need to concentrate on outcome-directed, real-life functional activities because independent performance of these activities at home is the ultimate goal of therapeutic intervention. Interventions directed toward specific functional outcomes are typically reimbursable.[31] In addition, the activities are age appropriate, specific, and clearly relevant to the patient's concerns. For this reason, they tend to be the most motivating. The tasks can also be incorporated into a daily hospital routine. Dressing can be reinforced at bedside by the nursing staff, and eating skills can be reinforced at each mealtime.

The major limitation of this approach is that the methods learned in one task are not typically generalized to the performance of another task. The functional approach has been criticized as the teaching of splinter skills, in which the causes of the dysfunction are not addressed.

Cognitive Rehabilitation and the Quadraphonic Approach

Cognitive rehabilitation focuses on training individuals with brain injury to structure and organize information.[37] It addresses memory, high language disorders, and perceptual dysfunction under one umbrella.[38] Information processing, problem solving, awareness, judgment, and decision making are among the areas included. The therapist using a cognitive remediation approach might be concerned with the patient's perceptual style, including perceptual strategy, response to different types of cues, and rate and consistency of task performance.[39] Diller and Gordon[40] provide a review of the literature pertaining to intervention strategies for cognitive deficits.

Research has demonstrated that even in a non–brain-injured population, skills learned in one task do not automatically transfer to other tasks.[41] Hence, cognitive strategies can be used to facilitate the carryover of skills learned in therapy to functional activities. In her multicontext treatment approach to cognition, Toglia[41] proposes that learning can be conceptualized as a dynamic interplay between characteristics of the patient, characteristics of the task, and the environment in which

it is performed. This has also been termed a *dynamic interactional approach.*[42] Characteristics of the individual patient that might affect learning include information processing strategies, metacognition (including awareness of one's own performance), and prior experience, attitudes, and emotions. Task-related variables that are proposed to affect learning include the nature of the task itself (familiarity with the task, spatial arrangements, instruction set, and movement and postural requirements), and the criteria that are used to determine the learner's abilities. Environmental variables include the social and cultural environment in which treatment occurs, as well as the physical context.

The *cognitive rehabilitation approach* to treatment proposes a number of strategies relevant to physical therapist practice. These treatment strategies include the following[41]:

- Analyzing the characteristics of the task to establish criteria to determine if transfer of learning in fact took place.
- Providing interventions to increase patient awareness of abilities, the level of difficulty of the task, and promote self-examination of performance.
- Relating new information or skills to previously learned ones.
- Using multiple environments in which to carry out the training activity to enhance transfer of learning.

Although these treatment strategies are well known within the field of cognitive–perceptual rehabilitation, the efficacy of the techniques remains to be established with the post-stroke population. For a comprehensive understanding and practical guidelines to the evaluation and treatment of patients with cognitive impairments from a dynamic perspective, the reader is referred to Toglia[42] and Abreu.[43]

Abreu[44] has further developed these treatment strategies as the *quadraphonic approach.* The quadraphonic approach is an interactive rehabilitation approach that provides a holistic perspective for the management of stroke, TBI, brain tumors, cerebral palsy (CP), and other neurological conditions. The quadraphonic approach is based around the idea that the therapist can apply both micro (reductionistic) and a macro (holistic) perspectives for evaluation and treatment, which is an assumption shared by many occupational therapists who work in this field. Diagrammatic presentations of the components of the four key areas of the micro and four key areas of the macro perspectives (hence the term *quadraphonic*) are provided in Figures 27.1 and 27.2, and explained in the text. The *macro* perspective is holistic or humanistic and provides guidelines for the management of functional performance and real-life occupations. In other words, this component of the quadraphonic approach is functional or top-down in focus. When viewing Figure 27.1, the reader can see that the outer square is composed of four characteristics of a client (*lifestyle*, *lifestage*, *health*, and *disadvantage status*) that the therapist can explore though interviews and asking the clients to tell their stories. The therapist can then use this information in order to explain and predict the client's behavior and performance. An evaluation then needs to be made of the client's will (volition) and goals, opportunity, and capacity for action as depicted in the triangle. From there the therapist is able to develop a therapy plan with the client (and significant others such as family) that is unique to that client.

In contrast, the *micro* perspective is more remedial in focus and provides guidelines for the management of

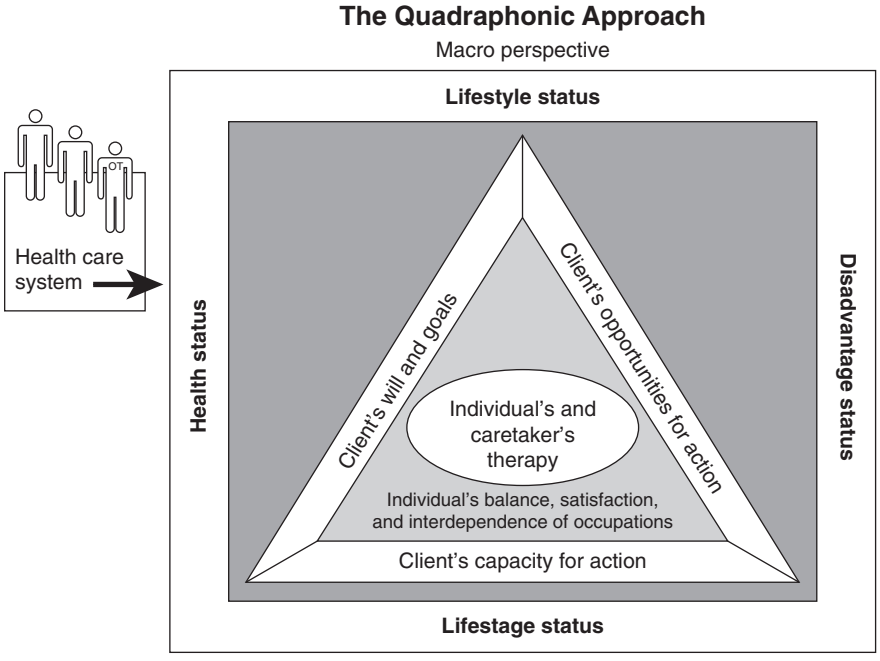

Figure 27.1 The quadraphonic approach—macro perspective. *From Abreu,[43, p. 187] with permission.*

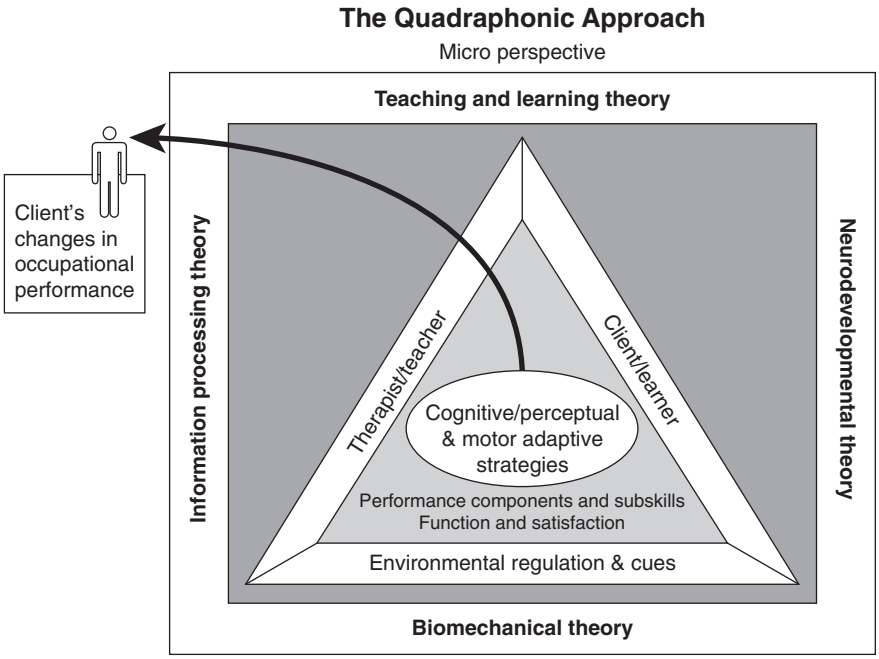

Figure 27.2 The quadraphonic approach—micro perspective. *From Abreu,[43, p. 185] with permission.*

performance components or sub-skills that include attention, visual perception, memory, motor planning, postural control, and problem solving. Evaluation and treatment of these performance components is based on a frame of reference that incorporates four theories: (1) information processing; (2) teaching/learning; (3) neurodevelopmental; and (4) biomechanical. These theories are listed in the outer square of Figure 27.2. This figure then presents an inner triangle that depicts how changes in the client's condition are further influenced by three dominant factors, which are the therapist (teacher), the environment in which therapy takes place, and what the client brings to therapy as well. The therapist and client work together to develop cognitive, perceptual, and motor strategies to enhance the client's performance and improve life satisfaction (as shown in the central circle of Fig. 27.1). Hence, the micro perspective is bottom-up or remedial in its focus. An example of a therapist using this approach when working with a patient who has memory and learning problems may be found in Abreu.[43]

EXAMINATION OF COGNITIVE AND PERCEPTUAL DEFICITS

The use of systematic data collection provides the scientific basis for guiding intervention. Its importance cannot be overemphasized with respect to all facets of therapeutic intervention, including remediation of cognitive and perceptual dysfunction. **Task analysis** is the breakdown of an activity or task into its component parts together with a delineation of the specific motor, perceptual, and cognitive abilities necessary to perform each component. Task analysis is another tool critical to appropriate therapeutic intervention. For example, the strength, ROM, and balance abilities necessary to accomplish bed mobility and ambulation activities can be clearly defined by the physical therapist. However, the specific perceptual and cognitive requirements of each step needed to perform these two tasks may not be known. Without knowledge of the perceptual and cognitive requirements for successful completion of a task, the therapist cannot simplify the task for the patient and progressively upgrade it.

Purpose of the Examination

The presence of cognitive and perceptual dysfunction must be confirmed if it is suspected to be interfering with the patient's ability to carry out functional activities.[1] Perceptual performance is positively correlated with ability to perform ADL; however, it is often difficult to correlate specific perceptual deficits gleaned from testing with specific elements of functional ability and loss.[1,45] Thus, formal testing is indicated when there is a functional loss unexplained by motor or sensory impairments, or deficient comprehension. It should be noted that not all areas of functional loss are typically detected within the hospital setting. It is not uncommon for the patient to perform adequately in self-care skills after therapy in the hospital but to fail on the same tasks in other environmental contexts, such as the home. Higher-level tasks, such as driving, banking, or planning a meal, may only emerge as areas of difficulty once the patient is discharged home. When appropriate, the patient's competence in these areas should be considered within the context of an examination of instrumental activities of daily living (IADL) with the occupational therapist while the patient is still hospitalized.

The purpose of patient examination is to determine which cognitive and perceptual abilities are intact and which are limited. Understanding the manner in which a particular deficit influences task performance will foster the application of a therapeutic strategy in which intact capabilities may be used to compensate for or to overcome deficits.[1]

Failure in the performance of a task may result from any number of processes underlying cognition and perception. For example, a patient's inability to complete a jigsaw puzzle may result from an inability to organize the pieces or problem solve where they go (disorder of executive function) or difficulty in attending to one half of the picture (unilateral neglect). The patient may be incapable of concentrating on the instructions (attention deficit), unable to know what the pieces are for (ideational apraxia), or unable to manipulate them (ideomotor apraxia). Although it is often difficult to implicate reliably one or another of these problem areas, the therapist must be aware of the different deficits that may produce similar patterns of behavior.[1,5]

A fascinating study conducted by Galski et al[46] concerning the prediction of driving ability following brain injury (including stroke) in 35 patients underscores the critical nature of carefully selected perceptual and cognitive tests. In this study, 64% of actual behind-the-wheel driving performances were predicted by performance on a selected battery of neuropsychological tests that measured visual perception. Examination of individual test results uncovered the reasons for unsafe driving (such as problems with visual perception, visuomotor coordination, and visuoconstructive abilities), enabling instructors to focus on remediating these specific deficits in preparation for safe driving.

Patient examination is not an end in itself. Careful examination paves the way for realistic and cost-effective intervention.[47] Continuous monitoring of the patient's cognitive and perceptual status will ensure the use of appropriate treatment strategies and their modification when necessary.

Factors Influencing Patient Examination

Psychological and emotional status plays an important role in the patient's ability to cope with disability and with the testing situation. The therapist needs to be aware of behaviors that reflect a patient's psychological response to illness rather than particular cognitive or perceptual abilities. Psychological adjustment to disability depends on many factors, including age, vocational status, education, economic situation, attitude toward the reactions of others, family support, and feelings of competence before the onset of disease (see Chapter 26, Psychosocial Disorders).[45,48,49]

When examining psychological and emotional status the following should be noted: whether the patient is confused; the level of comprehension for verbal instructions (written and spoken); whether communication is enhanced through the use of visual cues and demonstration; the ability to recognize errors; the level of cooperation and initiative (whether the patient is realistic about capabilities and goals); and emotional stability.[50] Disturbances of emotional response are evidenced by rapid and frequent mood changes and low frustration tolerance. Difficult tasks may cause a catastrophic reaction.[45]

The patient's ability to detect relevant cues from the environment or to discriminate between relevant and irrelevant stimuli (necessary for cognitive and perceptual competence) may be adversely influenced by poor judgment, fatigue, and prior expectations. Poor judgment is a major contributor to accidents in patients with hemiplegia. This is related in part to the diminished awareness by these patients as to their altered capabilities. The ambiguity of having one set of functional limbs and one set that is not functional may lead the patient to rely on solutions to the problems of daily living that are familiar but now inappropriate.[45]

Anxiety over capabilities may inhibit optimal performance during examination and treatment. The patient's capacity to perform optimally on testing and to learn is enhanced if anxiety can be reduced.[45] Motivation is influenced by many factors, among them premorbid personality. It is of utmost importance for the therapist to structure the therapeutic environment so that the patient will be positively motivated to learn to his or her maximum ability.[45] To this end, therapeutic tasks should be structured to ensure success, thereby diminishing frustration.

Other factors that may limit a patient's performance on cognitive and perceptual tests include reduced receptive and expressive communication skills, depression, and fatigue. Before a formal examination, the therapist should consider the patient's language skills, and confirm these observations with the speech-language pathologist. The therapist should also be aware of any medications the patient is taking and how these may affect performance. For example, many medications produce drowsiness as a side effect that would affect patient performance during testing.[1] Following stroke, 30% to 50%[12] of people are said to experience depression, the symptoms of which can easily be mistaken for cognitive or perceptual problems. Finally, a determination should be made of the patient's level of fatigue before any examination procedure.

The patient's behavior should not be misinterpreted because of a cultural bias, such as a lack of experience in taking tests. Premorbid intellectual ability should be ascertained from an interview with family or friends, because intellectual abilities may affect performance on some of the tests and measurements, as well as affect behavior in general. Premorbid memory should also be determined.

Finally, it is very important to conduct a sensory examination *before* cognitive or perceptual testing to establish whether the patient has sufficient sensory abilities to proceed with testing (this includes visual

screening as well). Distinguishing between sensory and cognitive or perceptual problems is explored in more detail in the next section of this chapter. Each of these problems may adversely influence performance and may also reduce the patient's performance in treatment and capacity to learn from treatment. The therapist should be aware of the potential for these problems arising, and seek to minimize their impact.

Distinguishing between Sensory and Cognitive and Perceptual Deficits

Cognitive and perceptual dysfunction must be differentiated from sensory loss, language impairment, hearing loss, motor loss (weakness, spasticity, incoordination), visual disturbances (poor eyesight, homonymous **hemianopia**), disorientation, and lack of comprehension. The therapist must rule out pure sensory impairments before testing for cognitive and perceptual deficits, otherwise the therapist may incorrectly attribute poor performance to perceptual problems and design treatment accordingly when in fact the problem has a sensory base and should be treated quite differently. The therapist should conduct tests of deep (proprioceptive) sensations (kinesthesia, position sense, vibration), superficial sensations (pain, temperature, light touch, and pressure), and combined cortical sensations (stereognosis, tactile localization two-point discrimination, barognosis, graphesthesia, and recognition of texture) using methods described in Chapter 3, Examination of Sensory Function. The patient's hearing also requires testing. For example, if the patient does not seem to understand what the therapist is saying, hearing problems should be ruled out before more extensive language and cognitive tests are conducted. The therapist may need to confirm with the family if the patient wears a hearing aid and ensure its availability during therapy. If in doubt, the therapist may need to request testing by the speech-language pathologist or audiologist.

The therapist must also determine if the patient has visual impairments because they can easily be mistaken for perceptual problems. Given the prevalence of sensory-based visual problems, the following section focuses on identification of these impairments and the importance of distinguishing between visual and perceptual origins for treatment purposes.

Visual Impairments

Visual impairments are one of the most common forms of sensory loss affecting the patient with hemiplegia.[51,52] The lesion resulting from a stroke may affect the eye, optic radiation, or visual cortex and subsequently the reception, transmission, and appreciation of any visual array. Visual impairments commonly encountered by patients with hemiplegia include poor eyesight, diplopia, homonymous hemianopia, damage to the visual cortex, and retinal damage. Awareness of the presence of these deficits is important so as not to confuse them with visual perceptual deficiencies, and to ensure their consideration during treatment planning and therapeutic intervention.

The critical nature of the basic visual skills (i.e., acuity, oculomotor control, and intact visual fields) in forming a basis for higher-level visual perception is highlighted by Warren[53,54] in a hierarchical model for the evaluation and treatment of visual perceptual dysfunction. In this developmental model, the basic visual skills enumerated above form the foundation for the next level of visual skills, which include *visual attention* (focusing on one aspect of the environment while ignoring others), *visual scanning* (using eyes to follow a target), and *pattern recognition* (recognition of structures that make a recognizable whole). These skills, along with memory, are required to facilitate the highest-level visual skill termed *visual cognition*.[53,54] This model has implications for the evaluation and treatment of visual perceptual disorders in a bottom-up sequence[54] (i.e., working from the "bottom" initially focusing on underlying skills that will then promote recovery of the next level of skills).

Impairments of oculomotor control (control of eye movements) are a common occurrence following a CVA. Poor visual acuity is another frequent finding following stroke or brain injury, even in the absence of other visual problems.[55] Therefore, it is recommended that the patient receive a comprehensive eye examination and have his or her eyeglass prescription checked.

Diplopia, or double vision, is often present following brain damage. The patient sees two of the entire environment (horizontally, vertically, or diagonally). Diplopia is usually the result of defective function of extraocular muscles in which both eyes are used but not in focus. Treatment usually consists of exercises for the eye muscles. In addition, the patient usually is instructed to wear a patch on alternate eyes until the condition clears. If the condition does not clear, the optometrist may recommend prisms.

Visual field deficit is probably the most common visual deficit affecting patients with hemiplegia[56] and occurs most frequently following damage to the middle cerebral artery near the internal capsule.[9] The diagnostic term for this deficit is *homonymous hemianopia*. The frequency of hemianopia following a right-hemisphere stroke is around 17%.[12] In addition, there is a significant correlation between the presence of visual field deficits and visual neglect.[57] Most important, the presence of a visual field deficit is a significant prognostic sign, predicting both a higher death rate following stroke and poorer performance in ADL, even following rehabilitation.[12,58]

Figure 27.3 demonstrates the normal functioning of the visual fields, in which the left side of the environment (the tree) is perceived by the nasal retina of the left eye and the temporal retina of the right eye, and the right side of the environment (the car) is perceived by the nasal retina of the right eye and the temporal retina of the left eye.

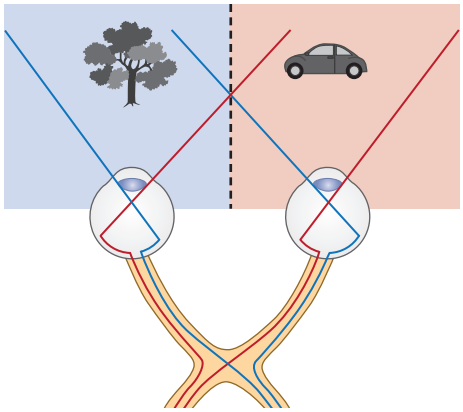

Figure 27.3 Normally functioning visual system; right and left visual fields. See text for explanation.

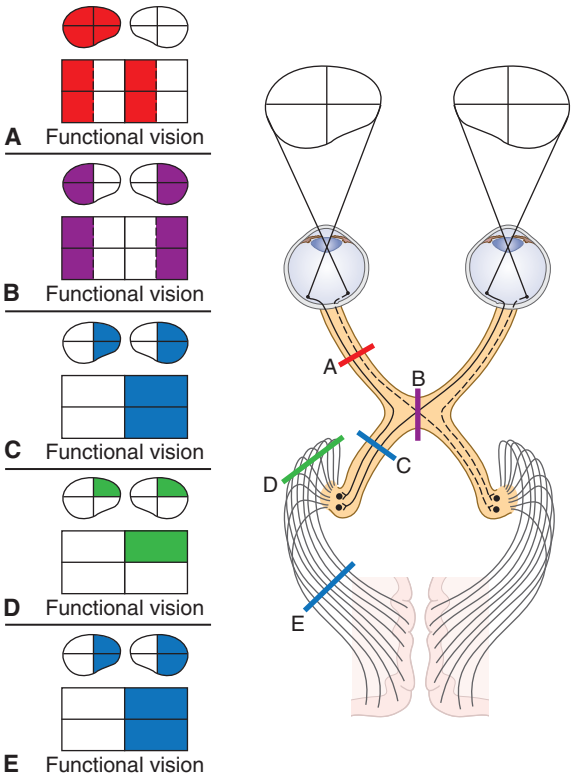

Figure 27.4 Visual field deficits (with functional loss) and associated lesions. Vision is shown as clear and visual loss is colored in examples **A–E,** which denote **(A)** blindness in one eye; **(B)** bitemporal hemianopia (tunnel vision); **(C)** homonymous hemianopia; **(D)** quadrantanopia; and **(E)** homonymous hemianopia.

The lesion producing homonymous hemianopia interrupts inflow to the optic pathways on one side of the brain. This produces a loss of the outer half of the visual field from one eye and the inner half of the visual field of the other eye. The result is a loss of incoming information from half of the visual environment (left or right) contralateral to the side of the lesion. Thus, the loss of the left half of the visual field accompanies left hemiplegia and loss of the right visual field accompanies right hemiplegia. Zhang et al[59] suggested that this is a common condition following stroke, and noted a spontaneous recovery rate in less than 40% of cases. Figure 27.4 illustrates visual field deficits associated with a number of lesions to the visual system.

The presence of a visual field cut may inhibit performance in many daily activities. The patient is usually unaware of the condition and does not automatically compensate by turning the head unless specifically instructed. One of the dangers in this condition is street crossing (Fig. 27.5). Another example of the effects of a visual field cut is illustrated in Figure 27.6. When presented with a newspaper, a patient with right homonymous hemianopia may attend to one half of the newspaper page, either to or from the midline.

Because of its prevalence, it is essential for the therapist to determine whether homonymous hemianopia is present or not. A number of testing procedures are currently employed. In the confrontation method, the patient sits opposite the therapist and is instructed to maintain his or her gaze on the therapist's nose (Fig. 27.7). The therapist slowly brings a target, such as the therapists' finger or a pen, into the patient's field of view simultaneously or alternately from the right or left. The patient is instructed to indicate when and where he or she sees the targets.

To help the patient compensate for the visual field deficit, the patient can first be made aware of the deficit and then be instructed to turn the head to the affected side. Patients usually require constant reminders at first,

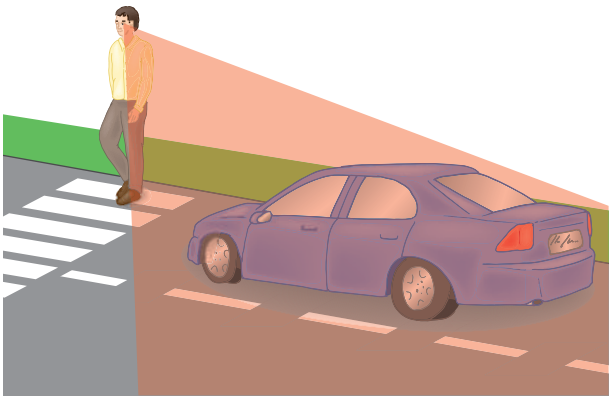

Figure 27.5 The functional significance of hemianopia—it may lead to accidents.

which may be tapered off with time and practice. Early in therapy, items (e.g., eating utensils, writing implements) should be placed where the patient is most apt to see them (on the less affected side). They can be moved progressively to the midline and then to the more affected side, when appropriate. The nursing staff should be made

Figure 27.6 A newspaper as it might appear to a patient with right homonymous hemianopia following a stroke. The shading indicates that the patient may be unable to read the right side page.

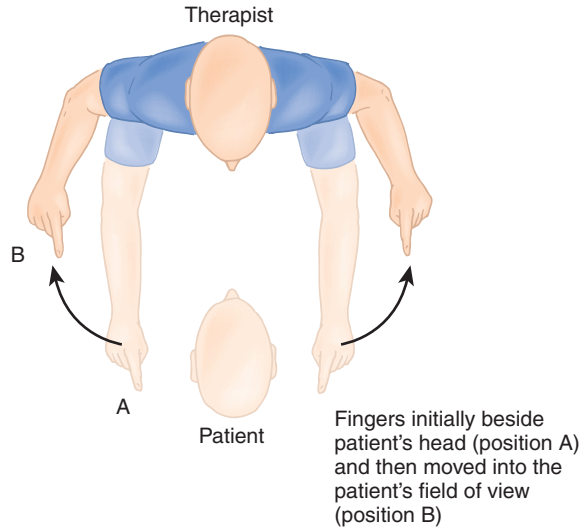

Figure 27.7 Method for testing hemianopia.

aware of the condition and be requested to place the patient's essential bedside needs such as telephone, tissues, and so forth within the intact visual field. The therapist initially should sit on the patient's less involved side when instructing or giving demonstrations and should alternate this with the more affected side so that the patient receives maximum stimulation. Of course, the patient will have to be reminded to turn the head at first. External cues can be employed as well. For reading, a red line can be drawn on the side of the page that is not seen. Red tape can be placed on the floor, mat, or parallel bars to attract the patient to scan to the side of the environment that is not seen. The patient should be taught to look for these cues. These external cues can be slowly tapered off over time. Patients can be instructed and encouraged to devise their own cues to clue them into the unseen side of the environment in situations that have not been addressed per se in therapy. Exercises that require motor crossing of the midline can be used to reinforce visual crossing of the midline and turning of the head.[60,61]

Oculomotor impairment is another area of deficit in basic visual skills that is common in patients who have had a stroke. Eye movements, which are controlled by the extraocular muscles, are used to detect, identify, and derive meaning from objects and the environment. They allow a person to become oriented to and explore the critical visual aspects of the environment.[11] Two types of eye movements are important to examine: (1) **visual fixation**, which allows the patient to maintain focus on an object as it is brought nearer or farther away; and (2) **ocular pursuits**, which enable the eyes to follow a moving object and visually scan the environment. Often the eyes will not follow a moving object visually, although the patient seems aware of the presence of that object and can locate it if asked. The patient is visually hypoactive. Oculomotor dysfunction often accompanies visual–perceptual dysfunction[62] and is frequently related to attention deficits.[63]

Visual scanning can be tested as follows. Sit opposite the patient. Hold up a pencil with a colorful pencil topper 18 in (45.7 cm) in front of the patient's eyes. Slowly move the pencil horizontally, then vertically, then diagonally. Repeat each direction two to three times. Note the smoothness of eye movements, the presence of a midline jerk or jump, and whether the eyes move together.[2,62]

Aside from the visual sensory impairments outlined above, many patients suffer from visual–perceptual impairment. Damage to areas of the cortex on which visual information converges with information from other senses may interfere with the recognition and interpretation of visual information, even though the visual stimuli may have arrived at the visual cortex uninterrupted. A total failure to appreciate incoming visual sensory information owing to a lesion in the cortex is referred to as **cortical blindness**.[62] There is no statistical correspondence between the presence of visual field cuts and the presence of visual–perceptual disorders.[64] Similarly, there is no correspondence between aphasia, age, and time since infarct, and measures of visual–perceptual dysfunction.[64] However, within the realm of visual–perceptual impairments, there is a significant difference between the performances of patients with right hemiplegia and those with left hemiplegia. Patients with left hemiplegia have frequently been found to perform more poorly on measures of visual–perceptual dysfunction than patients with right hemiplegia. Thus, therapists should be aware of the possibility of visual–perceptual deficits, particularly in the population with left hemiplegia.

Standardized Cognitive and Perceptual Tests

A standardized test is one that has a uniform procedure to administer and score, provides operational definitions for all terms, is norm-referenced,[65] and information is

available concerning its reliability and validity, which is essential for correct interpretation of results.[66] Results from standardized tests of cognition and perception can be communicated to other therapists who will share an understanding of the patient's capacities or abilities. Standardized tests can be administered both at admission and at discharge to provide the therapist with a reliable and valid measure of the outcome of therapy.

When conducting a standardized test, the patient should be sitting comfortably and wearing glasses and/or a hearing aid if needed. Ideally, the room should be quiet and free of distraction. The therapist should be positioned opposite or next to the patient. Since the performance of a patient who has had a stroke may vary from day to day, a single testing session may be unreliable.[67] A number of short sessions scheduled on successive days may be preferable. To enhance its practical value, perceptual testing must be done in conjunction with observation in self-care and ADL skills, where the patient's judgment and discriminative abilities with regard to real-life tasks can be determined. It is not uncommon for patients to test poorly for visual–perceptual skills but to perform adequately in ADL with minimal effort or assistance.[63]

The quality of the patient's response to the test media (e.g., how the task is approached, how and why the error is made) is as important to note as the success or failure in completing the selected task. Some aspects of response in the testing situation or during ADL can be referred to as the patient's individual *perceptual style*. Included under this rubric are the patient's perceptual strategy, response to various cues (such as auditory, visual, and tactile), rate of performance, and consistency of performance.[37]

Occupational therapists use a variety of standardized tests to determine the presence of cognitive and perceptual impairments and resulting disabilities. When selecting a standardized test the therapist must consider many factors. The selection depends on what the therapist wants to learn about the patient, and what the test can potentially reveal.[1] In many cases a single test will not provide all the information required by a therapist to plan treatment, so several tests may be administered (Table 27.1).[5,68-82] In addition to those presented in Table 27.1, other instruments used to measure more global outcomes of rehabilitation include the following:

- *Medical Outcomes Study (MOS), Short Form Health Survey (SF-36)*[83]
- *Australian Therapy Outcome Measures—Occupational Therapy (AusTOMS-OT)*[84]
- *Canadian Occupational Performance Measure (COPM)*[85]
- *Rivermead Rehabilitation Centre Life Goals Questionnaire*[86]
- *Reintegration to Normal Living Index (RNL)*[87]
- *Functional Independence Measure (FIM_{MR}^{SM})*[88]

Some of these instruments also incorporate items that measure cognition and perception. For example, the FIM_{MR}^{SM} includes three cognition-related items (social

Table 27.1 Summary of Standardized Tests

Test	Description
Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE)[5]	This test was developed to measure a patient's neurobehavior through daily living tasks (dressing, grooming, hygiene, transfer and mobility, feeding, and communication). Occupational therapists must undertake a 5-day training and certification course to qualify to administer this test. A wide variety of cognitive and perceptual impairments can be detected with this instrument.
Structured Observational Test of Function (SOTOF)[68]	The SOTOF was designed to examine older persons' level of occupational performance and neuropsychological functioning following neurological damage of cortical origin.[69] The instrument consists of a screening test, neuropsychological checklist, and four ADL scales (eating from a bowl, pouring a drink and drinking, putting on an upper body garment, and washing and drying hands). After analyzing observational data, a wide variety of neuropsychological deficits are extrapolated.[68]
Allen Cognitive Level Test (ACL)[70,71]	The ACL is used as a screening tool to estimate a person's cognitive level. Although originally developed for use with clients who have psychiatric problems, this test is also used with people who have acquired brain damage, or experience a dementing illness such as Alzheimer's disease. Following an interview to gain information concerning the client's educational and work background, the client is observed performing the visuomotor task of leather lacing. It is assumed that the client's cognitive functioning is reflected through his or her motor actions.[1]
Chessington Occupational Therapy Neurological Assessment Battery (COTNAB)[72]	The COTNAB was designed to examine cognitive and perceptual deficits in patients 16 years of age and older following stroke or head injury. The battery consists of 12 tests divided into four sections examining visual perception, constructional ability, sensory-motor ability, and ability to follow instructions. Further information about this instrument may be found in Stanley et al[73] and Sloan et al.[74]

Table 27.1 Summary of Standardized Tests—cont'd

Test	Description
Loewenstein Occupational Therapy Cognitive Assessment (LOTCA)[75]	The LOTCA is a battery-style test lasting 35 to 40 minutes and composed of 20 subtests that examine four areas: orientation, visual and spatial perception, visuomotor organization, and thinking operations. The instrument was developed for use with people who have experienced stroke, traumatic brain injury, or tumor.
The Behavioural Inattention Test (BIT)[77]	The BIT was developed to examine clients for the presence of unilateral visual neglect and to provide the therapist with information concerning how the neglect affects the client's ability to perform everyday occupations.[78] The BIT consists of nine activity-based subtests and six pen-and-paper subtests. Many of these test items have been used in the past in a nonstandardized way to examine for the presence of neglect.
Rivermead Perceptual Assessment Battery (RPAB)[79]	This instrument was designed to examine visual perceptual impairments in patients following head injury or stroke. The RPAB is a battery consisting of 16 performance tests that examine form discrimination, color constancy, sequencing, object completion, figure–ground discrimination, body image, inattention, and spatial awareness. The test can be completed in approximately 1 hour. For further information on the RPAB, the reader is referred to Jesshope et al.[80]
Rivermead Behavioural Memory Test (RBMT)[81]	This battery was designed to examine everyday memory abilities. It offers the therapist an initial determination of the client's memory function, an indication of appropriate areas for treatment, and enables the therapist to monitor memory skills throughout the treatment program. The RBMT can be administered in approximately 30 minutes by occupational therapists, speech-language pathologists, and psychologists. For further information on the RBMT, the reader is referred to Baddeley at al.[81] and Wilson et al.[82]

interaction, problem solving, and memory). The tests described in the section on specific cognitive and perceptual deficits are used widely in the clinic. Although some of the instruments presented are not standardized, they are still useful, particularly for examining the quality of response to the test stimuli.

INTERVENTION

Treatment Approaches

Five major approaches to cognitive and perceptual rehabilitation are commonly employed by occupational therapists. They are the *retraining approach,* the *sensory integrative approach,* the *neurofunctional approach,* the *rehabilitation/compensatory approach,* and the *cognitive rehabilitation/quadraphonic approach.* These approaches were described earlier in the chapter. Although research directly comparing the efficacy of the various approaches has been sparse, attempts have been made recently to empirically define and test the methodologies.[21,25,34,89] Issues to consider in examining the approaches are the availability of standardized measures of change in functional status and ADL, group versus individual treatment, specific stimulus properties, format, length and frequency of feedback, and individual information processing styles.[21]

Neistadt[25,34] described these treatments dichotomously as either remedial or adaptive/compensatory. The remedial approach encompasses the retraining approach, the sensory integrative approach, and the cognitive approach.[1] The neurofunctional approach and the rehabilitation/compensatory approach are described as adaptive or compensatory. The quadraphonic approach brings together aspects of both the remedial and compensatory approaches. A description of the key components of these two main approaches is presented below. A discussion on education is also provided because no intervention program would be complete without the provision of education to both the patient and the caregivers. Finally, a discussion is provided on integrating these three elements within a rehabilitation program.

The Remedial Approach

Remedial approaches focus on the patient's deficits and attempt to improve functional ability by retraining specific perceptual components of behavior.[25] The assumption uniting this set of tactics is that facilitation of, or training in, underlying skills will enhance the recovery or reorganization of deficient CNS functioning.[21,25] This, in turn, will automatically translate into improvement in functional skills. Remedial approaches are also referred to as bottom-up approaches. These approaches work from the bottom, which is the recovery of underlying skills, and assume that the patient will be able to generalize skills to occupational performance, which is at a higher level.[1,47]

The Adaptive/Compensatory Approach

The adaptive or compensatory approach mandates direct training in the functional skills that are deficient. It does not assume automatic carryover from tasks that are not

obviously similar to the functional task to be learned, and thus minimizes the need for generalization. In an adaptive or "top-down" approach, the therapist works with the patient on specific tasks that are required, or those that the patient wants to achieve. In other words, the therapist starts at the top, which is the desired functional outcome, rather than working with the patient on the underlying performance components.[35] Table 27.2 presents a comparison of the assumptions underlying the remedial and adaptive approaches.

Patient, Family, and Caregiver Education

Education for the patient, family, and caregivers is essential for continuity of care. Appendix 27.A includes Web-based resources for clinicians, families, and patients with cognitive and perceptual deficits. The patient and caregivers should understand why it is inadvisable or impossible for the patient to do some things safely or independently, and why other things must be done in a specific way. Explaining the reasons why the patient behaves in a particular way reduces the likelihood of inappropriate expectations from those without the background to know that brain damage affects not only how the patient moves but also how he or she experiences and thus responds to the world.

Feedback is essential to the patient's learning. The patient's own feedback may be inaccurate owing to perceptual and cognitive dysfunctions. Thus, the individual may be unaware that a task has not been accomplished or that it has not been performed in the safest or most efficient manner. Feedback should be provided in the form of **knowledge of results (KR)** and **knowledge of performance (KP)**. Knowledge of results is information regarding whether or not the patient attained the correct outcome. Knowledge of performance is information regarding the manner in which the task was accomplished.[90]

The form in which this feedback is delivered depends on the specific limitations and strengths of the patient. For example, the physical therapy goal for a patient with left hemiplegia and visual perceptual involvement might be to walk to the end of the parallel bars. KR would consist of a verbal confirmation by the therapist as to whether or not the patient reached the end of the parallel bars. KP might include comments by the therapist concerning the adequacy of the patient's visual scanning, positioning of the lower extremities (LEs), correct posture, and appropriate use of the upper limbs. For the patient with communication impairments, feedback would need to be visual. Tactile input also can be used effectively to cue patients with either right or left hemiplegia. A combination of inputs, using a number of sensory modalities, often facilitates patient success at a given task.

When involving the patient in education sessions, the patient must be addressed as a competent adult, and not patronized. He or she must be regarded as the principal participant in the rehabilitation process. In situations in which the perceptual deficit does not interfere with assimilation of information, the patient should have the major role in the decision making process regarding the goals of therapy.

Table 27.2 Common Assumptions of Adaptive and Remedial Approaches

Adaptive Approach	Remedial Approach
The adult brain has limited potential to repair and reorganize itself after injury.	The adult brain can repair and reorganize itself after injury.
Intact behaviors can be used to compensate for ones that are impaired.	Repair and reorganization is influenced by environmental stimuli.
Adaptive retraining can facilitate the substitution of intact behaviors for impaired ones.	Cognitive, perceptual, and sensorimotor exercises can promote brain recovery and reorganization.
Adaptive activities of daily living provide training in functional behaviors.	Cognitive, perceptual, and sensorimotor exercises provide training in the cognitive and perceptual skills needed for those exercises.
Training in specific, essential activities of daily living tasks is necessary because adults with brain injury have difficulty generalizing learning.	Remedial training in cognitive and perceptual skills will be generalized across all activities requiring those skills.
Functional activities require cognitive and perceptual skills.	Functional activities require cognitive and perceptual skills.
Adaptation and compensation will lead to improved functional performance.	Cognitive and perceptual remediation will lead to improved functional performance.

Refocusing Intervention

Many clinicians begin an intervention program by adopting remedial strategies. In these circumstances, therapists are aiming to maximize recovery of function and educate their patients about the problems experienced and ways that can improve their function. However, some patients may not make much progress. In some cases, the patient may have inadequate language skills to be able to work with the therapist, or may have limited insight to his or her problems and therefore will not work with the therapist. In other cases still, improvements simply do not seem to occur for a variety of reasons that the therapist may not be able to pinpoint. Finally, in the current climate of managed care, the therapist may not have very much time

allocated to work with the patient using remedial techniques. The patient's discharge may be imminent, and yet he or she may not be independent or safe enough to be discharged. In such cases, the therapist may switch from a remedial approach to a compensatory one.

When using an adaptive compensatory approach, the therapist will address education of the caregivers as well as the patient. Intervention strategies will focus on changing the environment or the strategy for task completion so that the patient can be safe and independent as quickly as possible. In many instances, therapists use a three-point approach to intervention where they educate patients and caregivers, begin the program using remedial techniques, and then switch to compensation techniques when the patient's improvements have plateaued and/or discharge is imminent.

The Impact of Managed Care

The introduction of managed care in the United States health care system has many implications for treatment of patients with cognitive and perceptual deficits. The most striking of these is the reduction in time allocated for inpatient evaluation and treatment.[36] Cognitive and perceptual problems are not readily visible and are therefore more easily overlooked than physical problems. Hence, pressure to discharge patients quickly, possibly before the full extent of cognitive and perceptual deficits has been revealed, means that patients may be discharged to potentially hazardous situations at home. Therapists need to do an initial screening of all patients with brain damage to determine potential problems as early as possible, and ensure that patients are discharged to a safe environment. Although inpatient rehabilitation time is reduced, there is opportunity for outpatient services conducted in the clinic or in the patient's home.[91] The advantage of home care is that therapists have an opportunity to work with the patient in his or her own environment, and tailor therapy to the patient's current circumstances. Patients with cognitive and perceptual deficits often perform better in their own familiar environments.

The major disadvantage of reduced inpatient treatment time for many patients, including those with cognitive and perceptual deficits, is that a home discharge may not be safe after only limited inpatient rehabilitation. The situation is complicated by having to discharge a patient who does not have family support to another type of institutional care (possibly a nursing home or skilled nursing facility) when in the long term this level of care may not be necessary. It is distressing for patients who are confused owing to cognitive and perceptual problems to be moved, particularly when they may believe the move is permanent.

DISCHARGE PLANNING

Discharge planning begins as soon as the patient is admitted for rehabilitation.[92] The most important question to be answered during this stage is where the patient will live after discharge. There are two major types of housing available to persons with disabilities: community-based accommodation and supported accommodation. Community-based accommodation includes private homes, retirement villages, and hotels or rooming houses. Supported accommodation may be defined as any accommodation that provides personal care and medical services on a consistent, continual, or per need basis, and includes nursing homes, skilled nursing facilities, assisted living centers, and sheltered or group housing.[93,94]

The key to discharge planning is to consider the match between the patient's skills and the demands of the environment, and then factor in the support systems available from a spouse, friends, or family to assist with tasks that the patient cannot manage.[94,95] This approach works well when patients and their families have insight and an understanding of the patient's problems. However, cognitive and perceptual deficits are often not very visible and it may be difficult for the family and the patient to understand the functional impact of these deficits. For example, a patient may regain full motor function following a stroke, but experience ongoing difficulties with unilateral neglect. This problem is not readily apparent to the untrained onlooker. However, this patient cannot drive and may be in danger when simply crossing the road. These problems have major lifestyle implications for the patient.

Interventions that facilitate a patient's return to community-based housing usually center on enabling the patient to carry out ADL skills in an acceptable and safe manner. If this cannot be achieved and the patient does not have a live-in caregiver, supported housing such as a nursing home may be the only alternative. Research examining the discharge process for a sample of 62 patients following stroke revealed that the majority were reluctant to consider alternatives to returning home despite having significant self-care deficits.[95] Our housing is central to who we are as individuals and it is very difficult for patients, particularly those with limited insight, to understand and accept that they can no longer live in the community.

OVERVIEW OF COGNITIVE AND PERCEPTUAL DEFICITS

This section is divided into seven parts: *attention deficits, memory impairments, impairments of executive function, body scheme and body image impairments, spatial relations impairments, agnosia,* and *apraxia* (Table 27.3). Each category encompasses a constellation of deficits, which are grouped together for ease of understanding. Information pertaining to each deficit will be organized identically as follows:

1. Definition(s)
2. Clinical Examples
3. Lesion Area
4. Testing
5. Treatment Suggestions

Table 27.3 Summary of Cognitive and Perceptual Impairments

Area of Deficit	Specific Impairments
Cognition	
Attention deficits	Sustained attention
	Selective attention
	Divided attention
	Alternating attention
Memory impairments	Immediate recall
	Short-term memory
	Long-term memory
Higher-order cognition	
Impairment of executive functions	Volition
	Planning
	Purposive action
	Effective performance
Perception	
Body scheme/body image impairments	Unilateral neglect
	Anosognosia
	Somatoagnosia
	Right–left discrimination
	Finger agnosia
Spatial relation impairments (complex perception)	Figure–ground discrimination
	Form discrimination
	Spatial relations
	Position in space
	Topographical disorientation
	Depth and distance perception
	Vertical disorientation
Agnosias	Visual object agnosia
	Auditory agnosia
	Tactile agnosia
Apraxia	Ideomotor apraxia
	Ideational apraxia
	Buccofacial apraxia

The value of dwelling on probable areas of cortical damage is controversial. The indication of cortical loci is an attempt to relate the study of neuroanatomy to actual patient behavior involving cognitive and perceptual dysfunction. An examination of cortical loci will give the reader a sense of which cognitive and perceptual deficits are likely to be seen together.

As therapists, we are required to assist the patient to bridge the gap between maladaptive behavior and independent function in ADL skills. Whether or not the area of the brain purported to produce a particular dysfunction appears damaged on a computed tomography (CT) scan or other neurological or radiological test is not a key determinant of the rehabilitative approach to therapy. The patient's approach to task performance and the relative strengths or weaknesses of the patient (motor, cognitive, and perceptual), which the therapist ascertains through thorough observation and testing, are much more pertinent to the selection of appropriate therapeutic strategies than the locus of the lesion.

Testing tools are described for each cognitive or perceptual deficit to enhance the reader's awareness of the complexity of behavior ascribed to perceptual deficiencies. Familiarity with the tools used to examine cognitive or perceptual deficits can serve as an aid in communication between physical and occupational therapists engaged in the treatment of the same patient.

The following section also includes specific treatment suggestions from the sensorimotor, transfer of training, and functional approaches described. The intervention strategies most relevant to physical therapist practice are those dealing with the functional approach and adaptation of the environment. In these sections, examples are given of how to facilitate the patient's success within a treatment session. Information is provided on how the therapist might gear language, demonstrations, feedback, and the use of media and the environment to the individual needs of the cognitively or perceptually impaired patient. The evidence base for treatment is not strong for many of these treatment techniques, and further research is required to support their efficacy.

Attention Deficits

1. *Definitions.* The inability of many patients with hemiplegia to maintain attention during therapy is a frequent complaint of therapists. **Attention** is the ability to select and attend to a specific stimulus while simultaneously suppressing extraneous stimuli.[96] A patient who is inattentive or distractible will have difficulty in processing and assimilating new information or techniques.[97] Often, patients who have suffered a CVA will have low arousal levels, and require a great deal of sensory input to be alerted to the environment. Low arousal thus must be considered as a cause for seeming inattention.

   Four different kinds of attention are generally discussed in the literature. These are sustained attention, focused or selective attention, alternating attention, and divided attention. **Sustained attention** is a capacity to attend to relevant information during activity. Sustained attention implies that a person can maintain a consistent response during a continuous activity. **Focused** or **selective attention** is the capacity to attend to a task despite environmental visual or auditory stimuli. **Alternating attention** is the capacity to move flexibly between tasks and respond appropriately to the demands of each task. **Divided attention** is the capacity to respond simultaneously to two or more tasks or stimuli when all stimuli are relevant.[1]
2. *Clinical Examples.* The patient with a disorder of sustained attention may report that he or she starts to watch a TV program and then "just drifts off."

A patient who has to stop a dressing activity to talk to the therapist may be demonstrating difficulties with focused attention. Patients who are easily disturbed by music or other forms of background noise may also be experiencing problems with focused attention.

A problem with focused attention is often referred to as distractibility. Divided attention is required when more than one response is needed or more than one stimuli needs to be monitored.[98] Selective attention is required when certain stimuli need to be ignored.[99] Patients who have difficulty with divided and alternating attention may have great difficulties with more complex daily living activities such as cooking a meal or driving.

3. *Lesion Areas.* Multiple brain regions are thought to be responsible for producing attention. These include the reticular formation (which regulates arousal), the various sensory systems that deliver and code relevant sensory information, and the limbic and frontal regions that underlie the drive and affective components of concentration.[99]
4. *Testing.* General screening tests such as the *Loewenstein Occupational Therapy Cognitive Assessment*[75] or *Chessington Occupational Therapy Neurological Assessment Battery (COTNAB)*[72] include subtests that examine attentional abilities. To investigate problems of attention, neuropsychologists generally administer the *Stroop Test*,[100] the *Paced Auditory Serial Attention Test (PASAT)*,[101] and the *Trail Making Test.*[102]
5. *Treatment Suggestions.* The purpose of therapy is to increase the patient's attention to appropriate stimuli, and disregard inappropriate stimuli.
   a. *Remedial Approach.* Clinically, the ability to attend to a task has implications for the therapeutic process. Patients should be instructed to scan the visual environment in a slow and systematic manner. In the presence of right hemiplegia, the patient should be spoken to more slowly to afford an opportunity to process verbal information and be taught to use visualization techniques to facilitate attendance to verbal tasks. In addition, patients with left hemiplegia should be encouraged to use verbalization to improve performance in visual tasks. A randomized clinical trial (RCT) with 12 patients investigating the effect of training on divided attention skills reported positive outcomes as measured on a rating scale of attentional behavior.[103] Patients were trained to do two computer-based or pen and paper tasks simultaneously. However, there was no generalization from this training to nontarget tasks. In other words, the benefits of this training were not transferred to patient activities of daily living.

      Some additional tools that may be used for the remediation of attentional deficits and distractibility are setting time or speed limits, amplification of critical stimuli, and making the crucial stimuli salient (noticeable) to the patient.[63] The environment can be graded by having the patient initially perform some aspects of therapy in a nondistracting setting (closed environment) and then slowly increasing potentially distracting elements, both visual and auditory, as patient tolerance improves (progressing to a more open environment).[1]
   b. *Compensatory Approach.* For many patients, the inability to attend to significant stimuli is compounded by distraction due to extraneous stimuli in the environment. Often noise is the most distracting stimulus, causing irritability and diminished concentration. Ponsford et al[104] provide further ideas for working with patients who have limited attention.

      A Cochrane review titled *Cognitive Rehabilitation for Attention Deficits following Stroke*[105] revealed a small number controlled trials of attention training in patients with stroke. The results of these studies suggested that training improved alertness and sustained attention on measures of these capacities, but there was no evidence to support or refute the use of cognitive rehabilitation for attention deficits to improve functional independence.

Memory Impairments

Memory can be defined as a "mental process that allows the individual to store experiences and perceptions for recall at a later time."[97, p. 78] All memory is not localized in one particular place in the nervous system; rather, many and perhaps all regions of the brain may contain neurons with adequate plasticity for memory storage.[106] Memory comprises acquisition or learning, storage or retention, and retrieval or recall.[107] Learning is a crucial element of rehabilitation. If the patient is unable to learn, time in rehabilitation may not be well spent. Hence, it is very important for the therapist to take steps to evaluate the patient's memory before beginning physical rehabilitation programs. Three levels of memory will be examined: immediate recall, short-term memory, and long-term memory.

Immediate Recall and Short-Term Memory

1. *Definitions.* **Immediate recall** involves retention of information that has been stored for a few seconds. **Short-term memory** mediates retention of events or learning that has taken place within a few minutes, hours, or days.[4]
2. *Clinical Examples.* A patient with immediate recall difficulties may not be able to remember the instructions given only seconds before by the therapist for what the patient is to do. A patient with a short-term memory problem may not come back to the physical therapy department, even though the therapist asked him or her to return in an hour. Alternatively, the

therapist may teach the patient a new transfer technique, and on the following day find that the patient has not retained any of the steps involved. Patients with severe short-term memory problems may not even be able to hold a simple conversation.[1]

3. *Lesion Areas.* Memory is a complex capacity involving many brain regions including four of the major structures of the cerebral cortex (the frontal, parietal, temporal, and occipital lobes) and the limbic system.[4]
4. *Testing.* The *Rivermead Behavioural Memory Test (RBMT)*[81] can be used to examine memory function. Alternatively, the adequacy of memory functions can be ascertained by having the patient recall lists or collections of objects that have just been presented (immediate recall) or by teaching the patient a new verbal or visual task and asking him or her to recall it a few hours or a day later (short-term memory). Frequently there is a loss of short-term memory following stroke, and this particularly interferes with the patient's ability to benefit from rehabilitation, especially from those activities involving the use of new and heretofore unfamiliar techniques.[45]
5. *Treatment Suggestions.* The purpose of memory retraining is to enable the patient to effectively encode and recall information so that learning can occur.
   a. *Remedial Approach.* Because good attention skills are vital for memory, the therapist must ensure that attention problems are addressed and improvements are noted before initiating work on memory retraining.[1,43] A primary focus of this approach is working with the patient to effectively encode information so it can be more easily retrieved when appropriate. This may include organizing material to be remembered and making logical associations. A determination should be made of how the patient used to remember information and build on these past strategies. There is very little evidence to suggest that drills, computer games, or memory tests such as recalling a list of items that have been covered over have any effect on retraining memory. On the other hand, if the therapist assists the patient to develop memory strategies when playing these games, then these strategies may be generalized to everyday activities. In a Cochrane review,[108] the authors drew on findings from two studies and reported that there was insufficient evidence to support or refute the effectiveness of memory retraining on functional outcomes or measures of memory, and called for further robust trials in this area.
   b. *Compensatory Approach.* The use of a diary or notebook system (memory log) can help many patients to manage their daily living activities. However, the patient needs to have sufficient memory to use this system. Environmental prompts such as a beeper or a wall calendar can be useful to assist patients to remember their routine or to look at their diary. When external aids are used, the patient needs to be taught how to use them. Guidelines for the use of such devices may be found in Sohlberg and Mateer[109] and McKerracher et al.[110]

Long-Term Memory

1. *Definition.* **Long-term memory** consists of early experiences and information acquired over a period of years. Patients who do not have long-term memory are often described as having amnesia.[45]
2. *Clinical Examples.* Patients who experience long-term memory problems may have difficulty recalling events from many years ago such as a child's birth, or their own work experiences. Long-term memory problems are common following brain injury and in Alzheimer's disease, but are not commonly seen following stroke.[45]
3. *Lesion Areas.* As described, memory is a complex capacity involving many brain regions. For a detailed discussion, the reader is referred to Fuster[111] and Lezak.[4]
4. *Testing.* The adequacy of memory functions can be determined by having the patient recall personal historical events. The *Rivermead Behavioural Memory Test (RBMT)*[81] can be used to test memory in a standardized way. It is advisable to question the patient's family as to premorbid memory, because many patients in the stroke-prone age group have already begun to experience declining memory as part of the aging process.
5. *Treatment Suggestions.* Treatments for assisting patients overcome long-term memory impairments are similar to those outlined above for immediate recall and short-term memory impairments. Further information on the management of memory impairments may be found in Wilson and Moffat.[112]

Although the literature contains many studies exploring a variety of memory treatments, few of these were designed as randomized controlled trials (RCTs). A Cochrane review[113] found only one controlled trial in which at least 75% of participants had a stroke. The study reviewed was conducted by Doornheim and De Haan[114] and showed that memory training had no significant effect on memory impairment or subjective memory complaints. The Cochrane reviewers concluded that there is currently insufficient evidence to support or refute the effectiveness of cognitive rehabilitation for memory problems after stroke.

Impairments of Executive Functions

1. *Definition.* As defined by Lezak, "executive functions consist of those capacities that enable a person to engage successfully in independent,

purposive, self-serving behavior."[4] Lezak goes on to describe executive functions as consisting of four overlapping components: volition, planning, purposive action, and effective performance.

Volition is the capacity to determine what one needs and wants to do. It also encompasses a future realization of one's needs and wants. Volition encompasses goal planning and task initiation, self-awareness, awareness of the environment, and social awareness. *Planning* is "the identification and organization of the steps and elements (e.g., skills, material, other persons) needed to carry out an intention or achieve a goal."[4, p. 653] Planning involves weighing alternatives and making choices. *Purposive action* includes productivity and self-regulation, which encompasses the ability to initiate, maintain, switch, and stop complex action sequences in an orderly manner to realize a goal. *Effective performance* is the capacity for quality control, including the ability to self-monitor and self-correct one's behavior. Problems with effective performance are associated with ineffective self-monitoring and difficulty with self-correction; for example, patients may not even perceive their mistakes, whereas others may identify them but take no action to correct them.[115]

2. *Clinical Examples.* Although some patients with executive function disorders are unable to formulate realistic goals or intentions (volition) or plan, others may be able to formulate goals and initiate goal-directed task performance, but owing to defective planning are not able to realize their goals. Patients with planning problems may say or intend one thing, but do another.[4] Family and hospital staff may complain of the patient's apparent apathy, poor or unreliable judgment, inappropriate behavior, difficulty adapting to new situations, and/or lack of attention to the needs and feelings of others.[115]

3. *Lesion Area.* Executive functions have traditionally been associated with the frontal and prefrontal cortex,[6] but the current view is that these capacities are mediated by reciprocal connections with other cortical and subcortical regions via the dorsolateral prefrontal–subcortical circuit.[116]

4. *Testing.* Tests of executive functions include the *Behavioural Assessment of the Dysexecutive Syndrome (BADS),*[117] the *Executive Functions Assessment,*[118] and the *Good Samaritan Hospital for Cognitive Rehabilitation's Executive Functions Behavioural Rating Scale.*[119]

5. *Treatment Suggestions.* The combination of impulsiveness, poor judgment, poor planning ability, and lack of foresight, which is particularly problematic in patients with left hemiplegia, does not bode well for independent functioning. The severity of these impairments may diminish somewhat over time.[9] Although some general remedial and adaptive treatment suggestions are described here, for more specific details refer to Ponsford et al[104] and Duran and Fisher.[115]

a. *Remedial Approach.* By providing structure, feedback, and routine, a person's performance can be enhanced (e.g., providing structure by giving the patient steps to follow, assisting the task to become routine by repeated practice, or providing immediate feedback about the patient's behavior and the effect it has on others). The therapist initially acts as the patient's frontal lobes, and gradually transfers these responsibilities to the patient. Unless the patient has some awareness of the problems, a remedial approach will not be particularly successful.[104] Honda[120] reported a study with three patients over a 6-month period who were provided with self-instructional training, a problem-solving procedure, and physical-set changing exercises described as moving the four extremities and trunk in time to a metronome. In this study, "Patients were instructed to follow a videotape for 20 minutes. In the tape, a physical therapist moves four extremities and his trunk in time to a metronome. He changes activities every 2 or 3 minutes. The patients were trained with these methods for a total of 6 months. In the self-instructional procedure and problem-solving training phase, psychologists guided and trained patients 1 hour per day twice a week. In the physical set changing exercise phase, patients were advised to practice twice a day watching the instruction videotape. Each training phase lasted 6 weeks."[120, p. 18] While two of the subjects revealed improvements on the neuropsychological test used as an outcome measure, all subjects improved in basic and instrumental ADL. Of course, a limitation of this study is the small sample size and lack of control subjects, since it could be expected that these patients would make spontaneous recovery over the 6-month study period.

Hewitt el al[121] proposed that people with TBI have difficulty with planning because they are not spontaneously using autobiographic memories. The authors asked a control and experimental group of 15 subjects to describe how they would plan common activities. The experimental group underwent a 30-minute training session aimed at prompting retrieval of specific memories to support planning. This intervention was found to be effective in increasing specific memories that could aid planning.

b. *Compensatory Approach.* The therapist can assist the patient to compensate for poor abilities by utilizing other intact cognitive functions and/or modifying the environment. For example, the therapist might ask the patient to perform a task

in a room with minimal distractions, or change the demands of the patient's work, home, or community to diminish the need to employ executive functions. A beeper or alarm clock may be used to help a patient overcome poor initiation.

Body Scheme and Body Image Impairments

Body image is defined as a visual and mental image of one's body that includes feelings about one's body, especially in relation to health and disease.[122] The term **body scheme** refers to a postural model of the body, including the relationship of body parts to each other and the relationship of the body to the environment. Commonly, body scheme and body image problems are termed *difficulties with body awareness*. Body awareness is derived from the integration of tactile, proprioceptive, and interoceptive (visceral) sensations, in addition to the individual's subjective feelings about the body.[122] An awareness of body scheme is considered one of the essential foundations for the performance of all purposeful motor behavior.[122] The terms *body awareness*, *body image*, and *body scheme* are often used interchangeably; therefore, when researching this topic, close attention should be paid to the particular definition put forth by each individual author. Specific impairments of body image and body scheme are unilateral neglect, somatoagnosia, right–left discrimination, finger agnosia, and anosognosia.

Unilateral Neglect

1. *Definition.* **Unilateral neglect** is the inability to register and integrate stimuli and perceptions from one side of the body (*body neglect*) and the environment or **hemispace** (*spatial neglect* of the area surrounding one side of the body), which is not due to a sensory loss. Unilateral neglect is also referred to as unilateral spatial neglect, hemi-inattention, hemineglect, and unilateral visual inattention.[123] It is important for the therapist to be familiar with this disorder because it is a frequent clinical finding. Neglect following right cerebral infarction has been reported in between 12% and 95% of patients.[124] The reporting rates vary enormously due to differences in time selected for reporting and techniques used to detect the neglect. However, this disorder is commonly seen in the clinic as having a functional impact on about 20% of patients. Unilateral neglect usually, although not always, affects the left side of the body or hemispace, and for purposes of this discussion, we will assume that it is the left. If a patient has unilateral neglect, he or she seems to ignore the left side of the body and stimuli occurring in the left personal space. This may occur despite intact visual fields, or concomitantly with right or left homonymous hemianopia; however, it is not caused by homonymous hemianopia.[125]

When working with a patient who has unilateral neglect, the therapist should also determine which sensory modalities are affected, including visual, tactile, and auditory. Input from one or all of these modalities may be neglected. Neglect can also be understood in terms of the area of space that is neglected. For example, unilateral neglect may express itself as a disorder of attention and goal-directed behavior in:

- Contralesional personal space (defined as pertaining to the body) such as shaving only the right half of the face, or failing to wash the left side of the body, or
- Contralesional peripersonal space (that area of space within arm distance), for example, failing to use objects on the contralesional side of the meal tray, or
- Contralesional extrapersonal space (that area of space beyond arm length) such as failing to negotiate obstacles, doorways, and so forth during locomotion.[50,123]

Unilateral neglect is also demonstrated by an impaired ability to attend to either the object or the environment as a whole. It is possible that while some patients may neglect half of the environment, others may neglect half of objects in the total environment. In the first case, the patient may neglect most elements of the left side of the entire visual scene (Fig. 27.8). In the second case, a patient may neglect the left side of an object, regardless of its absolute position in the visual display. For example, the patient may neglect the left side of a cup even though it is on his or her right side or omit the left side of objects when drawing items such as an umbrella, picnic basket, and bucket and spade as depicted in Figure 27.9.

Frequently, a patient with unilateral neglect has sensory loss on the more affected side, which compounds the problem. Although a patient with left-sided hemianopia has actual loss of vision from the left visual field of both eyes, he or she may be aware of the problem and compensate automatically or learn to compensate by turning the head. A patient with visual neglect has intact vision but seems unaware of the problem and does not attempt to compensate spontaneously by turning the

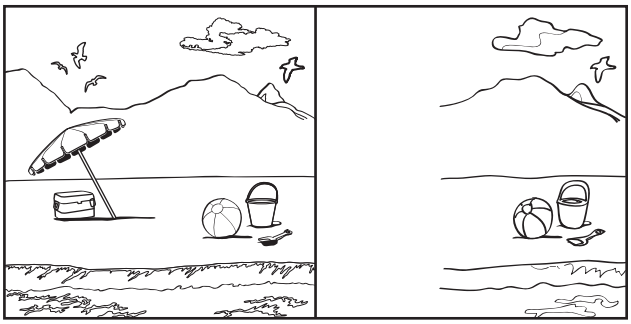

Figure 27.8 Example of a drawing by a patient with unilateral neglect. Therapist's drawing of a beach scene **(left).** Impaired copying by a patient with unilateral neglect—environment neglect following a stroke **(right).**

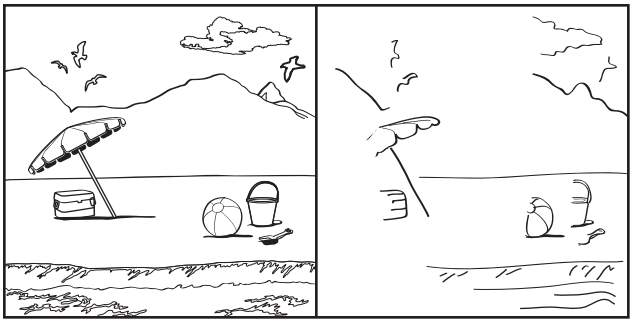

Figure 27.9 Example of a drawing by a patient with unilateral neglect. Therapist's drawing of a beach scene **(left).** Impaired copying by a patient with unilateral neglect—object neglect following a stroke **(right).**

head. In extreme cases the patient appears totally indifferent to the left side of the body and environment, and may deny that the left extremities belong to him or her.[126] More time seems to be required to learn to compensate for this impairment than for hemianopia. There is great difficulty in integrating all stimuli from the left half of the body and personal space for use in ADL skills. As with hemianopia, the patient with visual unilateral neglect often avoids crossing the midline visually or motorically.[61]

2. *Clinical Examples.* The patient may ignore the left half of the body when dressing and forget to put on the left sleeve or left pants leg. Often a male patient will forget to shave the left half of his face. A woman may neglect to put makeup on the left side of her face.[127] The patient may neglect to eat from the left half of a plate and will start reading a newspaper from the middle of the line. Typically, the patient bumps into objects on the left side or tends to veer toward the right when walking or propelling a wheelchair.

3. *Lesion Area.* It has been suggested that lesions involving the inferior–posterior regions of the right parietal lobe are significant determinants of neglect.[125,128]

4. *Testing.* A variety of techniques are useful. No single test is adequate to identify unilateral neglect in all patients because the impairment may be manifested differently in each patient.

a. The *Behavioural Inattention Test (BIT)*[77] can be used to examine unilateral neglect (see Table 27.1). The patient may also be observed during basic activities of daily living (BADL) such as dressing, or an IADL such as preparing a meal. The therapist observes performance and observes changes in the patient's behavior in response to cueing.

b. The purpose of therapy is to increase awareness of the left side of the body and space. Current beliefs concerning the mechanisms underlying unilateral neglect guide the majority of treatment approaches. Rizzolatti and Berti[129] combine the popular attentional and representational models in their premotor theory of neglect. The basis of this theory is that spatial attention is dependent on several independent neural circuits. Attention, and therefore perception of stimuli, is enhanced as a direct result of activation of motor circuits, as occurs when a person moves. Hence, activating motor circuits of the ipsilesional hemisphere (via voluntary movements of the left upper or lower limbs) may facilitate associated sensory circuits. Such movement may in turn lead to improvements in the processing of stimuli from the contralesional (left) side.[123]

5. *Treatment Suggestions.*

a. *Remedial Approach.* Capitalizing on the rationale of the premotor theory of neglect, the following suggestions are proposed. Stimuli that are specialized for the right side of the brain, such as shapes and blocks, should be used to enhance right brain activation. At the same time, the presence of stimuli that are known to activate the left side of the brain, such as letters and numbers, should be minimized. Use of verbal instructions should be minimized. Simple verbal instructions should be used to encourage the patient to turn the head to the left to anchor his or her attention to that side of space.[126] In addition, research suggests that conducting motor activities with the left body side, such as simply clenching and unclenching the fist, can improve attention to the left body side and hemispace. Robertson et al[130] conducted a study with six individuals with hemiplegia who were asked to walk through a doorway. Each of the subject's walking trajectory (pathway) was measured, and it was found that all trajectories were significantly deviated to the right of center. The subjects were then asked to clench and unclench their left hands before, and during, walking through the doorway. The researchers found that this procedure significantly assisted subjects to center their walking trajectories. Other techniques that have been used to treat patients with unilateral neglect include eye-patching, optokinetic stimulation and prism glasses, neck vibration,[131] and trunk rotation. A review of these treatment techniques may be found in Luauté et al.[132] A review of the effectiveness of a range of these therapies is included in Box 27.1 Evidence Summary.[133-141]

b. *Compensatory Approach.* The patient is initially educated about the condition, and then strategies to assist managing everyday activities are devised. For example, when reading a book or newspaper, a red ribbon may be placed on the left margin and the patient is taught to scan back to this point after completing each line. The environment may

also be adapted within this approach. The patient is addressed and given demonstrations from the less affected side. The nursing staff should place the patient's call button, telephone, and other essential items on the less affected side. A bold red line may be drawn on the side of the page that is neglected.[122] A mirror may be placed in front of the patient while he or she is dressing or ambulating to draw attention to the neglected side.

c. Several Cochrane reviews have been conducted concerning the effectiveness of cognitive and perceptual rehabilitation. An overview of findings from small Cochrane reviews in the areas of attention and memory rehabilitation was presented earlier. A more extensive Cochrane review[133] was conducted concerning the effectiveness of therapy for unilateral neglect, because there has been an abundance of studies and trials conducted on this puzzling disorder over the past 20 years. Box 27.1 Evidence Summary contains a summary of selected controlled trials included in the Cochrane review[133] and a small number of studies published after the review. Cochrane reviews only include controlled trials and each trial is rated (A, B, or C) on the quality of its randomization process. "A" studies are considered adequate, "B" unclear, and "C" inadequate. Of the 12 studies included in the Cochrane review, the Evidence Summary Box contains all the studies with an A classification (Fanthome et al,[134] Jacquin-Courtois et al,[135] Kalra et al,[136] and Tsang et al[137]) and two randomly selected studies rated as B (Watanabe and Amimoto[138] and Wiart et al[141]). As a result of conducting this review, Bowen and Lincoln[133] concluded that there is some evidence that cognitive rehabilitation for patients with unilateral neglect improves performance on some impairment-based tests. However, the effects of cognitive rehabilitation on reducing activity limitations are unclear. Additional well-designed RCTs and more basic research are required to develop outcome measures in the field.

Anosognosia

1. *Definition.* **Anosognosia** is a severe condition including denial and lack of awareness of the presence or severity of one's paralysis.[50] Anosognosia is defined as a lack of awareness, or denial, of a paretic extremity as belonging to the person, or a lack of insight concerning, or denial of, paralysis.[50] Presence of this disability may compromise rehabilitation potential greatly, because it limits the patient's ability to recognize the need for, and thus to use, compensatory techniques.
2. *Clinical Examples.* Typically, the patient maintains that there is nothing wrong and may disown the paralyzed limbs and refuse to accept responsibility for them. The patient may claim that the limb has a mind of its own or that it was left at home, or in a closet.
3. *Lesion Area.* The pathogenesis of anosognosia remains unclear,[50] although the region of the supramarginal gyrus has been proposed.[142]
4. *Testing.* Anosognosia is identified by talking to the patient. The patient is asked what happened to the arm or leg, whether he or she is paralyzed, how the limb feels, and why it cannot be moved. A patient with anosognosia may deny the paralysis, say that it is of no concern, and fabricate reasons why a limb does not move the way it should.
5. *Treatment Suggestions.* Anosognosia often resolves spontaneously in the first 3 months following stroke.[143] Maeshima et al[143] also noted that until the condition resolves, it seriously hampers rehabilitation. It is extremely difficult to compensate for the condition if it persists long term. Safety is of paramount importance in the treatment and discharge planning for patients suffering from anosognosia, because they typically do not acknowledge their disability and will therefore refuse to be careful.[9]

Somatoagnosia

1. *Definition.* **Somatoagnosia**, or impairment in body scheme, is a lack of awareness of the body structure and the relationship of body parts to oneself or to others. Somatoagnosia is also referred to as *autopagnosia* or simply *body agnosia*.[144] Patients with this deficit may display difficulty following instructions that require distinguishing body parts and may be unable to imitate movements of the therapist.[67] Often patients report that the more affected arm or leg feels unduly heavy. Lack of proprioception may underlie or compound this disorder.[145]
2. *Clinical Examples.* The patient may have difficulty performing transfer activities because he or she does not perceive the meaning of terms related to body parts; for example, "Pivot on your leg and reach for the armrest with your hand." In addition, a patient with a body scheme disorder will have difficulty dressing. Patients may have a hard time participating in exercises that require some body parts to be moved in relation to other body parts; for example, "Bring your arm across your chest and touch your shoulder."
3. *Lesion Area.* The lesion site is often the dominant parietal lobe.[142] Therefore, this disorder is seen primarily with right hemiplegia. However, impairment in body scheme may also occur with left hemiplegia.
4. *Testing.*
   a. The patient is requested to point to body parts named by the therapist, on himself or herself, on the therapist, and on a picture or puzzle of a human figure. Zoltan[2] provides details of these testing procedures. An example of verbal directives from these

Box 27.1 Evidence Summary Evidence Addressing the Use of Cognitive Rehabilitation Techniques to Increase Activity in Patients with Unilateral Neglect Following Stroke

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Fanthome et al[134] (1995)	Patients with recent RH stroke E = 9; C = 9 Gender (M/F): E = 6/3 C = 6/3 Time post-onset (months): E = 1.0; C = 0.6 IC = <80 years age, no history of dementia or psychiatric problems, not unwell, R handed, score > 6 on Abbreviated Mental Test, score <130 on BIT	RCT Blinded examiner E = Ss wear specially modified glasses which provide a reminder beep if patient fails to move eyes to the L in a 15-second interval C = No treatment for visual inattention	4 wk E = Treatment 2 hr 40 min/wk C = No treatment	After 4 wk, no significant difference between groups in either eye movements or BIT scores.	E and C appeared adequately matched on demographic and clinical data although C slightly older than E; no baseline BIT data.
Jacquin-Courtois et al[135] (2010)	22 Ss, 12 with RH stroke and 10 healthy Ss. IC for stroke Ss = no previous neurological damage; L neglect as detected using line cancellation, line bisection and a copy drawing task; L ear extinction; adequate hearing; R handedness. 11 Ss randomly assigned each to E or C groups. No differences between E and C Ss at baseline for age, or time between stroke and entry to the study	Random allocation of Ss to E and C but randomization not blind and not fully reported. Sought to determine if prism adaptation effects generalize to those neglect symptoms not directly linked to visuo-manual adaptation. Hence, auditory extinction was assessed in neglect Ss before and after treatment with prism glasses. E = wore prism glasses with a 10° shift to the R. C = wore neutral glasses. Outcome measures included a verbal dichotic listening task including 60 pairs of stimuli administered to the R and L ears simultaneously	E = 50 pointing responses to visual targets presented 10° to the R or L of midline lasting approximately 8 min. Dichotic listening test presented 3 times; before prisms, after prisms, and 2 hr later. C = neutral glasses and same dichotic listening test	Prism adaptation found to improve L sided auditory dichotic listening tasks immediately after prism adaptation, and when measured 2 hr later.	The findings suggest that visual adaptation may also affect performance in other sensory modalities (audition) and suggests prism adaptation may have broader treatment effects than for vision alone.

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Kalra et al[136] (1997)	Patients 2–14 days post-stroke with VN E = 24; C = 23 Mean age (SD): E = 78 (9) C = 76 (10) Median time post-onset: 6 days (2–14 range) EC = TIAs, reversible neurological deficits, hemianopia, or severe dysphasia	RCT (blinded examiner) E = Spatiomotor cueing based on *attentional–motor integration* model; early emphasis on restoration of function; C = Conventional therapy focusing on restoration of tone, movement pattern, and motor activity before addressing skilled functional activity	12 wk Initial baseline measures and following the 12 wk; mean therapy time = 47.7 hr	6 types of outcome data collected: (1) mortality; (2) BI; (3) discharge destination; (4) length of hospital stay; (5) duration of therapy input; and (6) RPAB (cancellation subtest and discharge home). Patients with VN have similar discharge destination despite lower BI scores (compared to patients without VN); spatiomotor cueing improves (p <.05) outcome in patients with VN.	Principle behind approach: Movements of affected limb in the deficit hemispace led to summation of activation of affected receptive fields of 2 distinct but linked spatial systems for personal and extrapersonal space; this resulted in improvements in attentional skills and appreciation of spatial relationships on the affected side.
Tsang et al[137] (2009)	35 Ss recruited over 6 months with 1 dropout. Gender M/F (21/13). IC = initially, clients required BIT <129, then other IC applied if R CVA on CT or MRI, with L sided neurological involvement, evidence of visual field inattention, right handed, within 8 wk post-stroke and Glasgow Coma Scale = 15. EC = severe dysphagia, transient TIA or	Single-blind RCT, with pre-test, post-test. E = 17 Ss wore R half-field eye-patching glasses throughout OT treatment. C = 17 Ss with no eye patching. All Ss measured on admission and at 4 wk	E = 4 wk of conventional OT with eye-patching, C = 4 wk of conventional OT	E group had significantly higher BIT scores compared to C at 4 wk, but no difference between group on FIM scores.	Eye patching leads to a reduction in impairment as measured on the BIT but the potential benefits in terms of function were not confirmed in this study. However, FIM may not be the best measure to pick up any functional gains. Also, power analysis revealed that a sample of 59 Ss in each group needed to show statistical significance.

Reference	Subjects	Design/Intervention	Duration	Results	Comments
	reversible neurological deficit, significant impairment in visual acuity (e.g., as caused by cataracts); history of other neurological disease, psychiatric disorder or alcoholism. No difference at baseline between E and C for age, sex, stroke type, lesion site, time since onset, past history of stroke, and educational level.				
Watanabe and Amimoto[138] (2010)	10 Ss with unilateral neglect. IC = R-handed with R hemisphere lesion sustained within past 40 days, and capable of driving a wheelchair for 7 m (23 ft) without assistance. EC = unable to distinguish symbols due to visual impairment, who could not understand the research tasks, and if accomplishing the task would be physically difficult. Ss then further screened with Japanese edition of the BIT and were below the cutoff score in at least one of the subtests	Prospective cohort design, with staff blinded to purpose of the research. E = Ss wore fitted prism glasses, displacing Ss visual field by 7° to R. Ss then reached 50 times in front of them in quick succession with R hand for a target. Ss were then blindfolded and measured in 10 trials of pointing straight ahead, and then a wheelchair driving task. Ss timed as they drove 7 m to reach a cone target.	Same day pre-test post-test	10 Ss completed all tasks. Significant shifts between pre-test and post-test in straightening of pointing and in reaching the target faster in the wheelchair.	Findings suggest generalization of prism adaptation on both a pointing task and the ADL task of driving a wheelchair. Study would benefit from use of a control group.

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Serino et al[139] (2009)	20 R handed Ss with L neglect were divided into matched groups based on neglect severity. IC = scores on the BIT. EC = widespread mental deterioration using MMSE or psychiatric disorders. E = 10, C = 10. Gender (M/F): E = 8/2; C = 6/4. No differences reported between mean age (E = 62, C = 61), education, or time since stroke	Matched pairs, comparison design. Prism glasses that shifted the field of view 10° to the R were worn by Ss in E group. Neglect measured before and after each treatment and 1 month after the end of treatment. During intervention, patients repeatedly point at visual target with R index finger	E and C = 90 trials each weekday (lasting approximately 30 min) for 2 wk	Both groups improved; however, E showed statistically significant improvement over C. Effects confirmed 1 month after treatment ceased.	Design could be strengthened by random allocation to E and C with a larger sample to control for neglect severity. Further research to understand the mechanism by which prism adaptation may be working is required.
Turton et al[140] (2010)	34 Ss post-stroke with L neglect E = 16; C = 18 Mean age: E = 72; C = 71 Gender (M/F): E 8/8, C 11/7 Time post-onset (mean days): E = 45; C = 47 IC = RH stroke at least 20 days before study; self-care problems identified by OT, ability to sit and point with the unaffected hand, and ability to follow instructions	RCT E = repeated touching of target with index finger on a box screen while wearing prism glasses; glasses were 10 diopter prisms that shifted the field of view 6° to the R; C = same task while wearing neutral glasses	E and C = 90 trials each weekday (lasting approximately 30 min) for 2 wk	Data collected: 4 days after finishing treatment, at follow-up 4 wks later. Measures: the CBS and pen-and-paper tests from the BIT. E = showed increased leftward bias in pointing to targets, but no effect of treatment on BIT.	Study appeared to control for bias and compared well-matched groups. Authors suggested differences may not have shown since outcomes were measured 4 days after treatment ended, and previous literature suggests that treatment effect may be immediate and short lived. Authors also suggested that although the current study used prisms that shifted the field of view 6° to R, other studies have used 10° and 15° prisms, and research is needed to determine optimum prism strength and frequency of treatment sessions.

Box 27.1 Evidence Summary Evidence Addressing the Use of Cognitive Rehabilitation Techniques to Increase Activity in Patients with Unilateral Neglect Following Stroke—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Wiart et al[141] (1997)	22 patients post-stroke with severe L neglect (positive findings for neglect on 3 tests); E = 11; C = 11 Mean age: E = 66; C = 72 Gender (M/F): E 6/5, C 6/5 Time post-onset (mean days): E = 35; C = 30 EC = history of stroke; alteration of general status; cognitive difficulties incompatible with rehabilitation	RCT E = experimental treatment is Bon Saint Come (one of the author's) method; thoracolumbar vest worn with attached metal pointer above head; patient points to target on mobile panel; audible and luminous signals provide biofeedback when targets are touched; therapist participates actively during the session, stimulating, guiding, and correcting; C = 3–4 hr traditional rehabilitation per day	E = 1 hr/day (20 days) of experimental treatment followed by traditional rehabilitation (physical therapy for 1–2 hr and 1 hr of occupational therapy); C = 3–4 hr of traditional rehabilitation per day	Two types of outcome data collected: (1) quantitative scoring of neglect (line bisection, line cancellation, bell cancellation); (2) autonomy (FIM). Data collected: day 0, day 30 (after therapy), and day 60. All quantitative and FIM scores improved significantly more in E than in C.	E was younger and had a higher initial FIM score than the C; C had more, but not significantly so, omissions on line cancellation (C = 16; E = 14) and R deviations on line bisection (C = 53%; E = 50%) at baseline compared with E; the Bon Saint Come method shows promise and should be further tested.

BI = Barthel Index; BIT = Behavioural Inattention Test; C = control group; CBS = Catherine Bergego Scale; CT = computed tomography; CVA = cerebrovascular accident; E = experimental group; EC = exclusion criteria; FIM = Functional Independence Measure; HFVS = Harrington Flocks Visual Field Screener; HHA = homonymous hemianopia; IC = inclusion criteria; L = left; MMSE = Mini-Mental Status Examination; MRI = magnetic resonance imaging; MVPT = Motor-Free Visual Perceptual Test; OT = occupational therapist/therapy; R = right; RCT = randomized controlled trial; ReyCFT = Rey Complex Figure Test; RH = right hemisphere; RPAB = Rivermead Perceptual Assessment Battery; S, Ss = subject, subjects; TIA = transient ischemic attack; UK = United Kingdom; VN = visual neglect; WAIS-R = Wechsler Adult Intelligence Scale—Revised.

tests is, "Show me your feet. Show me your chin. Point to your back." The words "right" and "left" should not be used because they may lead to an inaccurate diagnosis in patients who have difficulty with right–left discrimination. Aphasia should be ruled out as a cause of poor performance.

b. The patient is asked to imitate movements of the therapist. For example, the therapist touches his or her cheek, arm, leg, and so forth. A mirror-image response is acceptable.[2]

c. The patient is requested to answer questions about the relationship of body parts. For example, "Are your knees below your head? Which is on top of your head, your hair or your feet?" For patients with aphasia, questions should be phrased to require a yes or no, or true or false response. Patients with intact function in this area should respond correctly most of the time and within a reasonable period of time. Those patients with receptive aphasia are particularly likely to do poorly on tests for somatagnosia.[144]

5. *Treatment Suggestions.* Using a remedial approach, the therapist aims for the patient to associate sensory input with an adaptive motor response.[2] Facilitation of body awareness is accomplished through sensory stimulation to the body part affected. For example, the patient is asked to rub the appropriate body part with a rough cloth as the therapist names it or points to it.[22] Alternatively, the patient verbally identifies body parts, or points to pictures of them as the therapist touches them.

Right–Left Discrimination

1. *Definition.* A **right–left discrimination disorder** is the inability to identify the right and left sides of one's own body or of that of the examiner.[125] This includes the inability to execute movements in response to verbal commands that include the terms "right" and "left." Patients are often unable to imitate movements.[125]

2. *Clinical Examples.* The patient cannot tell the therapist which is the right arm and which is the left. The right shoe cannot be discerned from the left shoe, and the patient is unable to follow instructions using the concept of right–left, such as "turn right at the corner." The patient cannot

distinguish the right from the left side of the therapist.

3. *Lesion Area.* The lesion site is the parietal lobe of either hemisphere.[125] A close relationship between aphasia (usually owing to left hemisphere damage) and deficits in right–left discrimination has been reported. In patients without aphasia (usually those with right hemisphere damage), a relationship has been reported between general mental impairment and right–left discrimination disorder.[144]
4. *Testing.* The patient is asked to point to body parts on command, such as right ear, left foot, right arm, and so forth. Six responses should be elicited on either the patient's own body, on that of the therapist, or on a model or picture of the human body.[144] To rule out somatoagnosia, the patient should be tested first without using the words "right" and "left."
5. *Treatment Suggestions.* If using a compensatory approach, when giving instructions to the patient, the words "right" and "left" should be avoided. Instead, pointing or providing cues using distinguishing features of the limb may be more effective (e.g., "the arm with the watch"). These guidelines are particularly salient for the therapist teaching locomotion or transfers, where confusing instructions may have dangerous consequences. The right side of all common objects such as shoes and clothing should be marked with red tape or seam binding.

Finger Agnosia

1. *Definition.* **Finger agnosia** can be defined as the inability to identify the fingers of one's own hands or of the hands of the examiner.[125]
2. *Clinical Examples.* The disorder is characterized by difficulty in naming the fingers on command, identifying which finger was touched, and, by some definitions, mimicking finger movements. This deficit usually occurs bilaterally and is more common in the middle three fingers.[146] Finger agnosia correlates highly with poor dexterity in tasks that require movements of individual fingers in relation to each other,[1] such as buttoning, tying laces, and typing.
3. *Lesion Area.* Finger agnosia may be the result of a lesion located in either parietal lobe,[147] often in the region of the angular gyrus of the left hemisphere. It is often found in conjunction with an aphasic disorder,[144] or with general mental impairment.[125,144] Bilateral finger agnosia along with right–left discrimination problems, **agraphia**, and *acalculia* is termed *Gerstmann's syndrome.*[125] Gerstmann's syndrome usually is associated with a focal lesion of the dominant hemisphere in the region of the angular gyrus.[142]
4. *Testing.* A portion of *Sauguet's test*[2,144] is recommended. Sauguet's test includes asking the patient to move or point to his or her finger when named by the therapist to determine if finger agnosia is present. Between five and ten commands from the therapist is adequate. The test is not standardized.
   a. The patient is asked to name the fingers touched by the therapist, with the eyes open (five times) and if successful, with vision occluded (five times).
   b. The patient is asked to point to the fingers named by the therapist on the patient's own hands (10 times), on the therapist's hands (10 times), and on a schematic model (10 times).
   c. The patient is asked to point to the equivalent finger on a life-sized picture when the therapist touches each finger.
   d. The patient is asked to imitate finger movements; for example, curl the index finger, touch the thumb to the middle finger.
5. *Treatment Suggestions.* There is very limited evidence to support the efficacy of treatment techniques for finger agnosia. When using a remedial approach, the patient's discriminative tactile systems (touch and pressure) are stimulated. A rough cloth can be used to rub the dorsal surface of the more affected arm, hand, and fingers, and the ventral surface of the more affected fingers. Pressure can be applied to the ventral surface of the hand. For additional details the reader is referred to Zoltan.[2]

Spatial Relations Disorders (Complex Perception)

Spatial relations disorders encompass a constellation of impairments that have in common a difficulty in perceiving the relationship between the self and two or more objects.[148] Research suggests that the right parietal lobe plays a primary role in space perception. Thus, a spatial relations impairment most frequently occurs in patients with right-sided lesions with resulting left hemiparesis.[148]

Spatial relations disorders include impairments of figure–ground discrimination, form discrimination, spatial relations, position in space, and topographical disorientation. Additional visuospatial impairments, such as depth and distance perception and vertical disorientation, will also be discussed in this section. In a study comparing the effectiveness of the cognitive remediation (sometimes referred to as the *transfer-of-training technique*) versus the functional approach, Edmans et al[149] found that both approaches were equally successful in treating perceptual impairments. However, since this study did not control for the effects of spontaneous recovery in both groups, further research is required.

Figure–Ground Discrimination

1. *Definition.* An impairment in visual figure–ground discrimination is the inability to visually distinguish a figure from the background in which it is embedded.[5] Functionally, it interferes with the patient's ability to locate important objects that are not prominent in a visual array. The patient has difficulty ignoring irrelevant visual stimuli and cannot

select the appropriate cue to which to respond.[5] This may lead to distractibility, resulting in a shortened attention span,[150] frustration, and decreased independent and safe functioning.[67]

2. *Clinical Examples.* The patient cannot locate items in a pocketbook or drawer, locate buttons on a shirt, or distinguish the armhole from the remainder of a solid-colored shirt. The patient may not be able to tell when one step ends and another begins on a flight of stairs, especially when descending.

3. *Lesion Area.* Parieto-occipital lesions of the right hemisphere and less frequently the left hemisphere commonly produce this disorder.[151]

4. *Testing.*
   a. The *Ayres Figure–Ground Test* (subtest of the *Southern California Sensory Integration Tests*)[152] requires the subject to distinguish the three objects in an embedded test picture, from a possible selection of six items. This test was standardized on children but may be useful as a clinical tool in identifying perceptual disorders in adults with brain damage.[4] Normative data have been generated for normal adult males.[153] Many other tests have since used a similar approach to test figure–ground perception by showing the patient overlapping line drawings of everyday objects and asking clients to name these as illustrated in Figure 27.10.
   b. *Function-based Tests.* A white towel can be placed on a white sheet, and the patient is asked to find the towel. The patient can be asked to point out the sleeve, buttons, and collar of a white shirt, or to pick out a spoon from an unsorted array of eating utensils. It is necessary to rule out poor eyesight, hemianopia, visual agnosia, and poor comprehension to improve the validity of these testing techniques.

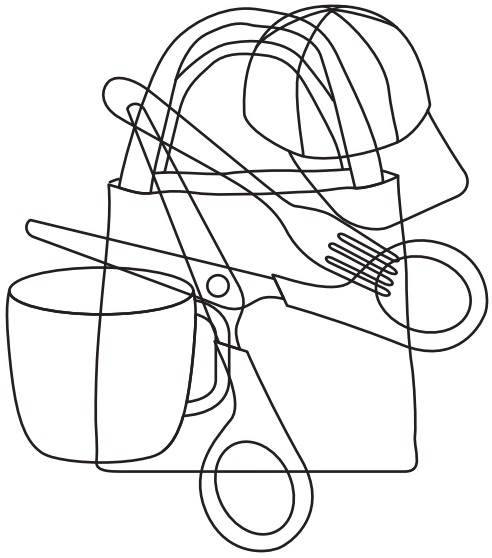

Figure 27.10 An example of a figure–ground perception test.

5. *Treatment Suggestions.*
   a. *Remedial Approach.* The therapist should arrange for practice in visually locating objects in a simple array (such as three very different objects), and progress to more difficult ones (four or five dissimilar objects and three similar ones).
   b. *Compensatory Approach.* The patient is taught to become aware of the existence and nature of the deficit. The patient should be cautioned to examine groups of objects slowly and systematically and should be instructed to use other, intact senses (e.g., touch) when searching for items such as clothing or silverware. When learning to lock a wheelchair, the patient should be advised to locate the brake levers by touch rather than by searching for them visually. Red tape may be placed over the hook-and-loop closure of the shoe or orthosis to aid the patient in locating it. Few items should be placed in the patient's drawers or nightstand, and they should be replaced in the same location each time. Brightly colored tape can be used to mark the edges on stairs. Repetition is a key element of this approach and repeated practice is used in each specific area of difficulty. The same procedure should be employed during each practice session, incorporating verbal cues and touch as adjuncts to vision.

Form Discrimination

1. *Definition.* Impairment in **form discrimination** is the inability to perceive or attend to subtle differences in form and shape. The patient is likely to confuse objects of similar shape or not to recognize an object placed in an unusual position.

2. *Clinical Examples.* The patient may confuse a pen with a toothbrush, a vase with a water pitcher, a cane with a crutch, and so forth.

3. *Lesion Area.* The lesion site is the parieto-temporo-occipital region (posterior association areas) of the nondominant lobe.[4]

4. *Testing.* A number of items similar in shape and different in size are gathered. The patient is asked to identify them. One set of items might be a pencil, pen, straw, toothbrush, and watch, and the other might be a key, paper clip, coins, and ring. Each object is presented several times in different positions (e.g., upside down). Visual object agnosia must be ruled out as a cause for poor performance by first presenting objects separately and asking the patient to identify them or to demonstrate how they are used (see Visual Agnosias below).

5. *Treatment Suggestions.*
   a. *Remedial Approach.* The patient should practice describing, identifying, and demonstrating the use of similarly shaped and sized objects. The

patient should sort like objects and should be assisted to focus on differentiating object cues.

b. *Compensatory Approach.* The patient must be made aware of the specific deficit. If the patient can read, frequently used and confused objects can be labeled. The patient should be encouraged to use vision, touch, and self-verbalization in combination when objects are confused.

Spatial Relations

1. *Definition.* A **spatial relations disorder**, or spatial disorientation, is the inability to perceive the relationship of one object in space to another object, or to oneself. This may lead to, or compound, problems in constructional tasks and dressing.[5] Crossing the midline may be a problem for patients with spatial relations deficits.[148] Spatial relations skills are required to manage most ADL.
2. *Clinical Examples.* The patient might find it difficult to place the cutlery, plate, and spoon in the proper position when setting the table. The patient may be unable to tell the time from a clock because of difficulty in perceiving the relative positions of the hands.[2,29] The patient may have difficulty learning to position his or her arms, legs, and trunk in relation to the wheelchair to prepare for transferring.
3. *Lesion Area.* The lesion site is predominantly the inferior parietal lobe or parieto-occipital-temporal junction, usually of the right side.[5] Arnadottir and Gudrun[148] explain how a patient with perceptual deficits may have difficulty putting on a shirt. This is illustrated in Figure 27.11. Since the CNS works in a holistic way, the task of putting on a shirt requires visual, tactile, and auditory information as well as attentional and memory capacities and motor output. Figure 27.11 suggests that while damage in a variety of brain areas may affect visuospatial processing, the most common lesion site is the right inferior parietal lobe.
4. *Testing*. Recommended tests include the *Rivermead Perceptual Assessment Battery (RPAB)*[79] and the *Arnadottir OT-ADL Neurobehavioural Evaluation (A-ONE)*.[5] To improve the validity of these tests, unilateral neglect and hemianopia should be ruled out as the causes of poor performance. If these impairments are present, the stimulus array should be positioned appropriately.
5. *Treatment Suggestions.* When using a remedial approach, patient ability to orient to other objects can be improved by giving the patient instructions to position himself or herself in relation to the therapist or another object. The therapist might say, "Sit next to me," "Go behind the table," or "Step over the line." In addition, the therapist can set up a maze of furniture (obstacle course). Having the patient copy block or matchstick designs of increasing difficulty will increase awareness of the relationship between one object (block or matchstick) and the next. If the patient avoids crossing the midline, activities that require crossing the midline both motorically and visually can be incorporated into other therapeutic activities (e.g., proprioceptive neuromuscular facilitation [PNF] chop patterns). One specific activity is to have the patient hold a dowel in front with both hands. The therapist guides it from the less involved side to the more involved side. Later, the patient can progress to manipulating the dowel with only verbal or visual cues, and finally to guiding it independently.[154]

Position in Space

1. *Definition.* **Position in space impairment** is the inability to perceive and to interpret spatial concepts such as up, down, under, over, in, out, in front of, and behind.
2. *Clinical Examples.* If a patient is asked to raise the arm "above" the head during ROM activities or is asked to place the feet "on" the footrests, the patient may behave as if he or she does not know what to do.
3. *Lesion Area.* The lesion is usually located in the nondominant parietal lobe.[151]
4. *Testing.* To test function, two objects are used, such as a shoe and a shoebox. The patient is asked to place the shoe in different positions in relation to the shoebox; for example, in the box, on top of the box, or next to the box. Alternatively, the patient is presented with two objects and asked to describe their relationship. For example, a toothbrush can be placed in a cup, under a cup, and so forth, and the patient is then asked to indicate the location of the toothbrush.

   Another mode of testing is to have the patient copy the therapist's manipulations with an identical set of objects. For example, the therapist hands the patient a comb and a brush. The therapist then takes an identical set and places them in a particular relationship to each other, such as the comb on top of the brush. The patient is requested to arrange his or her comb and brush in the same way. Success in this task may represent sufficient ability to use position in space functionally.

   Figure–ground difficulty, apraxia, incoordination, and lack of comprehension should be ruled out when performing these tests. Objects should be positioned to avoid compounding of results with hemianopia and unilateral spatial neglect.
5. *Treatment Suggestions.* If using a retraining approach, three or four identical objects are placed in the same orientation (wrist weights, combs, mugs, and so forth). An additional object is placed in a different orientation. The patient is asked to identify the odd one, and then to place it in the same orientation as the other objects.

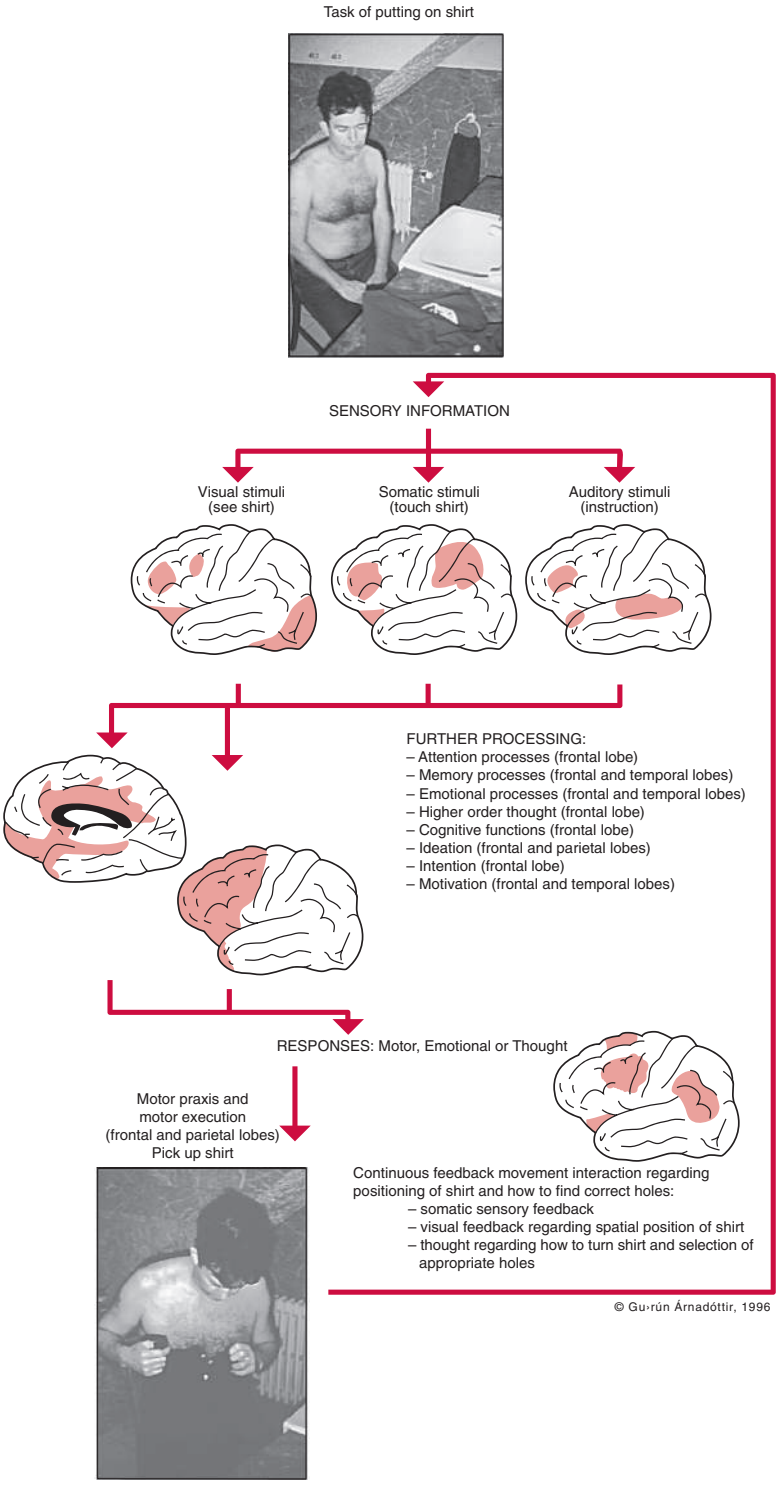

Figure 27.11 Spatial relation processing as a man puts on a shirt. *From Arnadottir and Gudrun,*[148, p. 405] *with permission.*

Topographical Disorientation

1. *Definition.* Topographical disorientation refers to difficulty in understanding and remembering the relationship of one location to another.[155] As a result, the patient is unable to get from one place to another, with or without a map. This disorder is frequently seen in conjunction with other difficulties in spatial relations.[45]
2. *Clinical Examples.* The patient cannot find the way from his or her room to the physical therapy clinic, despite being shown repeatedly. The patient cannot describe the spatial characteristics of familiar surroundings, such as the layout of his or her bedroom at home.[151]
3. *Lesion Areas.* The majority of cases involve damage to the right retrosplenial cortex, with Brodmann's

area 30 compromised in most patients.[155] Bilateral parietal lesions, and more rarely, left-side parietal lesions, can produce this problem.[151]

4. *Testing*. The patient is asked to describe or to draw a familiar route, such as the block on which he or she lives, the layout of his or her house, or a major neighborhood intersection.[145] A patient with topographical disorientation will be unable to succeed in this task. However, the therapist must differentiate between memory problems and topographical orientation difficulties.
5. *Treatment Suggestions.* This deficit usually resolves 8 weeks after onset.[155] However, several treatment techniques can be used to hasten recovery, or to assist long term if the condition persists.
   a. *Remedial Approach.* The patient practices going from one place to another, following verbal instructions. Initially, simple routes should be used, and then more complicated ones.[2]
   b. *Compensatory Approach.* Frequently traveled routes can be marked with colored dots. The spaces between the dots are gradually increased and eventually eliminated as improvement takes place.[2] This is an example of taking a normally right-hemisphere task and (because there is right-sided damage) converting it into a left-hemisphere task. In this instance we take the spatial task of remembering routes (right-hemisphere task) and substitute sequential landmarks (sequencing is typically a left-hemisphere strength) to accomplish the goal of getting from place to place. The patient should be reminded not to leave the clinic, room, or home unattended, because he or she may get lost.

Depth and Distance Perception

1. *Definition.* The patient with a disorder of depth and distance perception experiences inaccurate judgment of direction, distance, and depth. Spatial disorientation may be a contributing factor in faulty distance perception.
2. *Clinical Examples.* The patient may have difficulty navigating stairs, may miss the chair when attempting to sit, or may continue pouring juice once a glass is filled.[150]
3. *Lesion Areas.* This impairment may occur with a lesion in the posterior right hemisphere in the superior visual association cortices; it may be evident with right-sided or bilateral lesions.[151]
4. *Testing.*
   a. For a functional test of distance perception, the patient is asked to take or to grasp an object that has been placed on a table. The object may also be held in front of the patient, in the air, and the patient is again asked to grasp it. The patient with impaired distance perception will overshoot or undershoot.[2] However, the movements look purposeful and smooth, which distinguishes this problem from a coordination deficit.
   b. To determine depth perception functionally, the patient can be asked to fill a glass of water.[2] A patient with a depth perception deficit may continue pouring once the glass is filled.
5. *Treatment Suggestions.* The patient should be assisted in becoming aware of the deficit (education to increase cognitive awareness). Emphasis should be placed on the importance of walking carefully on uneven surfaces, particularly the stairs.
   a. *Remedial Approach.* The patient is requested to place the feet on designated spots during gait training.[55] Also, blocks can be arranged in piles 2 to 8 in (5 to 8 cm) high. The patient is asked to touch the top of the piles with the foot. This is done to reestablish a sense of depth and distance.[154]
   b. *Compensatory Approach.* Practice in compensating for disturbances in depth and distance perception occurs intrinsically in many ADL skills, both those involving moving through space and those that involve manipulation. For example, the patient can hold the armrests of a chair to assist with sitting squarely.

Vertical Disorientation

1. *Definition*. **Vertical disorientation** refers to a distorted perception of what is vertical. Displacement of the vertical position can contribute to disturbance of motor performance, both in posture and in gait. Early in recovery, most patients post-CVA demonstrate some impairment in the sense of verticality.[156] This is not associated with or affected by the presence of homonymous hemianopia.[67] Scores on one test for visual perception of the vertical position were found to correlate with differences in walking ability.[67]
2. *Clinical Example.* A person with distorted verticality views the world differently and this may affect upright posture as depicted in Figure 27.12.
3. *Lesion Area.* The lesion site is in the nondominant parietal lobe.
4. *Testing.* The therapist holds a cane vertically and then turns it sideways to a horizontal plane. Researchers use a luminous rod with patients seated in a darkened room.[156] The patient is handed the cane and asked to turn it back to the original position. If the patient's perception of the vertical position is distorted, the cane will most likely be placed at an angle, representing the patient's conception of the world around himself or herself.
5. *Treatment Suggestions.* The patient must be made aware of the deficit. The patient should be instructed to compensate by using touch (tactile cues) for proper self-orientation, especially when going through doorways, in and out of elevators, and on the stairs.

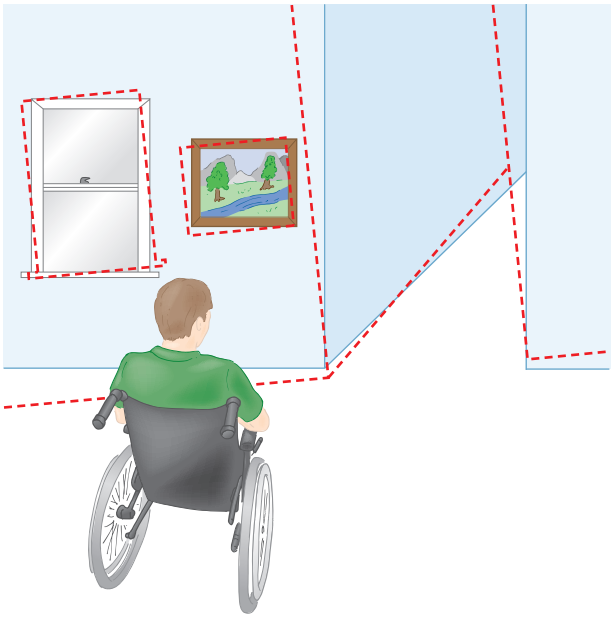

Figure 27.12 Vertical disorientation may contribute to disturbances of posture and gait.

Agnosias (Simple Perception)

Agnosia is the inability to recognize or make sense of incoming information despite intact sensory capacities. Although this condition is relatively rare (as listed by the National Institutes of Health Office of Rare Diseases), it can affect any sensory modality (e.g., vision, audition, touch, taste) and anything (e.g., faces, sounds, colors, familiar or less familiar objects). Although there is an inability to recognize familiar objects using one or two of the sensory modalities, the ability to recognize the same object using other sensory modalities is usually present.[142,157]

Visual Agnosias

1. *Definition.* **Visual object agnosia** is the most common form of agnosia.[4] It is defined as the inability to recognize familiar objects despite normal function of the eyes and optic tracts.[157]
2. *Clinical Examples.* One remarkable aspect of this disorder is the readiness with which the patient can identify an object once it is handled (i.e., information is received from another sensory modality).[158] The patient may not recognize people, possessions, and common objects. Specific types of visual agnosia include **simultanagnosia**, **prosopagnosia**, and color agnosia.
   a. *Simultanagnosia*, also known as Balint's syndrome,[4] is the inability to perceive a visual stimulus as a whole. The patient perceives an entire array one part at a time. The lesion is usually in the dominant occipital lobe.
   b. *Prosopagnosia* was traditionally considered to be the inability to recognize familiar faces. Current thought suggests this phenomenon is related to any visually ambiguous stimulus, the recognition of which depends on evoking a memory context, such as different species of birds or different makes of cars. Prosopagnosia is usually accompanied by visual field impairments. Bilaterally symmetrical occipital lesions are thought to be responsible for this impairment.[15,50,159]
   c. *Color agnosia* is the inability to recognize colors; it is not color blindness. The patient is unable to identify or name colors on command, although color chips can be correctly paired.[50] However, the meaning of color is lost so that the patient no longer associates a duckling as yellow or the sea as blue.[157] Color agnosia is frequently associated with facial or other visual object agnosias.[4,151] It is usually the result of a dominant hemisphere lesion.[4] The simultaneous occurrence of left-sided hemianopia, alexia (inability to read; word blindness), and color agnosia is a classic occipital lobe syndrome.[4]
3. *Lesion Area.* The lesions associated with visual object agnosias are thought to occur in the occipito-temporo-parietal association areas of either hemisphere. These areas are responsible for the integration of visual stimuli with respect to memory.[142] Recent evidence suggests visual object angnosias may result from damage in the medial structures of the ventral occipito-temporal cortex.[160]
4. *Testing.* To test for this deficit, several common objects are placed in front of the patient. The patient is asked to name the objects, to point to an object named by the therapist, or to demonstrate its use. It is important to rule out aphasia and apraxia, although this is not easily done. Details of other nonstandardized and standardized testing procedures are provided in Laver and Unsworth.[157]
5. *Treatment Suggestions.*
   a. *Remedial Approach.* Drills can be used to practice discrimination between faces that are important to the patient (using photographs) and discrimination between colors and common objects. The therapist should assist the patient in picking out salient visual cues for relating names to faces.

      Note: Another tool for treating visual agnosia, as well as many other cognitive and perceptual deficits, is the Easy Street Environment®. These environments have been incorporated into rehabilitation centers in the United States for almost 20 years. The Easy Street Environment® is a modular "world" of life-size streets (with a variety of ambulation surfaces, stairs, curbs, and so forth), vehicles, shops, and offices, which are constructed in a dedicated area within the rehabilitation setting. The Easy Street Environment® has many advantages since it allows occupational therapists, physical therapists, and speech-language pathologists to

work with a patient in a safe, private, and comfortable environment where the patient can try out relearned or new skills. The therapist can also save considerable time by taking the patient down the corridor to the Easy Street Environment® rather than to their own local community, although ultimately such an outing to the local community may be undertaken. Figure 27.13 shows a patient with a visual object agnosia learning to use the Easy Street Environment® Automatic Teller Machine (ATM). This patient may also learn new strategies to identify groceries and therefore be able to practice shopping in the Easy Street Environment® Market Place (Fig. 27.14). Behrmann et al[161] have also presented a case study of a 24-year-old male and reported that the patient improved in identifying novel and common objects through recognition training. Positive results were not found for face identification.

b. *Compensatory Approach.* The patient is instructed to use intact sensory modalities, such as touch or audition, to distinguish people and objects.

Auditory Agnosia

1. *Definition.* **Auditory agnosia** refers to the inability to recognize nonspeech sounds or to discriminate between them. This rarely occurs in the absence of other communication disorders.[4]
2. *Clinical Examples.* The patient with auditory agnosia cannot tell, for example, the difference between the ring of a doorbell and that of a telephone, or between a dog barking and thunder.
3. *Lesion Area.* The lesion is located in the dominant temporal lobe.[4]
4. *Testing.* Testing is usually carried out by a speech-language pathologist. The patient is asked to close the eyes and to identify the source of various sounds. The therapist rings a bell, honks a horn, rings a telephone, and so forth, and asks the patient to identify the sound (verbally or by pointing to a picture).
5. *Treatment Suggestions.* Treatment generally consists of drilling the patient on sounds, but this has not been found to be particularly effective.[1,2]

Figure 27.14 Clients with agnosias and many other cognitive and perceptual deficits can practice daily living skills in the controlled Easy Street Environment® such as provided in the Market Store. *Courtesy of Easy Street Environments,® Scottsdale, AZ 85260.*

Tactile Agnosia or Astereognosis

1. *Definition.* Tactile agnosia, or *astereognosis,* is the inability to recognize forms by handling them, although tactile, proprioceptive, and thermal sensations may be intact. This impairment commonly causes difficulties in ADL skills, inasmuch as many self-care activities that are normally done in the absence of constant visual monitoring require the manipulation of objects. If tactile agnosia is present in combination with unilateral neglect or other sensory loss, performance in ADL skills may be severely hampered.[67]
2. *Clinical Examples.* If a patient is handed a familiar object (key, comb, safety pin) with vision occluded, the patient will fail to recognize it.
3. *Lesion Area.* The lesion is in the parieto-temporo-occipital lobe (posterior association areas) of either hemisphere.[4]
4. *Testing.* The patient is asked to identify objects placed in the hand by examining them manually without visual cues.
5. *Treatment Suggestions.*
   a. *Remedial Approach.* The patient practices feeling various common objects, shapes, and textures with vision occluded. The patient is instructed to

immediately look at the object for visual feedback and note special characteristics of the object.

b. *Compensatory Approach*. To improve cognitive awareness, the patient is educated concerning the nature of the deficit and is instructed in visual compensation.

Apraxia

Apraxia is an impairment of voluntary skilled learned movement. It is characterized by an inability to perform purposeful movements, which cannot be accounted for by inadequate strength, loss of coordination, impaired sensation, attentional difficulties, abnormal tone, movement disorders, intellectual deterioration, poor comprehension, or uncooperativeness.[162-164] Many patients with apraxia also present with aphasia, and the two deficits are sometimes difficult to distinguish.[4] Donkervoot et al[165] report the prevalence of apraxia among patients with first left hemisphere stroke in rehabilitation as around 28%. The two main forms of apraxia discussed in the literature are *ideomotor* and *ideational apraxia*. Ideomotor and ideational apraxias are generally thought to be the result of dominant hemisphere lesions and may be particularly difficult to test in the patient with aphasia. Although aphasia and apraxia often occur together, there is not a strong correlation between the severity of the aphasia and the severity of the apraxia. A third form of apraxia, *buccofacial apraxia,* is actually a type of ideomotor apraxia and is characterized by difficulties with performing the purposeful movements that involve facial muscles related to the mouth. This may include responding to the command "pretend to blow out a candle," or producing an orderly sequence of phonemes to produce speech. Hence, apraxia is a disorder of skilled movement and not a language disorder.[50] Some rehabilitation texts also describe constructional and dressing apraxias. However, it is generally believed that these are not true apraxias, but rather are difficulties in the application of cognitive and perceptual skill to these tasks. In other words, they are terms used to describe specific difficulties with a construction or drawing task or dressing. Both these problems are more frequently associated with right hemisphere lesions.[166]

Ideomotor Apraxia

1. *Definition.* Ideomotor apraxia refers to a breakdown between concept and performance. There is a disconnection between the idea of a movement and its motor execution. It appears that the information cannot be transferred from the areas of the brain that conceptualize to the centers for motor execution. Thus, the patient with ideomotor apraxia is able to carry out habitual tasks automatically and describe how they are done but is unable to imitate gestures or perform on command.[167,168] Patients with this form of apraxia often **perseverate**;[142] that is, they repeat an activity or a segment of a task over and over, even if it is no longer necessary or appropriate. This makes it difficult for them to finish one task and go on to the next. Patients with ideomotor apraxia appear most impaired when requested to perform tasks that require use of many implements and that have many steps. This form of apraxia can be demonstrated separately in the facial areas, upper extremity (UE), lower extremity (LE), and for total body movements.[169] Patients with apraxia are often observed to be clumsy in their actual handling of objects. Impairment is often suspected when observing the patient during ADL or during a routine motor examination.
2. *Clinical Examples.* Several examples of ideomotor apraxia follow. The patient is unable to "blow" on command. However, if presented with a bubble wand, the patient will spontaneously blow bubbles. The patient may fail to walk if requested to in a traditional manner. However, if a cup of coffee is placed on a table at the other end of the room and the patient is told, "Please have coffee," the patient is likely to traverse the room to get it.[145] A male patient is asked to comb his hair. He may be able to identify the comb and even tell you what it is used for; however, he will not actually use the comb appropriately when it is handed to him. Despite this observation in the clinic, his wife reports that he combs his hair spontaneously every morning. A female patient is asked to squeeze a dynamometer. She appears not to know what to do with it, although her comprehension is adequate, the task has just been demonstrated, and it is clear that she has adequate strength.
3. *Lesion Area.* Apraxia results most frequently from lesions in the left, dominant hemisphere. There is evidence that both frontal lesions and posterior parietal lesions can result in apraxia.[170]
4. *Testing.* The *Goodglass and Kaplan*[169] test for apraxia is composed of universally known movements, such as blowing, brushing teeth, hammering, shaving, and so forth. It is based on what the authors consider a hierarchy of difficulty for patients with apraxia. First the patient is asked, "Show me how you would bang a nail with a hammer." If the patient fails to do this or uses his or her fist as if it were a hammer, the patient is told, "Pretend to hold the hammer." If the patient fails following this instruction, the therapist demonstrates the act and asks the patient to imitate it. The patient with apraxia typically will not improve after demonstration but will improve with use of the actual implements.[4] The ability to correct oneself on following verbal cueing is considered not indicative of apraxia. Additional apraxia tests may be found in Butler[166] and the work of van Heugten et al,[171] who have adapted the Arnadottir OT-ADL Neurobehavioural Evaluation (A-ONE)[5] as an observational method of testing for apraxia.

5. *Treatment Suggestions.*

a. *Remedial Approach.* In the remediation of apraxias, it is advised that the therapist speak slowly and use the shortest possible sentences. One command should be given at a time, and the second command should not be given until the first task is completed. When teaching a new task, it should be broken down into its component parts. One component is taught at a time, physically guiding the patient through the task if necessary. It should be completed in precisely the same manner each time.[166] When all the individual units are mastered, an attempt to combine them should be made. A great deal of repetition may be necessary.[67] Family members must be advised to use the exact approach found to be successful in the clinic. Performing activities in as normal an environment as possible is also helpful. Butler[166] provides a case example of a young woman relearning how to drink from a cup using this technique. Using the sensorimotor approach, multiple sensory inputs are used on the affected body parts to enhance the production of appropriate motor responses. The reader is referred to the work of Okoye[172] for additional details on this approach.

b. *Compensatory Approach.* Donkervoot et al[173] report an RCT that showed the effectiveness of an occupational therapy treatment program including "strategy training" over regular occupational therapy. Strategy training involves teaching the patient compensatory techniques to overcome the apraxia such as use of pictures in the correct sequence to support ADL skills. This approach has been developed further and is now widely used to help patients overcome apraxia. Further studies to support this approach have also come from a group of occupational therapists in the Netherlands and include trials by Donkervoort et al[174] and Geusgens and colleagues.[175,176]

Ideational Apraxia

1. *Definition.* Ideational apraxia is a failure in the conceptualization of the task. It is an inability to perform a purposeful motor act, either automatically or on command, because the patient no longer understands the overall concept of the act, cannot retain the idea of the task, or cannot formulate the motor patterns required. Often the patient can perform isolated components of a task but cannot combine them into a complete act. Furthermore, the patient cannot verbally describe the process of performing an activity, describe the function of objects, or use them appropriately.[177,178]
2. *Clinical Examples.* When presented in the clinic with a toothbrush and toothpaste and told to brush the teeth, the patient may put the tube of toothpaste in the mouth, or try to put toothpaste on the toothbrush without removing the cap. Further, the patient may be unable to describe verbally how tooth brushing is done. Similar phenomena may be evident in all aspects of ADL (washing, meal preparation, and so forth) and so may limit the safety and potential independence of the patient.[5] It has been shown that patients with ideational apraxia who test poorly in the clinical situation appear more able to perform ADL skills at the appropriate time and in a familiar setting.[172]
3. *Lesion Area.* The lesion causing ideational apraxia is thought to be in the dominant parietal lobe. This deficit also may be seen in conjunction with diffuse brain damage, such as cerebral arteriosclerosis.[142]
4. *Testing.* The tests for ideational apraxia are similar to those for ideomotor apraxia. The major expected response difference is that the patient with ideomotor apraxia can perform a motor act spontaneously and automatically at the appropriate time, but the patient with ideational apraxia is unable to do so. Refer to Butler[166] for full testing protocols.
5. *Treatment Suggestions.* The treatment techniques are the same as those for ideomotor apraxia.

Buccofacial Apraxia

1. *Definition.* Buccofacial or oral apraxia involves difficulties with performing purposeful movements with the lips, tongue, cheeks, larynx, and pharynx on command. An unusual condition, Pedersen et al[179] report the prevalence rate in patients with acute stroke as around 6%.
2. *Clinical Examples.* A patient may have difficulty responding to the command "pretend to blow out a candle" or "blow a kiss." However, in a normal context where the patient may perform these actions automatically, performance is not impaired. In addition, while patients may be able to produce the individual phonemes required for speech, the patient may have difficulty in producing an orderly sequence of phonemes. Formulaic speech (common, routine phrases) or automatic expressions such as "have a nice day" may be preserved.[180]
3. *Lesion Area.* Difficulties with buccofacial apraxia seem associated with lesions in the frontal and central opercula, anterior insula, and a small area of the first temporal gyrus (adjacent to the frontal and central opercula). Although buccofacial apraxia often coexists with Broca's aphasia, the two may be seen independently.[180]
4. *Testing.* The patient should be examined by a speech-language pathologist.
5. *Treatment Suggestions.* The speech-language pathologist can advise the health care team on strategies to communicate with patients who have buccofacial apraxia.

SUMMARY

Cognition and perception, the processes by which an individual thinks and selects, integrates, and interprets stimuli from the body and surrounding environment, are critical to the normal functioning of each human being. The patient with brain damage may be lacking in those abilities that allow one to make sense of and to respond appropriately to the outside world. It is essential for the therapy team to work together to be able to recognize when a patient is experiencing some type of cognitive or perceptual dysfunction and to have the requisite tools to understand the causes of the behavior. The team can then determine the best interventions and consistently deliver these. Although it is often the occupational therapist, neuropsychologist, and speech-language pathologist who will guide the selection and implementation of evaluations and interventions for patients with cognitive and perceptual problems, it is essential that the physical therapist understands how these cognitive and perceptual impairments affect the patient's performance and the strategies that improve performance.

This chapter provided an overview of cognitive and perceptual deficits that may occur following brain damage, particularly those resulting from a stroke, and how such deficits can affect the functioning of the patient, especially within the context of the rehabilitation setting. The importance of differentiating cognitive and perceptual deficits from problems related to lack of motor ability, inadequate sensation, poor language skills, and simple uncooperativeness has been emphasized. Although alluded to in a very abbreviated fashion, activity analysis and systematic data collection remain two of the most powerful tools at the disposal of the therapist attempting to develop a firm rationale for, and to empirically justify the efficacy of, any treatment selected. Treatment in the form of adaptation of the physical environment and instructional sets and the teaching of compensatory techniques has been singled out as one of the most effective avenues for intervention.

Questions for Review

1. Patients with cognitive and perceptual deficits display what general characteristics during execution of a task?
2. Identify the underlying premise of the *transfer-of-training approach* to treatment.
3. What is the underlying assumption of the *sensory integrative approach* to treatment? Provide examples of the treatment modalities employed with this approach.
4. How is the performance of specific functional skills enhanced using the *functional approach* to treatment? What are the inherent benefits of using the functional approach?
5. Describe general suggestions for optimizing teaching/learning strategies when using compensatory techniques.
6. Identify the four treatment strategies included in the *cognitive approach* to treatment.
7. What potential influencing factors must be considered when examining a patient with cognitive and perceptual deficits?
8. What examination procedures will assist the therapist in distinguishing between sensory and cognitive or perceptual problems?
9. Differentiate between feedback provided in the form of knowledge of results (KR) versus knowledge of performance (KP).
10. Identify and define the four different types of attention.
11. What is the purpose of memory retraining? Compare and contrast the focus of the *remedial approach* and the *compensatory approach* to memory retraining.
12. Define the following terms: *unilateral neglect*, *anosognosia*, *somatoagnosia*, *finger agnosia*, and *right–left discrimination*.
13. Identify five spatial relations deficits. What general clinical manifestation do these disorders have in common? Define each of the deficits identified and provide an example of how each would influence patient performance of a task.
14. Provide examples of the functional implications of a visual *figure–ground discrimination deficit*. What is the most common lesion site producing this disorder?
15. What is the characteristic feature of apraxia? Define the three types of apraxias and provide examples of task performance characteristics associated with each type of apraxia.

CASE STUDY

The patient is a 72-year-old woman who has just been admitted to a rehabilitation facility following a stroke. The patient experienced a right parietal hemorrhagic stroke. A CT scan revealed a 1.5 in (4 cm) hemorrhage that was subsequently drained. She will be able to stay in the rehabilitation facility for 20 days. Although the patient has some physical problems, the emphasis of this case study is on cognitive and perceptual tests and interventions. The occupational therapist and the physical therapist are collaboratively using a combination of cognitive retraining and the functional approach in therapy.

PAST MEDICAL HISTORY

The patient's past medical history includes insulin-dependent diabetes and mild rheumatoid arthritis in her right shoulder and both hands causing some morning pain and stiffness.

SOCIAL

The patient lives alone in her own home. Supportive friends and family, her two children, and their families live nearby. A local health maintenance organization (HMO) provides her insurance. She is retired from the police force and enjoys gardening, reading, and watching television. She previously drove an automobile with an automatic transmission.

PHYSICAL THERAPY EXAMINATION

When the patient was approached from the left, she seemed to ignore the physical therapist and did not respond to greetings. However, when the therapist sat in the chair on the patient's right side, she seemed to have no problems talking to the therapist.

Range of Motion, Muscle Tone, and Balance

Examination revealed functional ROM, reduced strength in the left upper extremity (UE) with strength generally within the Fair (3/5) range; difficulty manipulating small objects with left hand; and some reduced dynamic standing balance reactions.

Sensation

The physical therapist tested sensation and noted normal sensation in all areas (sharp/dull, light touch, temperature, proprioceptive sensations, cortical sensations) on the right side. However, the patient seemed to have difficulties on the left side and her performance in detecting stimuli seemed inconsistent. Because the physical therapist suspected cognitive and perceptual deficits, a complete sensory test was deferred until the occupational therapist could fully examine the patient.

Functional Status

The physical therapist examined the patient's transfer abilities and instructed her in a safer way to get in and out of bed. The therapist scored the patient on the *Functional Independence Measure (FIM)*[88] and found the following:

Self-Care:

- Eating: FIM level = 4
- Grooming: FIM level = 5
- Bathing: FIM level = 3
- Dressing—upper body: FIM level = 5
- Dressing—lower body: FIM level = 4
- Toileting: FIM level = 6

Transfers:

- Bed, chair, wheelchair: FIM level = 5
- Toilet: FIM level = 5
- Tub: FIM level = 4

Locomotion:

- Walk: FIM level = 5

The physical therapist asked about her family and she was able to provide many details. However, she seemed puzzled about where she was and expressed concern that she was not looking her best and needed to do her hair. The therapist suggested that she might like to brush her hair. The brush was on the table on the patient's left side, and she said she did not have one. The physical therapist cued her to check her bedside table, but on checking she maintained she did not have a brush. At the end of the session (which lasted about 40 minutes) the therapist asked her to demonstrate the bed transfer technique again that she had been taught at the beginning of the session. She seemed confused and could not do what the physical therapist had taught her.

OCCUPATIONAL THERAPY EXAMINATION: COGNITION AND PERCEPTION

The occupational therapist conducted two standardized tests: the *Rivermead Behavioural Memory Test (RBMT)*[81] because the patient demonstrates memory impairments, and the *Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE)*[5] to examine the impact of the patient's problems on her daily living activities. The occupational therapist also reasoned that further tests of the patient's IADL, including home and driving abilities, would need to be conducted closer to her discharge. The patient's FIM scores for the Social Cognition Items were as follows:

Social Cognition FIM

- Social interaction: FIM level = 6
- Problem solving: FIM level = 6
- Memory: FIM level = 3

GUIDING QUESTIONS

1. What are some of the functional difficulties the patient is having and what cognitive and perceptual deficits might be causing these? Note that there may be more than one deficit affecting the functional problems noted.
2. Develop a clinical asset and problem list.
3. Identify anticipated goals and expected outcomes appropriate for this patient.
4. Identify two treatment strategies to improve spontaneous use of left upper extremity and decrease unilateral neglect.
5. Identify two treatment strategies to improve the patient's memory.
6. How can the success of the patient's rehabilitation program be measured?

Chapter 28

Neurogenic Disorders of Speech and Language

Martha Taylor Sarno, MA, MD (hon) CCC-SLP, BC-ANCDS
Jessica Galgano, PhD, CCC-SLP

LEARNING OBJECTIVES

1. Differentiate the organization of language with respect to the role of phonological, lexical, syntactic, and semantic systems.
2. Understand the role of the motor speech system in the speech production process.
3. Discuss and characterize the classic aphasic syndromes.
4. Identify and explain the critical factors in the evaluation of recovery and rehabilitation of aphasia.
5. Identify and describe general approaches to aphasia rehabilitation and some specific treatment methods.
6. Identify etiologies of cognitive-communication disorders.
7. Compare and contrast deficits in executive function, pragmatic language, and motor speech in persons with cognitive-communication disorders.
8. Describe the primary types of dysarthria and rationales for dysarthria treatment.
9. Describe apraxia of speech and its treatment.
10. Gain an understanding of swallowing disorders.
11. Describe the goals and rationales for the use of augmentative communication systems.

CHAPTER OUTLINE

THE ORGANIZATION OF LANGUAGE *1268*

- Treatment of Dysphagia *1283*

SUMMARY *1285*

Most people take the ability to produce and understand speech for granted and pay little attention to the nature and function of the processes involved in communication. Yet speech, like tool making, sets us apart from animals and is one of our most human behaviors. Even in primitive societies, humans have used the oral–motor speech code to share experiences, ideas, and feelings. Not all communities have developed writing and reading systems.

The use of speech for communication contributes to our identity as human beings and to the perception of "self." As a result, disruptions in the ability to communicate, whether caused by structural abnormalities (e.g., cleft palate), neurological conditions (e.g., stroke, Parkinson's disease), or nonorganic conditions (e.g., nonorganic articulatory disorders) may affect a person's daily life in important ways. For some, the acquisition of a communication disorder may have sufficient impact to cause an individual to withdraw from the workforce. For those whose communication disorders have persisted since childhood, the disorder may represent a significant vocational handicap. In other cases, a disorder that does

not impede an individual's vocational life nonetheless interferes with everyday socialization. Communication disorders are complex, multifaceted behavioral impairments often associated so closely with a person's self-image as to threaten the quality of his or her life.

The term **communication** encompasses all of the behaviors, including speech, that human beings use to perceive and transmit information and interact with others. Speech comprises a delicate and rapid sequence of sensory and motor events requiring the coordinated activity of several parts of the body. The use of speech for communication involves many levels of human activity, ranging from the fine motor coordination of components of the oral–motor system to the subtle shades of meaning that occur at the cognitive/semantic level. Gestures, pantomime, and other nonverbal *pragmatic language* behaviors, such as turn taking, are also essential elements of communication.

Among unimpaired speakers, speech behavior varies greatly, yet the oral–motor system is efficient for the exchange of even complicated information. The range of variability is so wide that individuals generally produce different sound waves with different characteristics even when producing the same word. But listeners do not rely solely on information derived from speech waves. We also depend on cues, which are components of what is referred to as *context.* Context includes aspects of a communicative exchange such as the purpose of the activity, the location of the exchange, the knowledge of the participants, the roles of each participant, and the level of formality required by the situation.

This chapter addresses the neurogenic disorders of communication, a category of communication disorders represented by the majority of patients receiving speech-language pathology services in rehabilitation programs. The most common of these disorders are **aphasia**, a language (cerebral) disorder, **dysarthria**, a motor–speech disorder, and cognitive-communication disorders.

The field of speech-language pathology, which came into being in 1925 with the establishment of the American Speech-Language-Hearing Association (ASHA), is dedicated to the diagnosis and treatment of individuals with congenital or acquired communication disorders. Communication disorders in children and adults are estimated to have prevalence in the United States of 5% to 10% and a cost to the economy of $154 billion to $186 billion per year. The number of persons in the United States with communication disorders is estimated at 14 million.[1,2] These statistics have increased by the addition of a large number of military personnel returning from active duty who may manifest a host of communication disorders, including hearing loss, speech-language disorders, and/or cognitive-communication disorders. A significant number of returning military personnel have cognitive-communication disorders secondary to traumatic brain injury (TBI), which include deficits in discourse, pragmatic language, and social communication.[3-6]

The National Institute on Deafness and Other Communication Disorders (NIDCD) reports that 6 to 8 million people in the United States have an acquired or developmental language disorder. It is estimated that about 100,000 persons acquire aphasia annually, and approximately 1 million people currently have aphasia.[7] In addition, approximately 7.5 million people in the United States have voice disorders. The prevalence of articulation or speech sound disorders in children up to 6 or 7 years of age is estimated at 8% to 9%. By age 6 or 7, about 5% of children continue to present with speech disorders. It is also estimated that over 3 million Americans stutter.[2]

Approximately 28 million Americans have a hearing loss. Fifty-five percent of those with hearing impairments are older than 65 years of age, and 12 out of every 1,000 children younger than 18 have a hearing impairment.[8,9] New technology has succeeded in providing the development of cochlear implants (CIs) for persons with profound hearing loss, which have been implanted in children as young as 6 months of age. CIs stimulate the surviving dendrites, spiral ganglion cells, and vestibulocochlear-nerve fibers in the inner ear, making auditory sensations available. Immediate benefits are reported following CI activation, including improvement in speaking, which generally increases over time.[10]

The speech-language pathologist (SLP) profession has grown rapidly. Affiliates (members and certificate holders) in the ASHA increased from 1,623 to 140,000 between 1950 and 2010. Speech-language pathology is a master's degree entry field. As of 2009, 47 states required a license to practice. The ASHA awards the Certificate of Clinical Competence (CCC) to SLPs who meet specified academic and clinical experience requirements, which includes a Clinical Fellowship Year (CFY), a 9-month period of supervision and mentoring by a speech and language pathologist holding ASHA certification. Fifty-seven percent of SLPs work in educational organizations, 37% in residential health care facilities, and approximately 15% in home health, private practice, and speech and hearing centers.[11] The term *SLP* is the official designation of professionals in the field who hold the CCC. The term *speech therapist,* although no longer considered professionally appropriate, is a term that is often used informally.

In order for the presence and degree of speech or language pathology as it is manifest in a given person to be identified and measured, performance must be compared with a standard of "normal." One may choose as the standard (1) the language common to the cultural community of unimpaired persons in which the person lives, in which case an individual's verbal function would be compared with that of others in the same community of similar age, gender, education, and achievement, or (2) the person's verbal behavior before the onset of illness or trauma. The latter will vary from individual to individual and is based on premorbid educational

achievement, specific cultural characteristics, personality, and other factors such as cognitive functioning. A person is verbally impaired when he or she deviates in any parameter of language and/or speech processing from the "normal" communication behavior of the community in which he or she functioned premorbidly.

A "normal" standard is implied in the terms *impairment, disability,* and *handicap*. This chapter uses the current World Health Organization (WHO) classification schema, in which the term *disability* is defined as the nature and extent of functioning, and the term *handicap* is defined as a person's involvement in life situations.[12,13]

THE ORGANIZATION OF LANGUAGE

When an individual generates an idea that he or she wishes to express, it is transformed into words and sentences by calling into play certain physiological and acoustic events. The message is converted into linguistic form. The listener, in turn, fits the auditory information into a sequence of words and sentences that are ultimately understood.

We refer to the system of symbols that are strung together into sentences expressing our thoughts and the understanding of those messages as *language.* In the first few years of life, infants and children gain a great deal of practice and experience in the use of language, until it becomes habitual and is used with different levels of conscious awareness.

Phonology refers to the study of the sound system of language. Words are made up of speech sounds or *phonemes,* which are generally classified as either *vowels* or *consonants.* Phonemes in and of themselves do not symbolize ideas or objects, but when put together they are the basic linguistic units that make words. Words comprise the *lexicon,* or vocabulary, of a language. English is comprised of 16 vowels and 22 consonants, which are combined into larger units called *syllables.*

A syllable usually consists of a vowel as a central phoneme surrounded by one or more consonants. There are between 1,000 and 2,000 syllables in English. Most languages have their own rules about how phonemes may be combined into larger units. For example, in English, syllables never start with the *ng* phoneme. The most frequently used words in English are sequences of from two to five phonemes. Some have as many as 10 phonemes or as few as one. In general, the most frequently used words have few phonemes. Even though only a small number of phoneme combinations are possible, new words are added to the English language every day. Although there are several hundred thousand English words, we use a repertoire of only about 5,000 to 10,000 words 95% of the time.

The grammar, or *syntax,* of a language determines the sequence of words that are acceptable in the formation of sentences. In English, for example, it is possible to say "The black box is on the table," but the sequence "Box black table on the" is unacceptable. Another example is "The old radio played well," which is syntactically correct, but "Old the well played radio" is not. The sentence "The boy walked to the store" is meaningful, but the sentence "The book walked to the store" is not. The language system that refers to the meanings of words is called *semantics.*

In addition to the phonological (sounds), lexical (vocabulary), syntactical (grammar), and semantic (meaning) language systems, we also utilize *prosody* (stress and intonation) to help make distinctions between questions, statements, expressions of emotional feelings, shock, exclamations, and so forth.

SPEECH PRODUCTION

The speech organs consist of the lungs, trachea, larynx (which contains the vocal cords), pharynx, nose, and mouth. When considered together, these organs comprise a "tube" referred to as the *vocal tract,* which extends from the lungs to the lips. Moving the tongue, lips, and any other parts of the tract varies vocal tract shape. Changes in the configuration of the vocal tract act to modify the aerodynamic qualities of the air stream during speech (Fig. 28.1).

The primary function of the vocal organs relates to basic life-sustaining functions such as breathing and swallowing. These organs not only take on different roles

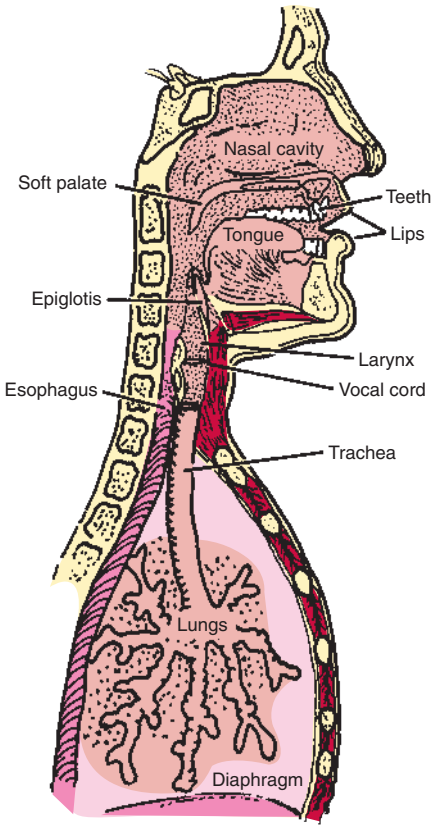

Figure 28.1 The human vocal organ.

for speech, but also function differently when engaged in speech production. For example, breathing for life-sustaining purposes is far more rapid than for speech production. A full cycle of inhalation/exhalation takes approximately 5 seconds, whereas while speaking we control the breathing rate according to the demands of the words and sentences we are producing, sometimes reducing the rate of breathing to as little as 15% devoted to inhalation. This is dictated in part by the fact that, when speaking, we generally take in enough air to vocalize a complete thought and we exhale the air gradually during the production of the thought.

The steady stream of air exhaled from the lungs is the source of energy for speech production, which is made audible by the rapid vibration of the vocal cords. During speech, we continuously alter the shape of the vocal tract by moving the tongue, lips, and other parts of the system. By moving parts of the vocal tract, thereby modifying its acoustic properties, we are able to produce different sounds. That is, by altering the shape of the vocal tract during *phonation,* we transform the air stream into a resonance chamber (Figs. 28.2 and 28.3).

The *larynx* acts as a barrier to prevent food from entering the trachea and lungs by closing automatically during the act of swallowing, which is also helped by the action of the epiglottis. By opening and closing the flow of air from the lungs, the larynx acts as a valve between the lungs and the mouth. The laryngeal valve also acts to lock air into the lungs, which we do automatically when we perform heavy work using our upper extremities. The larynx is not a fixed, rigid organ, but because of its cartilaginous construction and corresponding connecting muscles and ligaments moves up and down during both swallowing and speaking.

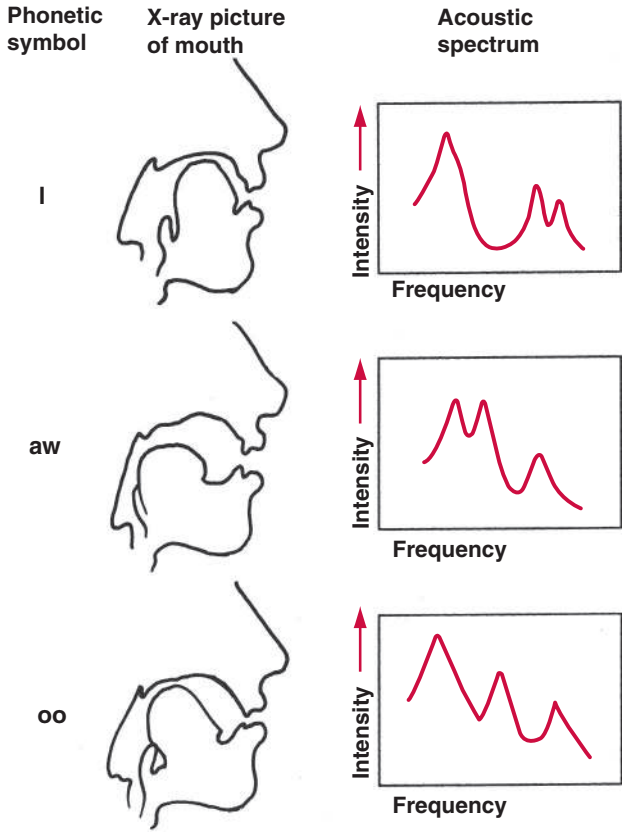

Figure 28.3 Vocal tract configuration and corresponding spectra for three different vowels. The peaks of the spectra represent vocal tract resonances. The vertical lines for individual harmonics are not shown.

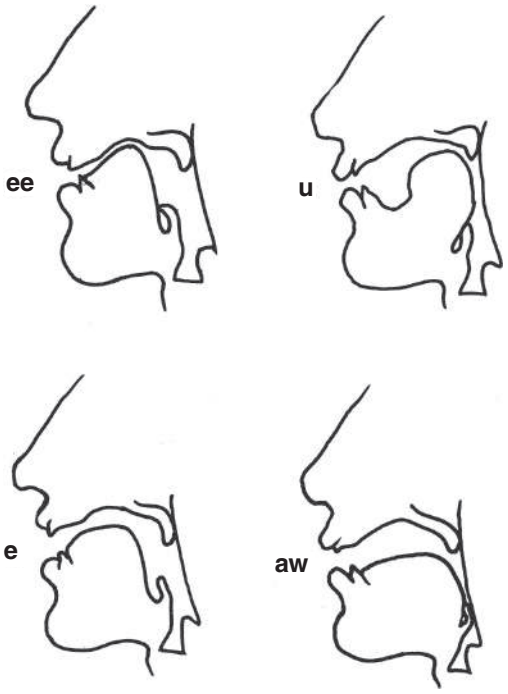

Figure 28.2 Outlines of the vocal tract during articulation of various vowels.

The *vocal cords,* which create the sounds of speech, are located on either side of the larynx from the Adam's apple at the front to the arytenoid cartilages at the back. Recent neuroimaging research has reported findings that reflect the complexity of motor planning and control of vocal cord movement for voice production, showing that subcortical and cortical interactions control the movement of the vocal cords.[14] We refer to the space between the vocal cords as the *glottis.* When the cords are pressed together, the passage of air is sealed off and the valve is shut. Because the cords are held together at the front where they articulate with the Adam's apple, the open glottis is V-shaped, opening only at the back. When we speak, we vibrate the vocal cords in a rhythmic fashion, opening and closing the air passage from the lungs to the oral/nasal cavities.

The frequency of sound produced by the vocal cords is directly related to their mass, tension, and length. The tension and length of the vocal cords is continuously altered while speaking. In normal speech, the range of vocal cord frequencies is from about 60 to 350 cycles

per second (cps). Most people use a vocal cord frequency range that covers about one and a half octaves.

The *pharynx* is the area of the vocal tract connecting the larynx with the nose and mouth. We isolate the nasal cavity from the pharynx and back of the mouth by raising the soft palate. The most adjustable component of the vocal tract is the mouth, whose shape and size can be modified more than any other organ of the oral–motor system by changing the relative position of the palate, tongue, lips, and teeth. The lips are rounded, spread, or closed to alter the shape and length of the vocal tract or to stop airflow. The teeth and their relationship to the lips or tongue tip change the airflow. An important component of the teeth ridge is the *alveolus*, which is the area covered by the gums.

The term *articulation* refers to the articulating, or "meeting," of the various organs of the oral-pharyngeal cavity to produce the sounds of speech. Speech *intelligibility* refers to the adequacy of the acoustic signal produced by a speaker and represents a significant factor in understanding a speaker. A number of factors can influence judgments of intelligibility, such as the presence or absence of visual cues or of extraneous movements (i.e., tremor). The precision of the production of consonant sounds is one of the primary factors that contribute to speech intelligibility. Consonants are described by specifying their place and manner of articulation and whether they are voiced or unvoiced (Table 28.1). The "places" of articulation are the lips (labial), teeth, gums (alveolar), palate, and glottis. The *manner of articulation* refers to the plosive, fricative, nasal, liquid, and semivowel categories.

Plosive sounds, sometimes referred to as "stop" sounds, are those produced by building up air pressure in the oral cavity and suddenly releasing it (e.g., *p, t*). The blockage can occur by pressing the lips together or by pressing the tongue against either the gums or soft palate. There are plosive consonants that are labial, alveolar, or velar (consonants articulated with the back part of the tongue).

Fricatives are produced by making the air turbulent (e.g., *f, v*). Most consonants are produced with the soft palate raised, thereby closing off the flow of air to the nasal cavity, except for the *nasals* (e.g., *m, n, ng*), which are made by lowering the soft palate and blocking the oral cavity somewhere along its length. *Liquids* are sounds made with the soft palate raised: /r/, /l/.

Semivowels refer to those sounds produced by maintaining the vocal tract in a vowel-like position, then changing the position rapidly for the vowel that follows (e.g., *w, y*).

Speech sounds are affected by their *context,* that is, the sounds that immediately precede or follow. A speech sound wave is a continuous event rather than a sequence of discrete segments. The identification of a speech sound depends on relating acoustic features of the sound wave at different points in time.

A standard reference for the quality of vowels is the eight cardinal vowels (Fig. 28.4). This schema of the positions of the tongue for the production of the vowels of the language helps us visualize the tongue's movements during speech. It is, in a sense, a map of the tongue positions for vowel production. Tongue placement is described by specifying the location of the main body of the tongue at its highest point. For example, for the sound /ee/ as in the word *beat,* the tongue tip is pointed in a high frontal configuration, whereas for the sound /ah/ as in the word *father,* the highest point of the tongue is low and posterior in the oral cavity.

All vowel sounds and some consonant sounds are *voiced.* That is, the vocal cords vibrate during their production. When a sound is produced without vocal cord vibration, we say that it is *unvoiced* or voiceless (e.g., *p, s*). Table 28.1 shows that many consonant sounds are articulated in the same manner, and differ only with respect to voicing (e.g., *p-b; s-z; f-v; k-g*).

Speech behavior comprises a complex motor event that goes well beyond the skilled movements required of the oral–motor system. Yet we produce speech without thinking about it even while simultaneously involved in

Table 28.1 Classification of English Consonants by Place and Manner of Articulation

	Manner of Articulation				
Place of Articulation	Plosive	Fricative	Semivowel	Liquids (including laterals)	Nasal
Labial	p b	—	w	—	m
Labiodental	—	f v	—	—	—
Dental	—	_ th	—	—	—
Alveolar	t d	s z	y	l r	n
Palatal	—	sh zh	—	—	—
Velar	k g	—	—	—	ng
Glottal	—	h	—	—	—

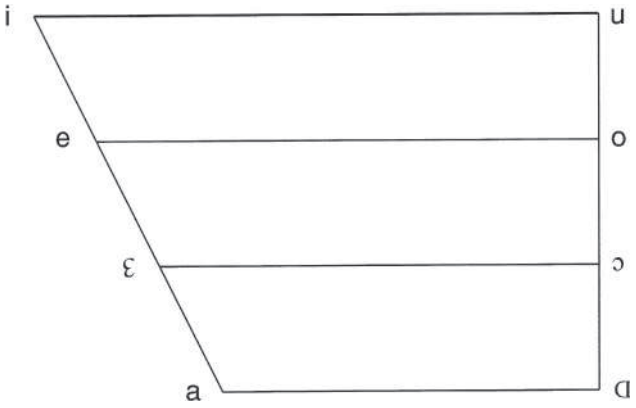

Figure 28.4 The cardinal vowels represented as a vowel quadrilateral. The cardinal vowels are extremely placed reference points for vowel articulation. Vowels on the same horizontal line are believed to have an equally high tongue height while vowels in the left–right position are assumed to be equally backed and fronted. *Adapted from Ladefoged, P: A Course in Phonetics. Harcourt Brace Jovanovich, New York, 1975, with permission.*

other activities. However, to transform thought into speech takes some voluntary, conscious behavior that allows us to take information stored in memory and translate it into a coherent production of words and utterances that follow certain grammatical rules.

In addition to its linguistic aspects, neurogenic communication disorders often involve coexisting mild to severe cognitive deficits that may not only aggravate the communication disorder but also make it difficult to differentiate cognitive from communication deficits. The communication disorder manifest in persons with right brain damage, which is addressed in this chapter, is an example of a disorder in which the cognitive component is a major issue.

The importance of the communication process and its underlying systems becomes apparent when we consider the two most common neurogenic communication disorders: *aphasia* and *dysarthria*. This chapter focuses primarily on aphasia and dysarthria but also considers verbal apraxia, dysphagia, cognitive-communication disorders, and the use of augmentative/alternate systems of communication.

APHASIA

An increase in the population of individuals with aphasia is anticipated by the projection that by 2050, 21% to 22% of the U.S. population will be over age 65.[15] It has been estimated that there are over 1 million individuals with aphasia in the United States alone.[2,16,17] In a survey of 850 patients in the first month post-stroke, aphasia was present in 177 patients.[18] It is further estimated that there are more than 100,000 new patients with aphasia each year.[11,19] The majority are currently older than 65 years of age and acquired aphasia as a result of a stroke. A smaller number are the result of head trauma and neoplasms. Aphasia is also often present in the early stages of Alzheimer's disease.[20] Ellis et al[19] report that the incidence of aphasia and its demographic characteristics has been generally consistent in the United States from 1997 to 2006.

Classification and Nomenclature

In this chapter, the term **aphasia** refers to the acquired communication disorder that is manifest in individuals who were previously capable of using language appropriately. It does not refer to developmental language disorders that may be present in individuals who never developed normal language and for whom the ability to use language may never reach age-appropriate performance levels.

In acquired aphasia, central nervous system (CNS) disease or trauma compromises certain structures in a focal rather than generalized fashion. The study of the neuroanatomical correlates of the aphasias has engaged neurologists since the late 19th century, and the correlation between aphasic syndromes and cerebral localization is relatively consistent. Recent advances in neuroradiological technology have provided many new methods for studying the neural substrates of language and language impairment.[21,22]

Aphasiologists generally agree that there are distinct major aphasic syndromes that adhere to specific profiles of impairment. This is not surprising, because the lesions that produce aphasia, particularly in the patient with cerebrovascular disease, tend to be located in brain loci that are especially vulnerable. It is not always possible, however, to classify patients according to these syndromes. Estimates of the proportion of cases that can be unambiguously classified range from 30% to 80%.[23]

The characteristics of an individual's speech production are used to determine aphasia classification. Speech output that is characterized as hesitant, awkward, interrupted, and produced with effort is referred to as *nonfluent aphasia* in contrast to speech output that is facile in articulation, produced at a normal rate, with preserved flow and melody, and is referred to as *fluent aphasia.* Fluency judgments are made during extended conversation with a patient and are defined as follows.

Fluent Aphasia

Fluent aphasia is characterized by impaired auditory comprehension and fluent speech that is of normal rate and melody. Fluent aphasia is usually associated with a lesion in the vicinity of the posterior portion of the first temporal gyrus of the left hemisphere. When fluent aphasia is severe, word and sound substitutions may be of such magnitude and frequency that speech may be rendered meaningless. Patients with fluent aphasia tend to have greatest difficulty in retrieving those words that are substantive (nouns and verbs). Since their lesions are located in the posterior portion of the brain, distant

from motor areas, they also tend to have some degree of impaired awareness and are rarely physically disabled. There are several types of syndromes subsumed under the fluent aphasia classification (Table 28.2).

The most common type of fluent aphasia is *Wernicke's aphasia* (also referred to as *sensory aphasia* and/or *receptive aphasia*). Wernicke's aphasia is usually the result of a lesion in the posterior portion of the first temporal gyrus of the left hemisphere. It is characterized by impaired auditory comprehension and fluently articulated speech marked by word substitutions. Reading and writing are usually severely impaired as well. Although patients with Wernicke's aphasia may produce what seem like complete utterances and use complex verb tenses, they often add a word or phrase and "augment" speech production. Speech is often produced at a rate greater than normal. Although the production of speech sounds is generally precise, patients with Wernicke's aphasia may reverse phonemes and/or syllables (hopspipal/trevilision) and may produce *neologisms* (nonsense words).

In the course of recovery Wernicke's aphasia may evolve into anomic aphasia. *Anomic aphasia* is characterized by a significant word-finding difficulty in the context of fluent, grammatically well-formed speech. Auditory comprehension is generally impaired, especially when listening to complex and/or rapid speech. Speech output may be somewhat vague and the patient may be proficient in producing *circumlocutions* to skirt the lack of specificity of language use.

Nonfluent Aphasia

Nonfluent aphasia is characterized by limited vocabulary, slow, hesitant speech, some awkward articulation, and restricted use of grammar in the presence of relatively preserved auditory comprehension. Nonfluent aphasia is associated with anterior lesions usually involving the third frontal convolution of the left hemisphere. Patients with nonfluent aphasia tend to express themselves in vocabulary that is substantive (nouns, verbs) and lack the ability to retrieve less substantive parts of speech (prepositions, conjunctions, pronouns). Patients with nonfluent aphasia tend to have good awareness of their deficit and usually have impaired motor function on the right side (right hemiplegia–paresis).

Broca's aphasia is a nonfluent type of aphasia also sometimes referred to as *expressive aphasia*, *motor aphasia*, and/or *verbal aphasia*. Broca's aphasia is the result of a lesion involving the third frontal convolution of the left hemisphere, the subcortical white matter, and extending posteriorly to the inferior portion of the motor strip (precentral gyrus). It is characterized by awkward articulation, restricted vocabulary, and restriction to simple grammatical forms in the presence of a relative preservation of auditory comprehension. Writing skills generally mirror the pattern of speech and reading may be less impaired than speech and writing. The patient may be limited to one- and two-word productions for expression and find it impossible to combine words into sentences. Articulation may be awkward and effortful (see later section titled Apraxia of Speech). Nonfluent Broca's aphasia is less common after TBI. Anomic disturbances predominate in aphasia secondary to TBI.

Global Aphasia

A severe aphasia with marked dysfunction across all language modalities and with severely limited residual use of all communication modes for oral–aural interactions is referred to as *global aphasia.* Global aphasia is not a type of aphasia but rather a designation of severity. The patient with global aphasia generally has extensive damage, which may be anywhere in the left hemisphere, and is sometimes bilateral.[24] Global aphasia has been cited as among the most common types of aphasia in patients referred for speech rehabilitation services.[25,26]

Acquired Aphasia

Acquired aphasia in children as a result of cerebral damage caused by head injury, tumor, or stroke results in the same syndromes manifest in adults with aphasia.[27-30] In children with aphasia secondary to TBI, anomic disturbances predominate and there is generally a reduction of output with hesitancy, difficulty initiating speech, and sometimes mutism.[31] Follow-up studies report that a significant number of children with acquired aphasia are slow to develop language and academic skills. Since cerebral plasticity decreases across the developmental spectrum, the age of aphasia onset is a factor in determining the extent of recovery.[30]

Primary Progressive Aphasia

Primary progressive aphasia (PPA), a condition that was first described in 1982, is now a recognized diagnostic category.[32,33] PPA is a slowly progressive isolated aphasia not due to stroke, trauma, tumor, or infection, which does not fit neatly into existing aphasia classification schemes. It can exist in the absence or relative absence of generalized intellectual and behavioral disturbances or cognitive impairment generally associated with dementia. Activities of daily living, judgment, insight, and behavior are usually preserved for at least 2 years and may remain unimpaired and isolated from the language impairment for as long as 20 years.[34] About half of those with PPA eventually develop symptoms of a more pervasive dementia. Spontaneous recovery does not occur.

In its initial presentation, PPA is commonly reported and observed as being a speech or articulation disorder or difficulty in naming. PPA progresses at different rates and in its most severe form can result in the inability to speak. In these cases comprehension usually remains relatively preserved. However, in other cases initial difficulties with and a progressive decline in word retrieval skills and comprehension with relatively preserved speech production abilities is noted.[35] The longer the

Table 28.2 Classification by Aphasia Syndromes

	Wernicke's Aphasia	Broca's Aphasia	Global Aphasia	Conduction Aphasia	Anomic Aphasia	Transcortical Motor Aphasia	Pure Word Deafness
Area of infarction	Posterior portion of temporal gyrus	Third frontal convolution	Third frontal convolution and posterior portion of superior temporal gyrus	Parietal operculum or posterior superior temporal gyrus	Angular gyrus	Supplementary motor areas	Both Heschl's gyri or connection between Heschl's gyrus and posterior superior temporal gyrus
Spontaneous speech	Fluent	Nonfluent	Nonfluent	Fluent or nonfluent	Fluent	Nonfluent	Fluent
Comprehension	Poor	Good	Poor	Good	Good	Good	Poor
Repetition	Poor	Poor (but may be better than spontaneous speech)	Poor	Very poor	Good	Excellent	Poor
Naming	Poor	Poor (but may be better than spontaneous speech)	Poor	Poor	Very poor	Poor	Good
Reading comprehension	Poor	Good	Poor	Good to poor	Good to poor	Good	Good
Writing	Poor	Poor	Poor	Poor	Good to poor	Poor	Good

duration of aphasia as an isolated symptom, the less likely that other signs of dementia will develop.

Historical Perspective

Language disturbances were recorded as early as 3500 BC, and attempts to "retrain" individuals with aphasia have been recorded throughout history.[36] Some of the first documented cases of both natural recovery and intervention were the patients of Nicolo Massa and Francisco Arceo in 1558.[37]

In a landmark paper in the late 19th century, "Du siège de la faculté du langage articulé," Paul Broca was one of the first to discuss the possibility of retraining in aphasia.[38] Dr. Charles K. Mills was the first to address recovery and rehabilitation in aphasia in an English-language publication. He reported the training of a patient with post-stroke aphasia whom he and Donald Broadbent treated, using methods largely determined by the patient, who began by systematically repeating letters, words, and phrases.[39,40] Mills' observations and approach to aphasia rehabilitation, published over a century ago, are remarkably similar to much present-day practice and thought. Mills noted that not all patients benefit from retraining to the same degree and acknowledged that spontaneous recovery might have an influence on the course and extent of recovery.

World War I and its brain-injured combat survivors led to the establishment of treatment centers where patients with post-traumatic aphasia were treated, especially in Europe. Reports of aphasia rehabilitation experiences during and after the war in England and the United States were also published.[41,42] One of the most comprehensive descriptions of the systematic treatment of a large number of patients with aphasia secondary to head trauma, of whom 90 to 100 were followed for a 10-year period, was

provided by Kurt Goldstein in Frankfurt during the Second World War.[43]

Until World War II, reports of retraining civilians with post-stroke aphasia were rare. The aphasia literature was based almost exclusively on post-traumatic aphasia. In 1933, Singer and Low[44] reported the case of a 39-year-old woman who suffered an apparent vascular infarct after a full-term delivery and showed continuous language improvement with consistent training over a 10-year period.

In a landmark 5-year study supported by the Commonwealth Fund, Weisenburg and McBride[45] addressed the general topic of aphasia and commented on the effectiveness of reeducation. The study concerned 60 patients who were younger than 60 years of age, a majority of whom had suffered strokes, and concluded that reeducation increased the rate of recovery, assisted in facilitating the use of compensatory means of communication, and improved morale. Their work also documented the psychotherapeutic benefits of treatment.

Before World War II, aphasia and its concomitant neurological deficits in the patient with stroke were generally viewed as natural and necessary components of the aging process. The treatment of aphasia in the civilian population was not an option.

Many variables had an influence on making the treatment of aphasia the common practice that it is today. The advent of speech and language pathology as a health profession, the emergence of rehabilitation medicine as a medical specialty, the mass media explosion, a larger and more affluent middle class, an increase in the life span, the number of stroke and brain injury survivors, and public expectations of medicine in the age of technology are among them. The last has been particularly true in the industrialized world, where it is widely believed that there is a treatment for every human ill.[46]

Journals devoted to brain/language issues have become indispensable information sources for aphasiologists (e.g., *Journal of Medical Speech and Language Pathology*, *Aphasiology, Brain and Language,* and *Cortex*). The Academy of Aphasia, a scholarly society dedicated to the study of aphasia, was established in 1962. The National Aphasia Association (NAA) was founded in the United States in 1987 for the purpose of providing information to the public about aphasia, advocating for the aphasia community, and encouraging the establishment of a network of support groups called Aphasia Community Groups (ACGs).[47]

Several informational publications designed for use by the families and friends of patients with aphasia also appeared in the period following World War II.[48-53] One of these, "Understanding Aphasia: A Guide for Family and Friends," is still widely read and has been published in 12 languages.[53]

Aphasia Measures

Many measures of aphasia and related disorders have been developed for use in both clinical and research settings. In an inpatient setting, patients with aphasia are generally screened at bedside. The purpose of a bedside screening is to obtain a general idea of a patient's profile of deficits and preserved areas of language function as a basis for recommendations for more comprehensive testing and possible rehabilitation. However, a comprehensive examination is required to provide a baseline measure against which to gauge progress in the course of rehabilitation.

Comprehensive language tests designed to measure aphasic impairment generally contain specific domains of performance. In addition to the general requirements for the construction of tests, such as reliability, standardization, and demonstrated validity, certain factors are important in the design of tests intended to identify and measure aphasia. These include range of item difficulty, efficacy in measuring recovery, and ability to contribute to diagnostic classification.[2,54] Aphasia tests are generally based on examinations of linguistic task performance and at a minimum include tasks of visual confrontation *naming*; a spontaneous or conversational *speech sample* that is analyzed for fluency of output, effort, articulation, phrase length, prosody, word substitutions, and omissions; *repetition* of digits, single words, multisyllable words, and sentences of increasing length and complexity; *comprehension of spoken language* of single words, of sentences that require only yes/no responses, and pointing on command; *word retrieval* (word finding) measuring the ability to generate words beginning with a particular letter of the alphabet or in a particular semantic category (animals); *reading*; and *writing* from dictation and spontaneously. Some widely used aphasia measures include the *Boston Diagnostic Aphasia Examination (BDAE),*[23] the *Neurosensory Center Comprehensive Examination for Aphasia (NCCEA),*[55] and the *Western Aphasia Battery*.[56]

In addition to measuring performance on specific linguistic tasks, an aphasia evaluation also requires an examination of *functional communication.* This is necessary because an individual's actual use of language in everyday life may not correspond to the degree of pathology measured by specific language task performance.[57,58] Functional communication measures are generally rating scales with high interrater reliability. The *Functional Communication Profile (FCP),*[59,60] *Communicative Activities of Daily Living (CADL),*[61] *Communicative Effectiveness Index*,[62] and ASHA's *Functional Assessment of Communication Skills (ASHA FACS),*[63] which have high interrater reliability, are measures used for this purpose.

In addition to measures of language and functional communication, new tools have been developed to determine the impact of impaired communication skills on quality of life. The scope of SLP practice now encompasses all of the components and factors specified in the WHO framework.[13,65-68] Specifically, concern for the effect of aphasia on family, social, and community life is the basis for more recently designed measures

(e.g., Burden of Stroke Scale [BOSS], Functional Life Scale [FLS], Aphasic Depression Rating Scale [ADRS], Frenchay Activities Index, and Stroke and Aphasia Quality of Life Scale–39 [SAQOL-39]).[68-75]

Recovery

If complete recovery from aphasia is to occur, it usually happens within a matter of hours or days following onset. Once aphasia has persisted for several weeks or months, a complete return to a premorbid state is usually the exception. It is the general consensus that language gains in aphasia take place earlier rather than later, and that time since onset is an important recovery variable.[76-81]

Most patients do not consider themselves recovered unless they have fully recovered to previous levels of language performance.[46,82] When unrecovered patients are satisfied with their level of competence and consider themselves recovered, this is a psychological perception and should not be confused with an objective evaluation of communication abilities. For individuals with aphasia, the true test of rehabilitation outcome is their perception of the quality of their life. Measures of life function that include activity levels, socialization, mobility, and community reintegration can be used for this purpose.[83,84]

It is useful to distinguish between two separate recovery dimensions in aphasia: one that is objective and attempts to quantify the extent to which a person has regained language abilities; and another, which measures the recovery of functional communication.

The concept of a functional dimension of communication behavior emerged logically from the experience of treating patients with aphasia in rehabilitation medicine settings. Historically, rehabilitation medicine has acknowledged that the ability of patients to function in daily life (activities of daily living [ADL]) does not necessarily correlate with the degree of physical disability. Similarly, improvement in quantitative measures of language performance does not necessarily correlate with improvement in functional communication.[46]

The majority of patients experience a degree of natural recovery with or without intervention in the period immediately following onset. However, there is a lack of consensus about the duration of the *spontaneous recovery* period.[85-87] Culton[88] reported rapid spontaneous language recovery in the first month following the onset of aphasia, and a number of studies have concluded that the greatest improvement occurs in the first 2 to 3 months after onset.[89-93] Of 850 patients surveyed in the first month following stroke, 177 presented with aphasia. In the 4 to 12 weeks following the stroke, aphasia improved in 74% of the patients and cleared in 44%.[18] Butfield and Zangwill,[94] Sands et al,[95] and Vignolo[89] reported that the recovery rate dropped significantly after 6 months. Others have found that spontaneous recovery occurs up to 6 months[96] or 1 year.[88,90] Sarno and Levita[97] reported that the greater change took place within a 3-month rather than a 6-month post-onset period in a sample of patients with severe aphasia seen up to 6 months after stroke.

Recovery from aphasia after stroke is difficult to predict, especially during the early recovery stages.[98] Severity and location of lesion have been reported as predictors of language recovery.[99-102] However, these factors are very variable, making it difficult to generate a prognosis for individual patients.[103]

Most investigators have concluded that factors such as age, gender, and handedness do not affect recovery from aphasia.[98,103-105] Although age has been reported as a significant prognostic factor,[89,106-108] many do not support this view.[90,104,109-113] These wide discrepancies regarding the influence of age may relate to differences in sampling and methodology. In a study that compared aphasia recovery in the first post-stroke year between a middle-aged (50 to 64 years old) and older (65 to 80 years old) group, age did not emerge as a significant factor.[83] In addition, educational level or occupational status before illness does not always correlate with recovery. However, Sarno and Levita[97] reported that individuals with aphasia who were employed at the time of stroke recovered more than those who were unemployed. In the healthy aged, language performance declines significantly between the sixth and eighth decades.[106,114,115] Gender does not appear to have an important influence on outcome,[76,104,116] whereas handedness may have an effect.[117]

It is generally agreed that posttraumatic aphasia has a better prognosis than aphasia secondary to vascular lesions.[89,94] In fact, some cases of aphasia secondary to TBI have been reported to recover completely.[91,118] The finding that traumatic aphasia carries a better prognosis than vascular aphasia may be influenced by the fact that patients involved in traumatic events are generally neurologically healthy whereas patients who have had strokes may have widespread vascular involvement.[104]

Both type and severity of aphasia appear to carry predictive value, with global aphasia having the poorest prognosis.[76,119-121] Basso[104] reported that when patients with fluent and nonfluent aphasia of the same severity were compared, there were no differences in degree of recovery. In 881 consecutive acute stroke admissions to a community-based hospital, it was possible to make valid prognoses within 1 to 4 weeks after stroke depending on the initial severity of aphasia.[104]

Not surprisingly, most studies report that patients with severe aphasia do not recover as much as those with mild aphasia.[91,95,120-122] Sarno and Levita[76] found that people with fluent aphasia reached the highest level of functional communication, whereas patients with nonfluent and global aphasia made smaller gains in the 8- to 52-week post-stroke period. Global aphasia sometimes evolves to severe Broca's aphasia when there is significantly improved comprehension. Broca's aphasia

may become *anomic aphasia,* and Wernicke's aphasia may evolve to anomic or *conduction aphasia.*[76,91,120-124] When persons with aphasia recover a great deal of language function they are usually left with residual *anomia.*

Patients whose computed tomography (CT) scans show large dominant hemisphere lesions, many small lesions, or bilateral lesions are less likely to recover than those with smaller or fewer lesions.[82,120] Lesions in Wernicke's area or those that extend more posteriorly tend to lead to severe and persistent aphasia. The neuroradiological correlates of aphasia recovery have been addressed by some investigators.[93,125] Yarnell et al[82] reported little prognostic value in angiographic and radioscintigram findings. Similarly, CT scans did not help in predicting who might profit from language retraining in a Norwegian study.[86]

More recent functional imaging studies of aphasia secondary to stroke have suggested that language recovery is dependent on several factors. The neuroplastic changes that are needed during recovery are thought to depend more heavily on left hemispheric changes in activity that slowly manifest over time.[22] Following damage to the left hemisphere, rapid changes have been observed in temporal and frontal areas within the right hemisphere but may reflect maladaptive compensatory activity versus functional reorganization or recovery.[126-135]

Comprehension tends to recover to a greater degree than expression.[26,89,133-136] Although recovery of auditory comprehension involves bilateral temporal lobe activation, there does not seem to be a correlation between the activity of each hemisphere during this process.[126,137-139] As technology advances and research continues, new insights into the mechanisms of recovery and treatment will emerge.[140]

The presence of depression, anxiety, and paranoia have been cited as negative factors in recovery,[141-143] and premorbid personality traits have been identified as important prognostic factors. Eisenson and Herrmann felt that patients with outgoing personalities had a better prognosis than those with introverted, dependent, or rigid personalities.[144-146]

Efficacy of Treatment in Post-Stroke Aphasia

Many methodological problems have limited the number of studies that examine the efficacy of aphasia rehabilitation.[147-153] Nevertheless, treatment accountability issues are compelling and a focus of professional concern.

Studies that investigate treatment effects, specific techniques, and approaches have been reported since the late 1950s.[154] Vignolo,[89] Hagen,[155] and Basso et al[90,119] utilized untreated control and treated groups and showed a positive treatment effect. Edmonds et al[156] and Poeck et al[157] also yielded positive treatment effects with treated and untreated groups. In addition, several reviews and examinations have revealed significant treatment effects (i.e., improvements in communicative ability) with intense intervention provided over a short period of time.[158-160] Variables such as spontaneous recovery,[91,161,162] age,[109,163] duration, treatment intensity,[122,158-160] and timing of treatment[164] and specific treatment techniques[165-167] have been studied.

Although studies have varied in method and research focus, there have been strong indications for positive treatment effects.[154] Some have maintained that single case studies rather than randomized, controlled trials are the most appropriate method for addressing treatment efficacy.[168,169] Current research utilizing a standard approach to analyze data from single-subject designs are improving the ability to quantify treatment outcomes.[96] A single case approach to the study of aphasia treatment efficacy has not escaped criticism but is far less frequent than criticism of studies based on groups of people with aphasia.[96] Negative views of the group study model are based primarily on the view that individuals are unique, especially with respect to communication behavior.

The Academy of Neurologic Communication Disorders and Sciences (ANCDS) has issued evidence-based practice guidelines for neurogenic communication disorders.[153,170,171] Until now, SLPs have depended on meta-analyses of efficacy studies reported for 45 studies published between 1946 and 1988 and for 55 studies that support better clinical outcome for patients who receive early, intensive treatment.[152,172]

Psychological and Related Factors

It has been observed that the variability of patients' psychological reactions is rarely determined by the type or location of their lesions but is an expression of the whole life experience of the person who has had a stroke.[83,104,143,173,174]

Depression, anxiety, premorbid personality, fatigue, and paranoia are often cited as deterrents to recovery and communication. The social isolation experienced by people with aphasia and their families has a profound impact on quality of life.[83,151] The effect of aphasia on an individual's sense of "self" can be extremely negative, leading to a loss of self-esteem and feelings of helplessness. Also, the opportunity for "healing conversation," so essential to individuals who have suffered losses, is often unavailable to those with aphasia, which may be the result of inadequate social support.

In a study of patients with aphasia participating in a group psychotherapy program, Friedman[175] investigated the nature of psychological regression with impaired reality testing in aphasia. Beyond the communication difficulties posed by aphasia, he observed that patients remained psychologically isolated. They did not maintain a consistent level of group participation and expressed intense feelings that they were very different from other people. Both withdrawal and projection

were apparent as each patient acted in isolation and yet complained of these characteristic in others.

Treatment of Aphasia

Aphasia treatment is rarely the same in any two settings. Literally hundreds of specific speech and language treatment techniques are cited in the aphasia literature. The lack of therapeutic uniformity has undoubtedly impeded an adequate number of carefully controlled studies on the effects of language retraining. Most methods derive essentially from traditional pedagogic practices, relying heavily on repetition.[176]

In general, treatment methods can be categorized as those that are largely *indirect stimulation-facilitation* and those that are essentially *direct structured-pedagogic*.[78,118,141,177-180] The two principles that underlie most treatment methods reflect contrasting views of aphasia as either impaired access to language or a "loss" of language. The stimulation methods generally follow an impaired access model and pedagogic approaches are based on a theory of aphasia as a language loss.

In practice, however, much of aphasia treatment addresses the *performance* aspect of language in which repeated practice and "teaching" strategies are assumed to help restore impaired skills through a "task-oriented" approach (i.e., naming practice). One of the commonly used techniques involves self-cueing and repetition exercises that manipulate components of grammar and vocabulary. Another approach involves "stimulating" the patient to use residual language by encouraging conversation in a permissive setting where a patient's responses are unconditionally accepted and topics are of personal interest.[179]

The primary assumption that drives the treatment of aphasia is that language in the brain is not "erased," but that retrieval of its individual units has been impaired. Approaches to aphasia therapy have generally followed one of two models: a *substitute skill model* or a *direct treatment model,* both of which are based on the assumption that the processes that subserve normal performance need to be understood if treatment is to succeed.[180] An example of the substitute skill model can be found in deaf individuals, some of whom use speech reading, a visual input rather than an auditory input, as an aid to comprehend spoken language. If a direct treatment model is followed, specific exercises individually designed to ameliorate specific linguistic deficits are the basis of treatment.

Significant progress and improvements of language and communication performance have been reported in those with aphasia who have received intensive and/or extended periods of language therapy.[153,157,181,182] More recent reports of intensive treatment programs have shown significant improvement of communication abilities several years post-stroke, when aphasia is in the chronic stage.[167,182-184] Some benefits may also be received from pharmacological treatment with and without speech therapy.[185-192] In addition, improvements have also been documented with the use of transcranial magnetic stimulation,[193] functional magnetic resonance imaging,[194] and transcranial direct current stimulation.[195]

Visual communication therapy (VIC) is an experimental technique designed for persons with global aphasia.[196-200] It employs an index card system of arbitrary symbols representing syntactic and lexical components that patients learn to manipulate so as to (1) respond to a command and (2) express needs, wishes, or other emotions. The system attempts to circumvent the use of natural oral language, which is severely impaired and often unavailable to the patient with global aphasia. An adaptation and application of the VIC system, *Computer-Aided Visual Communication system (C-VIC),* was developed by Steele et al.[198,199] Weinrich et al[201] demonstrated that C-VIC training can lead to improved spoken language. Investigators conclude that the evidence supports the view that some patients who have severe aphasia can master the basics of an artificial language and that some of the cognitive operations entailed in natural language are preserved despite the severity of the impairment.

Visual Action Therapy (VAT) developed at the Boston Veterans Administration Medical Center by Helm-Estabrooks et al[202,203] was designed to train people with global aphasia to use symbolic gestures representing visually absent objects. The tasks leading to this goal include associating pictured forms with specific objects, manipulating real objects appropriately, and finally producing symbolic gestures that represent the objects used (e.g., cup, hammer, razor).

In an attempt to utilize systematized gestural language to facilitate oral production, American Indian sign language has been modified in a method that combines common gestural sign with oral speech production (Amerind) for selected cases.[204-206]

Melodic Intonation Therapy (MIT) is based on the observation that language may not be available in spontaneous speech but can sometimes be provided in association with known melody, as the therapist gradually introduces spoken material with a melodic rhythm. The patient is encouraged to participate in the process.[207-209]

In the *functional communication treatment (FCT)* method developed by Aten et al,[210,211] emphasis is placed on restoration of communication in the broadest sense. Treatment is designed to improve information processing in the activities necessary to conducting ADL, social interactions, and self-expression of both physical and psychological needs.[210,211]

Promoting Aphasics' Communicative Effectiveness (PACE), a technique intended to reshape structured interaction between clinicians and patients into more natural communicative exchanges, includes several pragmatic components common to natural conversation.[212,213]

Contextualized, constraint-induced language therapy (CILT) is an intensive form of language therapy that is usually administered over a short period of time. Treatment is conducted by an SLP in small groups of two to three persons with aphasia who are required to use and practice only those verbal skills that are difficult or impaired. Forms of communication that can be effective in total communication but are not verbal, including gesturing, drawing, or writing, are constrained.[167,214,215]

Maher et al[215] compared PACE and CILT on the same schedule of intensity and found that both groups made significant improvements but differed in the types of communication behaviors that improved. Those who received CILT performed better on measures examining verbal behaviors and those who received PACE improved on nonverbal behaviors.

Some investigators have reported the use of writing[216] or drawing as a potential means of communication.[217-220] Others have developed interactive approaches to aphasia treatment. Examples include the *communication partners* approach of Lyon,[217-219] a treatment plan designed to enhance communication and well-being in settings where the person with aphasia and the caregiver live; the *supported conversation* approach introduced by Kagan and colleagues,[221-225] in which volunteers are trained as conversation partners to facilitate conversation by using all available modalities, thereby revealing the individual's competence and permitting a communicative interaction; and the *social model of aphasia* approach introduced by Simmons-Mackie,[226-234] which focuses on the fulfillment of social needs and the encouragement of a greater conversational burden on the part of communication partners. Partners are trained to facilitate interaction by modifying some of their interactive behavior.

If an individual is unable to make himself or herself understood and has residual writing and spelling skills, aids that use the alphabet can provide a means of communication (e.g., an alphabet board). A communication book may consist of pictures or words arranged according to topics (e.g., foods, family members) in a notebook for easy access. The same type of material has also been adapted for computerized access in the form of tablet devices (e.g., iPad). Microcomputers were the basis for an approach that Seron et al[235] found effective in treating patients with writing disorders associated with aphasia. With continued exposure to training, improvement in accuracy and recognition time in reading commonly used words[236] and improvement in auditory comprehension were noted in a patient with aphasia who, when followed up at a later date, showed additional gains.[237,238] Computer-generated phonemic cues were effective in improving naming in five patients with Broca's aphasia.[239] An augmentative system was developed for a patient with Broca's aphasia;[240] a word retrieval facilitation program was developed for individuals with aphasia;[241] and Steele et al[199] and Weinrich et al[242] replicated and extended the findings of Gardner et al[196] and Baker et al[243] by training those with aphasia to use a computerized version of the VIC system.

Use of telecommunications, virtual clinicians, and computer-assisted treatments may lead to improvements in language and communication, especially when utilized as an adjunct to clinical therapy. Data suggest that these types of therapies may be effective for patients in various stages of recovery.[244-249]

Management of the Patient with Aphasia

The unfortunate reality is that once the condition of aphasia has stabilized, very few patients recover normal communication function, with or without speech therapy. Accordingly, aphasia rehabilitation should be viewed as a process of patient management in the broadest sense of the term. That is, the task is primarily one of helping the patient and his or her intimates adjust to the alterations and limitations imposed by the disability. Effective aphasia rehabilitation management requires the participation of several disciplines, including medicine, psychology, physical therapy, occupational therapy, social work, vocational counseling, and, most critically, aphasia therapy.

The selective and discriminating use of speech and language therapy to stimulate and support the patient through the various stages of recovery is an effective management tool.[87,250,251] Experienced aphasia therapists recognize that while working on aphasic deficits, they are simultaneously dealing psychotherapeutically with a readjusting personality.[143] Speech therapy, therefore, serves different purposes at different points along the way. Sometimes it allows patients to "borrow time," as Baretz and Stephenson[252] have aptly stated. Occasionally depression lifts after speech therapy has been initiated, reflecting the supportive and nurturing nature of the therapeutic relationship rather than an objective improvement in recovery of speech and language.[251]

Aphasia recovery can be viewed as a dynamic process consisting of a series of stages like the stages of mourning described by Kübler-Ross,[253] through which the majority of patients evolve. Some, of course, never emerge from a state of severe depression.[254,255] Kübler-Ross[253] and other authors have suggested that the stages through which someone with aphasia passes—including denial, rage, bargaining, and acceptance—could be characterized as attempts to overcome the sense of loss.

By directly addressing a patient's linguistic deficits and channeling attention and energies toward constructive goals, speech therapy may produce a noticeable reduction in depression. Therapy tasks in this instance act as an equivalent for work, which has long been recognized as an antidote for depression.

There is a great tendency to overestimate the capacity of individuals with aphasia to return to work, particularly if the verbal deficits are mild. Premature attempts to return to work can have a negative psychological

impact. Professional rehabilitation counselors are best equipped to explore and evaluate a patient's vocational potential and carry out the long and arduous process of evaluating work performance and job requirements.

Experienced aphasia clinicians stress the importance of the patient's family in the rehabilitation process. Some of the potentially negative reactions of the family include overprotectiveness, hostility, anger, unrealistic expectations, overzealousness, lack of knowledge of the dimensions of the disorder, and inability to cope with practical difficulties. The apparently natural tendency of family members to minimize the patient's communication impairment, particularly in the early stages of recovery, requires understanding and tactful management.[143]

The quality of premorbid relationships generally tends to be intensified after a catastrophic event; those that were problematic may deteriorate further, whereas the bond between a loving couple may become stronger. The reversal of roles, changes in levels of dependency, and a changed economic situation, so often a consequence of chronic disability, can have a critical negative impact on the patient and his or her family.[174]

In a positive family milieu, patients are encouraged to develop regular daily routines as close to premorbid patterns as possible and are treated as contributing members of the family. Patients need to be allowed some sense of control. Including the patient in rehabilitation planning promotes restoration of feelings of self-worth. In this regard, the emphasis on function rather than complete recovery, pointing out success rather than performance failure, adds to a patient's sense of self. It is essential to listen to patients, particularly to their expressions of loss. Commiseration is often more comforting than optimistic prognostic statements.

Group speech therapy, stroke clubs, and other social groups that are frequently used resources can be effective tools in the management of some patients with chronic aphasia. The National Aphasia Association (NAA) was founded in the United States in 1987, following the lead of existing advocacy organizations established in Finland (1971), Germany (1978), the United Kingdom (1980), and Sweden (1981). The NAA provides an extensive array of educational and resource information appropriate for patients, families, and professionals on its website (www.aphasia.org). Knowledge that one is not alone often helps to reduce depression and loneliness.[86,141]

Group therapy with peers also provides a comfortable atmosphere in which patients can meet new friends and share feelings, although not all individuals with aphasia find it beneficial. A positive effect seems to be related to level of comprehension, time since onset, and personality factors. Although group therapy generally plays an important role in aphasia rehabilitation, it should be noted that much of its effectiveness depends on the skill and experience of the group leader.[256,257]

Aphasia rehabilitation remains eclectic and specifically tailored to the individual patient. Fundamental to this therapeutic philosophy is the acknowledgement and appreciation of the uniqueness of the individual. No two persons with aphasia are exactly alike in pathology, personality, linguistic deficits, reactions to catastrophic illness, life experience, spiritual values, or a host of other factors. The influence of these factors carries different weight and strength at different stages of recovery and they are all related to recovery outcome.

Those who manage the rehabilitation of patients with aphasia face many ethical–moral dilemmas. One of the principal issues is a result of the necessity in many settings to select those individuals who will receive treatment. Rehabilitation medicine services are not only scarce in many situations, but they are also not considered to be a right or entitlement. Services are usually provided on a selective basis to those individuals believed to have the potential to benefit. This process assumes that we know who can benefit.[16,258-261] Many who are experienced in aphasia rehabilitation management hold the view that all people should be given a trial treatment period to determine their candidacy for further treatment and that trials should be provided at different points in the recovery course. Goal setting, the patient's right to self-determination, and the criteria appropriate in determining the termination of therapy are also important ethical issues.[143,261]

COGNITIVE-COMMUNICATION DISORDERS

When the neural regions responsible for the cognitive processes that support communicative function are damaged, a broad spectrum of deficits can result. Many conditions can cause cognitive-communication disorders, including TBI, stroke (especially right hemisphere damage), dementia, brain tumors, aging, degenerative neurological disease, alcohol/drug abuse, and medications. Impairments of executive function, including difficulties with attention and memory, may interfere with a person's ability to transform thoughts and ideas into spoken and/or written language.[262-265] Impaired memory can also affect word retrieval, topic maintenance, a person's ability to recall and integrate information, and the speed of processing information. In addition, organizing information, interpreting visual information, deficits in abstract reasoning, and decreased orientation to person, place, and time are common symptoms. Impairments in speech production, including reduced fluency and prosodic speech features (i.e., rate and rhythm of speech, stress within words to indicate meaning and within sentences to express variations of intent or meaning), are also common.[266] Given the nature of these deficits, participating in social situations can be especially difficult.[267] The difficulties may affect all modes of communication, including understanding, nonverbal and verbal expression, reading, and writing. These impairments can be

debilitating and socially isolating, because they impair a person's ability to establish and maintain relationships with others.[268,269]

Impairements of certain aspects of pragmatic language (i.e., language use) and nonverbal communication (including difficulty in initiating, maintaining, and ending conversations), which may result in difficulties maintaining a topic and taking turns in discourse; being concise;[270] understanding and expressing feeling through facial expressions; comprehending nonverbal methods of communication (i.e., gesturing); maintaining eye contact; engaging in conversation or narrative production that is self-focused; interpreting and expressing emotions appropriately; and reduced ability in understanding humor.

Examination of Cognitive-Communication Disorders

Many factors, including the heterogeneity of individuals, limitations of available standardized testing measures, performance differences in structured versus unstructured contexts, and environmental and personal factors, have made the examination of cognitive-communication disorders a challenging area in need of further study.[271,272] A standardized test battery for the identification and measurement of cognitive-communication disorders does not exist and depends entirely on the knowledge, experience, and expertise of the examiner.

Treatment of Cognitive-Communication Disorders

Intervention depends on the type and severity of the cognitive-communication disorder and is usually based on a combination of behavioral, meta-cognitive, and counseling approaches. Patients with cognitive-communication disorders are especially challenging since they often have reduced insight and/or denial.[269,273] The importance of providing speech-language pathology treatment using a team approach has been highlighted as an important element in the rehabilitation process. Such collaborative methods take into account each person's social network (e.g., family, friends, caregivers, and so forth.).[263,264,274,275]

The management of patients with cognitive-communication disorders begins with determining what environmental factors, if any, can be modified to provide the least visual or auditory distraction. Steps also need to be taken to establish a structured routine or daily schedule. These efforts help to reduce communication breakdowns and facilitate communicative success.[274,275] The later stages of intervention emphasize the carryover of skills acquired in therapy to a variety of daily activities and contexts.[263] Box 28.1 provides several suggested strategies to improve communication for patients with cognitive-communication disorders.

Box 28.1 Strategies for Improving Communication in the Presence of Cognitive-Communication Disorder

- Use visual materials/aids to help orient the person to time (e.g., clocks and calendars)
- Break long, complicated tasks into shorter tasks that are easier to follow
- Establish eye contact to initiate and maintain conversation
- When giving verbal directions, use simple sentences and repetitions as necessary
- Accommodate the presence of visual field deficits by helping the person find compensatory means for reading and writing
- Gently state when the topic in a conversation changes prematurely

DYSARTHRIA

The term **dysarthria** (sometimes called a *motor speech disorder*) refers to an impairment of speech production resulting from damage to the central or peripheral nervous system, which causes weakness, paralysis, or incoordination of the motor–speech system. Any one or all of the components of the motor–speech system (respiration, phonation, articulation, resonance, and prosody) may by compromised by neural damage. The type and degree of dysarthria depends on the underlying etiology, degree of neuropathology, coexistence of other disabilities, and the individual response of the patient to the condition. It is not unusual for dysarthria to coexist with aphasia in patients who have suffered cerebrovascular accident (CVA) or TBI. The severity of dysarthria may range from the production of occasionally imprecise consonant sounds to speech that is rendered totally unintelligible by the degree of impairment to the underlying systems. When patients are totally unintelligible as the result of severe motor–speech system impairment, they exhibit **anarthria**.

The incidence of dysarthria in the population of individuals with neurogenic disorders is approximately 46%, representing a significant proportion of the patients with communication impairments seen in medical settings.[276] It is difficult to estimate the total number of people affected by dysarthria, because the condition results from a wide range of etiologies (e.g., progressive neurological diseases, TBI, and stroke). For example, approximately 1% of the population older than 60 suffers from Parkinson's disease,[277] and about 89% of those with Parkinson's disease develop a motor speech disorder as the disease progresses.[278]

Dysarthria is generally reflected in deficits occurring in multiple motor–speech systems, but may sometimes

occur in a single system (e.g., an impairment of soft palate movement resulting in hypernasality). It is most notably prevalent in cerebral palsy, TBI, CVA, demyelinating diseases (e.g., multiple sclerosis), neoplasm, and progressive neurodegenerative diseases, such as Parkinson's disease, Huntington's chorea, and amyotrophic lateral sclerosis.

There are five primary types of dysarthria: *spastic, flaccid, ataxic, hypokinetic,* and *hyperkinetic.* When two or more types coexist, the term *mixed dysarthria* is used. Coexisting physical disabilities are present in a majority of patients who manifest dysarthria.

Classification and Nomenclature

Spastic dysarthria is characterized by imprecise articulation, slow labored articulation, hypernasality, harsh to strained phonation, and monotonous pitch. Syllables may be given equal stress and inflection. There is often reduced control of exhalation, with shallow inhalations and slow breaths. Spastic dysarthria is the result of bilateral pyramidal system damage involving the corticobulbar tracts (upper motor neurons). The pathology may cause weakness and paresis of the face and tongue musculature on the side opposite to the lesion. There is a high incidence of spastic dysarthria among those with cerebral palsy.[276]

Flaccid dysarthria is characterized by slow/labored articulation, hypernasality, and hoarse, breathy phonation. Phrases may be short, inhalation is shallow, and the control of exhalation may be reduced. There is often a reduction in the variation of pitch and loudness with audible inspirations. Most of these deviant speech characteristics are related to muscular weakness and reduced muscle tone, which affects speech accuracy.

Ataxic dysarthria is characterized by disturbances of timing, movement, range, control, and coordination of the muscles of speech and respiration. Speech is imprecise, slow, and irregular. There may be intermittent periods of explosive inflection, syllable stress, and loudness patterns. Phonemes may be prolonged; pitch and loudness are monotonous. The lesions producing ataxic dysarthria are bilateral, generalized lesions involving the deep midline nuclei and pathways of the cerebellum. Patients with multiple sclerosis and TBI with cerebellar damage often manifest ataxic dysarthria.

Hypokinetic dysarthria is characterized by variable articulatory precision, slow rate of speech, harsh, hoarse voice quality, excessive and overly long pauses, prolonged syllables, and reduced phonation. Patients with Parkinson's disease, Parkinson's-plus syndromes, or parkinsonian-like symptoms often manifest hypokinetic dysarthria, usually caused by lesions of the substantia nigra.

Hyperkinetic dysarthria is characterized by variable articulatory precision, vocal harshness, prolonged sounds and intervals between words, monotonous pitch, and loudness. It is manifest in patients with Huntington's chorea, caused by lesions of the basal ganglia and/or their extrapyramidal projections.

Treatment of Dysarthria

Dysarthria treatment must be individually designed to account for the profile of impairment, as well as the variability of its disabling effects. The performance of components of the motor–speech system does not necessarily result in changes to the disabling effects of dysarthria, that is, the intelligibility or comprehensibility of speech.[258,279] Goals that relate to the level of disability rather than normal speech are generally more realistic because they do not focus on normalcy, which is usually an unachievable goal, or improvement in the performance of a single component of the motor speech system, which may not, in the overall picture, be functionally important.

The ANCDS's initiative to develop evidence-based practice guidelines for neurogenic communication disorders[170,171] has resulted in meta-analyses of efficacy and effectiveness reported for 51 studies published between 1966 and 2004.[280] The focus of dysarthria treatment is sometimes based on an approach that emphasizes compensatory skills. These techniques tend to encourage the patient to minimize the overall disability by using strategies that may actually deviate from normal (i.e., slowing down the rate of speech production to increase intelligibility of consonant production).

Moreover, the overall aim of dysarthria treatment is to improve communicative effectiveness, which can be negatively affected if the speaker is in a noisy place. Patients and communication partners must be trained to seek the most optimal situations for communication interactions. One type of approach is to focus on one of the subsystems of speech production, such as velopharyngeal function.[281] Other approaches include utilizing an approach that results in a spreading of effects and is centered around improving coordination of the subsystems of respiration, phonation, articulation, and resonance.[282] Loudness, speaking rate, and prosodic features of speech (i.e., stress, intonation, rate, and rhythm of speech) have been investigated for their effectiveness in treating dysarthria.

Increasing the loudness of speech is a common target in the treatment of some types of dysarthria, especially Parkinson's disease. The majority of studies that have focused on loudness have examined the short- and long-term efficacy of the Lee Silverman Voice Therapy program (LSVT®/LOUD) for individuals with dysarthria due to Parkinson's disease. Treatment delivery is intensive and focused on high-effort speech and voice exercises to increase loudness, as well as a readjustment of the patient's perception of his or her own loudness levels when speaking.[283,284] Exercise has been reported to stimulate the production of dopamine, thereby reducing symptom presentation.[285] The program is based on several proposed exercise physiology principles that drive neuroplastic changes, including intensive practice, movement complexity, emotional saliency of tasks, timing of treatment

(i.e., the earlier, the better), and continuous/daily exercise to slow disease progression.[284] Studies that have examined this treatment method have also reported improvement in swallowing, articulation, and facial expression[286-289] and have demonstrated its success in individuals with dysarthria due to stroke, TBI,[291] multiple sclerosis,[292] cerebral palsy,[293] and Down syndrome.[294]

In addition to focusing on improving loudness, a variety of strategies are used to manipulate speech rate. Speakers tend to be more intelligible when they speak more slowly.[295] The ANCDS review of studies that investigated the effectiveness of rate control techniques concluded that they are dependent on the type and severity of dysarthria and the specific intervention strategies employed. Further study is still needed to delineate an individual's candidacy for this type of technique, as well as what the carryover can be to the natural communication environment.[280]

A third focus of dysarthria treatment is the improvement of the prosodic aspects of speech (i.e., stress patterns within words and sentences, intonation to express meaning, and rate-rhythm interactions). A variety of strategies that target prosody have been implemented, including those using biofeedback and behavioral instruction. Few conclusions can be drawn about the effectiveness of prosody training because of the small number of examinations and wide range of subject characteristics and techniques used.[280]

A limited number of studies have also reported outcomes of therapy focused on providing people with feedback about speech clarity or instructing people with dysarthria to use "clear speech." A meta-analysis of investigations in this area reports a lack of evidence supporting the effectiveness of this approach.[280]

Many persons with motor–speech impairments have been able to increase their communicative effectiveness using augmentative and alternative communication aids (ACA). Low-tech aids, which only require batteries and electricity, include devices such as telephones and communication books. High-tech aids include specially adapted computers and switching systems, as well as speech-generating programs that are available on mobile devices such as laptop or tablet computers and a variety of smartphones.

Recommendations of ACA for persons with dysarthria depend on the severity of the communication disorder and the projected course of the disease and must be carefully selected and managed by the speech-language pathologist.

APRAXIA OF SPEECH

Some patients with nonfluent (Broca's) aphasia present with articulatory difficulty characterized by speech sound errors, slow speech rate, slow transitions between sounds, syllables, and words, and impaired prosody in the absence of impaired strength or coordination of the motor speech system.[296-299] This profile of difficulty speaking is referred to as *apraxia of speech* (AOS) (or *speech dyspraxia, verbal apraxia, cortical dysarthria,* or *phonetic disintegration*). Additional behaviors that may be present in persons with AOS include difficulty initiating speech, articulatory struggling, periods of error-free speech production, and a greater number of sound production errors as utterance length increases. These characteristics may be so severe that the patient is barely intelligible but appears to be independent of difficulty in language processing. Unlike dysarthric speakers, individuals with AOS do not generally have deficits in performing nonspeech movements of the oral musculature. The possible independence of this deficit from the language disorder of Broca's aphasia remains controversial.

The disorder of articulation referred to as AOS is seldom, if ever, manifested in the absence of a coexisting Broca's aphasia, however mild. The speech dyspraxia component of this multifaceted communication disorder appears to be especially amenable to direct therapeutic intervention using approaches adapted primarily from traditional articulation therapy techniques, including stress and intonation drills. These approaches, designed to improve phonetic placement accuracy, typically depend on imitation, stress, and gradually shaping sounds currently available to patient until a desired sound is approximated, which is then drilled using kinesthetic, visual, and auditory cues. Generally, the stimuli used as the bases for these exercises are selected in a presumed order of difficulty, beginning with non-oral imitation, followed by sounds, words, phrases, and finally utterances.

Treatment of Apraxia of Speech

In an attempt to synthesize and assess available evidence from the literature, 59 studies were summarized and rated by the ANCDS. The most commonly used approaches are referred to as *articulatory kinematic.* These techniques aim to improve articulatory movements: modeling, imitation, repetition, shaping, electromagnetic articulography, and multimodal and articulatory placement cueing.[299-308]

Integral stimulation, a method originally introduced by Milisen,[309] is a commonly used articulatory kinematic technique that involves imitation and emphasizes the importance of helping the patient focus his or her attention on auditory and visual models of speech. Rosenbek et al[302] developed an eight-step continuum based on this approach that employs a hierarchy of cues in which the timing between the stimulus provided by the clinician and the response produced by the patient is varied.[302]

Sound production treatment, a five-step program based on the Rosenbek et al[302] eight-step continuum, incorporates principles of motor learning such as repeated practice and verbal feedback and is an approach that has been systematically investigated more than any other AOS treatment.[308,310-312]

Visual spectrographic, and *verbal feedback* utilize different sensory modalities to facilitate speech production.[304,306,307,313,314] The effect of the frequency and timing at which feedback is provided has been investigated and found to be important in the treatment of AOS.[306,315]

Rate and rhythm strategies are employed to improve speech sound accuracy by controlling the rate of speech and stress patterns within words and sentences.[316] External devices such as computer-generated pulses or programs, metronomes, pacing boards, and finger tapping are used to manipulate the rate of speech.[317-323]

The long-term nature of recovery of phonemic production in patients with verbal apraxia was confirmed in a study of a patient with Broca's aphasia who received speech therapy for 10 years. The errors that prevailed in the first post-stroke year were compared with performance at 10 years. The features of place and manner of production had improved; although voicing and addition errors (the addition of sounds) persisted, omission errors (the omission of sounds) were virtually eliminated.[324]

Alternative communication aid approaches are often recommended for persons with AOS. In most cases, the use of multiple communication modalities, such as writing, drawing, gesturing, and signing, is suggested as a facilitatory technique to enhance or substitute for impaired speech.[325-328]

Intersystemic facilitation or *reorganization approaches* use intact systems or preserved strengths or abilities of the patient to facilitate and improve accurate speech production.[329] These approaches employ and combine strategies that can be included in more than one category, such as iconic or rhythmic gestures, vibrotactile stimulation, imitation, modeling, and ACA.[330-333]

DYSPHAGIA

The swallowing process is composed of a number of complex neuromuscular events. Normal swallowing requires that an individual be able to move food or liquid from the mouth (*oral phase of swallowing*), through the pharynx (*pharyngeal phase of swallowing*), and into the esophagus. In the oral swallow phase, food is collected in the oral cavity in a single mass, or bolus, which is then propelled into the pharynx and further propelled under pressure into the esophagus. During the oral phase of swallowing, the bolus is first held between the tongue and palate and then propelled by the tongue from the front to the back of the oral cavity. The bolus moves over the back of the tongue into the pharynx, triggering the pharyngeal swallow and the neuromuscular events that propel the bolus into the esophagus. Velopharyngeal closure, tongue base posterior motion, pharyngeal contraction, laryngeal elevation and closure, and upper esophageal opening occur to allow bolus passage into the esophagus. Airway protection involves closure of the airway entrance and airway. The vocal folds close and the epiglottis moves downward to prevent food from entering the trachea during this process.

Dysphagia is defined as a condition in which an individual has had an interruption in either eating function or the maintenance of nutrition and hydration.[334] Many patients with neurogenic communication disorders also manifest deficits in swallowing (dysphagia). From 25% to 50% of individuals who have suffered strokes may have swallowing deficits ranging from mild to severe.[176,335-342] In some cases dysphagia is only present in the acute phase with rapid recovery of swallowing function taking place in the first 3 weeks post-stroke.[343] Swallowing deficits in post-stroke patients are often due to a combination of weakness and incoordination of the oral, pharyngeal, and laryngeal musculature, resulting in inefficient propulsion of a food bolus or liquid through the oral cavity, pharynx, and into the esophagus. Delayed triggering of swallowing is common after stroke.[334] Oral or pharyngeal transit times may be slow. Reduced elevation or closure of the larynx may result in material being misdirected into the airway (aspiration). Dysphagia is also often present in patients with Parkinson's disease,[344] Huntington's disease,[345] the dystonias and dyskinesias,[346,347] amyotrophic lateral sclerosis,[348] multiple sclerosis,[349] neoplasm,[350] dementia,[351] Alzheimer's disease,[352] and other degenerative neurological conditions, as well as cerebral palsy.[353] In addition, dysphagia is often present in TBI.[354]

A dysphagia examination usually begins at bedside and is followed by more objective, instrumental techniques if a pharyngeal phase swallowing disorder is suspected. The most frequently used instrumental technique to view swallowing physiology in a dysphagia examination is the modified barium swallow because it provides a radiographic view of the entire oropharyngeal swallow, including structural movement and bolus flow. Precise physiological swallowing disorders can be identified. In addition, the effects of therapeutic strategies on swallow physiology, safety, and efficiency can be examined. Another useful examination procedure is videoendoscopy. In most settings, the swallowing evaluation is carried out by the SLP.[343]

Treatment of Dysphagia

Dysphagia treatment is designed to improve swallowing efficiency for nutritional purposes and to increase swallowing safety. This can be accomplished by compensatory strategies and/or techniques designed to change swallowing physiology and reduce the risk of aspiration. Compensatory strategies include postural changes that affect the way food passes through the mouth and pharynx, dietary management, and placing food in the mouth in optimal positions. Postural techniques may also be introduced to reduce the possibility of aspiration.[338,355] Specific exercises (and maneuvers) are used to increase the coordination, range of motion, strength, and sensory input of the muscles and structures involved in the oral and pharyngeal phases of swallowing.

These exercises are designed to improve initiation of tongue movement, lingual propulsion, laryngeal elevation, closure, and tongue base approximation to the posterior pharyngeal wall.[356-359]

The physical therapist can play an important role in positioning the patient for optimum swallowing and providing treatment to reduce muscle spasticity, improve muscle strength and coordination, and prevent primitive reflex patterns from interfering with swallowing.[360-364] Box 28.2 provides an overview of implications for the physical therapist when treating patients with communication disorders. Table 28.3 presents Web-based resources for patients, families, and caregivers.

Box 28.2 Communication Disorders: Implications for the Physical Therapist

- Physical therapists often work in settings where they may be the first to become aware of a patient's communication disorder. In such situations, a referral should be made to a speech-language pathologist (SLP) for evaluation. The physical therapist can contribute to the patient's improvement in communication function in two important ways: by providing physiological support for speech functions, and by stimulating and facilitating communication through successful, fulfilling interaction with the patient. In either case, the physical therapist will want to work closely with the SLP to ensure that their treatment goals and interventions are compatible.
- The provision of physiological support for speech functions is especially relevant to the patient with pathology of the oral–motor system (e.g., dysarthria). The physical therapist will want to explore the influence of physiological support on the patient's speech in determining a comprehensive plan of care. Proper posture, for example, can help to inhibit reflexes that may trigger primitive movements. When overflow movements influence a patient's speech function, stabilization techniques may be indicated.
- Control of respiration is essential to the improvement of vocalization and the phrasing of speech. The muscles of respiration can be strengthened along with exercises designed to increase head control, stability, and sitting balance. Proper posture and eye contact enhance the possibility that speech will be audible and clear.
- When a patient is prescribed a communication board, the physical therapist contributes by determining a patient's sitting balance and tolerance, upper extremity motor control, and the best method for responding (e.g., pointing).
- Strengthening exercises to increase the speech and range of motion of the tongue, lips, and general facial musculature and to improve coordination of the oral–motor system also increase the probability of intelligible speech and help the patient with dysarthria and dysphagia. Strategies to improve postural control are especially important for patients with dysphagia, who require individual treatment programs designed to facilitate swallowing and prevent aspiration.
- Communication is a social activity and the physical therapy setting is a natural context for social interaction. The setting can be supportive by providing an atmosphere that is conducive to conversation and allows the patient to engage in a successful verbal interaction.
- Patients who are neurologically compromised often have difficulty processing information in a distracting setting. Excessive noise, competing voices, and the presence of other stimuli can make communication particularly difficult. When possible, the physical therapist should strive to work with patients who are communicatively impaired in a closed environment that is free of distractions. Patients with communication impairments do best when they are positioned in such a way that face-to-face communication is possible, including the visualization of gestures and facial expressions. For this reason, room lighting needs to be sufficient.
- Patients who manifest neurogenic speech-language disorders, especially those with aphasia, pose a considerable challenge to effective communication. The individual nature of each manifestation of aphasia argues for a close working relationship with the speech-language pathologist. This will ensure that the most effective communication strategies are used with each individual patient.
- One of the greatest difficulties in addressing the needs of patients with acquired aphasia has to do with determining and accounting for the patient's level of auditory comprehension. Virtually all patients with aphasia have some degree of difficulty in comprehending spoken language. Physical therapists need to become skilled at recognizing and addressing auditory comprehension deficits because they can be a major deterrent to successful rehabilitation.
- Misconceptions of the auditory comprehension level of a patient with aphasia can range from the assumption that a patient understands everything to the assumption that the patient comprehends nothing and must be excluded from conversation. A guiding principle to keep in mind is that auditory comprehension can vary greatly, depending on the context and complexity of the task at hand. Switching topics quickly, speaking too quickly, background noises, talking while a patient is engaged in physical activity, and conversing with more than one person at a time can impede the individual's ability to process auditory information. Sentences should be short and concise and the patient should be given sufficient time to process the information and formulate a response. Open-ended questions that require elaborate answers, such as *"Tell me about your vacation"* or *"What do you think about the latest news?"*

Box 28.2 Communication Disorders: Implications for the Physical Therapist—cont'd

are generally difficult for patients with aphasia to answer. It is best to ask questions that can be answered with "yes," "no," or another single word. Physical cues to comprehension such as gestures, facial expression, and voice inflection can facilitate and enhance a patient's understanding. It is important for the physical therapist to know that patients with aphasia often find it easier to respond to whole-body or axial commands ("stand up," "sit down") than distal commands ("point," "pick up").

- It can be tempting to try to remedy a laborious communication situation by "talking down" to a patient with aphasia as if speaking to a child, or raising one's voice as if speaking to someone with impaired hearing. The best strategy is to speak a little more slowly, using language that is not too complex, and remaining consistent in giving instructions. This can be particularly important in the physical therapy setting, where verbal commands are a fundamental element in the patient–therapist interaction. At times, it may be necessary to repeat a sentence to be understood.
- Rehabilitation team members almost universally overestimate the degree to which a person with aphasia understands spoken language. Physical therapists, when possible, should consult with the SLP for an indication of the patient's preserved auditory comprehension. It may be necessary to rephrase questions and supplement with body language to ensure comprehension.
- The use of accompanying visual cues, such as gestures and facial expressions, can be extremely helpful for some patients. Others may understand best if a message is supplemented by written cues. Sometimes one can assist by asking questions that can be answered by *yes* or *no* in a "20 questions" format. When someone with aphasia is having trouble with verbal expression it usually helps to allow the patient extra time to speak. If the patient becomes visibly frustrated, it is desirable to remain calm and suggest that the patient wait and try again later.
- During physical therapy interventions, patients with aphasia can be encouraged to produce single-word, repetitive speech that coincides with physical movements as a means of providing supplemental speech practice. Examples of this strategy include activities such as counting movements in series one to ten, and using words like *up*, *down*, *left*, and *right* while performing physical movements. The physical therapist, however, should always remain sensitive to the possibility of making speech demands that are beyond a patient's level of preserved communicative skill.

SUMMARY

Ever since World War II, SLPs have played an important role on the rehabilitation team in the management of patients with neurogenic speech-language disorders, especially aphasia and dysarthria. For the physical therapist, an understanding of normal and pathological communication behaviors can not only make this population of patients more interesting to work with, but can also enhance the quality of treatment he or she provides.

Communication using speech is a complex, species-specific behavior that consists of the coordinated interaction of cognitive, motor, sensory, psychological, and social skills. The neurogenic disorders of speech and language, specifically aphasia and dysarthria, dominate the population of patients with communication impairments in the rehabilitation setting. Viewed as a group, patients with neurogenic communication disorders comprise a relatively severely impaired segment of the disabled population.

The impact of neurogenic speech-language disorders on the self, family, community life, and vocational options makes these disorders especially challenging. The close relationship of one's verbal characteristics to personality and identity may cause even the mildest neurogenic communication disorder to affect the psychosocial domain. Current research is investigating the interaction of linguistic, cognitive, and psychosocial variables and their influence on the outcome of recovery and rehabilitation.

Questions for Review

1. Define *aphasia*.
2. Describe the differences that distinguish nonfluent from fluent aphasic syndromes.
3. Discuss the components of a comprehensive language test designed to measure aphasic impairment.
4. Describe some critical factors that influence recovery from aphasia.
5. Describe the psychological sequelae that may have a negative effect on the outcome of aphasia rehabilitation.
6. List several causes of cognitive-communication impairments.
7. Define *dysarthria*.
8. What neurological conditions are generally associated with dysphagia?
9. Describe augmentative communication systems and some specific techniques/devices that may enhance the treatment of aphasia.
10. How can the physical therapist contribute to the physiological support for speech?

CASE STUDY

The patient is a 62-year-old man who teaches high school. He sustained a right hemiplegia and difficulty communicating as the result of a hemorrhagic stroke, which occurred 8 months ago. At this time, except for dressing, he is independent in basic activities of daily living (BADL) and ambulates with a cane.

At 1 month post-stroke, the patient was limited to yes or no responses and a vocabulary ranging from 30 to 50 nouns and verbs, as well as everyday greetings (hello, goodbye). In the course of a communicative interaction, he often resorted to writing a letter or word or gesturing to help in his communication efforts. He appeared to understand most of what was said, especially when the topic was familiar. He received rehabilitation services during the acute post-stroke phase while hospitalized and received 20 sessions of speech-language pathology services as an outpatient.

At 8 months post-stroke, the patient's communication disorder is marked by a slow, hesitant production of one- and two-word utterances; easily produced automatic speech (i.e., everyday greetings); difficulty expressing complex information; awkward and labored articulation, which causes occasional articulatory imprecision; impaired writing; and some difficulty reading lengthy or complex material. Although the majority of his speaking vocabulary consists of nouns and verbs, adverbs and adjectives are now used with greater frequency. There is a persistent lack of conjunctions, articles, and prepositions in speech, which causes him to have impaired grammar. The patient has no apparent difficulty understanding spoken language except when it is rapid, complex, and/or unfamiliar.

Both the patient and his caregiver report that the frequency of social interactions in his current life has been curtailed dramatically. He continues to see close family members on a regular basis but he rarely sees friends or work companions. The family reports that he is frustrated and depressed over this and feels isolated from the community much of the time. They also indicate that there has been a gradual but noticeable increase in his speaking vocabulary, ability to write, and reading skill. He has recently joined a local stroke group where he hopes to meet others with similar communication difficulties.

GUIDING QUESTIONS

1. A team conference is scheduled the day after you assume treatment responsibilities for the patient. What types of information would you obtain in consultation with the SLP?
2. What communication strategies are generally useful with patients who have sustained a stroke?
3. What approach might you use if the patient became frustrated trying to express himself during a physical therapy treatment?
4. As a physical therapist, what might you do to decrease the patient's sense of isolation and enhance his emotional well-being?
5. In what ways can physical therapy treatment sessions serve to reinforce communication behavior?

Chapter 29

Promoting Health and Wellness

Beth Black, PT, DSc
Janet R. Bezner, PT, PhD

LEARNING OBJECTIVES

1. Explain the importance of health promotion and wellness initiatives.
2. Describe the role of physical therapists in health promotion.
3. Differentiate among the terms *health* and *wellness*, *illness* and *disease*, *quality of life*, *primary*, *secondary*, and *tertiary prevention*, *population health management*, *health promotion*, *health education*, *physical activity*, and *exercise*.
4. Discuss the evolution of models of health from the biomedical model to the current International Classification of Functioning, Disability, and Health (ICF) biopsychosocial model of human functioning.
5. Identify measures of health and wellness, health behaviors, and quality of life.
6. Describe key modifiable personal health behaviors.
7. Identify and discuss key theories of behavior change.
8. Explain motivational interviewing.
9. Explain how physical therapists can incorporate health promotion and wellness concepts into the plan of care for individuals with impairments and disabilities.

PHYSICAL THERAPISTS AS ADVOCATES *1315*
SUMMARY *1315*

THE IMPORTANCE OF HEALTH PROMOTION AND WELLNESS INITIATIVES

Despite being among the wealthiest countries in the world,[1] and spending more than $2.3 trillion a year in health care,[2] the United States is ranked only 31st in healthy life expectancy by the World Health Organization (WHO).[3] Some researchers have predicted that after years of increasing life expectancy, life expectancy in the United States will level off or even decline.[4] Researchers and health professionals are struggling to understand this apparent discrepancy between health care expenditures and healthy life expectancy by examining and addressing the determinants of health in the U.S. population. An individual's health is determined by the interaction of numerous factors, including biology and genetics, social and physical environments, health services, and individual behaviors.[5] The relative contribution of individual behaviors to levels of mortality and morbidity in the United States was first demonstrated in a landmark study published in 1993 by McGinnis and Foege.[6] Tobacco use was estimated to be implicated in 19% of deaths, and poor diet and physical inactivity levels contributed to 14% of deaths in the United States in 1990. Mokdad et al[7] later conducted a similar study to determine the behavioral contributors to premature death in the United States in 2000. Tobacco use was

responsible for 18.1% of deaths, and poor diet and physical inactivity were estimated to be responsible for 16.6% of deaths.

Recent studies of the U.S. population have shown that these key behaviors of smoking, poor diet, and insufficient physical activity continue at high levels in the population. The Behavioral Risk Factor Surveillance System (BRFSS), the largest telephone survey in the world, tracks the health behaviors and health status of over 200,000 adults in the United States annually.[8] The results of the BRFSS show that obesity levels in the country are climbing at an alarming rate (Fig. 29.1).[9]

According to the 2009 BRFSS, 36.2% of the adult population in the United States is overweight, and an additional 27.2% is obese.[10] A majority of the U.S. adult population does not consume the currently recommended five or more servings per day of fruits and vegetables[11] (Fig. 29.2). Almost half of adults in the United States report that they do not engage in recommended levels of physical activity[12] (Fig. 29.3) Given the strong relationship between these key health behaviors and health status, it is clear that the current health-related behaviors of adults in the United States are adversely affecting healthy life expectancy, and efforts to support healthier behaviors are essential.

The nation's current health promotion and disease prevention agenda is articulated in *Healthy People 2020*, a set of national health objectives developed through a wide-reaching collaborative consensus process and published by the U.S. Department of Health and Human Services.[5] Public health experts, government agencies, professional organizations such as the American Physical Therapy Association (APTA), and members of the public all provided input into this important document. The overall framework for *Healthy People 2020* is outlined in Table 29.1.

Given the broad range of factors that contribute to the health of the population, an **ecological approach** will be required to meet the *Healthy People 2020* goals and objectives. Interventions must be delivered not only at the level of the individual, but also at community, organizational, environmental, and policy levels (Fig. 29.4).

A number of topic areas requiring particular attention have been identified in *Healthy People 2020*, and for each of these 42 topic areas there is a set of specific objectives. For example, within the topic area of physical activity, there are 15 objectives (Table 29.2) accompanied by specific targets to be achieved within the next 10 years. The ecological approach to addressing the topic areas is clear

from the breadth of the objectives established for each of these 42 topic areas. For example, in the topic area of physical activity, one objective is to increase individuals' levels of leisure-time physical activity (Physical Activity Objective–1), whereas Physical Activity Objective–15 identifies the need for legislative policies to address environmental factors to support increased levels of physical activity in a community. Progress toward the objectives and specific targets established for *Healthy People 2020* will be tracked by measuring general health status, health behaviors, health-related quality of life and well-being, determinants of health, and measures of health disparities.

THE ROLE OF PHYSICAL THERAPISTS IN HEALTH PROMOTION

Interventions at individual, community, state, and national levels by a broad coalition of public health organizations, health professionals, educators, and government agencies will be required to achieve the objectives outlined in *Healthy People 2020*. All health professionals, regardless of their site or area of practice, have a key role to play in health promotion, either as individual practitioners or as members of an interprofessional health care team.[13] Physical therapists are participating in health promotion initiatives in a variety of ways, from examining what their role should be to providing individual and community-level interventions and programs.[14-17] A number of professional publications describe the important role for physical therapists in the area of health promotion and wellness.[18-21]

The *Guide to Physical Therapist Practice* clearly identifies health promotion and prevention as being within the scope of physical therapist practice.[18] It states, "Physical therapists provide prevention services that forestall or prevent functional decline and the need for more intense care. Through timely and appropriate screening, examination, evaluation, diagnosis, prognosis, and intervention, physical therapists frequently reduce or eliminate the need for costlier forms of care and also may shorten or even eliminate institutional stays. Physical therapists also are involved in promoting health, wellness, and fitness initiatives, including education and service provision that stimulate the public to engage in healthy behaviors."[18, p. S32] The patient history portion of the examination should include information about the client's health status and health habits, a systems review, and tests and measures as indicated to screen for potential problems that could affect current or future health status, such as hypertension, obesity, impaired balance, or poor fitness levels. Interventions that physical therapists can utilize to promote health and prevent or minimize impairments, activity limitations, and disabilities are extensive and can include such diverse activities as education in healthy lifestyle choices and healthy behaviors, physical activity and aerobic conditioning programs, fall prevention programs, or consultation in workplace redesign. Referrals to other professionals or special programs (e.g., smoking cessation or nutritional counseling) may also be indicated. The principles of evidence-based practice should be considered as physical therapists expand their practices to include not only rehabilitation, but also health promotion. Decisions regarding appropriate programs to institute should be based on evidence of effectiveness of the intervention, the knowledge and skill level of the physical therapist, and the appropriateness of that particular intervention for the individual client given his or her unique needs, preferences, and circumstances.

In the document titled *Professionalism in Physical Therapy: Core Values*, physical therapist behaviors believed to represent the behaviors of a doctoring profession include the following:[21, pp. 1-3]

- Participating in the achievement of health goals of patients/clients and society
- Focusing on achieving the greatest well-being and the highest potential for a patient/client
- Facilitating each individual's achievement of goals for function, health, and wellness
- Participating in achievement of societal health goals

These behaviors indicate a broad role and responsibility for physical therapists in health promotion and suggest the need for physical therapists to participate not only at the individual client level, but also at a societal level. Physical therapists are participating in discussions at a national level regarding public policy, health care reform, and major health initiatives, and are also involved in advocacy efforts to support the objectives articulated in *Healthy People 2020*.[22]

At the Physical Therapy and Society Summit (PASS) meeting, future roles for physical therapists were discussed relative to the evolving health care needs of society.[23] At this conference, the opportunity for physical therapists to take a leadership role in the area of prevention, health, and wellness was emphasized. There has also been a suggestion that physical therapists should be "birth to death" health practitioners, providing regular consultations on exercise and physical activity using a practice model that is similar to the dental model and geared toward prevention and health promotion.[24]

Given the tremendous need for health promotion, and the unique knowledge base and skill set of physical therapists, it is the professional responsibility of all physical therapists to engage in health promotion practice regardless of their practice setting. As physical therapists begin to integrate health promotion interventions into their clinical practice, they should become familiar with the various terms and definitions used in the field of health promotion.

KEY TERMS IN HEALTH PROMOTION

Health and Disease

Different terms are used in the field of health promotion to define **health**. Although health may be seen as pertaining to the physical domain only, most currently used definitions of health conceptualize and describe health as a multidimensional construct involving more than the physical domain. In 1948, the WHO defined health as "a state of complete physical, mental and social well-being and not merely the absence of disease," the definition of health still used by the WHO today.[25] Health has also been described as "a dynamic balance of physical, emotional, social, spiritual, and intellectual health."[26, p. iv] **Disease**, often considered the opposite of health, is defined as a pathological condition affecting the body.[18]

Wellness and Illness

The term **wellness** is also used in the field of health promotion. In 1959, Dunn discussed the relationship between body, mind, and spirit, and defined wellness as "a complex state made up of overlapping levels of wellness."[27, p. 786] Adams et al[28] defined wellness as an individual's sense of growth and balance across the physical, spiritual, emotional, intellectual, social, and psychological domains (Fig. 29.5). These two wellness definitions are worded in such a way that individuals with chronic disease could still be considered "well."

Corbin and Pangrazi describe wellness as "a multidimensional state of being describing the existence of positive health in an individual as exemplified by quality of life and a sense of well-being."[29, p. 1] Some current definitions of health appear similar to definitions of wellness, particularly those definitions of health that include more than the physical domain. Some in the health promotion field conceptualize wellness as a process versus a state.[30] Taken together, these various definitions of wellness indicate that wellness is multidimensional, that **salutogenic** or "health-causing" variables play a key role in well-being, and that the concept of wellness is specific to each individual. **Illness** is the opposite of wellness, is multidimensional, and has been defined as a social construct where individuals are not achieving balance in their lives and are unable to create a higher quality of life.[31]

Quality of Life

There are a number of different definitions for **quality of life**. The Centers for Disease Control and Prevention (CDC) describes health-related quality of life as an individual's or group's perceived physical and mental health over time.[32] Green and Kreuter describe quality of life as "the perception of individuals or groups that their needs are being satisfied and that they are not being denied opportunities to achieve happiness or fulfillment."[33, p. 508]

Health Promotion Models

Primary, Secondary, and Tertiary Prevention

Various health promotion models are used to identify needs and plan health promotion interventions. One such model is the health protection/disease prevention model. Within this model, health is conceptualized as the absence of disease/pathology, and health promotion is therefore aimed at preventing disease. Interventions in this model are categorized as primary, secondary, or tertiary prevention[34] (Fig. 29.6).

Primary prevention includes activities designed to prevent injury or the onset of illness or disease. The use of bicycle helmets and seat belts, water fluoridation, and immunizations are all examples of primary prevention. Physical therapists practice primary prevention when they conduct preseason evaluation and conditioning programs for high school athletes or teach back injury prevention programs at orientation programs for workers in a factory.

Secondary prevention interventions take place following the development of pathology and are intended

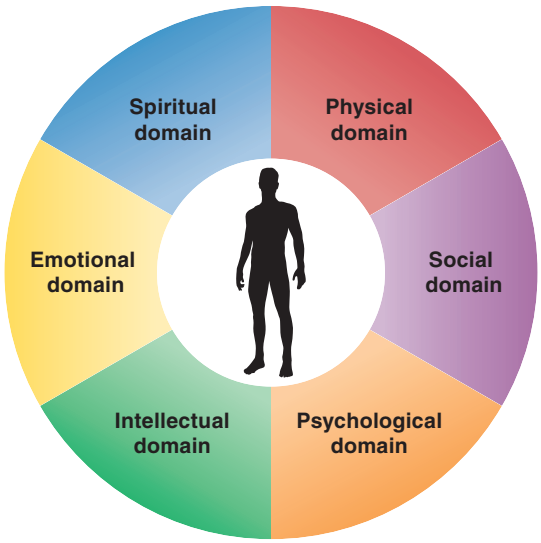

Figure 29.5 Domains of wellness.

Prepathology	Pathology Present	
Goals: Protect health Prevent disease Promote health	Goal: Early diagnosis and intervention to limit impairment and disability	Goal: Rehabilitation following significant impairment or disability
Primary prevention	Secondary prevention	Tertiary prevention

Figure 29.6 Primary, secondary, and tertiary prevention.

to identify and provide treatment for individuals in the early stages of disease in order to minimize the severity of the disease. Screening programs for breast cancer, high blood pressure, and osteoporosis are designed to identify and treat pathology in its earliest stages. Physical therapists engage in secondary prevention when they treat a patient/client with a recent injury or who has been recently diagnosed in the early stages of a chronic condition or disease.

Tertiary prevention activities are designed to slow progression of the disease and improve quality of life. Physical therapists engage in tertiary prevention when they work with patients/clients who have chronic disease or have sustained an irreversible injury—for example, with patients/clients who have long-standing rheumatoid arthritis. Physical therapists have traditionally participated primarily in secondary or tertiary prevention, but as they begin to join their fellow health professionals in health promotion practice, they will increasingly add interventions that fall under the category of primary prevention.

Population Health Management Model

A similar model to the health protection/disease prevention model is the population health management model, which is used to describe health promotion and prevention interventions for a population across a continuum of health risk[35] (Fig. 29.7). The population health management approach categorizes individuals based on risk for developing a disease, and then provides the appropriate intervention for the identified risk factor. Individuals at low or very minimal risk for disease receive interventions to keep them from moving across the continuum to a high-risk category or to actual development of disease or pathology.

HEALTH PROMOTION AND HEALTH EDUCATION

Green and Kreuter describe **health promotion** as "any planned combination of educational, political, regulatory, and organizational supports for actions and conditions of living conducive to the health of individuals, groups, or communities."[33, p. 506] The WHO defines health promotion as "the process of enabling people to increase control over, and to improve, their health. It moves beyond a focus on individual behaviour towards a wide range of social and environmental interventions."[36] Gorin and Arnold[37] describe health promotion as activities undertaken to encourage well-being that are directed toward actualizing an individual's potential. According to Gorin and Arnold, a health promotion model has a more positive orientation and connotation than the prevention models described above that focus on simply preventing disease. **Health education** is one component of health promotion. Green and Kreuter define health education as "any planned combination of learning experiences designed to predispose, enable, and reinforce voluntary behavior conducive to health in individuals, groups, or communities."[33, p. 506] Health education interventions aim to provide information to individuals and groups about health-causing actions and the impact of negative health behaviors in order to make a connection between voluntary behaviors and health. The first step toward positive health behavior change is awareness about the relationship between behavior and disease and injury.

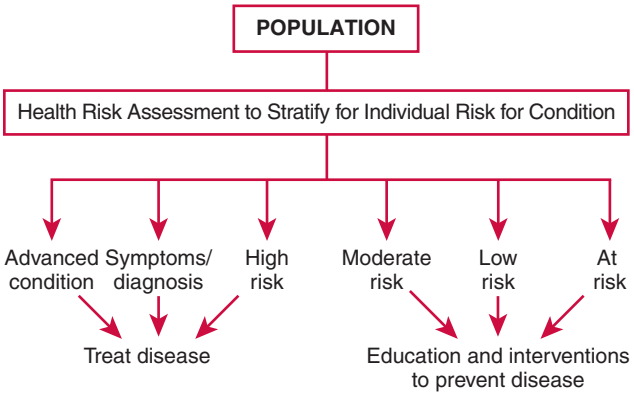

Figure 29.7 Population health management.

PHYSICAL ACTIVITY AND EXERCISE

The definitions for physical activity and exercise are not synonymous. **Physical activity** is defined as any body movement produced by skeletal muscle contraction that increases energy expenditure above resting level.[38] It includes body movement carried out not only within formal exercise programs, but also in occupational activities, leisure activities, and transportation activities such as walking and bicycling. **Exercise** is defined as a subcategory of physical activity, and is planned, structured activity that is intended to improve or maintain one or more components of physical fitness.[39] This differentiation is important for physical therapists to consider when they work with patients/clients to help them increase their overall levels of physical activity.

THE INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH AND HEALTH PROMOTION

Consistent with the newer multidimensional definitions of health and wellness, there has been a change in the overall framework used to guide evaluation, planning, and interventions to support and promote health. The prevailing model used in 20th century medicine was the **biomedical model**.[40] This model was based on the biological sciences, and health was conceptualized as the absence of disease. The locus of control in the biomedical model was with the health care providers and the patient was provided with the medical care deemed necessary by

health professionals. It was an effective model for managing acute and infectious diseases and illnesses, but proved less effective for managing chronic disease[40] or in addressing the psychological, social, or behavioral dimensions of illness.[41] With its primarily biological focus and external locus of control, it was also less useful in the field of health promotion where patients' decisions, behaviors, and environments are considered important elements in understanding and addressing the multiple determinants of health.[42] As the limitations of using a purely biomedical framework to understand the concept of health became apparent, the **biopsychosocial** model evolved. The various biopsychosocial models used today to explain health and illness incorporate those domains missing from the biomedical model, namely the psychological and social domains. The Nagi disablement model[43] is an example of a biopsychosocial model and was the model used to describe physical therapist practice in the *Guide to Physical Therapist Practice*.[18]

In 2001, the WHO endorsed the International Classification of Functioning, Disability, and Health (ICF) biopsychosocial model.[44] The ICF is intended to provide a common language to describe health, function, and disability to facilitate scientific communication within and across health professions. The APTA has endorsed the use of this model as a framework for physical therapists to use in classifying and describing health, function, and disability.[45] In this model, the complex interrelationships of biological, environmental, and personal factors and the impact of these variables on health, activity, and function are recognized. See discussion of the ICF model in Chapter 1, Clinical Decision Making.

Physical therapists have already begun the process of applying the ICF model to physical therapist practice in rehabilitation.[46-48] A number of health professionals have also started to demonstrate how the ICF can be used in the field of health promotion research and practice.[49-52] Howard et al[50] argue that the ICF, with its acknowledgment of the important contribution of the social and physical environment to an individual's health, supports the ecological approach used in the field of health promotion. The ICF provides both the rationale for physical therapists to look beyond purely biological and physiological factors when examining and evaluating their clients and a framework to guide their plans of care and interventions. Furthermore, the ICF model is consistent with many of the behavior change theories described later in this chapter that are used to plan and implement behavior change interventions.

MEASURES OF HEALTH, WELLNESS, QUALITY OF LIFE, AND HEALTH BEHAVIORS

There is no one standard tool for measuring health, wellness, health behaviors, or quality of life. Some tools have been specifically designed to measure the health or health behaviors of a population, whereas other tools are used to measure health and personal health behaviors at the level of the individual patient. A variety of measures of perceived health and quality of life have been developed and can be used at the level of a population, as well as at the level of the individual patient.

Clinical Measures of Health

Clinical measures of health include biometric and physiological measures such as body mass index (BMI), aerobic capacity, or blood pressure. Health risk appraisals (HRAs) are increasingly being used in workforce wellness programs to help assess the level and nature of an individual's current health risks based on history, personal behaviors, and clinical variables. The goal of a health risk appraisal is to provide information about the individual in order to plan and deliver specific interventions targeted to address his or her unique risk factors.[53]

The *Guide to Physical Therapist Practice* recommends that an evaluation of a patient/client's current health status and potential health risks be included in the initial examination through a thorough history and a systems review.[18] Numerous tests and measures can be used by physical therapists during initial examinations to measure patients'/clients' general health status and risk factors.[18]

Self-perceived Health, Wellness, and Quality-of-Life Measures

The importance of adding a measure of an individual's perception of his or her general health to the patient/client examination was demonstrated in a landmark study by Mossey and Shapiro in 1982.[54] In this study of 3,128 noninstitutionalized adults over age 64, self-rated health was the strongest predictor of mortality after age, and was found to be a better predictor of mortality than a number of morbidity and health care utilization measures such as medical diagnosis, number of physician visits, number of hospital admissions, and surgical history. The CDC includes a 14-item perceptual measure of health, the *Healthy Days Measure,* in the annual national BRFSS survey and in the National Health and Nutrition Examination Survey.[55] The National Institutes of Health is developing a *Patient-Reported Outcomes Measurement Information System (PROMIS)* that will be able to capture important health-related quality-of-life information about patients who have chronic diseases and conditions.[56] The goal of the PROMIS initiative is to be able to develop profiles of PROMIS scores across health domains for various chronic conditions that can then be used in clinical research studies. The WHO has developed the *World Health Organization Quality of Life Questionnaire (WHOQOL-100)*[57] and a shorter version, the *WHOQOL-Bref.*[58] Both versions measure self-perceived physical health, psychological health, social relationships, and the individual's perceptions about his or her environment. The WHO tools can

be used for the measurement of health at either the population level or the level of the individual patient/client.

Some self-report measures of perceived health, wellness, and quality of life are generic and can be completed by clients with a variety of conditions. One of the most commonly used measures of self-perceived health and quality of life is the *Medical Outcomes Study 36-Item Short-Form Health Survey (SF-36)*.[59] The SF-36 measures self-perceived health and function across eight scales that include physical, psychological, social, and emotional domains. It has been used in general populations and in specific populations, and normative scores for various groups and populations have been documented. Additional measures of self-perceived health used in clinical practice include the *Nottingham Health Profile*,[60] the *Sickness Impact Profile (SIP)*,[61] the *Dartmouth Cooperative Functional Assessment Charts (Dartmouth CO-OP charts)*,[62] and the *Duke Health Profile*.[63] The *Perceived Wellness Survey (PWS)* measures self-perceived wellness across psychological, physical, emotional, spiritual, social, and intellectual domains.[28] The survey consists of 36 statements with six items for each of the six domains. A composite score, a magnitude score, and a balance score can be computed (see Appendix 29.A). This tool has been tested and found to be valid and reliable for use with different populations.[28,64]

Disease-specific Measures of Self-perceived Health, Wellness, and Quality of Life

A number of disease-specific health and wellness measures have been developed for use with specific clinical populations. The items included in these measures may more specifically address issues related to the health and well-being of a particular population than the general measures described above. The *Arthritis Impact Measurement Scale (AIMS)*[65] and *AIMS2*[66] were developed to measure the physical, mental, and social domains of health in persons with rheumatic diseases. The *Child Health Questionnaire (CHQ)* measures the physical and psychosocial well-being of children, and has been found to be a valid and reliable measure of health status across a variety of conditions and disorders.[67] The *Cystic Fibrosis Questionnaire*[68] is a health-related quality-of-life questionnaire that has both parent and child versions to measure the physical, emotional, and social impact of cystic fibrosis on children and their families. Additional disease or condition-specific quality-of-life measures that have been developed include a health and quality-of-life measure for individuals who have had a stroke,[69,70] suffer from acute and chronic facial disorders,[71] and have chronic respiratory disease.[72] The *European Organisation for Research and Treatment of Cancer (EORTC)* has developed a series of questionnaires designed to assess the quality of life of individuals with cancer. The 30-item EORTC quality-of-life measure has been translated and validated into 81 languages, and has disease-specific modules that can be added to it.[73]

Assessing Health Behaviors

Reeves and Rafferty[74] identified four key behaviors as most indicative of a healthy lifestyle: engaging in regular physical activity, eating sufficient daily servings of fruits and vegetables, maintaining a healthy weight, and abstaining from smoking. It is currently recommended that health professionals routinely include an evaluation of these behaviors in their initial assessments of patients/clients.[75,76] The *Guide to Physical Therapist Practice* also recommends that physical therapists include questions regarding health-related behaviors in initial examinations.[18] The health behaviors of engaging in regular physical activity, eating sufficient fruits and vegetables, and abstaining from smoking can be determined through patient interview or through a questionnaire. If the anthropometric measures of height and weight are taken, the client's BMI can be calculated, and the physical therapist can determine whether the patient/client is overweight or obese (Box 29.1).

The *International Physical Activity Questionnaire*,[77] originally developed to track levels of physical activity in populations, has also been used in clinical practice to assess individual patient/client's levels of physical activity.[78] Research is underway to develop a general health behaviors questionnaire that can be used to collect key health behavior information in an efficient manner in the primary care setting.[79]

KEY MODIFIABLE PERSONAL HEALTH BEHAVIORS

The CDC's Healthy Living website provides information about numerous behaviors that contribute to a healthy lifestyle.[80] Some of the health behaviors have the support of organizations, agencies, and schools, for example healthy menus in school cafeterias, while others are enforced by local, state, or federal laws, such as seat belt use or nonsmoking environments. Others, though significantly influenced by social, environmental, and economic factors, are primarily the personal responsibility of the individual, such as maintaining a healthy weight, eating a healthy diet, and engaging in physical activity. Some personal health behaviors are considered to be more changeable than others based on clinical research. Behaviors that are more challenging to change

Box 29.1 Body Mass Index (BMI)

BMI	Weight Status
Below 18.5	Underweight
18.5 to 24.9	Normal
25.0 to 29.9	Overweight
30 or higher	Obese

are those with an addictive component, those with compulsive elements, and those strongly associated with cultural or family routines, such as diet.[33] The key behaviors of increasing physical activity, increasing fruit and vegetable consumption, and quitting smoking, all included in the objectives of *Healthy People 2020*, have been shown to be modifiable behaviors if the behavior change interventions are appropriately designed and delivered.

The U.S. Preventive Services Task Force (USPSTF) publishes recommendations for various preventative screening measures and health behavior change interventions based on the most current evidence of the effectiveness of interventions in changing or modifying behavior.[81] Clinicians can order a manual with these guidelines from the Agency for Healthcare Research and Quality[82] or can use a website-accessed electronic tool to quickly obtain this information within the clinical setting.[83] Although more research is needed to support the best counseling interventions to increase physical activity, the current evidence-based USPSTF recommendations for physical activity counseling are shown in Box 29.2.

A recent systematic review of the effectiveness of counseling to improve diet and increase physical activity found that behavioral counseling can change these behaviors if the counseling is provided at a sufficient intensity.[84] Given the empirical evidence to support the efficacy of smoking cessation programs, the USPSTF currently recommends that all health care practitioners ask their patients about tobacco use and make appropriate referrals when indicated.[85] There is also evidence to support the relationship between intensive physical activity interventions and decreased risk of falls in older adults.[86] There are, therefore, clinical research studies that support the value of clinicians addressing the modifiable behaviors of tobacco use, unhealthy eating, and inadequate physical activity with their patients/clients. Research in the profession of physical therapy has shown that some physical therapists have already started to address health behaviors with their clients,[14,15,17] but more therapists should be encouraged to engage in these discussions with their patients/clients. It may be necessary to ensure that physical therapists receive additional training in how to counsel patients/clients in behavior change.[87]

THEORIES OF BEHAVIOR CHANGE

The decision to engage in or change a health-related behavior is the result of a complex interaction of numerous factors. Just as physical therapists must understand theories of motor control when planning interventions to improve motor function, an understanding of key theories of health behavior change is necessary if physical therapists are going to be effective in helping clients change their behaviors. Various theoretical models of human behavior have been developed and can be categorized as individual models, interpersonal models, and community and group models.[88] Behavior change interventions based on these different theories have been carried out in clinical research trials and have been found to be effective in different situations with different populations.[88]

Health Belief Model

One of the earliest theoretical models developed to explain health behaviors was the *Health Belief Model* (HBM).[89] This individual model of health behavior

Box 29.2 U.S. Preventive Services Task Force Recommendations for Physical Activity Counseling

- Regular physical activity helps prevent cardiovascular disease, hypertension, type 2 diabetes, obesity, and osteoporosis. It may also decrease all-cause morbidity and lengthen life span.
- Benefits of physical activity are seen at even modest levels of activity, such as walking or bicycling 30 minutes per day on most days of the week. Benefits increase with increasing levels of activity.
- Whether routine counseling and follow-up by primary care physicians results in increased physical activity among their adult patients is unclear. Existing studies limit the conclusions that can be drawn about efficacy, effectiveness, and feasibility of primary care physical activity counseling. Most studies have tested brief, minimal, and low-intensity primary care interventions, such as 3- to 5-minute counseling sessions in the context of a routine clinical visit.
- Multicomponent interventions combining provider advice with behavioral interventions to facilitate and reinforce healthy levels of physical activity appear to be the most promising. Such interventions often include patient goal setting, written exercise prescriptions, individually tailored physical activity regimens, and mailed or telephone follow-up assistance provided by specially trained staff. Linking primary care patients to community-based physical activity and fitness programs may enhance the effectiveness of primary care clinician counseling.
- Potential harms of physical activity counseling have not been well defined or studied. They may include muscle and fall-related injuries or cardiovascular events. It is unclear whether more extensive patient screening, certain types of physical activity (e.g., moderate vs. vigorous exercise), more gradual increases in exercise, or more intensive counseling and follow-up monitoring will decrease the likelihood of injuries related to physical activity. Existing studies provide insufficient evidence regarding the potential harms of various activity protocols, such as moderate compared with vigorous exercise.

was initially developed and articulated in the 1950s, when social psychologists in the U.S. Public Health Service found that despite public education about the merits of various screening programs, for example, tuberculosis screening, large numbers of adults did not participate in the programs. Over the years, the HBM has been developed and extended to incorporate additional concepts and to explain a variety of health-related behaviors beyond screening. In the HBM, it is hypothesized that an individual's perceptions about his or her susceptibility to and the severity of the disease, along with beliefs about the benefits and barriers of taking the recommended action, will influence the decision to act (Fig. 29.8). Demographic variables, sociopsychological variables, cues to action (internal and/or external factors promoting the behavior change), and *self-efficacy*, defined as the confidence one has that one can successfully execute the action, will also influence the individual's decision to engage in the behavior. Results from numerous research studies conducted with different populations have provided support for this theoretical model,[88] and interventions based on this model have been found to be effective in supporting behavior change.[90-92] If using this model in the clinical setting to promote healthy behaviors, the clinician would first assess the individual's beliefs and perceptions relative to his or her health condition and the recommended health actions. Based on this assessment, the clinician would then provide appropriate interventions, for example, educating the individual about his or her susceptibility to the disease or the effectiveness of a recommended health behavior.

Theory of Reasoned Action and Theory of Planned Behavior

The *Theory of Planned Behavior*, along with its predecessor, the Theory of Reasoned Action, is an individual model of health behavior that emphasizes the importance of and relationship between cognitions (thought processes) and behavioral intention. In 1967 Fishbein proposed the *Theory of Reasoned Action*, in which he hypothesized that an individual's attitudes and beliefs about a particular behavior directly influence the intention to engage in that behavior, which then leads to the actual behavior.[93] The theory was later expanded to include the construct of perceived behavioral control and renamed the Theory of Planned Behavior[94] (Fig. 29.9).

The key constructs in this theoretical model are attitude toward the behavior, subjective norm, perceived behavioral control, and behavioral intention (Table 29.3). Clinical studies that have examined a variety of health-related behaviors have provided empirical support for the constructs and the relationships articulated in this theory.[88,95-97] A clinician using this theoretical model to design a clinical intervention to change a behavior should begin by assessing the individual's attitude toward the behavior and the individual's perceptions regarding what significant others think about the behavior. The individual's perceived behavioral control can be ascertained by inquiring about any personal, social, or environmental barriers that might limit the ability to successfully engage in the behavior. The clinician can then tailor the intervention to the individual by addressing any areas that were identified. For example, the clinician may need to help the individual problem solve to address a perceived barrier to engaging in the recommended behavior.

Transtheoretical Model (Stages of Change)

The *Transtheoretical Model* (TTM), first articulated by Prochaska in 1979, is categorized as an individual model of health behavior.[98] Key constructs within the TTM includes stages of change, decisional balance, self-efficacy, and processes of change (Table 29.4).

Prochaska[98] hypothesized that there are five stages of change: *precontemplation, contemplation, preparation, action,* and *maintenance* (Box 29.3). A sixth stage called *termination* is occasionally included as the final stage of change, and is defined as the stage when an individual has engaged in the behavior for more than 6 months, is no longer susceptible to temptation, and has high levels of self-efficacy for maintaining the behavior. An individual cycles through the first five stages as he or she makes changes in a particular behavior. Decisional balance and self-efficacy influence an individual's decision to move from one stage to another.

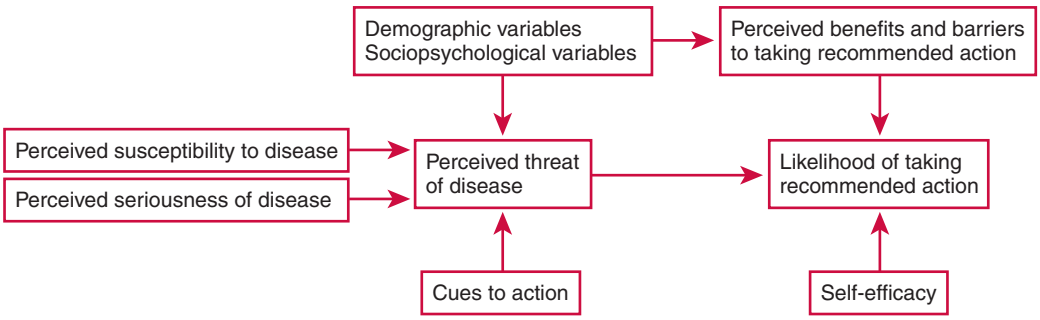

Figure 29.8 Health Belief Model.

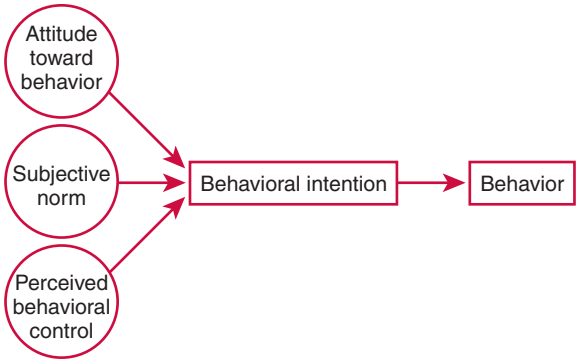

Figure 29.9 Theory of Planned Behavior.

Table 29.3 Key Constructs in the Theory of Planned Behavior[94]

Construct	Definition
Attitude toward behavior	Individual's overall attitude toward the behavior
Subjective norm	Individual's beliefs about whether others approve or disapprove of the behavior
Perceived behavioral control	Individual's perception about the level of control he or she has over the behavior
Behavioral intention	Individual's intention to engage in the behavior, the direct precursor to engaging in the behavior

Table 29.4 Key Constructs in the Transtheoretical Model[98]

Construct	Definition
Stages of Change	The stages an individual moves through when changing a behavior
Decisional Balance	The process of weighing the pros and cons of changing a behavior
Self-efficacy	The confidence the individual has that he or she can successfully engage in the behavior
Processes of Change	Activities used to support progress through stages

Different strategies (processes of change) are employed at different stages to support the behavior change (Table 29.5). Consciousness raising, dramatic relief, and environmental reevaluation are most useful in the earlier stages of change, whereas counterconditioning, helping relationships, reinforcement management, and stimulus control are most useful in the later stages of change.

Clinical interventions based on this theoretical model have been successful in changing behaviors, particularly in the areas of smoking, diet, and physical activity.[88] The TTM has also been examined in a study looking specifically at the exercise behaviors of adults with physical disabilities, and the key constructs and relationships hypothesized in this theoretical model of behavior were supported by the researchers' findings.[99] A clinician using this theoretical model to support behavior change in a client should first start with an evaluation of the individual's stage of change for the behavior, as well as an evaluation of the individual's level of self-efficacy for the behavior. See Box 29.4 for a sample stage of change questionnaire and Table 29.6 for a sample self-efficacy questionnaire. Appropriate processes of change can then be selected and implemented by the clinician to match the individual's stage of change and self-efficacy for the behavior (refer to Table 29.5). Low self-efficacy for the behavior can be addressed by discussing how to maintain the behavior even under challenging conditions.

Box 29.3 Transtheoretical Model: Stages of Change[88]

Precontemplation

- Individual does not intend to take action within the next 6 months

Contemplation

- Individual intends to take action within the next 6 months

Preparation

- Individual intends to take action within the next 30 days, and has taken some preliminary steps

Action

- Individual has engaged in the behavior for less than 6 months

Maintenance

- Individual has engaged in the behavior for more than 6 months

Termination

- Individual engages in the behavior, has high self-efficacy for the behavior, and is no longer tempted to return to the unhealthy behavior

Social Cognitive Theory

The previous models, with the emphasis on the cognitions and behaviors of the individual, can be categorized as individual models of health behavior.[88] *Social Cognitive Theory*, with its additional emphasis on the individual's physical and social environment, is an example of a model of interpersonal health behavior. In a 1962 article on social learning through observation, Bandura[100]

Table 29.5 Transtheoretical Model: Processes of Change[88]

Process of Change	Description	Stage in Which Process of Change Is Used
Consciousness raising	Individual increases level of awareness and acquires information about the behavior	Precontemplation Contemplation
Dramatic relief	Individual experiences negative emotions regarding health risks associated with not changing unhealthy behavior	Precontemplation Contemplation
Environmental reevaluation	Individual evaluates the negative impact on others of continuing the unhealthy behavior	Precontemplation Contemplation
Self-evaluation	Individual considers self-image and examines personal values	Contemplation
Self-liberation	Individual makes a commitment to change behavior	Preparation
Counterconditioning	Individual substitutes healthy behavior for unhealthy behavior	Action Maintenance
Helping relationships	Individual seeks social support for behavior change	Action Maintenance
Reinforcement management	Individual increases rewards for healthy behavior	Action Maintenance
Stimulus control	Individual removes cues for unhealthy behavior, adds cues for healthy behavior	Action Maintenance

Box 29.4 Sample Stage of Change Questionnaire

Circle the number before the statement that best describes your current intentions related to walking 150 minutes a week.

1. I currently do not walk 150 minutes a week and have no intentions to start walking 150 minutes a week. (Precontemplation)
2. I currently do not walk 150 minutes a week but plan to start walking 150 minutes a week sometime within the next 6 months. (Contemplation)
3. I currently do not walk 150 minutes a week but I plan to start walking 150 minutes a week sometime within the next month. (Preparation)
4. I walk 150 minutes a week, but have been doing so for less than 6 months. (Action)
5. I walk 150 minutes a week, and have been doing so for 6 months or more. (Maintenance)

hypothesized that individuals could learn through watching others' behaviors and rewards. In succeeding years, Bandura[101] further developed the theory, added additional constructs, and changed the name of the theory from Social Learning Theory to Social Cognitive Theory. According to Bandura, an individual's behavior is the result of the constant interaction among the individual's environment, personal factors (including cognitions), and behavior through a process called reciprocal determinism (Fig. 29.10).

Key constructs within the theory include environment, situation, behavioral capability, expectations, expectancies, self-control, observational learning, reinforcement, self-efficacy, and emotional coping responses (Table 29.7). According to Bandura, self-efficacy, the confidence that one can successfully engage in the behavior across different challenging situations, is the single most important prerequisite for behavior change: it affects the individual's level of effort and persistence in engaging in the behavior in the face of difficulty.[102]

A number of clinical trials support the constructs and relationships proposed by this theory.[88,103-109] Interventions incorporating Social Cognitive Theory constructs have been effective in changing health behaviors (see Box 29.5 Evidence Summary). Clinical application of this theoretical model requires attention to the key constructs as they apply for a given behavior and client. For example, the clinician may want to evaluate the individual's physical and social environment to determine what elements in the individual's environment must be changed in order to support the particular health behavior being promoted. If the individual does not have the behavioral capability to carry out a particular behavior, education and training in the skills needed to perform the behavior may be required. The clinician should also use a tool to measure the client's self-efficacy for the behavior and if low levels of self-efficacy are found, specific strategies can be incorporated to build confidence

Table 29.6 Sample Self-Efficacy Questionnaire

Place a checkmark (✓) in the box that corresponds to how confident you are that you could keep up your walking program in the following situations:

Situation	Not at All Confident	Slightly Confident	Moderately Confident	Very Confident	Extremely Confident
When there is bad weather					
When I am tired					
When I am having pain					
When I am away from home					
When I have too much work to do					

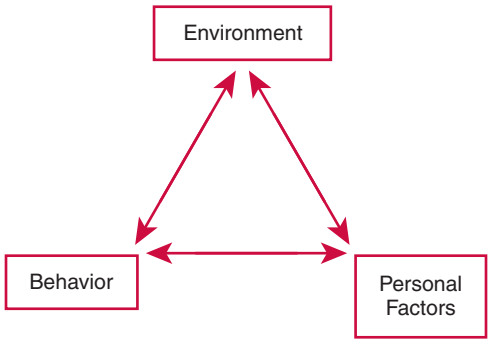

Figure 29.10 Social Cognitive Theory.

(Box 29.6). The role-modeling construct can be incorporated into a behavioral change program by using peer mentors or group leaders.

Physical Activity Model for People with a Disability

The preceding conceptual models can be applied to a variety of health behaviors with diverse populations. The recently proposed *Physical Activity for People with a Disability* (PAD) model has been developed to explain the behavior of physical activity in a population of people with a disability.[110] This model is based on the *Attitude,*

Table 29.7 Key Constructs in Social Cognitive Theory[88]

Construct and Definition	How to Address Construct in Behavioral Change Program
Reciprocal determinism: continuous interaction of individual, behavior, and environment	Consider individual's environment, personal skills, and attitudes when developing strategies to support behavior change
Environment: factors external to the individual that influences behavior	Consider how to incorporate physical and social support for the behavior
Situation: the individual's perception of his or her environment	Correct misperceptions about the environment and the behaviors of others
Behavioral capability: the individual has the knowledge and skills to successfully engage in the behavior	Provide education and skills training
Expectations: the outcomes the individual anticipates from engaging in the behavior	Provide education regarding positive outcomes of the behavior
Expectancies: value the individual places on the outcomes of the behavior	Relate the outcomes to the individual's personal values
Self-control: personal control of the behavior	Incorporate goal-setting and self-monitoring of progress
Observational learning: learning that occurs through watching others successfully engage in the behavior	Consider the use of peers as role models for the behavior
Reinforcement: the positive or negative reinforcement the individual receives after engaging in the behavior	Incorporate self-initiated rewards for meeting goals, and support/encouragement from significant others
Self-efficacy: confidence in ability to successfully perform a specific behavior	Build individual's self-efficacy by breaking the behavior into small achievable steps to ensure success
Emotional coping responses: how the individual copes with emotions	Teach problem solving skills and stress management

Box 29.5 Evidence Summary Studies Incorporating Social Cognitive Theory Constructs to Promote Changes in Levels of Physical Activity

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Annesi et al[103] (2011)	162 obese, sedentary women	Randomized controlled trial Control group: • Exercise prescription for 3 sessions a week at wellness center • Nutritional and weight loss information • Six 1-hour one-on-one meetings with wellness specialist Intervention group: • Exercise prescription for 3 sessions a week at wellness center • Nutritional and weight loss information • Six 1-hour one-on-one meetings with wellness specialist trained in using "Coach Approach" intervention based on Social Cognitive Theory (SCT): cognitive restructuring, goal setting, behavioral contracting, tailored feedback, instruction in self-regulation	6 months	Exercise session attendance was significantly greater for intervention group $p < .001$ Intervention group had greater improvements in Physical Self-Concept, Exercise Barriers Self-Efficacy, and Body Areas Satisfaction than control group.	Subjects in the control group received similar amount of personal contact time with exercise specialist as subjects in the intervention group to control for potential of bias due to Hawthorne effect. Separate facilities used for control and intervention groups to avoid cross-contamination.
Cramp and Brawley[104] (2006)	57 postnatal women	Randomized controlled trial Control group: • Four-week standard exercise program held twice a week at community fitness facility • Four-week home exercise program Intervention group: • Four-week standard exercise program held twice a week at community fitness facility plus six 20-min SCT-based group cognitive behavioral sessions on setting goals, overcoming barriers to exercise, and self-regulation • Four-week home exercise program with one telephone call from program staff member at end of second week	8 weeks	Intervention group had significantly greater change in frequency and amount of physical activity than control group. Intervention group had higher expectations of achieving positive physical outcomes with exercise, and higher self-efficacy for being able to overcome barriers to exercise.	Investigators ensured both groups had equal contact time with staff (10 hours) by increasing staff contact time for the control group during the 4-week standard exercise time.

Box 29.5 Evidence Summary Studies Incorporating Social Cognitive Theory Constructs to Promote Changes in Levels of Physical Activity—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Ince[105] (2008)	62 university students	Quasi-experimental pre-test/post-test design Intervention: • Two hours/week classroom discussion of health-related fitness, self-assessment and self-regulatory skills, group discussions • Two hours/week: Group gym activities	12 weeks	Significant improvement from baseline in nutrition behavior, health responsibility, social support, exercise behavior, stress management, and overall Adolescent Health Promotion Scale scores. Significant improvement from baseline in moderate, vigorous, and total physical activity levels as measured by the International Physical Activity Questionnaire.	No control group; cannot rule out Hawthorne effect.
Mihalko et al[106] (2006)	79 residents of three independent living communities, mean age 81.6	Randomized controlled trial Control group: • Information flyer advertising physical activity session Intervention group: • Information flyer advertising physical activity session plus brief cognitive-behavioral intervention based on SCT	One 30-minute individual counseling session	Significantly higher percentage of subjects in the intervention group attended the physical activity session.	Cannot rule out Hawthorne effect bias to account for increased attendance by intervention group.
Motl et al[107] (2011)	54 individuals with multiple sclerosis	Randomized controlled trial Control group: • Waitlist (no intervention) Intervention group: • Four multimedia Internet modules that included key elements of SCT: self-efficacy, outcome expectations, addressing barriers, and goal setting • Twice a week Internet chat sessions • Internet discussion forum	3 months	Intervention group significantly increased their physical activity level as measured by Godin Leisure-Time Exercise Questionnaire. No significant change in physical activity for control group. Intervention group significantly increased their goal-setting behaviors as measured by the Exercise Goal Setting Scale. No significant change in goal-setting behaviors for control group.	Subjects were paired at intake for physical activity and disability levels and then randomly assigned to either the control or intervention group to ensure similarity of both groups at baseline. Cannot rule out Hawthorne effect because control group did not receive any intervention.

Box 29.5 Evidence Summary Studies Incorporating Social Cognitive Theory Constructs to Promote Changes in Levels of Physical Activity—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
Rogers et al[108] (2009)	41 sedentary women with Stage I, II, or IIIA breast cancer receiving hormonal therapy	Randomized controlled trial Control group: • Received pamphlets about physical activity obtained from the American Cancer Society and were given information about website resources Intervention group: • Multidisciplinary physical activity behavior change program based on key constructs of SCT, and program preferences of subjects • Program components included both group and individual sessions • Six group sessions covered journaling, time management, stress management, dealing with exercise barriers, behavior modification • Twelve individual supervised exercise sessions and three individual counseling sessions with exercise specialists using SCT principles to counsel individuals on exercise and to develop a tailored home exercise program	12 weeks	Statistically significant improvements from baseline levels in physical activity, left handgrip strength, back and leg muscle strength, waist-to-hip ratio, and social well-being in intervention group versus control group.	Sociodemographic characteristics and health-related variables of both groups were similar at start of study. Investigators used an objective measure (accelerometer) for physical activity. Intervention group reported significant increase in joint stiffness.
Wilson et al[109] (2005)	48 underserved adolescents	Quasi-experimental design: Students at intervention school matched for age, gender, race, and percentage of students on free or reduced-price lunch program with students at control school Control school: • Students received four weeks of general health education that did not emphasize physical activity	4 weeks	Students in the intervention group showed a greater increase in time spent in moderate, moderate-vigorous, and vigorous activity from baseline to end of program than students in control group. Students in the intervention group	Groups were similar in sociodemographic variables at baseline. Total research staff/student contact hours were equivalent for both control group and intervention group.

Box 29.5 Evidence Summary Studies Incorporating Social Cognitive Theory Constructs to Promote Changes in Levels of Physical Activity—cont'd

Reference	Subjects	Design/Intervention	Duration	Results	Comments
		Intervention school: • Two hours after school three times a week • Program included a homework-snack component, a physical activity component, and an SCT-based and Self-Determination Theory–based motivational and behavioral component • SCT elements included skill development in self-monitoring and goal setting, and discussions about strategies for engaging in physical activity with friends and family		showed a greater increase in motivation for physical activity and in positive self-concept than students in the control group.	

Box 29.6 Strategies for Enhancing Self-Efficacy[88,101,102]

1. Break the behavior into small achievable steps
2. Set goals, establish a contract
3. Problem solve potential challenges individual might face
4. Mental practice and imagery
5. Log progress, document achievement of goals
6. Use peer role-modeling
7. Ensure positive reinforcement received from others
8. Ensure the correct interpretation of internal physiological states produced by the behavior

Social Influence, and Self-Efficacy (ASE) model.[111] It integrates behavioral theoretical models with disability models, and uses the ICF framework and terminology. In this model, environmental factors and personal factors interact to influence an individual's intention to engage in physical activity. Environmental factors include such variables as transportation, availability and accessibility of facilities, and assistance from others. Environmental factors also encompass social influence variables such as the opinion of family, friends, or health professionals. Personal factors include attitude, self-efficacy, health condition, and facilitators or barriers such as energy level, time, motivation, and skills. The authors of this model suggest that clinical application can include use of the TTM's stages of change. This new model is promising and could provide a helpful framework for physical therapists to use to address the physical activity levels of patients/clients with disabilities. Ongoing research on this model should be focused on identifying the important personal and environmental facilitators and barriers of physical activity for individuals with chronic disease or disability.

Community Models

A number of behavior change theoretical models have been developed to explain behavior change at a community level. Although a thorough discussion of community models is beyond the scope of this chapter, physical therapists who are interested in changing the health behaviors of a group or community may want to familiarize themselves with community and group models of health behavior change, ecological models of health behavior, and intervention planning models such as the *PRECEDE-PROCEED planning model*.[88]

MOTIVATIONAL INTERVIEWING

Motivational interviewing is a client-centered counseling method designed to facilitate a client's internal motivation to change by identifying dissonance between behaviors and values and resolving ambivalence.[112] This counseling technique, initially developed to support behavior change in the treatment of addiction, is now used with a variety of populations where clients' existing behaviors have adversely affected their health or quality of life. It has been effectively used to encourage adherence to medical recommendations in general practice populations, to resolve behavioral issues with criminal

justice populations, and to assist couples undergoing marital counseling.[112] Physical therapists have used motivational interviewing to improve adherence with rehabilitation programs.[113]

The hallmark of this technique is the emphasis on exploring the client's values and having the client recognize discordance between current behaviors and life goals. The clinician begins by asking probing questions to encourage the client to discuss his or her priorities in life and how current behaviors support or do not support those priorities. Encouraging the client to consider the pros and cons of continuing with current unhealthy behaviors versus changing to healthier behaviors may help resolve ambivalence by tipping the balance in favor of behavior change. Reflective listening by the clinician will allow a better understanding of the client's point of view and key contextual information related to potential challenges with behavior change. A clinician who is skilled in the motivational interviewing technique is respectful of personal choice and autonomy, is empathetic, avoids arguments, and provides encouragement to support self-efficacy for behavior change (Box 29.7).

Motivational interviewing has been used in the field of health promotion to encourage change in lifestyle behaviors. Regardless of the underlying theoretical behavior change model being used to structure a health behavior change intervention, motivational interviewing can be incorporated as a technique to engage the client in important collaborative discussions about his or her behaviors. There is some empirical evidence of the effectiveness of this technique in supporting behavior change across a number of health-related behaviors, although more research is needed.[114] It has been shown to be effective in encouraging weight loss,[115] physical activity,[116-119] smoking cessation,[120,121] and fruit and vegetable consumption.[119]

Box 29.7 Key Principles of Motivational Interviewing[112]

1. Express empathy
   - Listen respectfully
   - Do not judge
   - Build therapeutic alliance
   - Accept ambivalence
2. Develop discrepancy
   - Help client identify discrepancy between present behavior and personal goals and values
   - Have client present reasons for change
3. Roll with resistance
   - Avoid arguing
   - Acceptance of reluctance to change as natural
   - Turn problem back to client and encourage client to suggest solutions
4. Support self-efficacy
   - Enhance client's confidence in his or her ability to successfully change behavior

HEALTH PROMOTION AND WELLNESS FOR INDIVIDUALS WITH IMPAIRMENTS AND DISABILITIES

There is evidence that physical therapists in the United States are moving beyond their traditional roles in secondary and tertiary prevention, and engaging in primary prevention and health promotion practice in the general population.[14,15,17,87] Physical therapists are engaging in screening programs,[122,123] ergonomic consultations,[124] and sports injury prevention and conditioning programs.[125]

There is, however, a great need for physical therapists to engage in more health promotion activities with individuals with disabilities and chronic diseases. One of the specific goals stated in *Healthy People 2020* is to increase the number of health promotion programs for people with disabilities.[5] Research has shown that this population has lower levels of physical activity,[126-129] higher rates of smoking,[130] and higher levels of overweight and obesity than the age-matched general population.[131,132] Physical therapists have a unique knowledge and skill set that positions them well to be leaders in health promotion and wellness initiatives for individuals with disabilities. Unlike other health professionals, therapists also interact with patients over extended periods of time. This extended period of interaction and level of accessibility allows time to develop a rapport with patients and provides the therapist an opportunity to be influential in advocating for healthy behaviors.[133]

Examination and Evaluation

The patient management model in the *Guide to Physical Therapist Practice* provides a framework for therapists to carry out an examination and evaluation that will identify potential opportunities for prevention and health promotion interventions.[18] During the history, the therapist should look beyond questions related to a specific impairment and ask about perceived health or use a self-perceived health, wellness, or quality-of-life questionnaire as described earlier. The therapist should also inquire about health-related behaviors such as physical activity and current smoking status. A systems review should be carried out to screen for risk factors for disease or injury, and appropriate follow-up by the physical therapist or referral to other health professionals as indicated should occur. For example, physical therapists should routinely take blood pressure before having the patient/client engage in physical activity not only as a component of safe practice, but also to be able to identify and report hypertension. Therapists who

notice a mole should ask the client if he or she has discussed this predisposing factor for skin cancer with a physician. Fall risk assessments should be conducted with at-risk populations. Based on their examination and evaluation, physical therapists may identify the need to engage patients in discussions about healthy behaviors and discuss the impact unhealthy behaviors may have on recovery. For example, discussion can focus on the impact of nicotine on tissue healing, or high BMI on joint health and overall health and wellness. Referrals should be made to appropriate programs and health professionals when health issues that fall outside of the scope of practice and qualifications of the physical therapist are identified during the examination.

Interventions

Physical Activity/Exercise

The APTA encourages physical therapists and physical therapist assistants to be promoters and advocates for physical activity/exercise.[134] Individuals with chronic disease and disability report lower levels of physical activity and exercise than the general population.[126-129] The lower levels of physical activity/exercise reported by this population may be due to a host of factors, including limited mobility, chronic pain, fatigue, fear of aggravating their condition, or limited access to fitness facilities that have the necessary equipment and personnel to enable safe and effective physical activity.[135-138] Physical therapists are uniquely qualified to evaluate fitness levels and prescribe fitness programs for individuals with medical conditions. The APTA has identified two priority populations requiring the knowledge and skills of physical therapists in physical fitness prescription.[139] The primary priority population consists of individuals with acute and chronic impairments, activity limitations, and disabilities related to movement, function, and health, and the secondary priority population consists of individuals with identified risk for impairments, activity limitations, and disabilities related to movement, function, and health.

A physical therapy exercise program developed for a patient/client to prevent or remediate impairments falls under the category of secondary or tertiary prevention, but if therapists are truly engaging in primary prevention and health promotion, a physical activity and exercise program to improve overall fitness to the maximal level possible for that patient should also be considered. Participation in physical activity may reduce secondary health problems, improve levels of function, and improve subjective well-being in individuals with chronic medical conditions.[140] There is evidence that exercise can improve quality of life in individuals who are stroke survivors.[141] The CDC recommends that adults participate in 150 minutes of moderate-intensity or 75 minutes of vigorous-intensity aerobic activity every week and muscle-strengthening activities on 2 or more days a week.[80] Children should engage in 60 minutes or more of physical activity every day[80] (Table 29.8).

However, these physical activity recommendations were developed for the general population and may not be appropriate for patients/clients with disabilities and medical conditions. Physical activity recommendations should be tailored to ensure safety and effectiveness for the patient's unique medical condition. Physical therapists must consider not only the patient's condition, but also any co-morbidities and potential side effects or limitations associated with medical treatments when prescribing a physical activity program. There are excellent research-based resources to help physical therapists safely test fitness and prescribe exercise for patients with medical conditions.[16,142,143] Beyond appropriate content of a physical activity program,

Table 29.8 Physical Activity Guidelines

Adults	Aerobic activity every week: 150 minutes of moderate-intensity aerobic activity (e.g., brisk walking) **OR** 75 minutes of vigorous-intensity aerobic activity (e.g., jogging or running) **OR** an equivalent mix of moderate- and vigorous-intensity aerobic activity **AND** Muscle-strengthening activities on 2 or more days a week that work all major muscle groups (legs, hips, back, abdomen, chest, shoulders, and arms)
Children and Adolescents	Should do 60 minutes of physical activity each day Aerobic activity should make up most of the recommended 60 or more minutes of daily physical activity. Can include moderate-intensity aerobic activity, such as brisk walking, or vigorous activity, such as running, but should include vigorous-intensity aerobic activity on at least 3 days per week **AND** Muscle-strengthening activities, such as gymnastics or push-ups, at least three days a week **AND** Bone-strengthening activities, such as jumping rope or running, at least 3 days per week

Source: www.cdc.gov/HealthyLiving/.

physical therapists should consider the previously mentioned theories of behavior change and motivational interviewing to support patients/clients and optimize their chance for successful behavior change as they begin to increase their level of physical activity. Patients/clients can also be informed about physical activity programs in the community that are geared to specific populations. Physical therapists and patients/clients should refer to the consumer website of the National Center on Physical Activity and Disability (see Appendix 29.B) for education and specific information about exercise, as well as sports and recreational activities recommended for those with disabilities.[144] The benefits of engaging in sports should be discussed with patients/clients; people with disabilities who engage in sports have reported enhanced function, social benefits, and an increased sense of optimism.[52]

Smoking Cessation Counseling

There is strong evidence that even brief counseling of patients can be effective to support smoking cessation.[145,146] Given the strong evidence of the health risks associated with smoking and clinical evidence of the effectiveness of even brief counseling sessions, Bodner and Dean[146] effectively argue that counseling patients about smoking behaviors falls within the role of physical therapists and that physical therapists, given their prolonged contact with patients over the course of treatment, have the opportunity and the rapport necessary to be effective in smoking cessation counseling. In their systematic review, they found that intervention models based on the motivational interviewing technique are effective. The Agency for Healthcare Research and Quality recommends that clinicians include a question about smoking as part of their examination and evaluation and has designed a specific evidence-based program to assist clinicians in helping their clients address smoking behaviors.[147] The 5-A's tobacco cessation approach recommends that clinicians *A*sk their patients about tobacco use, *A*dvise tobacco users to quit, *A*ssess the client's readiness to quit, *A*ssist the client with a quit plan, and *A*rrange follow-up to review progress toward quitting (Box 29.8). Physical therapists should also be familiar with smoking cessation programs in the local area and refer patients/clients as appropriate to these specialized programs.

Healthy Weight and Healthy Eating Counseling

Overweight and obesity are associated with the development of numerous conditions and diseases[148] (Box 29.9). The *Guide to Physical Therapist Practice* recommends that anthropometric measurements be included in initial examinations. The measurement of height and weight will allow physical therapists to calculate the patient's BMI. Calculators and charts are available on the CDC website (see Appendix 29.B) to assist therapists in calculating the patient/client's BMI.[149]

Physical therapists should take the opportunity to educate the patient about the impact excessive weight has on the patient's current condition and future

Box 29.8 Helping Smokers Quit: A Guide for Clinicians

1. Ask about tobacco use.
Implement a system in your clinic that ensures that tobacco-use status is obtained and recorded.
2. Advise all tobacco users to quit.
Use clear, strong, and personalized language. For example, "Quitting tobacco is the most important thing you can do to protect your health."
3. Assess readiness to quit.
Ask every tobacco user if he or she is willing to quit at this time.

- If willing to quit, provide resources and assistance.
- If unwilling to quit at this time, help motivate the patient:
  - Identify reasons to quit in a supportive manner.
  - Build patient's confidence about quitting.

4. Assist tobacco users with a quit plan.
Assist the smoker to:

- Set a quit date, ideally within 2 weeks.
- Remove tobacco products from his or her environment.
- Get support from family, friends, and co-workers.
- Review past quit attempts—what helped, what led to relapse.
- Anticipate challenges, particularly during the critical first few weeks, including nicotine withdrawal.
- Identify reasons for quitting and benefits of quitting.

Give advice on successful quitting:

- Total abstinence is essential—not even a single puff.
- Drinking alcohol is strongly associated with relapse.
- Allowing others to smoke in the household hinders successful quitting.

Encourage use of prescribed medications.
Provide resources:

- Recommend toll-free number: 1-800-QUIT NOW (784-8669), the national access number to state-based quitline services.
- Refer to websites for free materials: www.ahrq.gov/path/tobacco.htm, www.smokefree.gov.

5. Arrange follow-up
Schedule follow-up.

- If a relapse occurs, encourage quit attempt.
- Review circumstances that caused relapse. Use relapse as a learning experience.
- Make appropriate referrals.

Adapted from www.ahrq.gov/clinic/tobacco/clinhlpsmksqt.htm.

Box 29.9 Conditions Associated with Overweight and Obesity

Hypertension
Dyslipidemia
Type 2 diabetes
Coronary heart disease
Stroke
Gallbladder disease
Osteoarthritis
Sleep apnea and respiratory problems
Endometrial cancer
Breast cancer
Prostate cancer
Colon cancer

health. As specific nutritional counseling is outside the scope of practice of the physical therapist, therapists should refer patients to qualified health professionals as appropriate. Most weight management programs include physical activity and physical therapists have the knowledge and skills to create and implement physical activity programs for high-risk patients/clients.

HEALTH PROMOTION AND WELLNESS AT THE PROGRAM LEVEL

Patients who are discharged from physical therapy to continue their exercise programs independently often find it challenging to find a facility with the necessary equipment or personnel who are sufficiently trained to address their unique medical challenges. Physical therapists have begun to recognize and address this need for physical activity programming that is specifically tailored to address the needs of patients with chronic conditions or disabilities. Fitness and health promotion programs geared to this population and offered in rehabilitation settings are growing in popularity. For example, physical therapists are providing fitness classes and health promotion programs to individuals with osteoporosis, arthritis, and cancer.[150-152] It is important to remember that these programs should comply with licensing requirements for physical therapists in the state, and that the same standards for physical therapist practice must be maintained whether the physical therapist is providing rehabilitation or health promotion interventions. An excellent resource for physical therapists is the APTA website *Physical Fitness for Special Populations* (see Appendix 29.B).[139] The website provides recommendations for the design of fitness programs tailored to the specific needs of individuals with various medical conditions, such as stroke, type 2 diabetes, and pulmonary pathology. The site also provides valuable information about malpractice and professional liability, Medicare coverage for fitness services, and other helpful resources for physical therapists.

PHYSICAL THERAPISTS AS ADVOCATES

One of the goals stated in *Healthy People 2020* is the need for increased health promotion programming for individuals with disabilities.[5] Physical therapists can make a meaningful contribution to the health of the nation by providing health and wellness to this population within their own practices as described above. In addition, physical therapists should recognize their broader social responsibility, as articulated in the *Core Values* document of the professional association, to advocate for the health and wellness needs of all.[21] Physical therapists, with their unique knowledge base and clinical experience, are extremely cognizant of the needs and challenges faced by individuals with chronic disease and disability, and should participate at both the community and national levels to ensure that this population is provided the same access to health promotion and wellness programming as the rest of the population.

SUMMARY

Physical therapists have the knowledge, the skill set, and the opportunity to engage in health promotion practice across the continuum of care. A population in special need of the guidance and support of physical therapists is the population with medical conditions and disabilities who face unique challenges when trying to incorporate healthy behaviors into their lives. At the Physical Therapy and Society Summit (PASS) meeting, the need for more research to be undertaken to better define physical therapists' role in prevention, health, and wellness, especially with respect to consumers with impairments, was identified.[23] The "Revised Research Agenda for Physical Therapy" identifies specific areas in health promotion requiring more investigation and discussion.[153] These areas include the need to examine the effectiveness of specific health promotion interventions related to the physical activity of clients/patients with movement disorders. As the profession

continues to define and develop its role in health promotion and wellness, physical therapists should identify opportunities within their current practice environments to promote optimal levels of health and wellness of their patients/clients.

Questions for Review

1. What factors contribute to the health of an individual?
2. What is *Healthy People 2020*?
3. How does the World Health Organization define *health*?
4. Identify the different domains of wellness.
5. Define *primary*, *secondary*, and *tertiary* prevention.
6. Where in the continuum of primary, secondary, and tertiary prevention have physical therapists traditionally practiced?
7. Differentiate between the terms *health promotion* and *health education*.
8. What is the difference between the terms *exercise* and *physical activity*?
9. What tools could a physical therapist use to measure a patient/client's self-perceived health, wellness, or quality of life?
10. What health-related behaviors should physical therapists inquire about during initial examinations of patients/clients?
11. Describe the following four theories of behavior change: Health Belief Model, Transtheoretical Model and Stages of Change, Theory of Planned Behavior, and Social Cognitive Theory.
12. What is the purpose of motivational interviewing?
13. What are the five steps of the 5-A's tobacco cessation approach?
14. What professional documents support the role of physical therapists in health promotion?

CASE STUDY

Elise Henry is a 72-year-old widow who recently moved into the assisted living center where physical therapy consultation services are provided. The client was referred by a member of the center staff who reports that she is unable to participate in the recreational programs offered by the center due to her physical condition.

PATIENT HISTORY

Mrs. Henry tells the therapist on her initial visit that she is unable to participate in many of the center activities owing to her increasing problems with leg pain. She relates that she was diagnosed with peripheral artery disease 10 years ago. She was not prescribed any medication, but found that if she limited her walking, she could prevent the pain from occurring.

SOCIAL HISTORY

Her former friends live too far away to visit her at the assisted living center. She misses her weekly bridge games with them. Her only son and his family live in another city about an hour's drive away. Her son, daughter-in-law, and two granddaughters visit her about once a month. Her son also phones her every Sunday evening.

SYSTEMS REVIEW

- Height: 5 ft 2 in
- Weight: 145 lb
- Resting heart rate: 72
- Resting blood pressure: 135/85
- No skin breakdown

Rubor of dependency test and pedal pulses are consistent with diagnosis of arterial insufficiency.

HEALTH-RELATED BEHAVIORS

- *Smoking*: Smokes 2 to 3 cigarettes/day; the client has smoked for 50 years.
- *Diet and Nutrition*: Does not eat breakfast, but has coffee and muffins delivered to her room mid-morning. Goes to the center dining room for lunch and dinner. Keeps cookies in her room for snacking during the day.
- *Physical Activity*: She currently spends most of her days watching TV in her room. Her only regular physical activity is walking to and from the dining room for lunch and dinner. The distance from her room to the dining room is approximately 50 feet. She has mild pain in both legs and is slightly short of breath at the end of the walk.

GUIDING QUESTIONS

1. Identify additional tests and/or measures that could be used to assess her level of health.
2. Identify additional tests and/or measures that could be used to assess her level of wellness.
3. What domains of wellness may be at lower levels?
4. Which health-related behaviors might be adversely affecting her health and wellness?
5. How should a conversation about her health and wellness be started?
6. If Mrs. Henry asked for help in changing her behaviors, select a theory of behavior change to guide the intervention. Which behaviors should be targeted?
7. What level of physical activity should Mrs. Henry strive to achieve for health-related benefits?

29.A Perceived Wellness Survey

The following statements are designed to provide information about your wellness perceptions. Please carefully and thoughtfully consider each statement, then select the *one* response option with which you *most* agree.

	Very Strongly Disagree					Very Strongly Agree
1. I am always optimistic about my future.	1	2	3	4	5	6
2. There have been times when I felt inferior to most of the people I knew.	1	2	3	4	5	6
3. Members of my family come to me for support.	1	2	3	4	5	6
4. My physical health has restricted me in the past.	1	2	3	4	5	6
5. I believe there is a real purpose for my life.	1	2	3	4	5	6
6. I will always seek out activities that challenge me to think and reason.	1	2	3	4	5	6
7. I rarely count on good things happening to me.	1	2	3	4	5	6
8. In general, I feel confident about my abilities.	1	2	3	4	5	6
9. Sometimes I wonder if my family will really be there for me when I am in need.	1	2	3	4	5	6
10. My body seems to resist physical illness very well.	1	2	3	4	5	6
11. Life does not hold much future promise for me.	1	2	3	4	5	6
12. I avoid activities that require me to concentrate.	1	2	3	4	5	6
13. I always look on the bright side of things.	1	2	3	4	5	6
14. I sometimes think I am a worthless individual.	1	2	3	4	5	6
15. My friends know they can always confide in me and ask me for advice.	1	2	3	4	5	6
16. My physical health is excellent.	1	2	3	4	5	6
17. Sometimes I don't understand what life is all about.	1	2	3	4	5	6
18. Generally, I feel pleased with the amount of intellectual stimulation I receive in my daily life.	1	2	3	4	5	6
19. In the past, I have expected the best.	1	2	3	4	5	6
20. I am uncertain about my ability to do things well in the future.	1	2	3	4	5	6
21. My family has been available to support me in the past.	1	2	3	4	5	6
22. Compared to people I know, my past physical health has been excellent.	1	2	3	4	5	6
23. I feel a sense of mission about my future.	1	2	3	4	5	6
24. The amount of information that I process in a typical day is just about right for me (i.e., not too much and not too little).	1	2	3	4	5	6
25. In the past, I hardly ever expected things to go my way.	1	2	3	4	5	6
26. I will always be secure with who I am.	1	2	3	4	5	6
27. In the past, I have not always had friends with whom I could share my joys and sorrows.	1	2	3	4	5	6

	Very Strongly Disagree					Very Strongly Agree
28. I expect to always be physically healthy.	1	2	3	4	5	6
29. I have felt in the past that my life was meaningless.	1	2	3	4	5	6
30. In the past, I have generally found intellectual challenges to be vital to my overall well-being.	1	2	3	4	5	6
31. Things will not work out the way I want them to in the future.	1	2	3	4	5	6
32. In the past, I have felt sure of myself among strangers.	1	2	3	4	5	6
33. My friends will be there for me when I need help.	1	2	3	4	5	6
34. I expect my physical health to get worse.	1	2	3	4	5	6
35. It seems that my life has always had purpose.	1	2	3	4	5	6
36. My life has often seemed void of positive mental stimulation.	1	2	3	4	5	6

PWS Scoring Sheet for Use with Individual Clients

Instructions: Record your score from the PWS instrument for each numbered item below. Note the * items indicating reverse scoring. Add the numbers in each column and divide by 6 to determine each subscale score.

SECTION THREE

Orthotics, Prosthetics, and Prescriptive Wheelchairs

Orthotics

Joan E. Edelstein, PT, MA, FISPO, CPed
Christopher Kevin Wong, PT, PhD, OCS

Chapter 30

LEARNING OBJECTIVES

1. Relate the major parts of the shoe to the requirements of individuals fitted with lower extremity orthoses.
2. Compare the characteristics, advantages, and disadvantages of plastics, metals, and other materials used in orthoses.
3. Describe the components of contemporary foot, ankle-foot, knee-ankle-foot, hip-knee-ankle-foot, trunk-hip-knee-ankle-foot, and trunk orthoses.
4. Explain the orthotic options available for patients with paraplegia.
5. Identify the features of lower extremity and trunk orthoses that are considered during the examination process.
6. Outline the physical therapist's role in management of patients fitted with lower extremity and trunk orthoses.
7. Analyze and interpret patient data, formulate realistic goals and outcomes, and develop a plan of care when presented with a clinical case study.

CHAPTER OUTLINE

TERMINOLOGY AND TYPES OF ORTHOSES *1326*
LOWER EXTREMITY ORTHOSES *1326*
- Shoes *1326*
- Foot Orthoses *1327*
- Ankle-Foot Orthoses *1330*
- Knee-Ankle-Foot Orthoses *1334*
- Hip-Knee-Ankle-Foot Orthoses *1337*
- Trunk-Hip-Knee-Ankle-Foot Orthoses *1338*
- Orthotic Options for Patients with Paraplegia *1339*

TRUNK ORTHOSES *1341*
- Corsets *1342*

- Preorthotic Examination *1346*
- Orthotic Prescription *1347*
- Orthotic Examination *1348*
- Facilitating Orthotic Acceptance *1351*
- Orthotic Instruction and Training *1352*
- Final Examination and Follow-up Care *1353*
- Functional Capacities *1353*
- Paraplegia *1354*
- Hemiplegia *1354*

SUMMARY *1354*

An **orthosis** is an external appliance worn to restrict or assist motion or to transfer load from one area of the body to another. The older term, *brace*, is a synonym. A splint connotes an orthosis intended for temporary use. An **orthotist** is the health care professional who designs, fabricates, and fits orthoses for the limbs and trunk, and a **pedorthist** is the health care professional who designs, fabricates, and fits only shoes and foot orthoses. The term *orthotic* is an adjective, although some use the word as a noun. Archaeological evidence indicates

that orthoses have been used at least since the fifth Egyptian dynasty (2750 to 2625 BC).[1] The term ***orthosis*** appears to have been coined in the mid-20th century.

This chapter presents the most frequently prescribed orthoses for the lower extremity (LE) and the trunk, as well as new developments in the field. Key elements in preparing patients to use orthoses are discussed. Focus is placed on orthotic design characteristics, their biomechanical rationale, merits of specific materials, and criteria for judging the adequacy of orthotic fit, function, and construction. Although every attempt is made to use evidence-based research to guide clinical practice, the heterogeneity within the population of orthotic users and within orthotic designs confounds this effort.[2]

TERMINOLOGY AND TYPES OF ORTHOSES

Generic terminology is superseding the traditional use of eponyms (surname of developer). Naming orthoses by the joints they encompass and the type of motion control facilitates communication among clinicians and consumers. Thus, *foot orthoses* (FOs) are appliances applied to the foot and placed inside or outside the shoe, such as metatarsal pads and heel lifts. *Ankle-foot orthoses* (AFOs) encompass the shoe and terminate below the knee. The *knee-ankle-foot orthosis* (KAFO) extends from the shoe to the thigh. A *hip-knee-ankle-foot orthosis* (HKAFO) is a KAFO with a pelvic band that surrounds the lower trunk. A *trunk-hip-knee-ankle-foot orthosis* (THKAFO) covers part of the thorax as well as the lower extremities (LEs). *Knee orthosis* (KO) and *hip orthosis* (HO) are other applications of the same system of nomenclature.

LOWER EXTREMITY ORTHOSES

Lower extremity orthoses range from shoes used for clinical purposes to THKAFOs. Characteristics and functions of the principal FOs, AFOs, KAFOs, HKAFOs, and THKAFOs, and trunk orthoses, together with the clinically important attributes of shoes, will be described. Although physical therapists also encounter KOs, HOs, and orthoses for special purposes, such as management of Legg-Calvé-Perthes disease, these orthoses are not included because they are used less frequently than the appliances that do appear in this chapter. Similarly, orthoses for the upper limb are omitted from this chapter because they are less commonly prescribed and in most instances are used only for a brief duration.

Shoes

The shoe is the foundation for most LE orthoses. Each part of the shoe contributes to the efficacy of orthotic management and offers many options for selection. Shoes transfer body weight to the ground and protect the wearer from the terrain and the weather. The ideal shoe should distribute bearing forces so as to provide optimum comfort, function, and appearance of the foot. For the individual with an orthopedic disorder, footwear can serve two additional purposes: (1) it reduces pressure on sensitive deformed structures by redistributing force toward pain-free areas; and (2) it serves as the foundation for AFOs and more extensive bracing. Unless the shoe is correctly fitted and appropriately modified, the alignment of the orthosis will not provide the designed pattern of weight-bearing. The major parts of the shoe are the upper, sole, heel, and reinforcements. These features are found in both the dress leather shoe (Fig. 30.1A) and the athletic shoe (Fig. 30.1B).

Upper

The portion of the shoe over the dorsum of the foot is the *upper*. It consists of an anterior component called the *vamp* and the posterior part, the *quarter*. If the shoe is to be used with an AFO having an insert as its foundation, then the vamp should extend to the proximal portion of the dorsum to secure the shoe and thereby the rest of the orthosis onto the foot. In a laced shoe, the vamp contains the lace stays, which have eyelets for shoelaces (Fig. 30.2). Laces provide more precise adjustment over the entire opening than do strap closures. The latter, however, enable individuals with limited manual dexterity to manage the shoe more easily. For most orthotic purposes, a *Blucher* lace stay is preferable; it is distinguished by the separation between the anterior margins of the lace stays and the vamp. The alternate design is the *Bal,* or *Balmoral*,

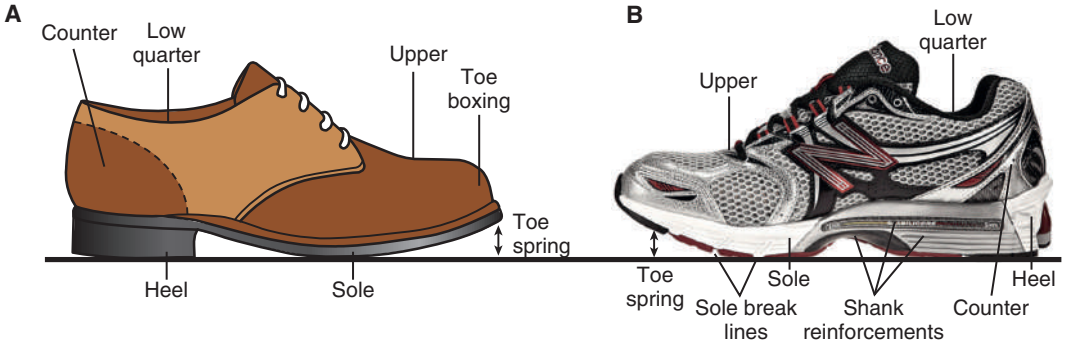

Figure 30.1 **(A)** Parts of a low quarter shoe with a Blucher lace stay. Note that the counter and toe boxing are internal reinforcing structures of the shoe. **(B)** Parts of a low-quarter running shoe.

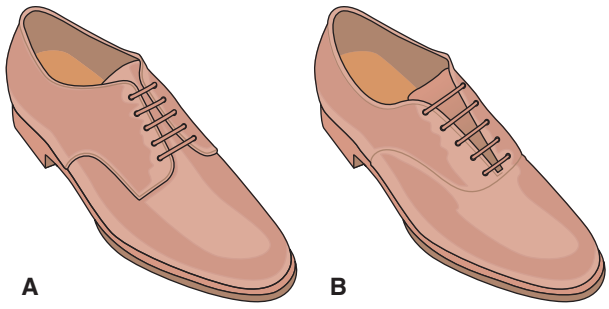

Figure 30.2 Low-quarter shoes: **(A)** Blucher (open lace) and **(B)** Bal (Balmoral) (closed lace). The Blucher lace stay is generally preferred for orthotic use owing to ease in donning (provides greater foot entry space to accommodate orthosis) and adjustability.

lace stay, in which the lace stay is continuous with the vamp. The Blucher opening permits substantial adjustability, an important feature for the patient with edema. It also offers a large inlet into the shoe, so that one can determine whether paralyzed toes lie flat within the shoe. An *extra-depth shoe* is one having an upper contoured with additional vertical space. The shoe is manufactured with a second inner sole that can be removed to accommodate an insert or thick surgical dressing.

Quarter height is another consideration in shoe prescription. The low-quarter terminates below the malleoli and is satisfactory for most clinical purposes. This style does not restrict foot or ankle motion. If the patient will be wearing a plastic orthosis molded about the ankle, it is not necessary to go to the additional expense of providing a high-quarter shoe for ankle support. A high-quarter shoe, covering the malleoli, is indicated to cover the foot having rigid **pes equinus**. It is also appropriate to augment foot stability in the absence of an AFO. The high-quarter shoe, however, is more difficult to don and more expensive than a comparable low-quarter one.

Sole

The *sole* is the bottom portion of the shoe. For use with a riveted metal attachment between shoe and orthosis, the sole should have an outer and an inner sole. Between the two lies a metal reinforcement that receives the rivets. This type of shoe, however, is heavier than an athletic shoe with a single sole. Leather soles absorb little impact shock and provide minimal traction as compared to natural or synthetic rubber soles. To absorb shock, the shoe may have a resilient outer sole, inner sole, or insert. Older people should wear shoes with firm, slip-resistant outsoles to reduce the risk of falling.[3,4]

Regardless of material, the outer sole should not contact the floor at the distal end; the slight rise of the sole is known as *toe spring* (see Fig. 30.1), which allows a rocker effect at late stance. If a lift is added to the sole to compensate for leg length discrepancy, the lift should be beveled to achieve toe spring.

Heel

The *heel* is the portion of the shoe adjacent to the outer sole, under the anatomical heel. A broad, low heel provides greatest stability and distributes force between the back and front of the foot most evenly. For adults, a 1-in (2.5-cm) heel tilts the center of gravity slightly forward to aid transition through stance phase, but does not disturb normal knee and hip alignment significantly. Slight heel lifts increase the contraction of the medial gastrocnemius and the tibialis anterior.[5] A higher heel places the ankle in greater plantarflexion range and forces the tibia forward. The wearer compensates either by retaining slight knee and hip flexion or by extending the knee and exaggerating lumbar lordosis. The high heel transmits more stress to the metatarsals[6] and knee.[7] Nevertheless, transferring load anteriorly may be desirable if the patient has heel pain. The higher heel also reduces tension on the Achilles tendon and other posterior structures and accommodates rigid pes equinus. Although most heels are made of firm material with a rubber plantar surface, a low resilient heel is indicated to permit slight plantarflexion if the ankle cannot move because of orthotic or anatomical limitation.

Reinforcements

Reinforcements located at strategic points preserve the shape of the shoe. *Toe boxing* in the vamp protects the toes from stubbing and vertical trauma; it should be high enough to accommodate hammer toes or similar deformity. The *shank* piece is a longitudinal plate that reinforces the sole between the anterior border of the heel and the widest part of the sole at the metatarsal heads. A corrugated steel shank is necessary if an orthotic attachment is to be riveted to the shoe. The *counter* stiffens the quarter and generally terminates at the anterior border of the heel. The patient with pes valgus, however, should have a shoe with a long medial counter that provides reinforcement along the medial border of the foot to the head of the first metatarsal, thus resisting the tendency of the foot to collapse medially.

Last

The *last* is the model over which the shoe is made. The last, whether of traditional wood, custom-made plaster, or computer-generated design, remains with the manufacturer; the shoe shape duplicates the last's contour. A given shoe size may be achieved with many lasts, each transmitting different forces to the foot. Consequently, the physical therapist should ascertain that the shoe shape fits the foot satisfactorily, rather than relying on a particular shoe size. The patient with a markedly deformed foot requires a shoe made over a special last, either a factory- or custom-made one.

Foot Orthoses

Foot orthoses are appliances that apply forces to the foot. These may be an insert placed in the shoe, an internal modification affixed inside the shoe, or an external

modification attached to the sole or heel of the shoe. They can enhance function by relieving pain. This may be accomplished by transferring weight-bearing stresses to pressure-tolerant sites, protecting painful areas from contact with the shoe, correcting alignment of a flexible segment, or accommodating a fixed deformity. Inserts can also improve the wearer's transition during stance phase, by altering the rollover point in late stance and by equalizing foot and leg lengths on both limbs. In many instances, a particular therapeutic aim can be achieved by a variety of devices.

Internal Modifications

Generally, the closer the modification is to the foot, the more effective it is. Biomechanically, inserts and internal modifications are identical. Both inserts and internal modifications reduce shoe volume, so proper shoe fit must be judged with these components in place. An insert permits the patient to transfer the orthosis from shoe to shoe, if the shoes have the same heel height; otherwise, a rigid insert may rock in the shoe. Most inserts terminate just behind the metatarsal heads; thus, they may slip forward, particularly if the shoe has a relatively high heel. Some inserts extend the full length of the sole, preventing slippage, but occupying the often limited space in the anterior portion of the shoe. Internal modifications are fixed to the shoe's interior, guaranteeing the desired placement, but limiting the patient to the single pair of modified shoes.

Inserts made of resilient materials, such as the rubber, viscoelastic plastics (e.g., Sorbothane and Viscolas), or polyethylene foam, reduce impact shock and shear, thus protecting painful or insensitive feet.[8] Inserts are also constructed of semirigid or rigid plastics and metal, often with a resilient overlay. A full-length insert tends to reduce gait unsteadiness by improving proprioception from the increased foot contact area.[9] A heel-spur insert orthosis (Fig. 30.3), for example, may be made of viscoelastic plastic or rubber.[10] The orthosis slopes anteriorly to reduce load on the painful heel. In addition, the orthosis has a concave relief to minimize pressure on the tender area.

Longitudinal arch supports are intended to prevent depression of the subtalar joint and flattening of the arch (pes planovalgus, **pes planus**). The orthosis may include a wedge (post) to alter foot alignment. The minimum support is a resilient *scaphoid pad* (Fig. 30.4) positioned at the medial border of the insole with the apex between the sustentaculum tali and the navicular tuberosity. Flexible flat foot can be realigned with a semirigid plastic *University of California Biomechanics Laboratory (UCBL) insert.*[11] It is molded over a plaster model of the foot, taken with the foot in maximum correction. It controls hindfoot valgus and limits subtalar motion. The insert encompasses the heel and midfoot. Corrective alignment includes a three-point counterpressure system and force couple for control of calcaneal eversion; forefoot abduction is controlled by a second three-point counterpressure system (Fig. 30.5).[12] A full-length insert reduces motion at the first metatarsophalangeal joint, resulting in pain reduction.[13,14] Wearing arch supports is associated with increased activation of the tibialis anterior and peroneus longus.[15] With regard to the effect of inserts on proximal joints, the evidence is equivocal; some investigations show that orthoses alter the onset of erector spinae and gluteus medius activity[16] and support the positive effect of FOs on reducing knee pain,[17-21] whereas others show little or no effect.[22,23] Some adults with plantar fasciitis also respond favorably to foot orthoses.[24-28] Children with pes planus may also benefit from wearing longitudinal arch supports, although the evidence is weak.[29,30]

Insert orthoses are also used to relieve pain and activity limitation associated with pes cavus.[31-33] The *metatarsal pad* (Fig. 30.6) is a convex component that may be incorporated in an insert or may be a resilient domed piece glued to the inner sole so that its apex is under the metatarsal shafts. The pad transfers stress from the metatarsal heads to the metatarsal shafts and is

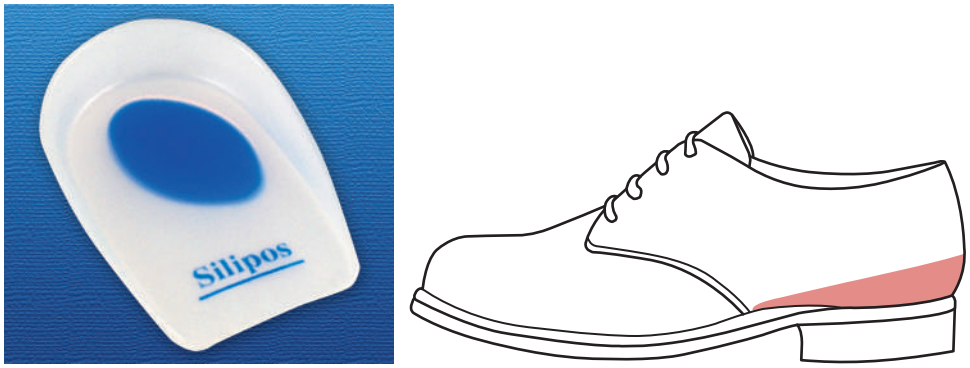

Figure 30.3 (*Left*) Plastic tapered heel spur cushion with concave relief to reduce pressure (available in multiple densities as well as with a removable central plug). *Courtesy of Silipos, Inc., Niagara Falls, NY 14304-3731.* (*Right*) The shaded area of the shoe on the right indicates the relative position of the heel spur cushion when placed in a shoe.

Figure 30.4 Scaphoid pads (*left*) are available with self-adhesive backing. They are positioned (*middle*) medial and plantar to the longitudinal arch; scaphoid pad (*right*) positioned inside of shoe.

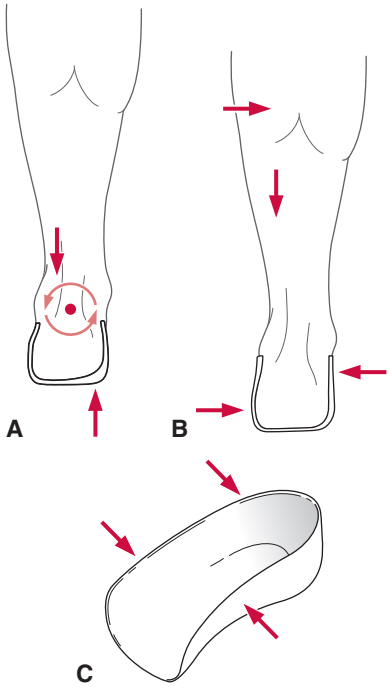

Figure 30.5 University of California Biomechanics Laboratory (UCBL) foot orthosis exerts control at the subtalar joint via a force couple **(A)** and three-point counterforces to control calcaneal eversion **(B).** A second counterforce system **(C)** restricts forefoot abduction. *From May and Lockard,[12, p. 239] with permission.*

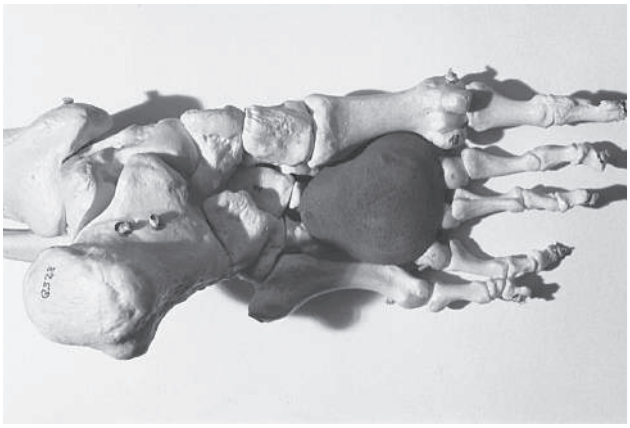

Figure 30.6 Rubber metatarsal pad. Whether used as an internal modification or as part of an insert, the pad should be oriented as shown on the skeletal model.

effective in reducing plantar pressure particularly in patients with diabetic neuropathy.[34-36]

Occasionally, modifications are sandwiched between the inner and outer soles; for example, the patient with marked arthritic changes in the front of the foot probably will be more comfortable if the shoe has a steel band between the soles to eliminate motion at the painful joints. The same effect can be achieved with a rigid insert.

External Modifications

An external modification ensures that the patient wears the appropriate shoes and does not reduce shoe volume, but will erode as the individual walks and is somewhat conspicuous. In addition, the client is limited to wearing the modified shoe, rather than being able to choose from a wide selection of shoes.

A *heel wedge* (Fig. 30.7) is a frequently prescribed external modification. It alters alignment of the rearfoot. A medial heel wedge, by applying laterally directed force, can aid in realigning flexible **pes valgus** or can accommodate rigid **pes varus** by filling the void between the sole and the floor on the medial side. A medial wedge is incorporated in a *Thomas heel*, intended for flexible pes valgus (Fig. 30.8 [middle]). The anterior border of the Thomas heel extends forward on the medial side to augment the effect of the medial wedge in supporting the longitudinal arch. A cushion heel is made of resilient material to absorb shock at heel contact. Because it provides slight plantarflexion, the cushion heel is indicated when the patient wears an orthosis with a rigid ankle. Sole wedges alter medial–lateral forefoot alignment. A lateral wedge shifts weight-bearing to the medial side of the front of the foot. It compensates for fixed forefoot valgus, allowing the entire distal foot to contact the floor.

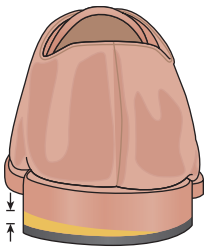

Figure 30.7 Medial heel wedge.

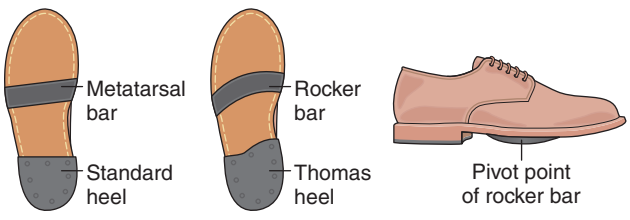

Figure 30.8 Illustrated here are (*left*) a metatarsal bar and standard heel, (*middle*) a rocker bar with a Thomas heel (note the medial extension), and (*right*) pivot point of rocker bar.

A *metatarsal bar* (see Fig. 30.8 [left]) is a flat strip of firm material placed posterior to the metatarsal heads. At late stance, the bar transfers stress from the metatarsophalangeal joints to the metatarsal shafts. A *rocker bar* (see Fig. 30.8 [middle and right]) is a convex transverse band affixed to the sole proximal to the metatarsal heads. It reduces the distance the wearer must travel during stance phase, improving late stance, as well as shifting load from the metatarsophalangeal joints to the metatarsal shafts.[37,38]

The patient with leg length discrepancy of more than 1/2 in (1 cm) will walk better with a shoe lift made of cork or other lightweight material. Approximately 3/8 in (0.8 cm) of the elevation can be accommodated on the insole at the heel of a low-quarter shoe.

Ankle-Foot Orthoses

The AFO is composed of a foundation, ankle control, foot control, and a superstructure.

Foundation

The foundation of the orthosis consists of the shoe and a plastic or metal component.

Insert

A plastic or metal insert or foot plate foundation (Fig. 30.9) has several advantages. Because internal modifications can be incorporated in it, the insert provides good control of the foot. It must be worn with a shoe that closes high on the dorsum of the foot to retain the orthosis. The insert facilitates donning the orthosis because the shoe can be separated from the rest of the brace. The insert also permits interchanging shoes, assuming that all shoes have been made on the same last. Less expensive shoes, such as sneakers, can be worn, because the foundation does not need to be riveted to the shoe. Because the insert is usually made of a thermoplastic material, such as polyethylene or polypropylene, the orthosis with an insert is relatively lightweight. The orthotist creates a plaster model of the patient's leg, then modifies the model, removing plaster in areas where the orthosis is to apply substantial pressure, and adding plaster where pressure relief is required. Thermoplastic is then heated and molded over the modified plaster model.

An insert foundation, however, is inappropriate if the patient cannot be relied on to wear the orthosis with a shoe of proper heel height. If the orthosis is placed in a shoe with too low a heel, the uprights would incline posteriorly, increasing the tendency of the wearer's knee to extend. Conversely, if the orthosis is worn with a higher heeled shoe, the patient might experience knee instability. The insert reduces interior shoe volume, and thus must be used with suitably spacious shoes. Custom-molded foot plates may be more expensive than other types of foundations. If the orthosis is to be used by a very obese or exceptionally active individual, a plastic foot plate may not provide adequate support.

Figure 30.9 AFO with plastic insert.

Stirrup

An older foundation for the AFO is the steel stirrup, a U-shaped fixture, the center portion of which is riveted to the shoe through the shank. The arms of the stirrup join the brace uprights at the level of the anatomical ankle, providing congruency between orthotic and anatomical joints. The *solid stirrup* (Fig. 30.10) is a one-piece attachment that provides maximum stability of the orthosis on the shoe. The *split stirrup* (Fig. 30.11) has three segments. The central portion has a transverse rectangular opening. Medial and lateral angled side pieces fit into the opening. The *split stirrup* simplifies donning the orthosis because the wearer can detach the uprights from the shoe. If a central piece is riveted to another shoe, the shoes can be interchanged. The

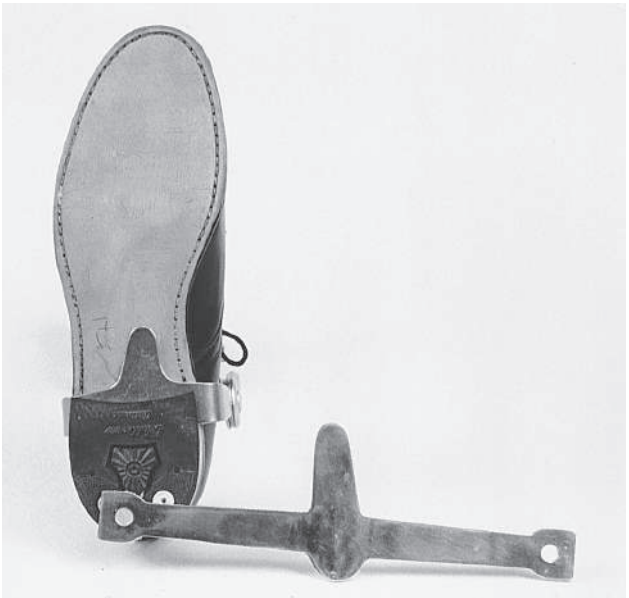

Figure 30.10 Solid stirrup. The stirrup in the foreground is as it comes from the manufacturer before it is U-shaped and fitted to the patient and shoe.

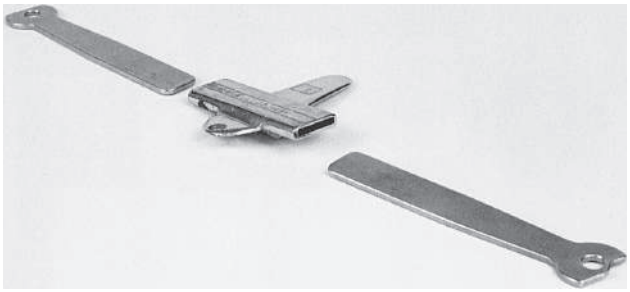

Figure 30.11 Split stirrup.

extremely active client may dislodge a side piece from its receptacle unintentionally. The split stirrup is bulkier and heavier than a solid stirrup.

Ankle Control

Most AFOs are prescribed to control ankle motion by limiting plantarflexion and/or dorsiflexion, or by assisting motion. The patient with dorsiflexor weakness or paralysis risks dragging the toe during swing phase. Dorsiflexion assistance can be provided by a *posterior leaf spring* that arises from a plastic *insert* (Fig. 30.12). During early stance, as the patient applies force to the braced foot, the upright bends backward slightly. When the patient progresses into swing phase, the plastic recoils forward to lift the foot. Thinner, narrower plastic permits relatively greater motion. Motion assistance can also be achieved with a steel dorsiflexion spring assist (Klenzak joint) (Fig. 30.13) incorporated into each stirrup. The coiled spring compresses in stance and rebounds during swing. The tightness of the coil can be adjusted. An orthosis with a dorsiflexion spring assist is noticeably bulkier than the posterior leaf spring model. Both types of spring assists yield slightly into plantarflexion at heel contact, affording the wearer protection against inadvertent knee flexion. Other AFO designs

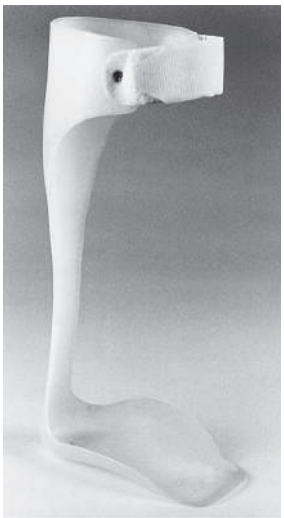

Figure 30.12 Plastic insert on posterior leaf spring AFO.

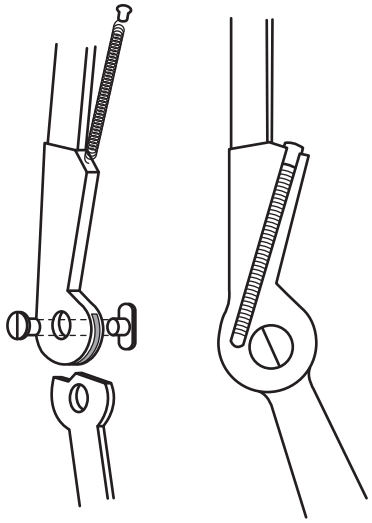

Figure 30.13 Steel dorsiflexion spring assist.

which control toe drag are presented in Figures 30.14 and 30.15. Healthy subjects wearing a posterior leaf spring AFO exhibited less hip extension and ankle plantarflexion during the transition from stance to swing phase.[39] AFOs with flexible ankle control altered the stance phase transition between rear- and forefoot among nondisabled adults.[40]

The alternate approach to prevent toe drag is plantarflexion resistance, which stops the ankle from plantarflexing so that the patient with weak dorsiflexors will not catch the toes and stumble during swing phase. A

Figure 30.14 ToeOFF® ankle-foot orthosis. This fiber glass, carbon fiber, and Kevlar orthosis is designed to provide dorsiflexion assistance in the presence of mild to severe foot drop accompanied by mild to moderate ankle instability. joint placed in a plastic hinged AFO (Fig. 30.16) or a steel posterior stop (Fig. 30.17) can be incorporated in the stirrup. The posterior stop also imposes a flexion force at the knee during early stance, preventing the knee from hyperextending. Healthy adults walking with the ankle fixed in plantarflexion consumed more oxygen than when walking with AFOs which kept the foot in neutral position.[41]

Figure 30.16 Plastic hinged ankle-foot orthoses. *Courtesy of Otto Bock, Minneapolis, MN 55447.*

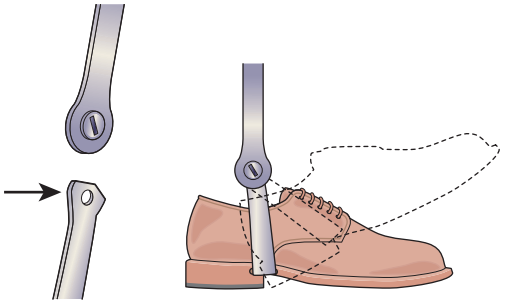

Figure 30.17 Steel stirrup (*left*) with posterior stop at its proximal end (*arrow*). Posterior stop (*right*) incorporated into a stirrup. A posterior stop is designed to allow dorsiflexion and prevent or stop plantarflexion.

An anterior ankle stop limits dorsiflexion, aiding the individual with paralysis of the triceps surae to achieve propulsion during late stance.

Limiting all foot and ankle motion can be done with a plastic *solid ankle-foot orthosis* (Fig. 30.18); its trimlines are anterior to the malleoli. Able-bodied adults fitted with solid ankle AFOs descended stairs more slowly than when walking without orthoses.[42] The solid ankle orthosis may be divided transversely at the ankle, with the two sections hinged, creating the *hinged ankle-foot orthosis* (see Fig. 30.16). It permits slight sagittal motion, facilitating progression to the foot-flat position in early stance. The joint at the hinge may be a plastic overlap or a flexible plastic rod. A versatile option is a pair of metal hinges that can be adjusted to alter the excursion of ankle motion. An alternative to the plastic solid ankle AFO is a metal joint that resists both plantarflexion and dorsiflexion, known as a limited motion joint. One type of limited motion joint is a pair of *bi-channel adjustable ankle locks (BiCAALs)* (Fig. 30.19) that consist of a pair of joints, each of which has an anterior and a posterior

Figure 30.18 Plastic solid AFO. *Courtesy of Otto Bock, Minneapolis, MN 55447.*

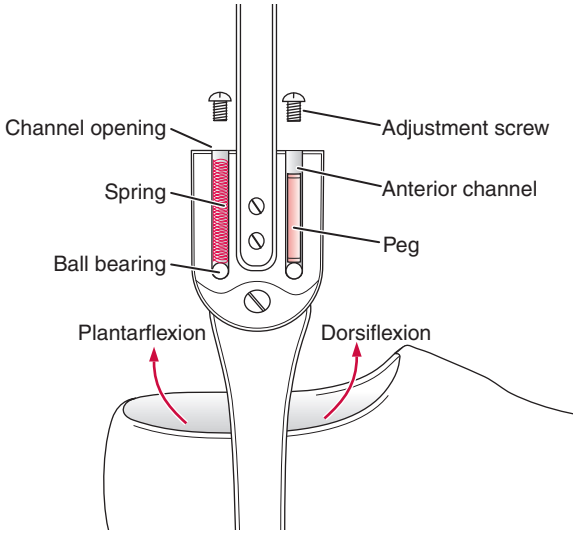

Figure 30.19 Bi-channel adjustable ankle locks (BiCAALs). Note that this ankle joint includes two channels. A spring placed in the posterior channel (shown) provides a dorsiflexion assist. A peg (or pin) placed in the anterior channel (shown) provides a dorsiflexion stop. A peg placed in the posterior channel creates a plantarflexion stop. *From May and Lockard[12, p. 254] with permission.*

spring. The springs may be replaced by metal pegs (or pins), the lengths of which determine the amount of motion provided by the orthosis. To compensate for lack of plantarflexion in early stance, the shoe worn with the solid AFO or the orthosis with a limited motion stop should have a resilient heel. Similarly, to facilitate rollover in late stance, the shoe sole should have a rocker bar. Hinged AFOs reduced frontal plane motion during ramp descent exhibited by subjects who have subtalar osteoarthritis.[43]

Adults with hemiplegia who wore AFOs demonstrated increased cadence, walking speed, step length, and ankle dorsiflexion,[44] and the AFO enabled some patients to walk with increased stride length and cadence.[45-50] Other subjects with stroke improved their scores on the Berg Balance Scale when wearing AFOs[51] and improved weight transfer during stance phase.[52] Balance improvement was also achieved by those wearing an anterior AFO,[53,54] while other subjects demonstrated better function with a posterior leaf spring AFO.[55] Orthoses may either contribute to improved compensatory functions of the nonparetic limb,[56] or may be less important during swing phase of the paretic limb as compared with pelvic obliquity.[57]

A hinged AFO with full-length insert and posterior stop improves early stance stability for subjects with hemiplegia.[58] The alignment of a solid AFO should be individualized to achieve optimal function.[59]

Limited investigation of energy expenditure of adults with hemiplegia wearing AFOs suggests that wearing orthoses results in more efficient gait.[60-62]

Adults with hemiplegia complicated by plantarflexor contracture walk with less plantarflexion and greater knee flexion when wearing either an AFO with posterior stop or a solid AFO.[63]

Functional electric stimulation is an alternative to an AFO for some adults with stroke and other central neuropathies. Various commercially available systems all incorporate a cuff on the proximal leg; the interior of the cuff contains a skin electrode over the peroneal nerve. The electrode is stimulated by a self-contained electrical unit. As compared to walking with an AFO, subjects report more positive results, particularly during swing phase.[64-68]

Children with hemiplegic cerebral palsy improved weight-bearing on the paretic limb while wearing either a posterior leaf spring AFO or a hinged AFO with plantarflexion stop.[69] Other children with similar disability showed slight gait improvement.[70-72] Energy expenditure lessened when children wore a hinged AFO.[73-76] Other investigators found that hinged AFOs were preferable to other designs for level walking[77,78] and stair climbing.[79]

Some young patients with excessive knee flexion achieved better gait when wearing AFOs with anterior band (floor reaction orthosis).[80-82] The desirable effect occurred only if the child did not have knee flexion contracture.

Foot Control

Medial–lateral motion can be controlled with a solid ankle AFO. The rigidity of the orthosis can be increased by using thicker or stiffer plastic, corrugating the plastic, forming the edges with a rolled contour, or embedding carbon fiber reinforcements. A solid ankle AFO (see Fig. 30.18) or a hinged solid ankle AFO (see Fig. 30.16) also controls frontal and transverse plane foot motion of children with cerebral palsy to a limited extent.[83] Less effective is a metal and leather orthosis to which a leather valgus (or varus) correction strap is attached. The valgus correction strap (Fig. 30.20) is sewn to the medial portion of the shoe upper near the sole, and buckles around the lateral upright, exerting a laterally directed force to restrain pronation. The varus correction strap has opposite attachments and force application. Either strap, although adjustable, complicates donning.

Superstructure

The proximal portion of the orthosis, the superstructure, consists of one or two uprights, and a shell, band, or brim. Plastic AFOs usually have a single upright or shell. Both the solid ankle and the hinged solid ankle AFOs have a posterior shell extending from the medial to the lateral midline of the leg, thus providing excellent medial-lateral control and a broad surface to minimize pressure. The posterior leaf spring AFO (see Fig. 30.12) has a single posterior upright that does not contribute to frontal or transverse plane control.

The *spiral AFO* (Fig. 30.21) is a design in which a single upright spirals from the foot plate around the leg,

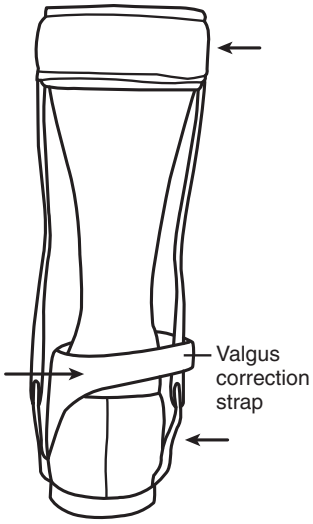

Figure 30.20 Valgus correction strap (also called a "T-strap"). Arrows indicate the three-point pressure system created by the corrective forces (right lower extremity).

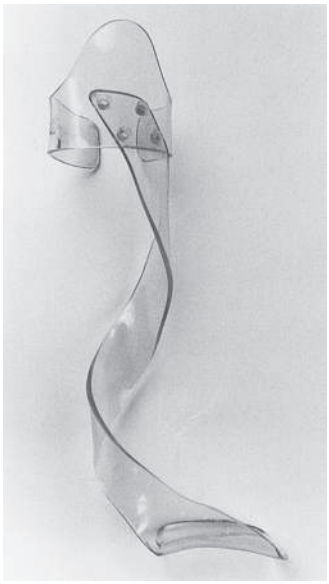

Figure 30.21 Spiral AFO.

terminating in a proximal band. It may be made of polypropylene, nylon acrylic, or carbon fiber. The spiral orthosis controls, but does not eliminate, motion in all planes. Orthoses with plastic shells or uprights are molded over a cast of the patient's leg and are designed to fit snugly for maximal control and minimal conspicuousness. Such AFOs are contraindicated for the individual whose leg volume fluctuates markedly, because the orthoses cannot be adjusted readily.

Metal and leather orthoses usually have medial and lateral uprights to maximize structural stability. Occasionally, a single side upright will suffice when the patient insists on a less conspicuous orthosis and the person is not expected to exert undue force. Some AFOs have an anterior upright, thereby avoiding pressure and shear stress on the calf and Achilles tendon. Aluminum uprights are typically used because they are lighter in weight than steel. Carbon graphite and titanium uprights weigh appreciably less than aluminum and rival the strength of steel; however, orthoses made of these materials are more expensive.

Most orthoses have a posterior calf band made of rigid plastic or leather-upholstered metal. The band has an anterior buckled or pressure closure strap (Fig. 30.22). The farther the band is from the ankle joint, the more effective the leverage of the orthosis; however, the band must not impinge on the peroneal nerve. An anterior band that is part of a solid ankle AFO imposes posteriorly directed force near the knee, enabling the AFO to resist knee flexion. Such an orthosis is known as a *floor reaction orthosis* (Fig. 30.23). In fact, all LE orthoses are influenced by the floor reaction when the wearer stands or is in the stance phase of gait. If the AFO is to reduce the amount of weight transmitted through the foot, it may have a *patellar-tendon-bearing brim* (Fig. 30.24), resembling a transtibial (below-knee) prosthetic socket. The plastic brim has a slight indentation over the patellar tendon, and is hinged to facilitate donning. The brim must be used with a plastic solid ankle or a steel limited-motion ankle joint.

Knee-Ankle-Foot Orthoses

Individuals with more extensive paralysis or limb deformity may benefit from KAFOs, which consist of a shoe, foundation, ankle control, knee control, and superstructure. KAFOs often include foot control. The shoe, foundation, ankle control, and foot control of the KAFO may be selected from the components already described. Patients with poliomyelitis who wore carbon-composite KAFOs walked better than with leather/metal or plastic/metal KAFOs.[84-86] Donning a plastic and metal KAFO

Figure 30.22 Conventional AFO with stirrup attachment, limited motion ankle joints, bilateral uprights, and upholstered metal calf band.

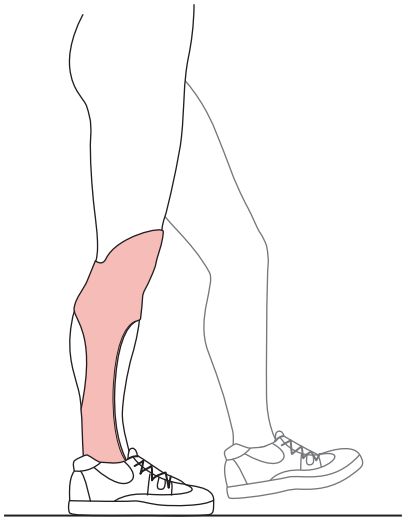

Figure 30.23 Floor reaction AFO with anterior band provides a knee extension moment in stance without preventing flexion during swing. *From May and Lockard,[12, p. 276] with permission.*

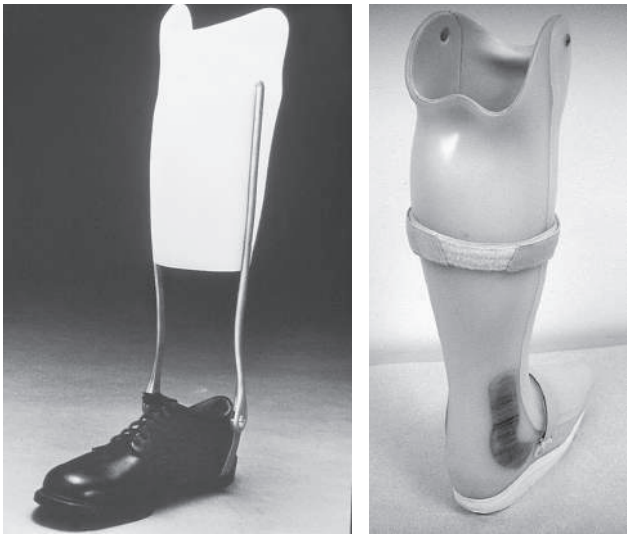

Figure 30.24 (*Left*) AFO with stirrup, hinged ankle joint, steel uprights, and plastic patellar-tendon-bearing brim. (*Right*) Plastic AFO with patellar-tendon-bearing brim to reduce weight-bearing on foot. *Courtesy of Ortho-Bionics Laboratory, Inc., South Ozone Park, NY 11420.*

is appreciably faster than putting on a metal and leather orthosis because the shoe can be separated from the rest of the orthosis.

Knee Control

The simplest knee joint is a hinge. Because most KAFOs include a pair of uprights, the orthosis has a pair of knee hinges that provide medial–lateral and hyperextension restriction while permitting knee flexion.

The *offset joint* (Fig. 30.25 [left and middle]) is a hinge placed posterior to the midline of the leg. When the wearer stands and walks on a level surface, the individual's weight line falls anterior to the offset joint, stabilizing the knee in extension during the early stance phase of gait. The offset joint does not hamper knee flexion during swing or sitting. The joint may, however, flex inadvertently when the wearer walks on ramps.

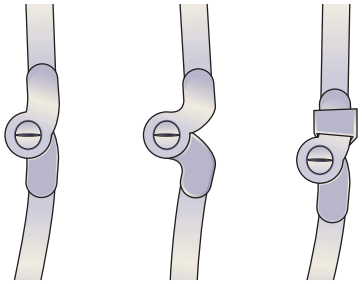

Figure 30.25 Two examples of offset knee joints (*left and middle*) and one of a drop ring lock (*right*).

The most common knee control is the drop ring lock (Fig. 30.25 [right]). When the client stands with the knee fully extended, the ring drops, preventing the uprights from bending. Although both medial and lateral joints should be locked for maximum stability, manipulating a pair of drop ring locks is inconvenient, unless each upright is equipped with a spring-loaded *retention button.* The button permits the wearer to unlock one upright, then attend to the other one without having the first lock drop. The buttons also enable the physical therapist to give the patient a trial period of walking with the knee joints unlocked.

The *pawl lock with bail release* (Fig. 30.26) provides simultaneous locking of both uprights. The pawl is a spring-loaded projection that fits into a notched disk. The patient unlocks the brace by pulling upward on the

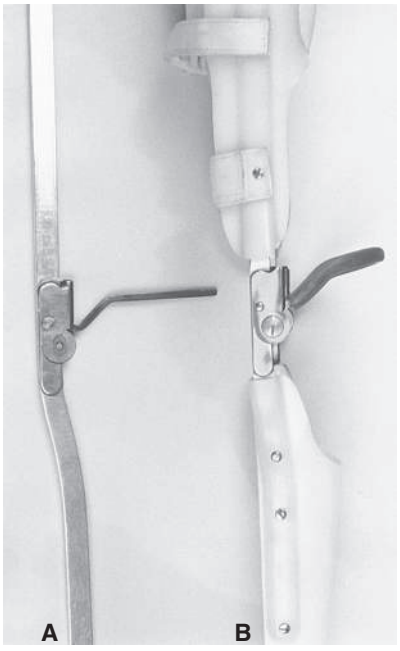

Figure 30.26 Knee joint hinge with pawl lock: basic component **(A)** and pawl lock installed in KAFO with bail shaped to curve posteriorly **(B).**

posterior bail. Some people are agile enough to be able to nudge the bail by pressing it against a chair. The bail is bulky and may release the locks unexpectedly if the wearer is jostled against a rigid object.

The offset joint and knee joints with basic drop ring or pawl locks are contraindicated in the presence of knee flexion contracture. If one cannot achieve full passive knee extension, an adjustable knee joint such as the fan lock, serrated lock (Fig. 30.27), or ratchet lock is required. Such joints usually have a drop ring lock for stability in the partially flexed attitude.

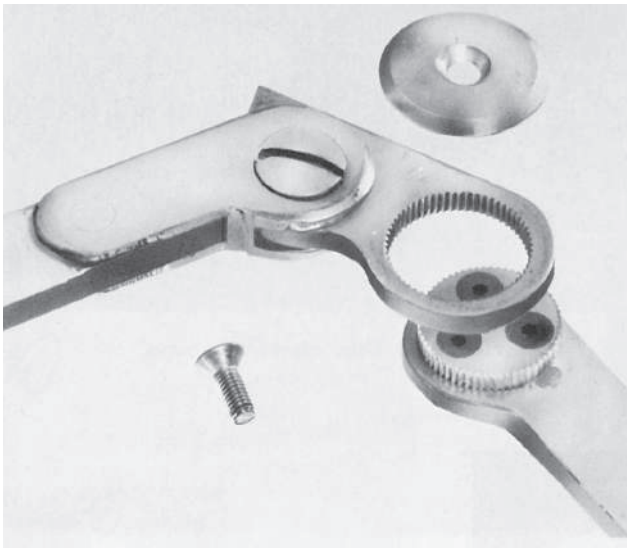

Figure 30.27 Knee joint hinge with serrated knee lock. Note the location of the knee hinge and the serrated disk. *From Fishman, S, et al: Lower extremity orthoses. In American Academy of Orthopaedic Surgeons: Atlas of Orthotics, ed 2. Mosby, St. Louis, 1985, p 213, with permission.*

Sagittal stability is augmented by a kneecap (Fig. 30.28A) or an anterior band or strap that completes the three-point pressure system necessary for stability. The cap or band applies a posteriorly directed force to complement the anteriorly directed forces from the back of the shoe and the thigh band. The leather knee cap has four straps buckled to both uprights above and below the knee. The knee cap requires the patient to buckle two straps when donning the orthosis. When the straps are tight enough to stabilize the knee, the cap is likely to restrict flexion when the wearer sits. A more practical alternative is a rigid anterior band, either a pretibial band or a suprapatellar band, both of which apply posteriorly directed force, but do not interfere with sitting and are easier to don. The bands generally are molded of plastic and thus not readily adjustable. The prepatellar band rests over the bony proximal portion of the leg and requires careful contouring to be comfortable. The suprapatellar band fits over the fleshy anterodistal thigh. Examples of combined metal and plastic KAFOs are presented in Fig. 30.28 (B and C).

Another means of obtaining sagittal stability involves a KAFO with an electronic stance control mechanism that prevents knee flexion during stance phase and permits knee flexion during swing phase. By moving a lever on the side of the joint, the patient can select the mode of action: (1) stance control that is disengaged during swing phase, (2) no stance control, and (3) lock in full extension. Preliminary investigation indicates that adults with LE paralysis walked faster and more efficiently, with increased cadence and step length, and fewer compensatory trunk movements, as compared with use of a locked KAFO.[87-95] KAFOs with computer-controlled knee joints are also available[96] (Fig. 30.29). A KAFO with electronic knee control enables some patients with stroke and other neuropathies to walk[97] (Fig. 30.30).

Figure 30.30 Patient moving from sit-to-stand wearing the Tibion Bionic Leg (Tibion Corporation, Sunnyvale, CA 94085). This is a KAFO with electronic knee control designed to support the rehabilitation process. A computer allows the therapist to program the amount of support the orthosis is providing during various tasks.

Frontal plane control may be achieved with plastic calf shells shaped to apply corrective force for **genu valgum** or **genu varum**. To reduce genu valgum, the medial portion of the shell extends proximally in order to apply laterally directed force at the knee. The semi-rigid shell is more effective than a valgum correction strap, which is a knee cap with a fifth strap designed to be buckled around the lateral upright. The opposite force application is indicated for the patient who has genu varum. The shell does not require time in donning and applies force over a broad area without impinging on the popliteal fossa.

Superstructure

Thigh bands provide structural stability to the orthosis. If the distal portion of the limb cannot tolerate full weight-bearing, then the proximal thigh band may be shaped to form a weight-bearing brim. To eliminate all weight-bearing through the lower extremity, the orthosis must include a weight-bearing brim, a locked knee joint, and a *patten* bottom. The patten is a distal extension that keeps the foot on the braced side off the floor (Fig. 30.31). To maintain a level pelvis, the patient must also wear a lift on the opposite shoe; the height of the lift should equal the height of the patten.

Hip-Knee-Ankle-Foot Orthoses

Addition of a pelvic band and hip joints converts the KAFO to an HKAFO.

Figure 30.31 The patten bottom is the distal component of an orthosis designed to eliminate weight-bearing from the limb. The patten bottom prevents the foot from contacting the floor.

Hip Joint

The usual hip joint is a metal hinge (Fig. 30.32) that connects the lateral upright of the KAFO to a pelvic band. The joint prevents abduction and adduction, as well as hip rotation. If the patient requires only control of hip rotation, a simpler alternative to the hip joint and pelvic band is a webbing strap. To reduce internal rotation, the strap resembles a Silesian belt on a prosthesis. The center of the strap is riveted to the rear of a waist belt. Each end of the strap is attached to the proximal end of the lateral upright. To reduce external rotation, a strap joins the lateral uprights of the KAFOs, passing anteriorly at the level of the groin. If flexion control is required, a drop ring lock is added to the hip joint. A two-position lock stabilizes the patient in hip extension for standing and walking, and at 90 degrees of hip flexion for sitting.

Pelvic Band

An upholstered metal band (Fig. 30.33) anchors the HKAFO to the trunk. The band is designed to lodge between the greater trochanter and the iliac crest on each side. HKAFOs are not used very often because they are much more awkward to don than KAFOs, and, if the hip joints are locked, they restrict gait to the swing-to or swing-through pattern. The pelvic band may be uncomfortable when the wearer sits.

Trunk-Hip-Knee-Ankle-Foot Orthoses

Patients who require more stability than provided by HKAFOs may be fitted with THKAFOs (Fig. 30.34), which incorporate a lumbosacral orthosis attached to

Figure 30.32 Hip joint with drop ring lock.

Figure 30.33 (*Left*) Conventional HKAFO with stirrup; uprights; hinged ankle, knee, and hip joints; drop ring locks at the knee and hip; and pelvic band. (*Right*) Plastic and metal HKAFO with hip and knee joints unlocked. *Courtesy of Orthomerica Products, Inc., Orlando, FL 32810.*

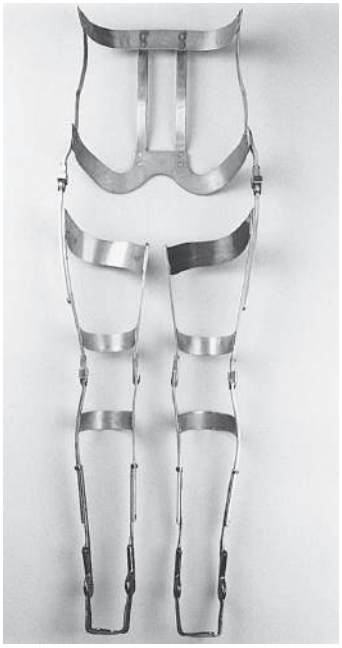

Figure 30.34 Conventional THKAFO without upholstery. This image illustrations the foundational structure of these cumbersome orthoses. To this large heavy metal frame, the additional weight of the upholstery, needed straps and pads, and shoes was added. Patients once leaving the rehabilitation setting often discarded such extensive bracing.

KAFOs. The pelvic band of the trunk orthosis serves as the pelvic band used on HKAFOs. Because the THKAFO is very difficult to don and is heavy and cumbersome, it is seldom worn after the client is discharged from the rehabilitation program. Alternative orthoses providing standing stability, with or without provision for walking, are available for some individuals with paraplegia.

Orthotic Options for Patients with Paraplegia

Orthoses are often prescribed for patients with spina bifida, spinal cord injury, or other disorders that result in paraplegia. The functional goals for such people include standing to maintain skeletal, renal, respiratory, circulatory, and gastrointestinal function and some form of ambulation. Upright posture also affords the individual important psychological benefits.

Mass-Produced Orthoses

Several appliances are marketed for children who have spina bifida or other disorders resulting in paraplegia. The mass-produced orthoses provide the youngster with considerable function and are less expensive and easier to don than many custom-made devices. The stabilizing points on these orthoses are the same, namely a means of securing the shoes to the base, an anterior knee band, posterior dorsolumbar band, and an anterior chest band. The orthoses permit the wearer to stand without crutch support, freeing the hands for play or vocational activities.

Standing Frame and Swivel Walker

The *standing frame* (Fig. 30.35) consists of a broad base, posterior nonarticulated uprights extending from a flat base to a midtorso chest band, and a posterior thoracolumbar band. Anterior leg bands contribute to stability. A similar orthosis is the *swivel walker*, which is made in both child and adult sizes. The major difference is the base. The swivel walker has two distal plates that rock slightly to enable a swiveling gait. Standing frames offering a variety of features are commercially available (Fig. 30.36).

Parapodium

The *parapodium* (Fig. 30.37) is manufactured in child sizes, and permits the wearer to sit. The base is flat. One version of parapodium has a provision for keeping the knees locked while the child unlocks the hips in order to lean forward to pick up objects from the floor. With some of these devices, the child can move from place to place by rotating the upper torso to shift weight, causing the frame to rock and rotate alternately on one edge then the other. For walking longer distances, the youngster uses crutches or a walker in the swing-to or swing-through pattern. The appliances are worn on the outside of clothing, which school-age children eventually find cosmetically objectionable.

Custom-Made Orthoses

Although the mass-produced devices afford considerable function to their users, many individuals seek more streamlined orthoses. Custom-made AFOs, KAFOs, and THKAFOs provide sufficient rigidity, either by metal

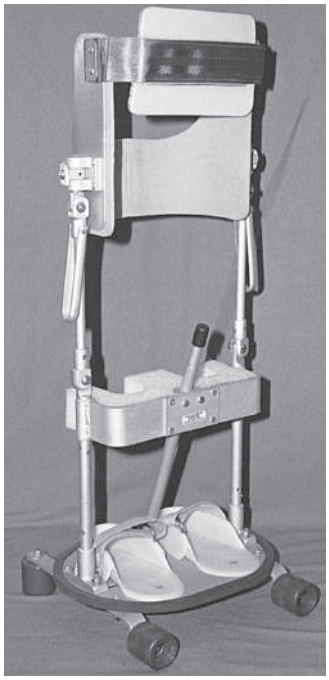

Figure 30.37 Parapodium. *Courtesy of Variety Village, Electro Limb Production Centre, Scarborough (Toronto), Ontario, Canada.*

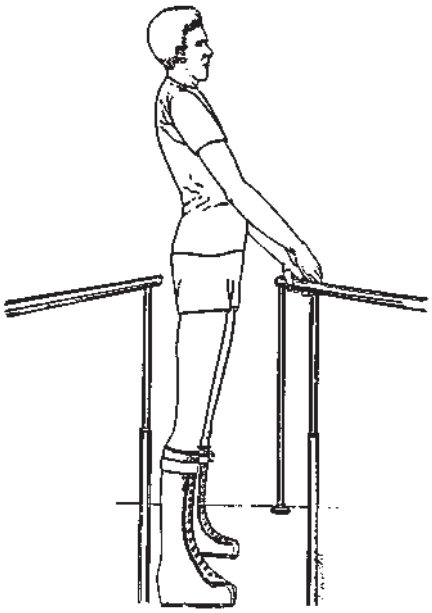

Figure 30.38 Stabilizing boots. *From Kent, HO: Vannini-Rizzoli stabilizing orthosis (boot): Preliminary report on a new ambulatory aid for spinal cord injury. Arch Phys Med Rehabil 73: 302, 1992, p 304, with permission.*

joints or orthotic alignment, to enable selected individuals to stand. Ambulation requires crutches or similar aids, together with well-coordinated use of the trunk and upper limbs. Some patients may not realize the extent of the physical conditioning program required to prepare them for ambulation. Consequently, a trial period is advisable using mass-produced, adjustable, temporary orthoses.

Stabilizing Boots

AFOs designed for adults with paraplegia include a pair of stabilizing boots molded to conform to the patient's legs and feet (Fig. 30.38). The foot plate is angled at approximately 15° plantarflexion to shift the wearer's center of gravity anterior to the ankles. The plastic component is inserted into leather boots which have flat soles. The legs are thus inclined posteriorly to keep the knees extended. The patient maintains standing stability by leaning backward, with the iliofemoral ligaments resisting a backward fall. A pair of crutches or a walker is needed for two- or four-point gait. Ambulation requires shifting the upper torso diagonally forward to allow one leg to swing ahead. The orthoses are easy to don and do not restrict sitting. The candidate must not have any hip or knee flexion contractures, and must be able to extend the hips and lumbar spine by trunk motion.

Craig-Scott KAFOS

A pair of *Craig-Scott KAFOs* (Fig. 30.39) may be prescribed for adults with paraplegia. Each orthosis includes either a shoe reinforced with transverse and longitudinal plates and BiCAAL ankle joints set in slight dorsiflexion

Figure 30.39 Craig-Scott KAFOs.

or a plastic solid ankle section, as well as a pretibial band, a pawl knee lock with bail release, and a single thigh band. The orthoses enable the patient to stand with sufficient backward lean so as to prevent untoward hip or trunk flexion. The gait pattern usually is swing-to or swing-through, with the aid of crutches or a walker. Although the orthoses do not restrict hip motion, the patient with thoracic spinal injury cannot control the

hips, and the orthosis has no mechanism to aid single-leg progression. Some individuals perform a two- or four-point gait by shifting the trunk enough to allow the leg to swing forward in a pendular manner.

The *Walkabout orthosis* consists of a pair of KAFOs with a hinge mechanism joining the medial uprights of the two orthoses. The mechanism permits hip flexion and extension, but restricts hip abduction, adduction, and rotation.

Reciprocating Gait Orthoses

Children and adults can be fitted with a *reciprocating gait orthosis (RGO)* (Figs. 30.40 and 30.41). The RGO is a THKAFO in which the orthotic hip joints are connected by one or two metal cables or rods. The knees are stabilized with knee locks, and the feet are encased in solid ankle orthoses. To walk, the wearer follows a four-stage procedure: (1) shift weight to the right leg, (2) tuck the pelvis by extending the upper thorax, (3) press on the crutches, and (4) allow the left leg to swing through. For the next step, one shifts to the left leg, tucks, presses, and then allows the right leg to swing. The steel cable(s) or rods prevent inadvertent hip flexion on the supporting leg. Reciprocal four- or two-point gait is stable, because one foot is always on the floor, but the pace is slow. For sitting, the wearer releases the cable(s) to enable both hips to flex. RGOs require substantial energy expenditure on the part of the wearer.[98-101]

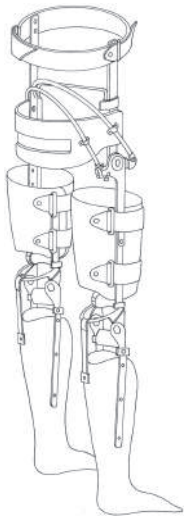

Figure 30.40 Reciprocating gait orthosis. *Courtesy of Fillauer Companies, Inc., Chattanooga, TN 37406.*

Alternatives for patients with thoracic level spinal cord injury are the ParaWalker and the ParaStep. The ParaWalker is a THKAFO with massive hip joints. The clinician can limit the flexion and extension excursion of the hip joints. Gait is similar to that with an RGO. Subjects who wore the ParaWalker had fewer pressure sores and no fractures.[102] The ParaStep is a system combining AFOs with skin electrodes over the quadriceps and glutei maximus. Energy expenditure with either device is very high.[103]

TRUNK ORTHOSES

Trunk orthoses may be used in association with LE orthoses or may be worn to reduce disabilities caused by low-back pain, neck sprain, scoliosis, or other skeletal or neuromuscular disorders. By supporting the trunk, the orthosis assists in controlling spinal motion; however, forces that the orthosis exerts are modified by the skin, subcutaneous tissue, and musculature that surround the vertebral column, and, in the case of higher orthoses, by the thoracic cage. Patients with spinal cord injury benefit from trunk orthoses in two ways: (1) the orthoses control motion of the lumbar region, with or without thoracic control, and (2) they compress the abdomen to improve respiration. Individuals with cervical lesions may need to wear an orthosis that restrains neck motion until stability is achieved by surgery or other means. A

special group of trunk orthoses is intended for children and adolescents with scoliosis.

Corsets

If abdominal compression is the sole goal, a corset (Fig. 30.42) will suffice. It is a fabric orthosis that has no horizontal rigid structures, although many have vertical rigid reinforcements. The corset may cover only the lumbar and sacral regions, or may extend superiorly as a thoracolumbosacral corset. The primary effect of a corset is to increase intraabdominal pressure, although the orthosis does reduce frontal movement.[104]

Some individuals with low back disorders find that corsets relieve pain.[105] The efficacy of orthotic intervention to reduce or prevent low back pain remains controversial.[106] The increase in intraabdominal pressure reduces stress on posterior spinal musculature, thus diminishing the load on the lumbar intervertebral disks. Although temporary reduction of abdominal and erector spinae muscular activity is therapeutic, long-term reliance on a corset can promote muscular atrophy[107-109] and contracture, as well as psychological dependence on the appliance.

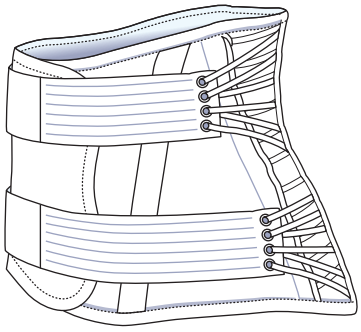

Figure 30.42 Lumbosacral corset (cotton/elastic polymer) with front hook-and-loop closure.

Rigid Orthoses

Most lumbosacral and thoracolumbosacral orthoses include a corset or a fabric abdominal front to compress the abdomen. Rigid orthoses are distinguished by the presence of horizontal, as well as vertical, rigid plastic or metal components. Motion limitation is accomplished by a series of three-point pressure systems, in which force in one direction is counteracted by two forces in the opposite direction.

Lumbosacral Flexion, Extension, Lateral Control Orthoses

A typical example of a rigid trunk orthosis is the *lumbosacral flexion, extension, lateral control (LS FEL) orthosis* (Fig. 30.43), also known as a *Knight spinal orthosis*. This appliance includes a pelvic band, which should provide firm anchorage over the midsection of the buttocks, and a thoracic band, intended to lie horizontally over the lower thorax without impinging on the scapulae. The bands, which may be foam-lined rigid plastic or leather-upholstered metal, are joined by a pair of posterior uprights on either side of the vertebral spines, and a pair of lateral uprights placed at the right and left lateral midlines of the torso. A corset or abdominal front completes the LS FEL orthosis. The orthosis restrains flexion by a three-point system consisting of posteriorly directed force from the top and bottom of the abdominal front or corset and an anteriorly directed force from the

posterior midportion of the orthosis. Extension is controlled by posteriorly directed force from the midsection of the abdominal front or corset and anteriorly directed force from the upper and lower posterior segments. The lateral aspects resist lateral flexion. Other rigid lumbosacral (LS) orthosis are made entirely of polyethylene with removable replaceable liners (Fig. 30.44).

Figure 30.44 Prefabricated, adjustable lumbosacral flexion, extension, lateral control orthosis. *Courtesy of Orthomerica Products, Inc., Orlando, FL 32810.*

Thoracolumbosacral Flexion, Extension Control Orthoses

Also called a *Taylor brace*, the *thoracolumbosacral flexion, extension control (TLS FE) orthosis* consists of a pelvic band, posterior uprights terminating at midscapular level, an abdominal front or corset, and axillary straps attached to an interscapular band. This orthosis reduces flexion by a three-point system consisting of posteriorly directed force from the axillary straps and the bottom of the abdominal front or corset, and anteriorly directed force from the midportion of the posterior uprights. Extension resistance is provided by posteriorly directed force from the midsection of the abdominal front or corset and anteriorly directed force from the pelvic and interscapular bands. Addition of lateral uprights converts the orthosis to a TLS FEL *Knight Taylor* orthosis (Fig. 30.45). Although TLSOs reduce segmental and gross spinal movements, the amount of movement reduction varies greatly from one person to another.[110] Trunk movement restriction is evident when the wearer walks.[111] A plastic *thoracolumbosacral jacket* limits trunk motion in the frontal, sagittal, and transverse planes providing maximum support.

Cervical Orthoses

Cervical orthoses are classified according to design characteristics. Minimal motion control is provided by collars (Fig. 30.46) that encircle the neck with fabric,

Figure 30.45 (*Left*) Conventional thoracolumbosacral flexion, extension, lateral control orthosis (TLS FEL). (*Middle*) Custom-fabricated plastic TLS FEL. *Courtesy of Orthomerica Products, Inc., Orlando, FL 32810.* (*Right*) Prefabricated, adjustable TLS FEL.

Figure 30.46 Soft foam rubber collar. *Courtesy of Camp Healthcare Corporation, Jackson, MI 49204.*

resilient foam, or rigid plastic. The therapeutic benefit of collars remains controversial.[112,113] The *Philadelphia collar* (Fig. 30.47) has mandibular and occipital extensions and a rigid anterior strut; it is sometimes used for upper cervical injuries.[114-117] For moderate control, a *four-post orthosis* (Fig. 30.48) is used. Usually it has two anterior adjustable posts joining a sternal plate to a mandibular plate and two posterior uprights connecting a thoracic plate to an occipital plate. The sternal plate is strapped to the thoracic plate and the occipital plate is strapped to the mandibular plate. If the cervical orthosis does not fit properly, motion restriction is compromised.[118]

Maximum orthotic control of the neck may be achieved either with a *Minerva* or a *halo orthosis* (Fig. 30.49). The Minerva orthosis is a noninvasive appliance that has a rigid plastic posterior section extending from the head to the midtrunk; the superior

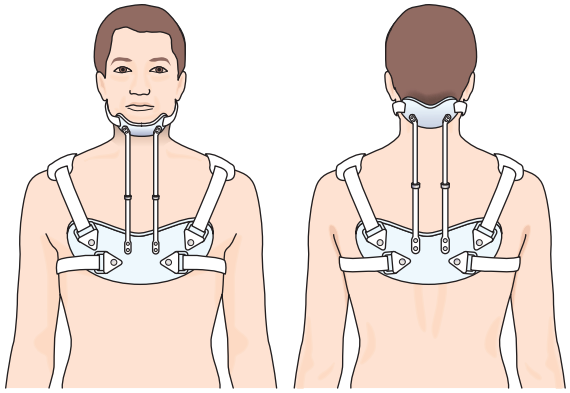

Figure 30.48 Four-post cervical orthosis.

portion is held in place by a forehead band. The halo orthosis has a circular band of metal that is fixed to the skull by four tiny screws. Uprights connect the halo to a thoracic vest. Recent investigations confirm that the halo vest allowed cervical fractures to heal,[119,120] particularly fractures of the second cervical vertebra.[121-123] By limiting upper trunk motion, this orthosis reduces stride length,[124] and results in temporary atrophy of neck muscles.[125]

Scoliosis Orthoses

Children and adolescents with kyphoses or thoracic, thoracolumbar, or lumbar scolioses may be fitted with a TLSO that applies distraction, derotation, and bending forces to realign the vertebral column and thoracic cage.[126-128] Brace effectiveness depends on the flexibility of the patient's torso[129] and snugness of contact with the wearer's trunk.[130] Although substantial improvement is evident when the orthosis is worn, long-term follow-up indicates that the major achievement is that the orthosis prevents the curve from increasing beyond its original contour. Bracing diminishes the likelihood of surgical correction of scoliosis.[131,132] Orthotic management is most effective for curves less than 35° Cobb angle.[133] Scoliosis orthoses are most effective on patients who have curves in the midthoracic or more inferior portions of the trunk. Although part-time wearing is better tolerated by adolescents, the classic protocol, which requires the youngster to wear the orthosis snugly 23 hours each day, is associated with more favorable results. Patients with larger curves achieve some curve reduction from bracing.[134,135] Braces do not impair standing balance.[136] Psychological factors, rather than the type or duration of brace wear, appear to be more important in self-reported quality of life among those for whom scoliosis braces are prescribed.[137,138] Adults with scoliosis do not benefit from orthoses.[139]

The Milwaukee orthosis (Fig. 30.50), the oldest of contemporary scoliosis orthoses, is still prescribed. It consists of a frame composed of a pelvic girdle, two

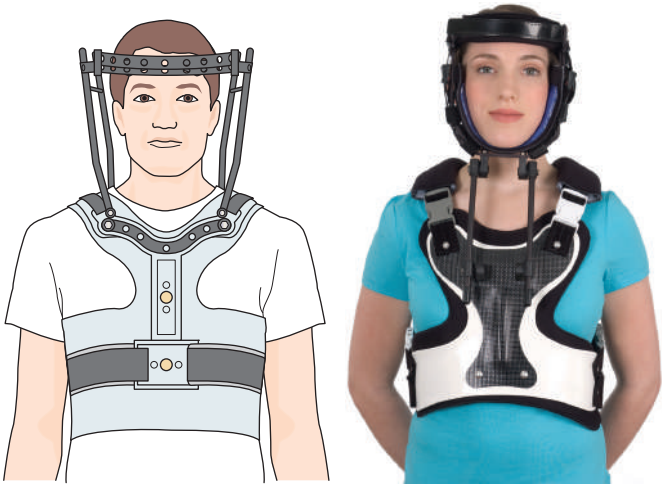

Figure 30.49 (*Left*) The halo cervical orthosis provides maximum stabilization of the head and cervical spine. The graphite ring (halo) allows placement of titanium pins into outer table of skull. (*Right*) Noninvasive halo devices are also available. They are effectively used as transitional bracing after removal of a halo cervical orthosis. Figure 30.51 Boston thoracolumbosacral orthosis.

posterior uprights, an anterior upright, and a superior ring that can be hidden by clothing. Various pads are strapped to the frame to apply corrective forces. The Boston orthosis (Fig. 30.51) usually does not extend as high as the Milwaukee orthosis; its foundation is a mass-produced plastic module that the orthotist alters to fit the individual patient. Effectiveness is enhanced by snugly strapping the interior pads to the torso.[140] Long-term results are favorable,[141] with patients preferring it to surgery.[142] The Wilmington orthosis is another option; it is a custom-made thoracolumbosacral jacket intended to guide the trunk to straighter alignment.

Night bracing is an alternate approach to scoliosis management. When the patient is in bed the effects of gravity are minimized allowing substantial corrective forces to be applied.[143] Nevertheless there is a higher risk of progression.[144] Both the Charleston bending brace and the Providence brace provide overcorrection of the spinal curve on the recumbent patient.[145,146] Scoliosis orthoses are also used for adolescents with hyperkyphosis.[147]

ORTHOTIC MAINTENANCE

To obtain the best service from orthoses, the patient should observe basic routine inspection and care procedures. Written instructions help reinforce the recommendations of the orthotist and therapist.

Shoes

Whether or not the shoe is attached directly to the orthosis, it is important that footwear be kept in good condition, with replacement of the sole and heel as soon as moderate wear is evident. The replacements should include whatever wedges, bars, or elevations were originally prescribed. The patient who tends to strike on the toe may need metal toe plates to preserve the sole. Shoes that are outgrown or distorted will not afford the wearer optimal function from the orthosis. If a stirrup is attached to the shoe, the patient should inspect the rivets

to make certain that none has separated; if so, the shoe should be returned to the orthotist for repair.

Clean hose without holes or mends should be worn. In addition, long hosiery or cotton leggings shield the leg from pressure at the edges of the brace uprights, bands, and shells.

Shells, Bands, and Straps

Plastic bands and shells should be wiped with a damp cloth to remove any surface soil. It is inadvisable to try to hasten drying by using a hair dryer or other heat source that might soften the plastic. The patient should check the plastic periodically for any cracking; if any is noted, the orthosis should be brought to the orthotist for immediate repair. Hook-and-pile straps eventually become infiltrated with lint, which interferes with the hook-and-loop closing action; the straps should be inspected to determine if they should be replaced. Leather bands require periodic cleaning and can be washed with mild saddle soap. If the original leather deteriorates to the point that portions of the underlying metal are exposed, new leatherwork is required. Leather straps eventually become brittle and may break. A loss of flexibility indicates that it is time to replace the straps, before they break.

Uprights

In a plastic and metal KAFO for a child, the metal upright is screwed or riveted to the plastic shell. The orthosis can be lengthened by removing the fasteners and inserting them in new holes drilled farther up on the calf shell and farther down on the thigh shell. In a metal and leather AFO or KAFO for a child, the uprights are overlapped and secured with screws. The orthosis is lengthened by removing all screws, setting the uprights at the appropriate distance, and reinserting the screws.

Joints and Locks

Metal components should be kept away from sand, liquids, and similar substances. If the joints do not move smoothly or become noisy or if the locks do not engage properly, cleaning and lubrication may remedy the problem. Otherwise, professional attention is required.

PHYSICAL THERAPY MANAGEMENT

Physical therapists participate in management of the wearer of an orthosis (1) before orthotic prescription, (2) at orthotic prescription, (3) on delivery of the orthosis, and (4) during training to facilitate proper use and care of the orthosis. In the ideal situation, the therapist is a member of an orthotic clinic team, working directly with the physician and orthotist to develop the orthotic prescription and examine the patient and orthosis before and after training. The physical therapist is also responsible for training the patient. Whether or not the hospital or rehabilitation center has a clinic team, the physical therapist is expected to accomplish the following.

Preorthotic Examination

The purposes of the preorthotic examination are to:

- Contribute to the orthotic prescription (analyze potential of orthotic components to remediate impairment, activity limitations, or disability).
- Examine the prescribed orthosis through analysis of (1) effects and benefits in terms of improved function, (2) movement while patient wears the device, (3) practicality and ease of use, (4) alignment and fit, and (5) safety during use of device.
- Facilitate orthotic acceptance.
- Train the patient to don, use, and maintain the orthosis.

Matching the patient's biomechanical requirements to the appropriate orthosis requires careful examination.

Joint Mobility

A thorough goniometric examination, including both active and passive range of motion, is a prerequisite to orthotic prescription. If the patient has a fixed foot deformity, either the shoe will have to be modified to accommodate the foot, or an insert will have to be fabricated. In either instance, the goal is to achieve comfortable contact of the entire plantar surface of the foot on the inner sole of the shoe. Knee flexion contracture necessitates prescription of accommodative joints, because the regular drop ring and pawl locks can be used only with a knee that can be brought to the fully extended position. Hip flexion contracture precludes the prescription of orthoses that depend on alignment for stability, such as the offset knee joint, stabilizing boots, or Craig-Scott KAFOs.

Limb Length

The therapist should ascertain whether leg lengths are equal. If the patient can stand, one can check the pelvis to determine if it is level. For the recumbent individual, one can measure each LE from the anterior superior iliac spine to the medial malleolus. A difference of more than 1/2 in (1 cm) should be compensated by a shoe elevation. For the patient with weakness in one limb, a 1/2-in (1 cm) lift on the contralateral shoe will aid clearance of the involved LE during swing phase.

Muscle Function

The manual muscle test (MMT) should be augmented by an examination of functional activities to determine what substitutions the patient makes to accomplish standing and walking. Although the muscle test may reveal marked weakness, if the patient can manage without an orthosis, it is unlikely that it will be accepted. For

example, the person with dorsiflexor weakness who can ambulate by exaggerating hip flexion during swing phase may not agree to an AFO with a posterior stop. An important consideration in examination of muscle function is that traditional MMTs may be inappropriate in the presence of marked spasticity. In such instances, functional tests of motor performance are essential.

Sensation

The clinician should record the extent of any sensory loss. Intimately fitted plastic orthoses are satisfactory for individuals with sensory loss if the edges of the orthosis are smooth and the orthosis does not pinch the patient's flesh. Proprioceptive loss may indicate the need for orthotic stabilization, such as a solid ankle AFO to control a Charcot neuropathic ankle. Patients should be taught to inspect the skin (including presence of volume changes) regularly and instructed to bring any changes to the attention of the physical therapist.

Upper Limbs

Although the patient is being considered as a candidate for LE or trunk orthoses, the therapist must determine the mobility and muscle power of the upper limbs. Significant weakness, stiffness, or deformity will interfere with donning the orthosis. Substitution of hook-and-loop closures for leather buckles may suffice. If the individual cannot ambulate without canes or crutches, the therapist should determine whether standard aids will be satisfactory or whether modification of the hand pieces is required. If the upper limbs are very weak, the patient will not be able to use the LE orthoses for walking. Alternate standing arrangements may be preferable, such as the use of a standing frame, standing table, or standing wheelchair to provide weight-bearing stress.

Psychological Status

Realistic orthotic prescription requires ascertaining that the patient is willing to wear the orthosis. The patient with a recent spinal cord injury may still deny the permanence of paralysis and thus oppose wearing orthoses that are visible reminders of disability. The adolescent with spina bifida may prefer to sit unbraced in a wheelchair rather than struggle with donning orthoses and walking slowly, in a manner very different from the individual's peers. The patient with spinal cord injury must be prepared to work vigorously to increase upper limb and trunk strength and aerobic capacity. The person who has sustained a cerebral vascular accident resulting in severe perceptual deficits may not be able to walk, even with orthotic assistance, because the environment now seems unfamiliar. An orthosis for prevention of contractures may be prescribed, rather than one that is designed to aid gait.

The therapist should determine the extent to which the patient is likely to comply with instructions pertaining to orthotic use and care. For example, if it is doubtful that the individual will wear appropriate shoes with an insert orthosis, then the prescription should specify stirrup attachment to suitable shoes.

Orthotic Prescription

Lower extremity orthoses benefit individuals with a wide variety of musculoskeletal and neurological disorders. The particular diagnosis is less important in formulating the prescription than consideration of the patient's impairments and activity limitations. Prognosis also influences prescription. The person who is likely to recover partial or full function should have an orthosis that can be adjusted to accommodate the changing status. An individual with recent hemiplegia, for example, may exhibit marked spasticity, indicating a need for limiting motion at the ankle. As the person regains voluntary control and spasticity decreases, the orthotic ankle joint can be adjusted to permit more movement.

Lifestyle has a bearing on orthotic selection. A very active patient requires an orthosis made of exceptionally sturdy materials. Split stirrups, for example, may not be appropriate because they can spring loose from the receptacle on the shoe if excessive medial–lateral or rotational stress is applied. The patient's concern with appearance is another practical consideration; it may dictate use of a shoe insert so that reasonably fashionable shoes may be worn. Similarly, plastic shells are less bulky than metal uprights and calf bands, and do not present a shiny metal appearance. Although most people want the orthosis to be as inconspicuous as possible, some children and adults opt for bright colors, which can be achieved with various plastics.

Ankle-Foot Orthoses

The primary candidates for AFOs are those with peripheral neuropathy, especially peroneal lesions, and hemiplegia. Those with foot drag can be fitted with an AFO with a posterior stop; this design, however, tends to cause the knee to flex excessively in early stance when controlled plantarflexion is normally achieved. In the absence of plantarflexion, the patient may flex the knee to effect a foot-flat position. The alternative is a resilient shoe heel, or an AFO with a plastic posterior leaf spring or a metal dorsiflexion spring assist, both of which permit controlled plantarflexion early in stance to reduce knee stress.

Orthotic management of a patient with hemiplegia depends on the extent of spasticity and paralysis. If the motor loss is confined to poor dorsiflexion, the posterior leaf spring AFO suffices. An even simpler and less expensive option is a 1/2-in (1-cm) lift on the heel and sole of the contralateral shoe to provide clearance for the paretic limb during swing phase. Those with medial–lateral and sagittal plane instability require an AFO with limited-motion ankle joints or a plastic spiral AFO. With pain or severe instability, a solid ankle AFO is required. In the presence of severe spasticity, a spring assist

for joint motion is contraindicated because the spring action may serve to increase spasticity.

Knee-Ankle-Foot and Other Lower Extremity Orthoses

A KAFO may be used to compensate for paralysis of the entire LE. The physical therapist should allow the patient the use a temporary orthosis in order to proceed more confidently with prescription of an expensive, custom-made orthosis. Several versions of temporary orthoses are manufactured and prove exceedingly useful in demonstrating whether the patient is likely to benefit from orthotic knee control.

Stabilizing AFOs, Craig-Scott KAFOs, HKAFOs, and the reciprocating gait orthosis are some options for patients with paraplegia. For the child, the orthotic program should start with a simple standing frame and progress to the parapodium before involving the child in the greater expense and donning difficulty of form-fitting bracing. Older children and adults may begin with a swivel walker or lightweight modular frames.

Trunk Orthoses

A corset may be adequate to increase intraabdominal pressure and thereby may reduce the discomfort of low back pain. Where greater motion restriction is indicated, such as for the individual with trunk paralysis, the LS FEL, TLS FE, or TLS FEL orthosis provides substantial support. Plastic lumbosacral or thoracolumbosacral jackets offer maximum support. Cervical orthoses, whether collars or post devices, restrain motion and remind the wearer not to move the head in an abrupt manner. Collars also retain body heat, which may prove therapeutic. For maximum neck control, a halo orthosis is required.

Many orthoses are available for management of patients with scoliosis. These include the Milwaukee orthosis, which covers the greatest body area, as well as the Boston and Wilmington orthoses. The Providence and Charleston braces are designed for nighttime use only.

Orthotic Examination

Examination is an essential element of orthotic management. The physical therapist should be certain that the orthosis fits and functions properly before attempting to train the patient to use it. Analysis may be conducted under the aegis of a formal orthotic clinic team. If so, when the orthosis is delivered, the team should determine the adequacy of the orthosis as pass, provisional pass, or fail. Pass indicates that the orthosis is altogether satisfactory and the patient is ready for training. Provisional pass means that minor faults exist, generally having to do with the cosmetic finishing of the appliance; the patient can wear the orthosis in the training program without harmful effect. Failure signifies that the orthosis has a major defect that would interfere with training; for example, shoes that are too tight for the patient. The problem must be resolved before training can begin. If the orthosis is not prescribed by a clinic team, the physical therapist should use the evaluation procedure to ensure that the orthosis meets the patient's needs. Final evaluation is performed at the conclusion of training to judge the fit and function of the orthosis and the patient's skill in using it.

Lower Extremity Orthotic Examination

Orthotic examination includes both static and dynamic elements. The *static* component examines the orthosis on the patient while standing and sitting, as well as examination of the device off the individual. The *dynamic* component of the examination addresses analysis of the wearer's gait. An LE orthotic examination form is provided in Appendix 30.A, and a trunk orthotic examination form is provided in Appendix 30.B.

Static Examination

The orthosis is inspected as the wearer stands and sits. The patient's skin and the construction of the orthosis are checked with the orthosis off the patient. The orthosis should be compared with the prescription. Departures from the original specifications must be approved by the individual who approved the prescription.

The patient should stand in parallel bars, or other secure environment, and should attempt to bear equal weight on both feet. The shoe should fit satisfactorily, particularly in length, width, and snugness of the counter. Whether or not wedges or lifts have been added to the shoe, the sole and heel should rest flat on the floor, except for the distal portion, which should curve upward slightly to aid in late stance. The orthotic ankle joint should be at the distal tip of the medial malleolus to be congruent with the anatomical ankle and avoid vertical motion of the orthosis on the leg during gait.

The calf band should terminate below the fibular head to avoid impingement on the peroneal nerve. If a patellar-tendon-bearing brim is used, it should have a concave relief to limit pressure on the fibular head. This component does not eliminate distal weight-bearing; however, one should judge to see that the shoe heel is somewhat unloaded. This can be estimated by placing a ribbon in the shoe before the patient dons the shoe. One end of the ribbon hangs out the back of the shoe. When the patient stands with the shoe and orthosis on, the therapist should be able to pull the ribbon out of the shoe. The calf shell, band, or patellar-tendon-bearing brim should not intrude on the popliteal fossa; if so, the patient would have difficulty flexing the knee when sitting. Donning ease is affected by the type of closure of both the shoe and band.

The mechanical knee joints should be congruent with the anatomical knee; for the adult, the usual placement is approximately 3/4 in (2 cm) above the medial tibial plateau. The knee lock should function properly, because use of a lock is often the major reason for

wearing a KAFO. The medial upright should terminate approximately 1.5 in (4 cm) below the perineum. The calf and distal thigh shells or bands should be equidistant so that when the orthosis is flexed, as in sitting, the plastic or metal parts will contact one another, rather than pinch the back of the wearer's leg.

If the KAFO has a quadrilateral brim to reduce weight-bearing through the skeleton, the brim should have adequate relief for the sensitive adductor longus tendon and should provide a sufficient seat for the ischial tuberosity.

The hip joint is set slightly above and anterior to the greater trochanter to compensate for the usual angulation of the femoral neck; setting the joint anterior to the trochanter takes into account the medial rotation of the femur. The pelvic band should conform to the contours of the wearer's torso, without edge pressure.

When the brace is off, the therapist should inspect the patient's skin to detect any irritations attributable to the orthosis. One should move the orthotic joints slowly to check range of motion. Binding refers to tilting of the distal portion of the joint in relation to the proximal member so as to interfere with movement. If the medial and lateral stops do not contact their respective stops at the same time, the stop that contacts first will erode more rapidly and may contribute to twisting of the orthosis.

Dynamic Examination

The gait pattern exhibited by the person who wears an orthosis reflects both the contribution of the wearer's general health status and orthotic motion control and assistance. Table 30.1 relates orthotic and anatomical causes of the most commonly observed gait deviations.

During early stance, the patient may exhibit foot slap, striking with toes first, or flat-foot contact, indicating inability to restrain plantarflexion or failure of the orthosis to support the foot and ankle. Excessive medial or

Table 30.1 Orthotic Gait Analysis

Deviation	Orthotic Causes	Anatomical Causes
Early Stance		
1. Foot slap: forefoot slaps the ground	Inadequate dorsiflexion assist Inadequate plantarflexion stop	Weak dorsiflexors
2. Toes first: tiptoe posture may or may not be maintained throughout stance	Inadequate heel lift Inadequate dorsiflexion assist Inadequate plantarflexion stop Inadequate relief of heel pain	Short LE Pes equinus Extensor spasticity Heel pain
3. Flat foot contact: entire foot contacts ground initially	Inadequate traction from sole Requires walking aid (e.g., cane) Inadequate dorsiflexion stop	Poor balance Pes calcaneus
4. Excessive medial (or lateral) foot contact: medial (or lateral) border contacts floor	Transverse plane malalignment	Weak invertors (evertors) Pes valgus (varus) Genu valgum (varum)
5. Excessive knee flexion: knee collapses when foot contacts ground	Inadequate knee lock Inadequate dorsiflexion stop Plantarflexion restriction (stop) Inadequate contralateral shoe lift	Weak quadriceps Short contralateral LE Knee pain Knee and/or hip flexion contracture Flexor synergy Pes calcaneus
6. Hyperextended knee: knee hyperextends as weight is transferred to LE	Genu recurvatum inadequately controlled by plantarflexion stop Excessively concave (deep) calf band Pes equinus uncompensated by contralateral shoe lift Inadequate knee lock	Weak quadriceps Lax knee ligaments Extensor synergy Pes equinus Short contralateral LE Contralateral knee and/or hip flexion contracture
7. Anterior trunk bending: patient leans forward as weight is transferred to LE	Inadequate knee lock	Weak quadriceps Hip flexion contracture Knee flexion contracture

Table 30.1 Orthotic Gait Analysis—cont'd

Deviation	Orthotic Causes	Anatomical Causes
8. Posterior trunk bending: patient leans backward as weight is transferred to LE	Inadequate hip lock Knee lock	Weak gluteus maximus Knee ankylosis
9. Lateral trunk bending: patient leans toward stance leg as weight is transferred to LE	Excessive height of medial upright of KAFO Excessive abduction of hip joint of HKAFO Requires walking aid (e.g., cane) Insufficient shoe lift	Weak gluteus medius Abduction contracture Dislocated hip Hip pain Poor balance Short leg
10. Wide walking base: heel centers more than 4 in (10 cm) apart	Excessive height of medial upright of KAFO Excessive abduction of hip joint of HKAFO Insufficient lift on contralateral shoe Knee lock Requires walking aid (e.g., cane)	Abduction contracture Poor balance Short contralateral LE
11. Internal (or external) rotation: LE internally (or externally) rotated	Uprights incorrectly aligned in transverse plane Requires orthotic control (e.g., rotation control straps, pelvic band)	Internal (or external) hip rotators spastic External (or internal) hip rotators weak Anteversion (retroversion) Weak quadriceps: external rotation
Late Stance		
1. Inadequate transition: delayed or absent transfer of weight over the forefoot	Plantarflexion stop Inadequate dorsiflexion stop	Weak plantarflexors Achilles tendon sprain or rupture Pes calcaneus Forefoot pain
Swing		
1. Toe drag: toes maintain contact with ground	Inadequate dorsiflexion assist Inadequate plantarflexion stop	Weak dorsiflexors Plantarflexor spasticity Pes equinus Weak hip flexors
2. Circumduction: LE swings outward in a semicircular arc	Knee lock Inadequate dorsiflexion assist Inadequate plantarflexion stop	Weak hip flexors Extensor synergy Knee and/or ankle ankylosis Weak dorsiflexors Pes equinus
3. Hip hiking: LE elevated at pelvis to enable the limb to swing forward	Knee lock Inadequate dorsiflexion assist Inadequate plantarflexion stop	Short contralateral LE Contralateral knee and/or hip flexion contracture Weak hip flexors Extensor synergy Knee and/or ankle ankylosis Weak dorsiflexors Pes equinus

Table 30.1 Orthotic Gait Analysis—cont'd

Deviation	Orthotic Causes	Anatomical Causes
4. Vaulting: exaggerated plantarflexion of contralateral LE to enable the limb to swing forward	Knee lock Inadequate dorsiflexion assist Inadequate plantarflexion stop	Weak hip flexors Extensor spasticity Pes equinus Short contralateral LE Contralateral knee and/or hip flexion contracture Knee and/or ankle ankylosis Weak dorsiflexors

LE = lower extremity.

lateral contact may indicate that the orthosis does not track the way the patient's limb does. Knee hyperextension or excessive flexion indicates that the orthosis is not applying adequate control. A posterior stop on the AFO should prevent the lax knee from hyperextending. If the patient wears a KAFO and has knee hyperextension, the stops in the knee joint are set improperly or have eroded, or the calf and thigh shells or bands are too deep. Anterior and posterior trunk bending are seen at early stance when the patient attempts to control a weak knee or hip. If the quadriceps are weak, the patient will bend forward. The person who fears that the knee may collapse may benefit from an AFO with a solid ankle and an anterior band, or a KAFO with a knee lock. If the gluteus maximus is weak, the individual is apt to lean backward. Lordosis indicates hip flexion contracture or a KAFO that does not fit properly. Lateral trunk bending in early stance phase may result from hip abductor weakness or hip instability; however, uncompensated shortness of the limb will also give rise to this problem, as will a medial upright on a KAFO that is too high, or an abducted pelvic joint on an HKAFO. A wide walking base may be the patient's compensation for a medial upright or shell that impinges into the perineum.

The client may have difficulty during late stance either delaying weight transfer or being unable to transfer weight over the affected foot. The problem can be mitigated with an anterior stop and a rocker bar. One should be certain that the trimlines of the solid ankle AFO or the stops on the stirrup function properly.

During swing phase, the patient must be able to clear the floor with the braced leg. Hip hiking (pelvic elevation) occurs when the hip flexors are weak, as well as when the limb is functionally longer than the contralateral limb. Increased length may be produced by a faulty posterior stop that no longer limits plantarflexion, or by a locked knee joint. The problem should be anticipated and, for the unilateral KAFO wearer, can be prevented by adding a 1/2 in (1 cm) lift to the contralateral shoe. Internal or external hip rotation may be caused by imbalance between medial and lateral musculature; the orthotic causes relate to malalignment of the brace. Similarly, excessive medial or lateral foot contact may indicate that the orthosis does not track the way the patient's limb does. A walking base that is abnormally wide can be caused by a limb that is longer than that on the opposite side. Vaulting refers to exaggerated plantarflexion on the contralateral limb during swing phase of the affected side. Vaulting occurs because the braced leg is functionally too long, possibly because the posterior ankle stop has eroded or a knee lock is used. The less agile patient may obtain foot clearance by hip hiking, that is, elevating the pelvis on the swing side.

Trunk Orthosis Static Examination

Lumbosacral and thoracolumbosacral orthoses usually include thoracic and pelvic bands, which should fit flat against the trunk without edge pressure. Uprights should not press against bony prominences, particularly when the patient sits. The abdominal front should extend from just below the xiphoid process to just above the pubic symphysis. The cervical orthosis should hold the head in the best tolerated position. Rigid components, such as a mandibular plate, occipital plate, sternal plate, or thoracic plate, should be shaped to apply maximum area to the body segment.

Facilitating Orthotic Acceptance

Clinic team management is valuable in fostering acceptance of the orthosis by the patient. The team also enables clinicians to join efforts to help the client achieve the maximum benefit from orthotic rehabilitation. Bringing the new wearer of an orthosis in contact with other users in the physical therapy department can help the new patient recognize that orthotic use is not a strange occurrence. Peer support groups for patients and their families are helpful for sharing concerns and anxieties and reaching workable solutions to common problems. Support groups usually are organized for people having particular disabilities, such as paraplegia or hemiplegia; many

clients will have orthoses as part of their rehabilitation. The physical therapist can guide some meetings of the group. The therapist works most closely with the patient, usually on a daily basis, and thus is able to identify those individuals whose response to disability is sufficiently aberrant as to require psychological attention. Appendix 30.C provides website-based orthotic resources for clinicians, families, and patients.

Orthotic Instruction and Training

Orthoses are designed to provide the individual with a maximum of function with a minimum of discomfort and effort. No single training program suits every orthosis wearer because of the wide range of disorders for which orthotic management is indicated. To the extent possible, however, the physical therapist should instruct the patient in the correct manner of donning the orthosis, developing standing balance, walking safely, and performing other ambulatory activities.

Optimal performance depends on the favorable interaction of many factors. Foremost is the extent of skeletal and neuromuscular involvement. The mobility, strength, and coordination of all body segments, especially in the LEs and trunk, are important, as are the individual's muscle tone, cardiovascular and pulmonary health, body weight, psychological status, and chronological age. The quality of the orthosis also influences the client's achievements.

Most orthosis wearers have chronic conditions, such as rheumatoid arthritis, or permanent sequelae from trauma, such as paraplegia following spinal cord injury. Orthotic management enhances function without necessarily influencing the underlying pathology. Training people with chronic disorders prepares the patient for lifelong activity with an orthosis. Persons with reversible disorders, such as peroneal nerve injury, often benefit from temporary use of an orthosis. Such individuals should learn proper use of the orthosis to prevent secondary disorders and should receive reexamination so that the orthosis may be altered as the condition changes. Patients with progressive disorders, such as muscular dystrophy and multiple sclerosis, require vigilant reexamination so that the extent of physical deterioration may be reflected in orthotic changes, as well as continual training to cope with altered functional abilities. For all situations, an individually devised exercise and activity program should enable the patient to manage efficiently for maximum independence.

Donning Orthoses

Regardless of type of LE orthosis, the patient should wear clean, properly fitting hose. The AFO with shoe insert is most easily donned by applying the orthosis to the foot and leg, before placing the braced limb in the shoe. If the AFO has a split stirrup, the shoe should be donned first; then the orthosis should be fitted into the box caliper on the shoe. If the AFO has a solid stirrup, the patient will have to insert the foot into the shoe, then fasten the calf band.

The same general procedures are useful with KAFOs. The patient may find donning easier if the brace is applied while lying on a bed or a mat table. If the KAFO is donned while the patient sits, the therapist should check the tightness of the orthotic knee cap, if this component is part of the orthosis. A kneecap that is comfortable for sitting will probably be too loose for effective knee control when the wearer stands. Donning HKAFOs and THKAFOs is much more arduous. The beginner should lie on a mat table alongside the orthosis. By rolling to one side, the patient should be able to pull the brace under the legs so as to permit lying in it. Then the patient sits with knees extended to don shoes and fasten straps.

Lumbosacral and thoracolumbosacral corsets and rigid orthoses should be donned while the patient is supine to achieve maximum compression of the abdomen. The orthosis should be fastened from the bottom upward.

Standing Balance

The problem of standing safely is most difficult for the individual who wears a pair of KAFOs or more extensive bracing. In ordinary standing, all weight passes through the feet, whereas when standing and walking with orthoses and crutches, the patient must learn to distribute weight partly on the hands and partly on the feet. With orthoses, the line of gravity falls within a tripod bounded by the hands and feet. The tripod is a compromise between leaning too far forward on the hands, to increase stability at the price of fatiguing the arms, and leaning too far backward, which reduces arm strain but makes balance precarious. As balance improves, the patient uses the hands only for balance, rather than for substantial weight-bearing.

The person who wears bilateral KAFOs will need crutches or other aids for independent gait. A prerequisite for crutch ambulation is the ability to shift weight. Shifting weight to the heels takes pressure off the hands so they can be moved. Using parallel bars, the beginner shifts all weight to the feet and raises and lowers one hand, then the other hand. The goal is to be able to lift both hands simultaneously, as may be done with crutches when performing a drag-to or similar gait. Once the patient is able to shift weight from the feet to the hands and back to the feet confidently, the same exercise should be done with crutches. Advanced skills, such as moving the hands and eventually the crutches, behind the body, should be practiced. Those who will walk in reciprocal fashion, alternating footsteps, need to practice diagonal weight shifting.

Gait Training

The various crutch gaits differ in the sequence of crutch and footsteps. Patterns vary in speed, safety, and amount

of energy required. The patient should learn as many gaits as possible, so as to modify walking in crowds, over long distances, and in situations in which speed is desired. In addition to walking forward, the client needs to be able to walk sideward, turn corners, and maneuver on different surfaces, such as rugs, gravel, grass, and through doors. A repertoire of gaits permits the client to adjust to environmental requirements. Gait selection depends on the individual's functional ability, including the following areas:

- *Step ability*: Can the patient take steps with either one or both LEs?
- *Weight-bearing and balance ability*: Can the patient bear weight and remain balanced on one or both LEs?
- *Upper-limb power*: Can the patient push the body off the floor by pressing down on the hands?

Reciprocal Gaits

The four- and two-point gaits require that one move the LEs alternately by hip flexion or pelvic elevation. The patient shifts weight as each LE is moved. The four-point sequence is (1) right hand, (2) left foot, (3) left hand, and (4) right foot. The two-point sequence requires greater balance and coordination, but is a faster mode of walking: (1) right hand and left leg; (2) left hand and right leg. The patterns also are useful when one is confronted with crowds or slippery surfaces. These gaits are suited to persons who lack the coordination and balance needed for simultaneous gaits.

Simultaneous Gaits

If both LEs are moved simultaneously, the patient places considerable stress on the upper limbs. The series includes the drag-to, swing-to, and swing-through patterns. Although the swing-through gait can be performed rapidly, simultaneous gaits generally are slow and very fatiguing, because the upper limbs are poorly adapted for ambulatory function; a sizable amount of nonfunctioning bodily structure must be controlled by a smaller muscular apparatus. The weight of the orthoses and, in the case of a patient with spinal cord lesion, absence of peripheral sensation aggravate the problem of using a simultaneous gait pattern.

The drag-to gait is the most elementary of the group, but it is very slow. The sequence is (1) advance both hands, then (2) push on the crutches enough to drag the feet forward. The feet do not pass ahead of the hands. The swing-to pattern is more rapid, because the patient swings rather than drags the LEs. Swinging is accomplished by extending the elbows and depressing the shoulder girdle to elevate the trunk and LEs. The swing-through gait is the most advanced pattern, requiring much balance, strength, and coordination of the upper limbs, because the patient swings the LEs beyond the hands, or crutch tips. The sequence is (1) advance both hands, (2) swing both LEs to a point in front of the hands to reverse the basic tripod position, and (3) advance both hands to the starting position. The swing-through gait requires extensive preliminary training, including push-ups to strengthen the arms. The gait is rapid but requires more floor space than the other patterns, to permit alternate swinging of LEs and crutches.

The ultimate test of walking proficiency is the ability to conduct a conversation while ambulating, an activity pattern that indicates some degree of automatic functioning. Practice in the clinical setting should be extended to walking on varied terrain, indoors and outdoors.

Related Activities

The patient should learn as many activities as physical condition permits. Daily life often involves negotiating stairs, curbs, and ramps, as well as transferring from the chair to the upright position, and into an automobile. Instruction in driving a suitably equipped car is an important part of rehabilitation. Not all individuals who wear orthoses achieve the full range of ambulatory activities, yet they benefit from partial independence in accomplishing tasks, at least from the psychological and physiological values attendant to ambulation.

Final Examination and Follow-up Care

Before discharge, the orthosis wearer and the brace should be examined to make certain that fit, function, appearance, and use are acceptable. The patient should return to the hospital or rehabilitation center at regular intervals so that the clinic team can monitor the individual's function and the orthosis, and can spot incipient abrasions or other signs of misfit or disrepair. The follow-up visit also enables the physical therapist to reinforce skills taught in the intensive program and address any new problems the patient may present.

Functional Capacities

The patient's ambulatory ability and capacity for other physical activities reflect both orthotic and anatomical factors. Energy measurement is a valuable guide to functional capacity. Energy cost is calculated from the amount of oxygen consumed as the subject performs. Consumption may be determined either per unit of distance traversed or per unit of time. Everyone tends to select a walking speed that requires the least energy per unit of distance. If the energy cost is too high, the patient will realize that ambulation is not practical. Sometimes, high energy cost is tolerable for short distances, as in household ambulation. Community ambulation, however, demands sustained effort for longer distances, plus the ability to maneuver over curbs and other irregularities in the walking surface and cross the street within the time allowed by the traffic light. Many energy studies have been conducted with the two largest groups of individuals who wear orthoses, namely those with paraplegia and those with hemiplegia.[148]

Paraplegia

The level of spinal cord damage is a critical determinant of functional capacity. Investigators generally conclude that functional ambulation is not feasible for those with lesions above the T11 segment of the spinal cord. Children wearing the reciprocating gait orthosis while performing the swing-through crutch gait have approximately the same energy expenditure as when propelling a wheelchair. Adults with thoracic injuries consume nine times the energy expended by nondisabled individuals per meter, and those with lumbar lesions require triple the normal amount of oxygen when walking at self-selected speeds. Those with high-level paraplegia use three times their own basal oxygen rate ambulating with Craig-Scott KAFOs; they choose a very slow walking pace. Subjects with lesions between T11 and L2 wearing bilateral KAFOs select walking speeds less than half that of nondisabled persons, with oxygen uptake six times normal. Wheelchair propulsion by the same group increases oxygen uptake less than 10% more than normal, at a considerably faster speed. The very high energy cost may be accounted for by the fact that the LE paralysis requires that the individual move by upper limb and thoracic action, usually in a swing-to or swing-through gait. This pattern is extremely strenuous, taxing nondisabled adults by at least 75% more energy than normal walking.

Of less significance in determining functional capacity is the type of orthosis. Restraining both plantarflexion and dorsiflexion, as provided by Craig-Scott KAFOs, reduces energy demand very slightly. Ankle restraint, however, makes no appreciable difference in the energy required to negotiate stairs and ramps. Performance is somewhat more efficient with molded plastic KAFOs, which weigh slightly less than traditional metal and leather braces. Most subjects fitted with a reciprocating gait orthosis preferred it primarily because of its appearance and perception of stability.

One should not lose sight of the principal purpose of ambulation, namely to get from one place to another, rather than to execute an exhausting physical stunt. The nearly universal abandonment of orthoses by individuals with thoracic spinal cord injury after discharge from the rehabilitation center attests to the fact that most decide that accomplishing vocational and recreational tasks is more important than struggling with brace donning and energy-costly ambulation.

Hemiplegia

Although the increased energy demand occasioned by hemiplegic ambulation is not nearly as dramatic as that for paraplegic gait, the cost should be considered in planning reasonable goals. Energy cost rises in proportion to the amount of spasticity. The increase ranges from no appreciable difference for persons with hemiplegia to a 100% increase for relatively inexperienced walkers. On average, comfortable gait is approximately half the speed of that for nondisabled individuals.

The type of orthosis does not appear to make much difference in functional capacity, although patients with hemiplegia perform more efficiently with some form of AFO than without any bracing. Investigation of the factors that influence energy expenditure, especially physical status, helps the clinician plan the most appropriate rehabilitation program and forecast long-term performance.

SUMMARY

This chapter has focused on lower extremity and trunk orthoses. The most frequently prescribed orthoses and orthotic components have been presented. In addition, the responsibilities of the physical therapist in orthotic management have been emphasized.

Ideally, an orthosis is prescribed by an orthotic clinic team composed of a physician, physical therapist, and orthotist. The prescription should be based on a thorough examination, with particular attention to the specific factors discussed in this chapter. Input from the patient and all team members during the decision making process is critical. This approach will ensure an optimum match between the patient's biomechanical and psychological requirements and an appropriate orthosis capable of performing its intended function. Once the orthosis has been prescribed, it should be evaluated to ensure satisfactory fit, function, and construction, and the patient should have the benefit of a suitable training program for donning the orthosis and using it effectively.

Questions for Review

1. Discuss the purpose of a correctly fitted shoe in orthotic management.
2. Describe the purpose (function) of the following external shoe modifications: heel wedge, sole wedge, metatarsal bar, and rocker bar.
3. What are the advantages of a plastic orthotic shoe insert as compared with the solid stirrup?
4. For the patient with dorsiflexor weakness or paralysis, explain how a posterior leaf spring AFO imparts its function during early stance and swing phases of gait.
5. What is the function of the proximal anterior band on a floor reaction AFO?
6. How do tone-inhibiting AFOs improve the patient's function?
7. Indicate the clinical use of an AFO with a patellar-tendon-bearing brim.
8. What strategies can be used to increase the rigidity of plastic orthoses?
9. What is the function of an offset knee joint on a knee-ankle-foot orthosis (KAFO)?
10. Describe the three-point system in a lumbosacral flexion, extension, control orthosis.
11. What data should be gathered before formulating an orthotic prescription?
12. Compare and contrast the orthotic options for a patient with hemiplegia.
13. What are the purposes of the preorthotic examination?
14. What features of the AFO are considered during the static evaluation?
15. What are the anatomical and orthotic causes of vaulting?

CASE STUDY

PATIENT HISTORY AND CURRENT PROBLEM

The patient is a 65-year-old woman who had poliomyelitis at age 3. She sustained complete paralysis of the right LE and left foot and ankle. During childhood she wore bilateral knee-ankle-foot (KAFO) orthoses and ambulated with a four-point gait with the aid of a pair of axillary crutches. When she was 18, she had a left ankle and subtalar fusion. She was fitted with a right KAFO, which included a stirrup foundation, posterior ankle stop, drop ring knee lock, knee pad, and leather-covered calf and thigh bands. For the next 40 years, she wore the same brace, and had the leather and shoe replaced whenever they became worn. She used a cane in the left hand when she walked outdoors. She returned to the rehabilitation department today complaining of pain in the right knee and fatigue. She also said that her brace tears her stockings at the knee. She is curious about new orthotic developments.

PAST MEDICAL HISTORY

Except for poliomyelitis, she enjoyed good health although her endurance was always less than that of her friends.

SOCIAL HISTORY

The patient is a reference librarian who lives with her husband. She enjoys visiting her grandchildren, attending the theater, and participating in political campaigns.

PHYSICAL THERAPY EXAMINATION FINDINGS

- *Cognitive status*: Alert, oriented, memory intact
- *Endurance*: Limited, primarily restricted by discomfort in her right knee. She can walk for three city blocks before having to rest.
- *Vision*: Intact with corrective lens
- *Blood pressure*: 136/74
- *Respiratory rate*: Within functional limits (WFL)

Range of Motion Examination

Motion	Right	Left
Hip flexion	WFL	WFL
Hip extension	WFL	WFL
Hip abduction	WFL	WFL
Hip adduction	WFL	WFL
Hip external rotation	WFL	WFL
Hip internal rotation	WFL	WFL
Knee	25°–0°–120°*	WFL
Ankle dorsiflexion	0°–5°	0° (no motion)
Plantarflexion	0°–40°	0° (no motion)
Inversion	0°–10°	0° (no motion)
Eversion	0°–5°	0° (no motion)

*Right knee exhibits 25° of hyperextension.
WFL = within functional limits.

Sensation

- All modalities WFL bilaterally in both limbs
- Sensation in both upper limbs WFL

Strength: Manual Muscle Test (MMT) Grades

Motion	Right	Left
Hip flexion	2–/5	4/5
Hip extension	0	4/5
Hip abduction	0	4/5
Hip adduction	0	4/5
Hip internal rotation	0	4/5
Hip external rotation	0	3+/5
Knee flexion	0	4–/5
Extension	0	3+/5
Ankle dorsiflexion	0	N/A
Plantarflexion	0	N/A
Inversion	0	N/A
Eversion	0	N/A
Upper limb strength	WFL	WFL

N/A = not applicable owing to fusion; WFL = within functional limits.

Orthotic Examination

Uprights malaligned permitting 20° knee hyperextension. Posterior ankle stop worn, permitting 10° plantarflexion. Leather on calf and thigh bands is worn.

Balance

Standing

- *Static*: Good; able to maintain static position for unlimited period.
- *Dynamic*: Good on level surface. Not tested on ramp; patient reports that balance on ramps is precarious.

Sitting
- WFL

Gait

Patient walks slowly with a right KAFO with considerable trunk bending to the right. Bending reduces when she uses a cane in the left hand. She reports that she has great difficulty ascending and descending ramps. Additional findings include the following:
- Overall decrease in speed of movement
- Broad walking base
- Circumducts right leg
- Right knee hyperextends within the orthosis
- Right ankle plantarflexion limited by orthosis
- Left foot and ankle immobile

Functional Status

- Independent in transfers: sit-to-stand; floor-to-stand transfer
- Independent in all basic activities of daily living (BADL)
- Independent in approximately 85% of instrumental activities of daily living (IADL) (limitations imposed by pain, fatigue, and low ambulatory tolerance)

PATIENT-DESIRED OUTCOME AND GOALS

- Walk without knee pain.
- Improve endurance.
- Improve appearance.
- Reduce frequency of torn stockings in the vicinity of the knee.

GUIDING QUESTIONS

1. Formulate a clinical problem list.
2. Formulate a patient asset list.
3. Establish anticipated goals and expected outcomes of physical therapy.
4. Formulate a physical therapy plan of care.

Lower Extremity Orthotic Examination

appendix 30.A

1. Is the orthosis as prescribed?
2. Can the client don the orthosis easily?

Standing

3. Is the shoe satisfactory and does it fit properly?
4. Are the sole and heel of the shoe flat on the floor?
5. If a shoe insert is used, is there minimal rocking between insert and shoe?

Ankle

6. Do the mechanical ankle joints coincide with the anatomical ankle (anatomical ankle joint axis is approximated by a horizontal line between the malleoli at level of the distal tip of the medial malleolus)?
7. Is there adequate clearance between the anatomical ankle and the mechanical ankle joints?
8. Does the valgus or varus correction strap control the foot position?

Knee

9. Does the mechanical knee joint(s) coincide with the anatomical knee (0.5–0.75 in [1.2–1.9 cm]) above medial tibial plateau?
10. Is there adequate clearance between the anatomical knee and the mechanical knee joint?
11. Is the knee lock secure and easy to operate?

Shells, Bands, Cuffs, and Uprights

12. Do the shells, bands, cuffs, and uprights conform to the contours of the leg and thigh?
13. Is there adequate clearance between the top of the calf shell or band and the head of the fibula?
14. Is there adequate clearance between the orthosis and the perineum?
15. Is the orthosis below the greater trochanter but at least 1 in (2.5 cm) higher than the medial shell or upright?
16. Are the uprights at the midline of the leg and thigh?
17. Do the shells, bands, and cuffs conform to the contours of the leg and thigh?
18. Is any flesh roll above the shell or band minimal?
19. Are the bottom of the thigh shell or distal thigh band and the top of the calf shell or band equidistant from the knee?
20. In a child's orthosis, is there adequate provision for lengthening the orthosis?

Weight-Relieving Components

21. In a patellar-tendon-bearing brim, is there adequate relief for the head of the fibula?
22. With a quadrilateral brim, is the client free from excessive pressure in the anteromedial and medial aspect of the brim?
23. With a quadrilateral brim, does the ischial tuberosity rest on the ischial seat?
24. With a patellar-tendon-bearing brim, is there adequate reduction in weight-bearing through the orthosis?

Hip

25. Is the center of the pelvic joint slightly above and ahead of greater trochanter?
26. Is the hip lock secure and easy to operate?
27. Does the pelvic band fit the torso accurately?

Stability

28. Does the orthosis provide adequate stability to the client?

Sitting

29. Can the patient sit comfortably with hips and knees flexed 90°?
30. Can the patient lean forward to touch the shoes?

Walking

31. Is the patient's performance in level walking satisfactory?
32. Is the patient's performance on stairs and ramps satisfactory?
33. Is the orthosis sufficiently rigid?
34. Does the varus or valgus correction strap provide adequate support?
35. Does the orthosis operate quietly?
36. Does the patient consider the orthosis satisfactory as to comfort, function, and appearance?

Orthosis Off the Patient

37. Is the skin free of abrasions or other discolorations attributable to the orthosis?
38. Is the construction satisfactory?
39. Do all components function satisfactorily?

appendix

30.B Trunk Orthotic Examination

1. Is the orthosis as prescribed?
2. Can the client don the orthosis easily?

Standing

Pelvic Band

3. Does the pelvic band lie flat on the trunk below the posterior superior iliac spines?
4. Does the pelvic band pass between the trochanters and iliac crests?

Thoracic Band

5. Does the thoracic band lie flat on the trunk below the scapulae?
6. Does the thoracic band lie horizontally on the trunk?

Uprights

7. Do the posterior uprights avoid pressure on bony prominences, such as the vertebral spines or scapulae?
8. Do the lateral uprights extend along the lateral midlines of the trunk?

Abdominal Front

9. Is the abdominal front of adequate size?

Cervical Orthosis

10. Is the head in the prescribed position?
11. Do all rigid components fit properly?

Sitting

12. Can the patient sit comfortably with the hips and knees flexed 90°?
13. Does the patient consider the orthosis satisfactory as to comfort, function, and appearance?

Orthosis Off the Patient

14. Is the skin free of abrasions or other discolorations attributable to the orthosis?
15. Is the construction satisfactory?
16. Do all components function satisfactorily?

Chapter 31

Prosthetics

Joan E. Edelstein, PT, MA, FISPO, CPed
Christopher Kevin Wong, PT, PhD, OCS

LEARNING OBJECTIVES

1. Describe the components of transtibial and transfemoral prostheses, including advantages and disadvantages of alternative components and materials.
2. Explain the distinctive features of partial foot, Syme's, knee and hip disarticulation prostheses, and bilateral prostheses.
3. Outline the maintenance program for prosthetic components.
4. Conduct static and dynamic evaluation of transtibial and transfemoral prostheses.
5. Summarize the physical therapist's role in management of individuals with lower-limb amputation.
6. Analyze and interpret patient data, formulate realistic goals and outcomes, and develop a plan of care when presented with a clinical case study.

CHAPTER OUTLINE

PARTIAL FOOT AND SYME'S PROSTHESES *1365*
TRANSTIBIAL PROSTHESES *1365*
- Foot-Ankle Assemblies *1366*
- Rotators and Shock Absorbers *1368*
- Shank *1369*
- Socket *1370*
- Suspension *1371*

TRANSFEMORAL PROSTHESES *1374*
- Foot-Ankle Assemblies and Shanks *1374*
- Knee Units *1374*
- Sockets *1377*
- Suspensions *1379*

DISARTICULATION PROSTHESES *1379*
- Knee Disarticulation Prostheses *1380*
- Hip Disarticulation Prostheses *1380*

BILATERAL PROSTHESES *1381*
- Bilateral Syme's and Transtibial Prostheses *1381*
- Bilateral Transfemoral Prostheses *1381*

PROSTHETIC MAINTENANCE *1381*
- Foot-Ankle Assemblies *1381*

- Prosthetic Training *1390*
- Final Evaluation and Follow-up Care *1392*
- Functional Capacities *1392*

SUMMARY *1393*

Physical therapists are concerned with the care of individuals with lower- and upper-limb amputations. Patients are often fitted with a *prosthesis* to replace the absent part of the leg or arm. In the broadest sense, prostheses also include dentures, titanium femoral heads, and plastic heart valves. A *prosthetist* is a health care professional who designs, fabricates, and fits limb prostheses.

The major causes of amputation are peripheral vascular disease, trauma, malignancy, and congenital deficiency. In the United States, vascular disease accounts for most leg amputations, particularly among patients with diabetes.[1] Individuals older than 60 constitute the largest group of people with amputation. Trauma is responsible for the majority of amputations in younger adults and adolescents. Men are more likely to sustain amputation because of trauma and vascular disease. Bone and soft tissue tumors are sometimes treated by amputation, with adolescence the period of peak incidence. Congenital deficiency refers to the absence or abnormality of a limb evident at birth.

This chapter focuses on the lower extremity (LE) because many more people have lost a portion of the LE, as compared with the upper extremity (UE). Physical therapists are key members of the rehabilitation team, working with prosthetists, physicians, occupational therapists, and others to foster the patient's welfare. For individuals with LE amputation, physical therapists have the major role in assisting the person to regain function. Lower extremity prostheses will be described, together with a program for training patients in their use. For patients with UE amputation, physical therapists may play a lesser role, cooperating with occupational therapists, depending on the administrative organization of the health care facility.

Historic records confirm that the concept of replacing a missing limb is very old. A forked stick that formed a peg leg to support a transtibial (below-knee) amputation limb was known in antiquity. Today, most individuals with LE amputation are provided with a prosthesis because function with one LE is very different from maneuvering with two.

The principal LE prostheses are partial foot, Syme's, transtibial, and transfemoral, as well as knee and hip disarticulation. The physical therapist should

be familiar with their characteristics and maintenance, as well as the rehabilitation of patients fitted with these devices.

PARTIAL FOOT AND SYME'S PROSTHESES

The purposes of partial foot prostheses are to (1) restore, as much as possible, foot function, particularly in walking; and (2) simulate the shape of the missing foot segment. The patient who has lost one or more toes may simply pad the toe section of the shoe to improve the appearance of the upper portion of the shoe. Standing will not be affected, assuming the metatarsal heads remain. When the individual walks, late stance will be less forceful, particularly if both phalanges of the great toe are absent. An arch support foot orthosis helps to maintain alignment of the amputated foot, especially if one or more proximal phalanges have been amputated.[2]

Transmetatarsal amputation disturbs foot appearance more noticeably. A prosthesis prevents the shoe from developing an unnatural crease in the forefoot area. The patient bears most weight on the heel and reduces the amount of time spent on the affected foot during walking. A particularly useful prosthesis consists of a plastic socket for the remainder of the foot. The socket is affixed to a rigid plate that extends the full length of the inner sole of the shoe. The plate has a cosmetic toe filler. The socket protects the amputated ends of the metatarsals, and the rigid plate restores foot length so that the person can spend more time during the stance phase of gait on the affected side than would otherwise be the case. To aid late stance, the bottom of the prosthesis or the sole of the shoe may have a convex rocker bar.[3]

Amputation or disarticulation through the tarsals, such as Lisfranc and Chopart disarticulations,[4] poses the additional problem of retaining the small foot segment in the shoe during swing phase. Foot length is apt to be diminished further by an equinus deformity of the amputated limb, resulting from unbalanced contraction of the triceps surae. Consequently, the prosthesis described for the transmetatarsal amputation may be augmented with a plastic calf shell, which is strapped around the leg.[5,6]

Syme's amputation involves surgical sectioning through the distal tibia and fibula, removal of the entire foot, and preservation of the calcaneal fat pad. The patient can usually bear significant weight through the distal end of the amputation limb.[7,8] The socket (Fig. 31.1) trimlines (edges) are located in the proximal portion of the lower leg. The socket has a relief (concavity) for the tibial crest. If the distal end of the Syme's limb is markedly bulbous, the lower part of the medial wall can be made removable; the patient dons the socket, and then fastens the wall section in place. The socket for an amputation limb having relatively vertical contours does not need a removable section; this design has a resilient liner that assists entry of the bulbous distal end of the amputated limb, enabling the wearer to don the prosthesis easily. The prosthesis includes a foot specifically designed to accommodate the long socket (Fig. 31.2). The Syme's prosthesis is suspended by the contour of its brims and socket walls, ordinarily without any other suspension mechanism.

Figure 31.1 Syme's prostheses. (*Left*) Socket with continuous walls. (*Right*) Socket with medial opening.

TRANSTIBIAL PROSTHESES

The transtibial level, formerly known as below-knee, refers to an amputation in which the tibia and fibula are transected. The patient retains the anatomical knee with its motor and sensory functions. This is the predominant site of amputation, particularly for individuals with vascular disease.[9] Prostheses for transtibial amputations include a foot-ankle assembly, shank (lower leg), socket, and suspension component.

Figure 31.2 Lo Rider foot for Syme's prosthesis. *Courtesy of Otto Bock, Minneapolis, MN 55447.*

Foot-Ankle Assemblies

A foot-ankle assembly restores the general contour of the patient's foot, absorbs shock at heel contact, plantarflexes in early stance, and simulates metatarsophalangeal (MTP) hyperextension (toe-break action) in the latter part of stance phase; patients appear to prefer a foot with a relatively rigid forefoot.[10] The foot is in the neutral position during swing phase. Many assemblies also provide slight motion in the frontal and transverse planes, attempting to mimic physiological foot action.[11-16] Newer feet are often made of carbon fiber, which is lighter and stronger than wood.

Nonarticulated Feet

In the United States, the most popular foot type is nonarticulated, without a space between the foot and lower portion of the shank. As compared with articulated feet, nonarticulated components are lighter in weight and more durable; some versions are made to suit high-heeled shoes.

SACH Foot

The nonarticulated *solid ankle cushion heel (SACH)* assembly is commonly prescribed (Fig. 31.3A). The longitudinal portion is a wooden or metal *keel*, which terminates at a point corresponding to the metatarsophalangeal joints. The keel is covered with rubber; the posterior portion is resilient, to absorb shock and permit plantarflexion in early stance. Anteriorly, the junction of the keel and the rubber toe sections allows the foot to hyperextend in late stance. The SACH foot is manufactured in a wide range of sizes to accommodate infants, adolescents, and adults. It is available with heel cushions of varying degrees of compressibility for those who strike the heel with different amounts of force. SACH feet can be ordered in several plantarflexion angles to fit shoes with diverse heel heights. The heel cushion allows a very small amount of medial–lateral and transverse motion.

Other Nonarticulated Feet

A newer version of the SACH foot is the *stationary attachment flexible endoskeleton (SAFE)* foot (Fig. 31.3B). It has a rigid ankle block joined to the posterior portion of the keel at a 45° angle, which is comparable to that of the anatomical subtalar joint. The junction permits the wearer to maintain contact with moderately uneven terrain, because of the relatively great range of medial–lateral motion permitted in the rear foot. The SAFE foot, however, is somewhat heavier and more expensive than the SACH foot.

Feet that have a springy sole store energy in early and midstance as the wearer moves over the foot, bending it slightly. In late stance, as the wearer transfers loading to the opposite foot, the spring in the prosthetic foot recoils, returning some of the stored energy. Such feet are described as energy storing/energy releasing, or dynamic.[11] Both the *Flex-Foot* and the *Springlite foot* (Fig. 31.4) include a long band of carbon fiber, extending from the toe to the proximal shank, as well as a posterior heel section. The long band acts as a leaf spring, enabling the foot to store considerable energy in early and midstance, and then to release energy at the end of stance phase. Active wearers, such as those who play basketball or run, utilize the energy-storing and energy-releasing capacity of these feet. The C-Walk® (Fig. 31.5) is another example of an energy-storing foot. Other energy storing prosthetic feet are shown in Figure 31.6. They are more expensive than SACH feet. Many of these

feet can be sheathed in a cosmetic cover (Fig. 31.7). Athletes may opt to interchange the basic prosthetic foot for one designed for sprinting (Fig. 31.8).

Articulated Feet

Manufactured with separate foot and lower shank sections, articulated feet have the sections joined by a metal bolt or cable. Rubber bumpers usually control the ease of foot motion. Articulated feet are subject to eventual loosening, which may be signaled by a squeaking noise.

Figure 31.7 Cosmetic foot covers. *Courtesy of Ossur, Aliso Viejo, CA 92656.*

Single-Axis Feet

The most common example of an articulated foot is the *single-axis foot* (Fig. 31.9). A rear bumper absorbs shock and controls plantarflexion excursion; it is easy for the prosthetist to substitute a firmer or softer bumper, depending on the force that the patient applies in early stance. A heavy or very active client requires a firm bumper, whereas a frail individual needs a bumper that is soft enough to permit the foot to plantarflex with minimal loading. At early stance, bearing-weight on the heel causes the foot to plantarflex, ensuring that the wearer achieves the stable foot-flat position. Anterior to the ankle bolt is firmer rubber or similar material, the dorsiflexion stop, which resists dorsiflexion as the wearer transfers weight forward over the foot. The single-axis foot does not allow medial–lateral or transverse motion. Some people prefer this simplicity of control.

Multiple-Axis Feet

These components move slightly in all planes to aid the wearer in maintaining maximum contact with the

Figure 31.8 Flex-foot Cheetah® foot. *Courtesy of Ossur, Aliso Viejo, CA 92656.*

Figure 31.10 Multiple-axis foot.

Figure 31.11 ProprioFoot®. *Courtesy of Ossur, Aliso Viejo, CA 92656.*

walking surface, even if the surface slopes or has slight irregularities (Fig. 31.10). A recent version of the multiple-axis foot is the ProprioFoot® (Fig. 31.11), which includes electronic sensors to detect when the wearer needs dorsiflexion; it also provides greater ankle excursion than other foot-ankle assemblies and reduces pressure on the amputation limb.[17,18] Multiple-axis feet are heavier and less durable than single-axis or nonarticulated feet.

Selection of the appropriate foot is based on the needs of the individual, considering the wearer's activity level, weight, and level of amputation, as well as the length and shape of the residual limb. The patient may also benefit from a rotator and a vertical shock absorber.

Rotators and Shock Absorbers

A rotator is a component placed above the prosthetic foot to absorb shear stress in the transverse plane. A shock absorber reduces vertical impact. These components protect the user from skin chafing, which would otherwise occur if the socket were permitted to slide against the skin.[19-21] Rotators and shock absorbers are

Figure 31.9 (*Left*) Single-axis foot. (*Right*) Cross section: anterior bumper controls dorsiflexion, posterior bumper controls plantarflexion.

most often used with single-axis feet and by very active individuals, especially those with transfemoral amputations. A rotator with or without a shock absorber may be contained within a prosthetic foot, such as Ceterus® (Fig. 31.6C), or may be installed in the shank, such as the Delta Twist® (Otto Bock, Minneapolis, MN 55447) (Fig. 31.12).

Shank

The shank is the substitute for the human leg, restoring leg length and transmitting body weight from the socket to the prosthetic foot. The shank is located between the foot-ankle assembly (or rotator) and the socket in a transtibial prosthesis. The two types of shank are *exoskeletal* and *endoskeletal*.

Exoskeletal Shank

The *exoskeletal shank* (Fig. 31.13 [*left*]), sometimes called *crustacean,* is typically made of rigid plastic (older versions are made of wood). The rigid exterior is shaped to simulate the contour of the anatomical leg. Although the shank is usually finished with plastic tinted to match the wearer's skin color, some individuals opt for a multicolored or patterned shank. The exoskeletal shank is very durable and, with the plastic finish, is impervious to liquids. Because they are less lifelike and do not permit changes in alignment of the prosthesis, exoskeletal shanks are less frequently prescribed.

Endoskeletal Shank

The *endoskeletal shank* (Fig 31.13 [*right*] and Fig. 31.14), or *modular shank,* consists of a central aluminum or rigid plastic tube (called a *pylon*) usually covered with foam rubber and a sturdy stocking or similar finish. With its cover, the endoskeletal shank is more natural in

Figure 31.12 Rotator/shock absorber intended to be installed in pylon. *Delta Twist®, Courtesy of Otto Bock, Minneapolis, MN 55447.*

appearance than the shiny exoskeletal shank. In addition, the pylon has a mechanism that permits making slight adjustment of the alignment of the prosthesis; this may contribute to comfort and ease of walking. A variety of prosthetic foot-ankle assemblies, such as the Flex Foot®, incorporate an endoskeletal shank. Some patients wear prostheses without a cover over the pylon.

Socket

The amputation limb fits into a plastic receptacle called the socket (Fig. 31.15). Although the original name for the modern transtibial socket was the *patellar-tendon-bearing (PTB)* socket, the socket is designed to contact all portions of the amputated limb for maximum distribution of load, as well as to assist venous blood circulation and provide maximum tactile feedback. The PTB socket features a prominent indentation over the patellar ligament, sometimes known as the patellar tendon. A newer socket variation is *total surface bearing*, which has a shallower anterior indentation.[22]

Sockets are custom made of plastic molded over a model of the patient's amputation limb. The model may be produced from a plaster cast of the amputation limb or by *computer-aided design/computer-aided manufacture (CAD-CAM).* The latter involves an electronic sensor, which transmits a detailed map of the limb to a computerized program consisting of socket-shape variations; the prosthetist selects the appropriate shape, which is transmitted to an electronic carver that creates the model over which the plastic is shaped. Whether the model is made by hand or by computer, it provides *reliefs,* concavities in the socket over areas contacting sensitive structures, such as bony prominences; reliefs are located over the fibular head, tibial crest, tibial condyles, and anterior–distal tibia. The posterior brim is shaped to provide adequate room for the medial and lateral hamstring tendons, so that the patient is comfortable when sitting. *Build-ups* are convexities in the socket over areas contacting pressure-tolerant tissues, such as the belly of the gastrocnemius; patellar ligament; proximomedial tibia, corresponding to the pes anserinus; and the tibial and fibular shafts (see Fig. 31.15).

When viewed from above, the socket resembles a triangle, the apex of which is formed by the relief for the tibial tubercle and crest, and the base angles of which are the hamstring reliefs. The anterior wall terminates at the mid-patella, or above. The medial and lateral walls extend at least to the femoral condyles. The posterior wall lies across the popliteal fossa.

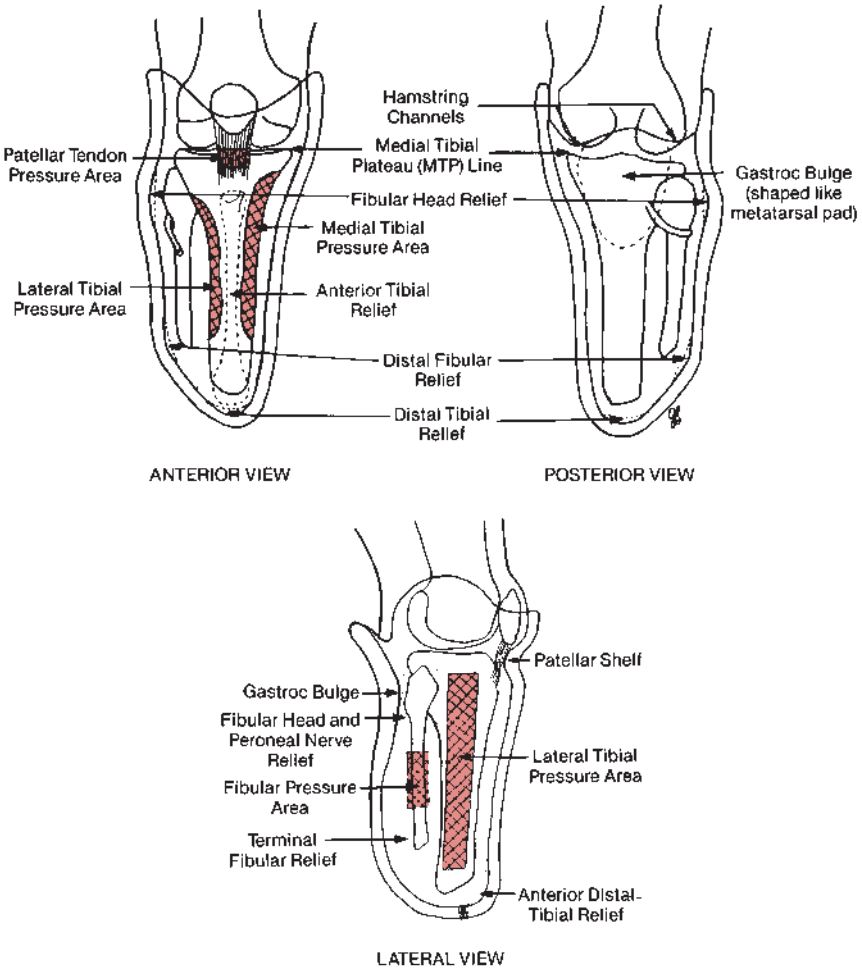

Figure 31.15 Transtibial patellar-tendon-bearing socket. Areas of relief (also called *channels*) over pressure-sensitive tissues. Build-ups (also called *bulges*) contact pressure-tolerant tissues. *From Sanders, GT: Lower Limb Amputations: A Guide to Rehabilitation. FA Davis, Philadelphia, 1986, p 176, with permission.*

The socket is aligned on the shank in slight flexion to enhance loading on the patellar ligament, prevent genu recurvatum, and resist the tendency of the amputation limb to slide too deeply into the socket. Flexion also facilitates contraction of the quadriceps muscle. The socket is also aligned with a slight lateral tilt to reduce loading on the fibular head.[23,24]

Lined Socket

The transtibial socket generally includes a resilient liner, made of polyethylene foam,[25] polyurethane,[26] silicone,[27] or similar materials. In addition to cushioning the amputation limb, the removable liner facilitates alteration of socket size; the prosthetist can add material to the outside of the liner, reducing the volume of the socket while preserving smooth interior contours. The liner, however, adds to the bulk of the prosthesis and is a heat insulator, which the wearer may find uncomfortable in hot weather. Individuals with Syme's and transtibial amputations usually wear cotton, wool, or synthetic fabric socks to ensure a snug socket fit. An alternative to the polyethylene liner is a sheath made of silicone or similar material, which fits so snugly that the wearer has little risk of abrasion between the socket and skin.

Socks, Sheaths, and Liners

All individuals with LE amputations, except those wearing transfemoral prostheses suspended by total suction or those using a sheath, require a supply of clean socks of appropriate material, size, and shape. It is expeditious to order at least a dozen socks at the time the prosthesis is prescribed, so that third-party payment may cover this relatively inexpensive but important accessory.

Fabric socks are woven in various thicknesses, referred to as *ply,* designating the number of threads knitted together. Cotton socks absorb perspiration readily and are the least allergenic; they are made in two-, three-, and five-ply, the last being the thickest. Wool socks provide good cushioning, woven in three-, five-, and six-ply; they are expensive and must be laundered carefully. Orlon/Lycra socks are manufactured in two- and three-ply thicknesses. They can be washed easily without shrinking. This synthetic fabric combination affords considerable resilience, but does not absorb much perspiration.

A nylon sheath creates a smooth surface over the skin, thereby reducing the risk of chafing, especially in hot weather and among those with much scarring. Some transtibial prosthesis wearers are able to use a woman's knee-high nylon stocking if the amputated limb is slender. Because nylon does not absorb sweat, liquid passes through the weave to be absorbed by an outer sock of cotton or wool. Silicone, urethane, and other synthetic sheaths provide excellent shock absorption and abrasion resistance; they also can aid in suspending the socket on the patient's limb, and are designed to be worn next to the skin. They are, however, more expensive than fabric socks or sheaths.

It is common practice to add more socks as the amputation limb volume reduces. Nevertheless, when the patient requires a total of 15-ply of socks to achieve snug fit, the socket should be altered or replaced by the prosthetist. Excessive sock padding distorts the weight-bearing characteristics of the socket, losing the effect of strategically placed build-ups and reliefs.

Regardless of material, the shape of the sock or sheath is important for comfort. An interface of proper size fits smoothly without wrinkling or undue stretching. The sock or sheath should be long enough to terminate above the most proximal part of the socket.

Silicone gel suspension liners are another form of socket-residual limb interface. These liners cushion the residual limb as well as function as a primary or secondary suspension system. Some include a nylon outer cover, with liner thickness tapering distally, and may be indicated for particularly active users and those with fragile or sensitive residual limbs. They are available in locking, custom, and seal-in designs (Fig. 31.16).

Unlined Socket

Although the unlined socket is sometimes referred to as a hard socket, that term is a misnomer, because the wearer has a soft interface provided by socks or a sheath worn with the unlined socket. Occasionally, a resilient pad is placed in the bottom of the unlined socket to cushion the distal end of the amputation limb. The unlined socket is a more satisfactory choice for the person whose limb has stabilized in volume, because it is easier to clean; however, it is more difficult to alter the shape of the unlined socket in comparison to the lined socket.

A newer type of unlined socket is made of thin thermoplastic in a rigid frame. The plastic can be spot-heated to facilitate alteration of socket fit. It adheres to the skin better than rigid plastic, thereby improving suspension. It contributes to comfort by dissipating body heat more effectively and responds to changes in amputation limb shape as the patient contracts and relaxes various muscles.

Suspension

During the swing phase of walking, or whenever the wearer is not standing on the prosthesis, such as when climbing stairs or jumping, the prosthesis requires some form of suspension to hold it in place.

Cuff Variants

The modern transtibial prosthesis originated with a supracondylar cuff (Fig. 31.17 [*left*]), which is still widely used. The cuff may be a leather, flexible plastic, or fabric-webbing strap. It encircles the thigh immediately above the femoral condyles, and permits the user to adjust the snugness of suspension easily. Some individuals, however, object to the profile of the distal thigh created by the cuff. Others who have severely arthritic

Figure 31.16 Silicone liners: (*Left*) Iceross® Dermo locking silicone gel liner. *Courtesy of Ossur, Aliso Viejo, CA 92656.* (*Middle*) Custom liners with fibular head padding. *Courtesy of Otto Bock, Minneapolis, MN 55447.* (*Right*) Seal-in designs. *From Roy, SH, Wolf, SL, and Scalzitti, DA: The Rehabilitation Specialist's Handbook, ed 4. hands or limited vision have difficulty engaging the buckle or pressure hook-and-loop closure on the cuff.

A fork strap and waist belt may be used to augment the cuff. The elastic fork strap extends from the outside of the anterior portion of the socket to a waist belt. The fork strap and waist belt may be indicated for individuals who climb ladders or engage in other activities during which the prosthesis is unsupported by the ground for long periods. Alternatives to the cuff include a rubber sleeve, a tubular component that covers the proximal socket and the distal thigh; or a sleeve that includes a distal pin to create a shuttle lock (Fig. 31.17 [*right*]), described in the following section titled Distal Attachments. The sleeve provides excellent suspension and a streamlined silhouette when the wearer sits. Donning the sleeve, however, requires two strong hands and a thigh that does not have excessive subcutaneous tissue.

Distal Attachments

Very secure suspension is achieved with the use of a silicone sheath with a distal metal pin (Fig. 31.18; see Fig 31.17 [*right*]). The sheath clings to the skin. The user inserts the sheathed limb into the prosthesis, guiding the attached pin into a receptacle, also called a shuttle lock, in the socket. During swing phase, the pin mechanism prevents the prosthesis from slipping.

Vacuum-assisted suspension is another alternative mode of suspension. The system (Fig. 31.19) combines a pump, liner, and sleeve to achieve elevated vacuum in an airtight environment. Vacuum promotes fluid exchange, reduces moisture buildup, regulates volume fluctuations, and increases proprioceptive awareness of the limb's position in space.

A surgical approach to distal attachment is known as *osseointegration*[28] in which the surgeon implants a metal post in the distal bone. The post protrudes through the skin and locks into a mechanism in the prosthesis. Osseointegration eliminates the need for other suspension apparatus; however, fluid drainage and infection at the skin/post interface are sometimes troublesome. The procedure was developed in Europe and is not yet readily available in North America.

Brim Variants

The socket walls may be extended proximally to suspend the prosthesis. With *supracondylar (SC) suspension* (Fig. 31.20 [*left*]), the medial and lateral walls extend above the femoral condyles. Some SC suspension designs include a plastic wedge on the medial wall (Fig. 31.20 [*middle*]). When donning the prosthesis, the client removes the wedge, places the amputation limb in the socket, and then places the wedge between the socket and the medial condyle to retain the prosthesis on the limb. Alternatively, the wedge can be incorporated in a liner; for donning, the patient applies the liner, and then inserts the limb, with liner, into the socket. Supracondylar suspension increases medial–lateral stability of the prosthesis, presents a pleasing contour at the knee, and eliminates the need to engage a buckle or hook-and-loop closure on a cuff. It is more difficult to fabricate (and, hence, more expensive), and it is not readily adjustable.

Presenting a contour of medial and lateral walls similar to the supracondylar suspension, the supracondylar/suprapatellar (SC/SP) suspension (Fig. 31.20 [*right*]) also features an anterior wall that terminates above the patella.

Figure 31.19 Harmony® Volume Management System. *Courtesy of Otto Bock, Minneapolis, MN 55447.*

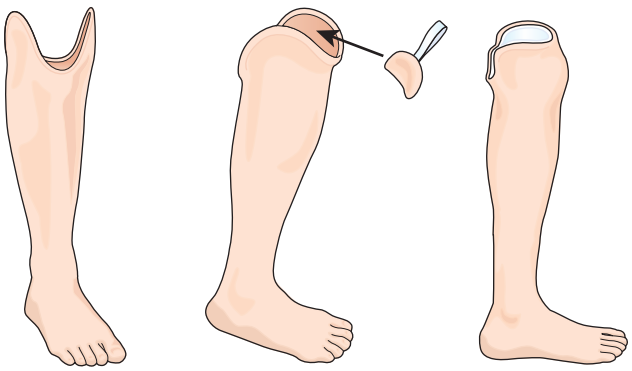

Figure 31.20 (*Left*) Transtibial prosthesis with supracondylar (SC) suspension. (*Middle*) SC suspension using wedge insert. (*Right*) Transtibial socket with supracondylar/suprapatellar (SC/SP) suspension.

Figure 31.18 Transtibial distal pin attachment. The pin fits into a receptacle in the socket bottom and is then tightened into place.

The short amputated limb is well accommodated by SC/SP suspension. The high anterior wall may interfere with kneeling and presents a conspicuous contour when the wearer sits.

Thigh Corset

Some individuals with very sensitive skin may benefit from thigh corset suspension (Fig. 31.21). Metal hinges attach distally to the medial and lateral aspects of the socket and proximally to a flexible plastic corset. Corset heights vary and may reach the ischial tuberosity for maximum weight relief on the amputation limb. The hinges increase frontal plane stability, and the corset increases area for weight-bearing load distribution. The resulting prosthesis, however, is heavier and apt to foster piston action because the hinges have a single pivot joint that does not articulate collinearly with the anatomical knee. Prolonged use of a thigh corset produces pressure atrophy of the thigh. A prosthesis with corset suspension is more difficult to don because the wearer must fasten a series of pressure closure hook-and-loop straps.

TRANSFEMORAL PROSTHESES

Individuals with amputation between the femoral condyles and greater trochanter are fitted with transfemoral (above-knee) prostheses. Those whose limbs retain the distal part of the femur can wear a knee disarticulation prosthesis, which differs from the transfemoral prosthesis in the type of knee unit and socket. If the amputation is proximal to the greater trochanter, the patient cannot retain or control a transfemoral prosthesis and is therefore a candidate for a hip disarticulation prosthesis. The transfemoral prosthesis consists of (1) foot-ankle assembly; (2) shank; (3) knee unit; (4) socket; and (5) suspension device.

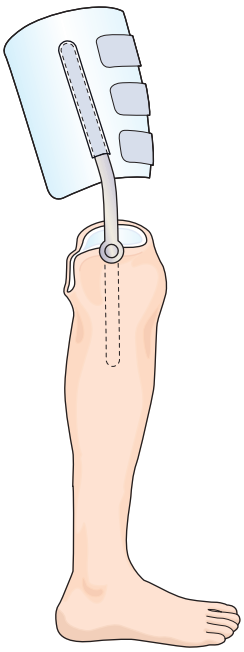

Figure 31.21 Transtibial thigh corset suspension.

Foot-Ankle Assemblies and Shanks

Although the SACH foot is often prescribed for transfemoral prostheses, the single-axis foot is more frequently used for transfemoral than for transtibial prostheses. The single-axis foot reaches the foot-flat position with minimal application of weight-bearing load. Nevertheless, almost any foot, including the energy storing/releasing designs, can be incorporated in a transfemoral prosthesis. As compared with wearers of transtibial prostheses, however, most wearers of transfemoral prostheses do not load the prosthesis as vigorously. Consequently, less energy would be stored and released in a dynamic response foot.

Either the sturdy exoskeletal shank or the more attractive endoskeletal shank may be used. The latter creates a more pleasing appearance, particularly in the knee area, is adjustable in alignment, and is lighter than an exoskeletal shank. Limited research is inconclusive regarding the merit of minimizing prosthetic weight.[29] Problems of durability remain, particularly at the knee, where constant bending of the joint, especially when the wearer is kneeling, accelerates deterioration of the rubber cover. A rotator with or without a shock absorber incorporated in the shank diminishes shear stress on the amputation limb.[30]

Knee Units

The prosthetic knee enables the user to bend the knee when sitting or kneeling and, in most instances, also permits knee flexion during the latter portion of the stance phase and throughout the swing phase of walking. Commercial knee units may be described according to four features: (1) axis; (2) friction mechanism; (3) extension aid; and (4) mechanical stabilizer. Many combinations of features are available; not every knee unit has all four components.

Axis System

The thigh piece can be connected to the shank either by a *single-axis hinge*, which is a common arrangement, or by *polycentric linkage*. Polycentric systems (Fig. 31.22) have pivoting bars and provide greater stability to the knee, inasmuch as the momentary center of knee rotation is posterior to the wearer's weight line during most of stance phase.[31] The polycentric knee provides mechanical swing control that allows a single optimal walking speed. For variable cadence, some polycentric knee units incorporate pneumatic or hydraulic swing control.

Friction Mechanisms

In the simplest sense, the leg of the transfemoral prosthesis is a pendulum swinging about the knee hinge. For the elderly individual who walks slowly for short distances, a basic pendulum is adequate. More energetic walkers, however, benefit from adjustable friction mechanisms that modify the pendulum action of the leg to reduce the asymmetry between the motions of the sound

Figure 31.22 (*Left*) Polycentric knee unit designed to provide stability during stance. *Courtesy of Ossur, Aliso Viejo, CA 92656.* (*Right*) Polycentric knee unit in place on a transfemoral prosthesis.

and prosthetic limbs. If the prosthetic knee does not have sufficient friction to retard its natural pendulum action, the person who walks rapidly experiences excessive knee flexion (high heel rise) at the beginning of swing phase and abrupt, often noisy, knee extension at the end of swing phase (terminal swing impact). Friction mechanisms change the leg swing by modifying knee motion during various parts of swing phase and by affecting knee swing according to walking speed. Two interrelated issues involved in friction mechanisms are the time during swing phase when friction affects the knee unit and the medium through which the mechanism operates.

Constant and Variable

The most commonly prescribed knee unit has *constant friction* (Fig. 31.23), generally a pair of clamps that grasp the knee bolt. The clamps resist shank motion throughout swing phase time, providing a constant amount of friction. The clamps are easy to loosen or tighten to change the ease of knee motion. A more sophisticated device applies *variable friction*, in which the amount of friction changes during a given portion of swing phase. At early swing, high friction is applied to retard excessive knee flexion; during midswing, friction diminishes to permit the knee to swing easily; at late swing, friction increases to dampen impact.

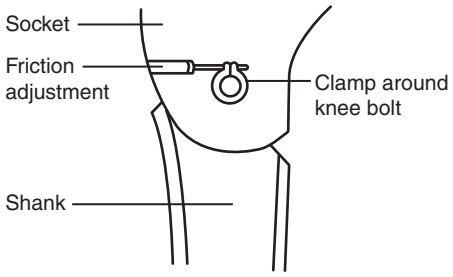

Figure 31.23 Constant-friction knee unit with clamp that encircles the knee bolt.

Medium

The medium through which friction is applied influences performance. The usual medium is *sliding friction,* contact of one solid structure on another. A clamp sliding about the knee bolt is simple and inexpensive, but it does not accommodate automatically to changes in walking speed. A more complex approach is *fluid friction,* either oil (*hydraulic friction*) (Fig. 31.24) or air (*pneumatic friction*). Unlike sliding friction, fluid friction varies directly with velocity. Thus with a hydraulic or pneumatic unit, if the wearer walks faster, the knee increases friction instantly to prevent excessive knee flexion and abrupt extension. Consequently, the movements of the prosthetic and sound limbs are less asymmetrical than would be the case with sliding friction. Oil or air is contained in a cylinder in the knee unit. A piston descends in the cylinder during early swing, causing the knee to flex. The speed of piston descent depends on the type of fluid and the walking speed. Later, the piston ascends, extending the knee. Hydraulic units provide more friction than do pneumatic devices. Both types are more expensive than the simpler sliding friction designs.

Microprocessor-controlled hydraulic units, such as the C-Leg® (Fig. 31.25), utilize electronic sensors, which detect the rate and range of shank movement 50 or more times per second, providing almost instant friction adjustment to changes in the gait pattern.[32-41] Units are programmed with a computer, and may provide stumble

recovery, locking option, and accommodation to walking on various terrain and bicycle riding. An alternative to oil-filled hydraulic units is the Rheo® knee (Ossur, Aliso Viejo, CA 92656), which has magnetized fluid and sensors that detect knee action in much smaller time units.[42]

Extension Aids

Many knee units include a mechanism to assist knee extension during the latter part of swing phase. The simplest type is an *external extension aid*, consisting of elastic webbing in front of the knee axis. The elastic stretches when the knee flexes in early swing and recoils to extend the knee in late swing. Webbing tension is easily adjusted, but tends to pull the knee into extension when the wearer sits. The *internal extension aid* is an elastic strap or coiled spring within the knee unit. It functions identically to the external aid during walking, but unlike the external aid, the internal type keeps the knee flexed when the individual sits. Acute knee flexion causes the strap or spring to pass behind the knee axis, maintaining the flexed attitude. Fluid-controlled knee units incorporate an internal extension aid.

Although most extension aids affect the wearer's performance during late swing and early stance phases, the Power Knee® (Fig. 31.26) also assists the user to ascend stairs step-over-step as well as to rise from a chair. The unit incorporates accelerometers, gyroscopes, a torque sensor, and an on-board computer.

Stabilizers

Most knee units do not have a special device to increase stability. The patient controls prosthetic knee action by hip motion, aided by the alignment of the knee in relation

Figure 31.26 Power Knee®. *Courtesy of Ossur, Aliso Viejo, CA 92656.*

to other components of the prosthesis. The knee axis is usually aligned posterior to a line extending from the greater trochanter to the ankle (trochanter-knee-ankle [TKA] line). The patient who has excellent balance and muscular control may have the knee bolt placed on the line, thus creating TKA alignment. Some hydraulic knee units are aligned with the knee axis anterior to the trochanter-ankle line. Elderly or debilitated patients may benefit from a stabilizing mechanism, as do some people who walk on very rough terrain, such as hunters.

Manual Lock

The simplest mechanical stabilizer is a manual lock (Fig. 31.27), in which a rod lodges in a receptacle and is released only when the wearer manipulates an unlocking lever. When engaged, the manual lock prevents knee flexion. The user is secure not only during early stance when stability is desired, but also throughout the entire gait cycle. To compensate for difficulty in advancing the locked prosthesis, the shank should be shortened approximately 1/2 in (1 cm). The manual lock must be disengaged when the wearer sits. Nevertheless, some people with impaired balance prefer the stability of the locked knee.[43]

Friction Brake

A more elaborate stabilizing system, the *friction brake*, provides very high friction during early stance as the wearer bears weight on the prosthesis, resisting the tendency of the knee to flex.[44] One design, incorporated in a sliding friction unit, involves the mating of a wedge and groove upon loading, assuming the knee is flexed less than 25 degrees. Another version of friction brake is found in some hydraulic units; during early stance, additional fluid resistance markedly retards piston descent within the fluid cylinder and thus stabilizes the knee. Microprocessor units include stance control and, in most instances, a manual lock option.

From midstance through heel contact, friction brakes do not interfere with knee motion. In addition, they do not impede the patient who transfers from sitting to standing. Such devices add to the cost of the prosthesis and, if improperly used, may not protect the patient from falling.

Figure 31.27 Single-axis knee unit with manual lock. Note that this configuration has a proximal release attached by a high-density plastic wire to the knee. For patients with impaired balance, the proximal release eliminates the need to flex forward and reach down to the knee unit for unlocking.

Sockets

As with all prosthetic sockets, the transfemoral one should be a total-contact receptacle to distribute load over the maximum area, thereby reducing pressure. Total-contact fitting also provides counterpressure to assist venous return and prevent distal edema, and enhances sensory feedback to foster better control of the prosthesis.

Most transfemoral sockets are made of a flexible thermoplastic socket encased in a rigid frame. The frame enables the wearer to transmit weight through the distal components of the prosthesis to the ground. The flexible socket provides sensory input from external objects, such as chairs; it also dissipates body heat and facilitates alterations in socket fit. A polyester laminate socket is entirely rigid.

Transfemoral sockets are designed to emphasize loading on pressure-tolerant structures, such as the gluteal musculature, sides of the thigh, and, to a lesser extent, distal end of the amputated limb. The socket must avoid excessive pressure on the pubic symphysis and perineum.

Quadrilateral Socket

The basic transfemoral socket shape is quadrilateral when viewed from above (Fig. 31.28). The socket features a horizontal posterior shelf for the ischial tuberosity and gluteal musculature, a medial brim at the same level as the posterior shelf, an anterior wall 2.5 to 3 in (6 to 8 cm) higher to apply a posteriorly directed force to the thigh to retain the ischial tuberosity on its shelf, and a lateral wall the same height as the anterior wall to aid in medial–lateral stabilization. Concave reliefs are (1) anteromedial, for the pressure-sensitive adductor longus tendon and obturator nerve; (2) posteromedial, for the sensitive hamstring tendons and sciatic nerve; (3) posterolateral, to permit the gluteus maximus to contract and bulge without being crowded; and (4) anterolateral, to allow adequate room for the rectus femoris. The anterior wall has a convexity, Scarpa's bulge, to maximize pressure distribution in the vicinity of the femoral (Scarpa's) triangle. The lateral wall may have reliefs for the greater trochanter and the distal end of the femur.

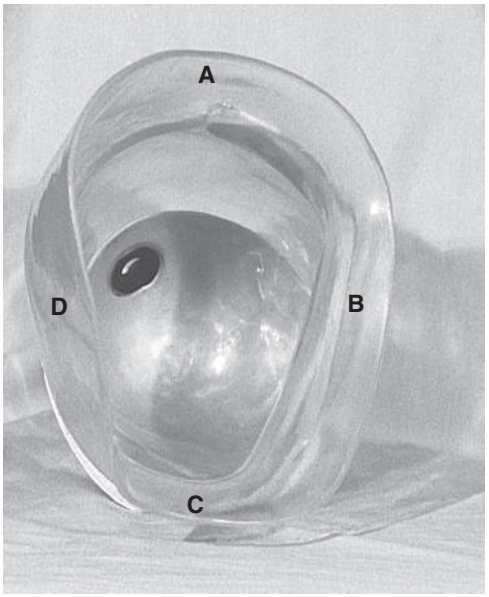

Figure 31.29 Ischial containment flexible transfemoral socket. **(A)** Anterior brim. **(B)** Medial brim. **(C)** Posterior brim. **(D)** Lateral brim.

Ischial Containment Socket

An alternate design type is the ischial containment socket (Fig. 31.29), sometimes called the *contoured adducted trochanter-controlled alignment method*.[45,46] Its walls cover the ischial tuberosity and part of the ischiopubic ramus to augment socket stability. To increase frontal plane stability and minimize bulk between the thighs, the mediolateral width of the socket is narrower than that of the quadrilateral socket. The anterior wall is lower than in the quadrilateral socket, whereas the lateral wall covers the greater trochanter. Weight-bearing occurs on the sides and bottom of the amputated limb.

Slight socket flexion is desirable for the following reasons: (1) to facilitate contraction of the hip extensors; (2) to reduce lumbar lordosis; and (3) to provide a zone through which the thigh may be extended to permit the wearer to take steps of approximately equal length. For wearers of quadrilateral sockets, socket flexion also enhances positioning of the ischial tuberosity on the posterior brim. Figure 31.30 presents a schematic of pelvic position within the ischial containment socket.

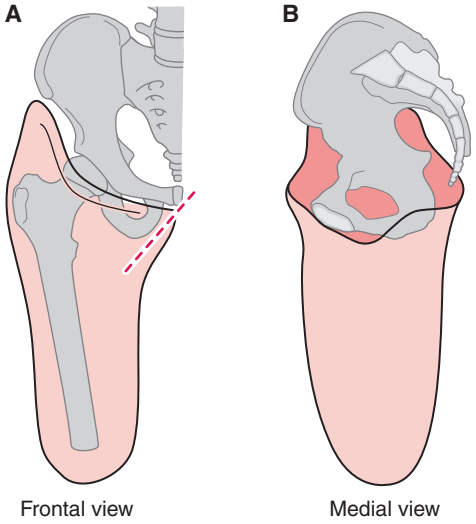

Figure 31.30 **(A)** Frontal view of the femur and pelvis in the ischial containment socket. **(B)** Medial view of the pelvis in the ischial containment socket. *From May, BJ, and Lockard, MA: Prosthetics and Orthotics in Clinical Practice. FA Davis, Philadelphia, 2011, p 95.*

ComfortFlex™ Socket

The ComfortFlex™ (Hanger, Inc., Oklahoma City, OK 73118) is a soft flexible socket (plastic and silicone materials) placed in a carbon graphic frame (Fig. 31.31). This sockets design is available for various-level amputations (e.g., transfemoral, transtibial, hip disarticulation, hemipelvectomy). The carbon fiber frame provides structural support while the intimately fit flexible socket allows for muscle contraction and improved control of the prosthesis. The transfemoral socket is designed to "lock" the ischium and pubic ramus into the socket improving anterior/posterior and lateral stability and reducing socket rotation. The sockets are contoured to accommodate bone and soft tissue structures (e.g., muscles, tendons, nerves, vascular structures).

Suspensions

Three means are used to suspend the transfemoral prosthesis: (1) total suction, (2) partial suction, and (3) no suction (require auxiliary suspension).

Suction Suspension

Suction refers to the difference between pressure inside and outside the socket. With suction suspension, internal socket pressure is less than external pressure; consequently, atmospheric pressure causes the socket to remain on the thigh. A one-way air-release valve located at the bottom of the socket enables residual air to be expelled.

Total Suction

Maximum control of the prosthesis, without any encumbering auxiliary suspension can be achieved only when the socket brim fits very snugly. Some people add a transfemoral suspension sleeve (Fig. 31.32), especially when engaging in vigorous activities. If the patient experiences reduction in amputation limb volume, suction will be lost and an auxiliary suspension will be required.

Partial Suction

A socket that is slightly loose may provide partial suction suspension combined with auxiliary suspension; the socket has a valve. The patient wears one or more socks, or a synthetic liner. Because air enters the space between the sock's fibers, auxiliary suspension is needed, either a fabric Silesian belt (Fig. 31.33), or a rigid plastic or metal hip joint and pelvic band. These aids encircle the pelvis. The Silesian belt also controls the transverse plane orientation of the prosthesis on the thigh, while the hip joint restricts transverse and frontal motion at the hip. The pelvic band adds weight to the prosthesis and may impose uncomfortable pressure against the torso when the wearer sits.

Figure 31.33 Silesian belt. *From Roy, SH, Wolf, SL, and Scalzitti, DA: The Rehabilitation Specialist's Handbook, ed 4. FA Davis, Philadelphia, 2013, p 977, with permission).*

No Suction

If the socket has a distal hole without a valve, then no pressure difference exists between the inside and the outside of the socket. The client wears one or more socks and requires a pelvic band. The pelvic band has a rigid metal or nylon single-axis hip joint attached to a leather belt, which encircles the pelvis. The relatively loose socket makes donning easy, but hinders control of the prosthesis and may make sitting uncomfortable.

Osseous integration is another less common suspension alternative. A metal post implanted in the femur locks into a fixture embedded in the distal portion of the socket.[45]

DISARTICULATION PROSTHESES

Individuals with knee or hip disarticulation wear prostheses that include the same distal components as prostheses

for lower levels. Any prosthetic foot can be used with either an endoskeletal or exoskeletal shank. The major distinction, therefore, is in the proximal portion of the prostheses.

Knee Disarticulation Prostheses

When amputation is at or distal to the femoral condyles, the patient should have excellent prosthetic control because (1) thigh leverage is maximum; (2) most of the body weight can be borne through the distal end of the femur; and (3) the broad condyles provide rotational stability.[46,47] The problem presented by knee disarticulation is primarily cosmetic; when the individual sits, the thigh on the amputated side may protrude forward of the sound knee. The knee disarticulation prosthesis has a streamlined knee that minimizes protrusion, as well as a specially designed socket.

Knee Units

Several units are specifically manufactured for knee disarticulation. All have a thin proximal attachment plate to minimize added thigh length. One may choose among hydraulic, pneumatic, and sliding friction units, with or without polycentric linkage. Even with a special knee unit, the thigh will be slightly longer. Consequently, the shank is shortened equivalently, so that when the person stands, the pelvis is level. When the individual sits, the thigh on the prosthetic side will project slightly.

Sockets

Two types of sockets are currently in use. Both are made of plastic and usually terminate below the ischial tuberosity. Generally, no additional suspension aids are needed. One version features an anterior opening to accommodate a bulbous amputation limb. After the limb is inserted, the wearer closes the socket with lacing or hook-and-loop closure. The other design has no anterior opening and is suitable for limbs that are not bulbous.

Hip Disarticulation Prostheses

A hip disarticulation prosthesis[48,49] (Fig. 31.34) is fitted to a person with amputation above the greater trochanter (very short transfemoral), removal of the femoral head from the acetabulum (hip disarticulation), or removal of the femur and any portion of the pelvis (transpelvic amputation, also known as hemipelvectomy). The modern prosthesis was developed in Toronto and is sometimes called the *Canadian Hip Disarticulation Prosthesis*. Prostheses for proximal levels share common hip, knee, and foot assemblies, but differ with regard to socket design. The endoskeletal thigh and shank predominate because they save appreciable weight in these massive prostheses. The prosthesis may be shortened slightly, to aid clearance during swing phase, encourage the wearer to apply maximum weight to the prosthesis, and increase stability.

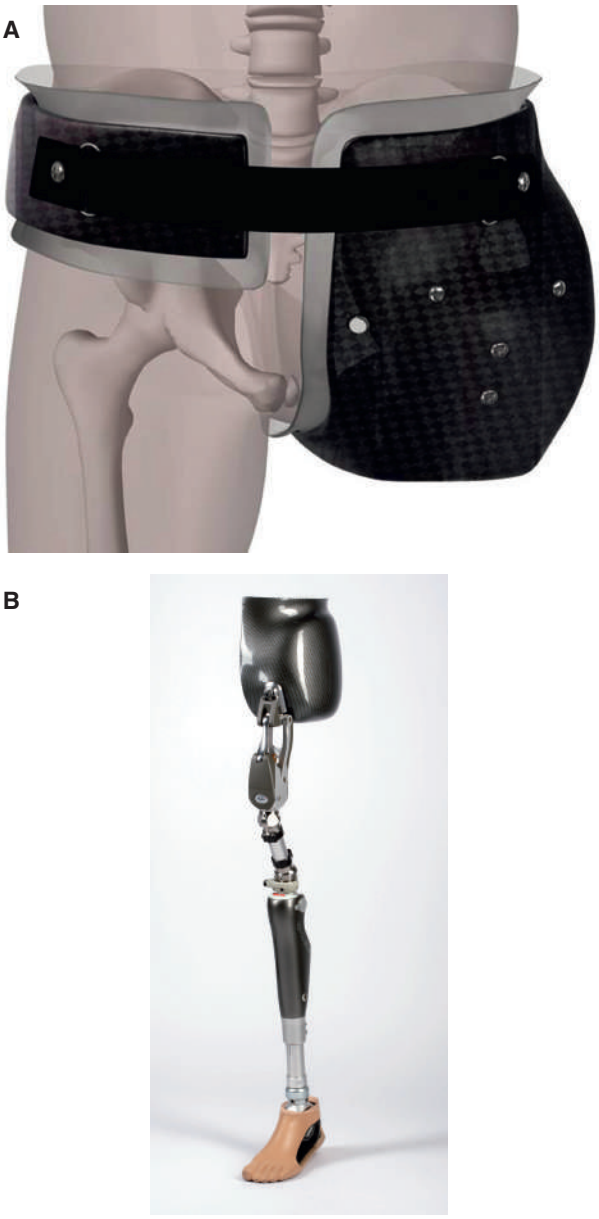

Figure 31.34 **(A)** Anatomical orientation of the Comfort-Flex™ hip disarticulation socket; additional components of the completed prosthesis included a hip joint, rotator, knee unit, pylon, and foot. Sockets

The basic socket is plastic molded to provide weight-bearing on the ipsilateral ischial tuberosity and buttock (gluteal musculature). The person with transpelvic amputation who does not retain the ipsilateral tuberosity or iliac crest has a socket with a higher proximal trimline, sometimes encompassing the lower thorax.

This individual supports weight on the remainder of the pelvis, on the abdomen, and perhaps on the lower ribs.

Hip Units

The prosthetic hip joint has an extension aid to bias the prosthesis toward the stable neutral position. Positioning the mechanical hip anterior to a point corresponding to the anatomical hip also contributes to hip stability. The joint is set below the normal hip, so that when the wearer sits, the prosthetic thigh will not protrude unattractively. All hip joints provide hip flexion; some also allow transverse rotation.[50,51]

Knee Units

Although virtually any knee unit can be incorporated into the hip disarticulation prosthesis, the unit should have an extension aid to resist knee flexion during stance phase. The prosthetic knee is aligned relatively posteriorly to contribute to stability.

BILATERAL PROSTHESES

Bilateral amputations occur either simultaneously, as in the case of trauma or congenital limb deficiency, or sequentially, as is seen with peripheral vascular disease. In the latter instance, previous experience with a unilateral prosthesis is invaluable in determining whether the patient will benefit from a pair of prostheses.

Bilateral Syme's and Transtibial Prostheses[52]

Any foot design can be worn, although both prosthetic feet must be the same design from the same manufacturer to reduce the likelihood of gait asymmetry. Ideally, foot and shoe size should be shorter than the person's preamputation size to facilitate transition through stance phase; wider feet contribute to stability. Shanks, sockets, and suspensions need not match; each component should suit the characteristics of the individual amputation limb.

Bilateral Transfemoral Prostheses[53,54]

Other than matching prosthetic foot design and size, each amputation limb is fitted on an individual basis. The patient will perform activities in a manner similar to someone with unilateral transfemoral amputation.

The patient may be fitted with short, nonarticulated prostheses. The lower center of gravity provides the individual with more stability. Gait is awkward, with exaggerated trunk rotation; crutches or canes need to be adjusted to suit the person's short stature. Transferring into an adult-size chair, as well as climbing stairs, is more difficult than with longer prostheses. Patients who object to the markedly altered appearance created by these short prostheses may refuse to wear them.

Longer prostheses should include a matched pair of feet. Endoskeletal shanks are highly desirable to reduce prosthetic weight and enable minute changes in alignment; typically the shanks are shortened by several inches to reduce the effort required to walk with the prostheses. Any type of knee unit may be worn; they need not be the same on both prostheses. Nevertheless, one should avoid a pair of manually locked knee units because they would make chair transfers and stair maneuvering very difficult. Sockets do not have to match; however, a pair of ischial containment sockets will minimize the walking base because the sockets have a relatively narrow mediolateral dimension, as compared with quadrilateral sockets. Any type of suspension may be worn.

PROSTHETIC MAINTENANCE

Optimal function depends on proper care of socks or sheaths, prosthesis, amputation limb, and intact limb, as well as general health maintenance. Guidelines for personal hygiene are presented in Chapter 22, Amputation. In addition to ensuring cleanliness, the individual should wear a well-fitting sock and shoe on the sound foot. It must be the mate to the shoe on the prosthesis. Both shoes should be in excellent condition.

As with any appliance, the prosthesis benefits from simple regular maintenance, which generally avoids costly, time-consuming repairs. Printed instructions pertaining to the prosthesis and socks or sheath are helpful for patient education.

Foot-Ankle Assemblies

One should avoid getting the prosthetic foot wet, especially if the foot is an articulated model. If this happens, the shoe and sock should be removed to allow the foot to dry completely, away from direct heat. The wearer should also avoid stepping into sand and similar materials that might enter the cleft between the foot and shank section and restrict the excursion of the foot. The prosthetist will have to disassemble the foot to clean it.

The client should inspect the foot periodically to spot cracking at the toe-break or tip of the keel; such a crack will curl the toes and prevent smooth transition during late stance. A deteriorated heel cushion or plantar bumper will cause one to appear to be walking in a hole. Although most feet are now molded to simulate toes, the patient should not walk without a shoe because the sole of the prosthetic foot is not intended to resist much abrasion.

Foot socks wear much more quickly on the prosthetic side, because the hard foot-ankle assembly and shank rub against the fabric. Stair risers also scuff the sock. Some people find that wearing two socks helps cushion the outer one against premature formation of holes.

The individual must be instructed regarding wearing shoes of the same heel height as was the case when the prosthesis was aligned. Too low a heel interrupts late stance; an unduly high heel makes the knee less stable. If the prosthesis has the usual foot designed for low-heeled shoes, and the wearer wishes to wear flat-heeled shoes, a 1/2 in (1 cm) shim (a thin tapered wedge)

should be placed inside both shoes at the heel. High-heeled shoes require that the foot be changed, either by unbolting it and replacing it with a foot with an appropriate plantarflexion angle, or by adjusting the heel-height feature found in certain models of feet (e.g., Runway® [Freedom Innovations, Fayette, UT 84630]; Elation® [Ossur, Aliso Viejo, CA 92656]). Boots and other footwear with stiff upper sections restrict the action of any foot assembly that is designed to provide substantial dorsiflexion and plantarflexion.

Removing the shoe is easier if the prosthesis is not worn. With the shoe unlaced completely, one grasps the rear of the shoe, then pulls the shoe off the back of the foot. Finally, the shoe is moved upward off the forefoot. The shoe should be put on the prosthetic foot with the aid of a shoehorn.

Shanks

The usual finish of exoskeletal shanks is polyester laminate, which is impervious to most liquids. It needs to be wiped only periodically with a cloth dampened with dilute detergent to remove surface soil. Marks can be gently removed with kitchen cleanser; excessive abrasion will dull the finish.

The soft foam cover of the endoskeletal prosthesis requires reasonable caution against exposure to direct heat, penetrating objects, and solvents. The outer covering will need replacement whenever it becomes unacceptably soiled or torn. The transfemoral version tends to deteriorate at the knee, especially if the wearer kneels a great deal.

Knee Units

Sliding friction mechanisms tend to loosen with walking and thus require periodic tightening to retain the original adjustment. The frequency of tightening depends on how much the wearer walks. Most units have a pair of screws in front or in the rear of the knee unit that can be turned clockwise with an Allen wrench (small L-shaped metal bar with hexagonal head at each end) or common screwdriver. After turning each screw a quarter turn, the client should walk for at least 5 minutes to ascertain the effectiveness of the adjustment.

Squeaking at the knee or articulated ankle usually indicates the need for oil. The rubber or felt extension bumper in the knee unit will erode after prolonged vigorous use, and the wearer will then notice that the knee begins to hyperextend. The bumper, visible when the knee is flexed, must be replaced by the prosthetist.

The external extension aid eventually loses its elasticity. The user will then experience high heel rise in early swing and slow knee extension at the end of swing phase. The simplest approach is to tighten the strap through its buckle. Eventually, the prosthetist will need to replace the elastic webbing. Internal elastic extension aids are not subject to rubbing from the trouser leg or skirt and thus do not lose elasticity as readily. Steel spring internal aids usually retain their effectiveness for the life of the prosthesis.

Pneumatic and hydraulic units must be protected against tears of the rubber shield protecting the piston. The piston must not be scratched, because this would allow air and debris to enter the cylinder. Air bubbles in the unit will cause a spongy feeling, and possibly noise with walking. At night, the prosthesis should be stored upright, with the knee extended to exclude air from the cylinder.

Electronic units must not be immersed or used in a particle-filled environment, such as a commercial bakery or lumberyard (sawdust).

Sockets and Suspensions

Plastic sockets should be washed with a cloth dampened in warm water that has a very small amount of mild soap dissolved in it. The socket is then wiped with a damp, soap-free cloth, and dried with a fresh towel. In warm climates, the socket should be washed every evening so that it will be completely dry when the patient dresses the following morning. Socket liners made of polyethylene foam can be washed by hand in tepid water with mild soap, rinsed, and air-dried overnight. They should not be subjected to direct sunlight when removed from the prosthesis. Other sheaths and liners should be maintained according to the manufacturer's instructions.

Leather corsets should be kept dry. Use of saddle soap will keep leather clean. If the patient is incontinent, the thigh corset should be made of flexible *polyester laminate* or polypropylene, which are impervious to urine.

The transfemoral suction valve should be brushed daily to remove talcum and lint, which might clog the tiny aperture. The valve should be inserted and removed only with one's fingers, because tools are apt to damage the internal mechanism or outer threads.

PHYSICAL THERAPY MANAGEMENT

Physical therapists participate in the management of patients with amputation at several key stages: (1) preoperative; (2) postoperative–preprosthetic; (3) prosthetic prescription; (4) prosthetic examination; and (5) prosthetic training.

The first two stages are described in Chapter 22, Amputation. The following discussion emphasizes the responsibilities of the physical therapist with regard to the patient and prosthesis. Ideally, the therapist works as a member of a clinic team, together with the physician and prosthetist. Others, such as a social worker, vocational counselor, and psychologist may participate in the team on a regular basis or as needed. The clinic team provides the best environment for exchange of information and viewpoints regarding the patient and fostering efficient treatment;[55,56] the team meets to formulate the prosthetic prescription, examine the newly delivered prosthesis, and reexamine the patient and prosthesis

upon completion of prosthetic training. The therapist, therefore, has an integral part to play in these critical points in rehabilitation, as well as conducting prosthetic training. If a formal clinic team is not established in the therapist's work setting, one must coordinate the recommendations of the physician and prosthetist.

With either administrative situation, the physical therapist:

- Addresses nonprosthetic considerations
- Contributes to prosthetic prescription
- Examines the prosthesis
- Facilitates prosthetic acceptance
- Instructs the patient in donning, use, and maintenance of the prosthesis

Preprescription Considerations

Successful prosthetic rehabilitation depends on matching the individual's physical and psychosocial characteristics to a prosthesis composed of carefully selected components. Although everyone who wears a prosthesis has an amputation or comparable limb deficiency, the reverse is not true. That is, some people with amputations are not candidates for prostheses or prefer not to use prostheses. Prostheses are contraindicated for patients with severe dementia or depression or advanced cardiopulmonary disease. If the person displays significant changes associated with organic brain syndrome, prosthetic fitting is contraindicated. Individuals with bilateral amputations who are unable to transfer independently or don underwear by themselves are unlikely to benefit from definitive prostheses. Similarly, a patient with bilateral amputations who had sustained unilateral amputation previously and was unable to don and walk with a unilateral prosthesis is not a candidate for a pair of prostheses. Some people with high amputations, especially hip disarticulation, find that a prosthesis is unduly cumbersome; they prefer to ambulate with a pair of crutches or depend on a wheelchair. Several sports, particularly swimming, are generally easier to perform without a prosthesis.

Physical Examination

The physical therapist should examine joint mobility and active and passive range of motion of all joints on both LEs. Knee and hip flexion contractures compromise prosthetic alignment and appearance. A knee lock may be needed in a transfemoral prosthesis. A patient with knee contracture requires an alternative transtibial socket design. Severe contractures may contraindicate provision of a prosthesis. The deleterious effects of contractures are especially serious with bilateral amputations.

The length of the amputation limb should be measured. The individual with a short transtibial amputation may require SC/SP suspension. Every attempt should be made to fit the patient with a short transfemoral amputation with suction or partial-suction suspension to retain the prosthesis on the thigh.

Strength of all limb and trunk muscles should be examined. Frequently, the elderly patient with vascular disease experiences reduced physical activity as LE pain and foot ulceration develop. Such an individual may present with marked debility, which would interfere with prosthetic use or necessitate use of a unit with a knee lock.

The therapist should inspect the skin, noting the status of the incision and any other lesions. The patient may require a nylon or silicone sheath to provide a smooth interface between socket and skin to avoid irritating tender or grafted skin.

An examination of sensory function should be performed. For example, someone with impaired proprioception at the knee will need extra prosthetic stability in the form of higher medial and lateral socket walls, or side joints attached to a thigh corset, on the transtibial prosthesis. Blindness does not preclude fitting, but it does pose problems with regard to selecting components that are easy to don, as well as altering the training program. If the patient complains of a neuroma, the problem must be addressed surgically or conservatively (e.g., cortisone injection) before fitting can proceed.

The therapist should examine the patient's ability to learn and retain new information, including both short- and long-term memory. Neurological conditions, such as cerebrovascular accident, complicate fitting and training. Ipsilateral hemiplegia is not as detrimental to prosthetic rehabilitation as contralateral paralysis. In both instances, the prosthesis should be designed for maximum stability. Patients with mild neurological impairments often respond favorably to altered training strategies, which the therapist designs on an individualized basis.

The circulation and anthropometric dimensions of the amputation and sound limbs require careful scrutiny. The physical therapist should teach the patient to inspect the intact foot, using a hand mirror to visualize the plantar surface. Inspection aims to identify skin lesions and incipient areas of abrasion so that corrective measures may be instituted before ulceration or infection ensues. In addition, the patient should be taught to keep the sound foot clean and should wear clean socks or stockings and a well-fitting shoe (see Chapter 14, Vascular, Lymphatic, and Integumentary Disorders, for additional guidelines for managing the patient with peripheral vascular disease). Sequential measurements of amputation limb circumference as well as palpation will indicate whether the individual has edema. Measures should be instituted to stabilize limb volume so that the patient can retain the fit of the prosthetic socket. The patient with vascular impairment may benefit from prosthetic fitting, which transfers some stress from the contralateral limb. In addition, should the person come to bilateral amputation, previous experience with donning and controlling a unilateral prosthesis is invaluable in adjusting to a pair of prostheses.

Prosthetic prescription is also based on the patient's aerobic capacity and endurance. The clinic team must

formulate realistic goals based on the individual's physical capacity, particularly related to exercise tolerance and level of deconditioning. The person who is not expected to walk rapidly is an unlikely candidate for an energy-storing/releasing foot or a fluid-controlled knee unit. Nevertheless, a fluid-controlled knee unit that incorporates a braking mechanism is appropriate for selected patients with generalized weakness.

Obesity is another factor to be considered in the preprescription examination. The obese individual is more apt to fluctuate in body weight, necessitating provision of socket liners and several socks to compensate for changing limb circumference. Similarly, those who have renal disease, especially if requiring dialysis, experience volume changes that need prosthetic accommodation.

Arthritis affects prosthesis prescription. Diminished LE mobility or deformity may compromise prosthetic alignment. Patients with hip or knee arthroplasty, however, function quite well with a prosthesis. Hand and wrist function affects the mode of donning; a laced corset should be avoided. Canes and crutches may require modification.

Functional examination is an essential component of physical therapy management (see Chapter 8, Examination of Function). Among the most useful examination procedures involves observing the patient's ability to transfer from sit-to-stand and bed-to-wheelchair. To accomplish these maneuvers, the individual must have reasonable strength, balance, and coordination, as well as adequate comprehension.

Psychosocial Considerations

Ordinarily, the physical therapist treats the patient more frequently than any other member of the clinic team and thus is more likely to be attuned to changes in the individual's psychosocial status. Ample evidence supports the psychological, as well as physical, benefit of clinic team management.[55,56] Many people with amputation confront psychosocial issues, which should be recognized and addressed.[57-64] For example, the patient who is excessively fearful may be served best by prosthetic rehabilitation beginning with a *temporary (provisional) prosthesis.*

Temporary Prostheses

Transtibial Temporary Prosthesis

Most transtibial temporary prostheses have sockets made of thermoplastic material that becomes malleable at temperatures low enough to permit forming directly on the patient. One can also obtain mass-produced adjustable sockets; it may be necessary to pad the socket bottom so that the amputation limb does not develop distal edema. Some temporary prostheses have a plaster socket molded to the amputated limb. Plaster is inexpensive, readily available, and easy to use. The resulting socket, however, is rather heavy and bulky. Suspension is usually by a cuff or thigh corset. The pylon can be an aluminum component manufactured for this purpose; such a pylon has a proximal fixture that permits small changes in prosthetic alignment. A simpler pylon can be made with polyvinylchloride piping, such as used for plumbing. The pipe is lightweight and can be spot-heated to enable slight alteration in alignment. A SACH foot is customarily used on temporary prostheses.

Transfemoral Temporary Prosthesis

The easiest approach is to use a polypropylene socket (Fig. 31.35), which is manufactured in several sizes and has straps for circumferential adjustment. The socket can be suspended with a Silesian bandage or pelvic band, and is mounted on a knee unit, which may include a manual lock. Alternatively, a custom-fabricated socket of plaster or low-temperature thermoplastic can be used. Some individuals with bilateral transfemoral amputations use a pair of short prostheses. These are nonarticulated prostheses; the sockets are mounted on short platforms, drastically reducing the wearer's height in order to increase balance stability. The platforms each have a rearward projection to protect the patient from a backward fall.

Motivation is a cardinal determinant of prosthetic outcome. Again, strong motivation demonstrated through use of a temporary prosthesis and adherence with other elements of the rehabilitation program is a reliable predictor of prosthetic success. One should guard against unrealistic expectations. Involving the patient and family in group situations with other persons with amputation in the physical therapy department and

Figure 31.35 Transfemoral temporary prosthesis with adjustable polypropylene socket, pelvic band, knee unit with manual lock, and adjustable shank with SACH foot.

in social environments fosters constructive attitudes. The therapist should also weigh the likelihood that the individual will be able to care for complex prosthetic mechanisms and have the financial resources to obtain prosthetic servicing, especially of less durable components, such as the foam rubber covering of the endoskeletal shank.

Prosthetic Prescription

No prosthetic component is ideal for all clients. It is necessary to select components that are most apt to meet each individual's needs. Alternatives to every element of the prosthesis have advantages and disadvantages. The task of the physical therapist, in conjunction with other team members, is to judge the relative merits of various feet, shanks, and other components in light of objective and subjective information pertaining to the prosthetic candidate. In 1995, Medicare identified functional levels applicable to individuals with unilateral transtibial and transfemoral prostheses:[65]

- K0: Not a candidate
- K1: Household ambulation
- K2: Limited community ambulation
- K3: Community ambulation and the ability to vary cadence with vocational, therapeutic, or exercise needs
- K4: High levels of activity such as demonstrated by active adults and athletes

These levels determine the medical necessity of knee and ankle-foot units.

Some people can be expected to function best with a sophisticated prosthesis that enhances the wearer's ability to engage in vigorous walking and athletics. Others are well served by simple, inexpensive devices. The most accurate predictor of future function is the patient's performance with a previous prosthesis. For the wearer who seeks a replacement prosthesis, the clinic team should consider the extent of use of the previous limb, together with any changes in the patient's health status and lifestyle. For example, if the person fitted with one prosthesis now returns with bilateral amputation, never having used the original prosthesis, that patient is a very poor candidate for bilateral prosthetic fitting. In contrast, another person who had been fitted with a simple transfemoral prosthesis expresses the wish to participate in sports. By demonstrating good use of the original prosthesis, that individual is likely to derive considerable benefit from a new prosthesis with a fluid-controlled knee unit and an energy-storing/releasing foot.

Prescription for the new patient is more difficult. Depending on the interval between amputation surgery and prescription, the amputation limb may not have stabilized in volume; the patient may not have achieved the maximum benefit from the preprosthetic program. The best criterion for prosthetic prescription in such an instance is performance with a temporary (provisional) prosthesis. As mentioned earlier, this appliance includes a well-fitting socket, suitable suspension, pylon, and foot; the transfemoral model usually has a knee unit. The temporary prosthesis allows preliminary gait and activities training. The major difference between the temporary and definitive (permanent) prosthesis is appearance. The temporary socket is designed for easy alteration to accommodate change in amputation limb volume. Ordinarily, little attention is paid to the color and exterior shape of the temporary prosthesis.

Prosthetic Examination/Evaluation

The prosthesis should be examined before the patient engages in prosthetic training and should be reexamined at the conclusion of training. The procedure is intended to determine the adequacy of prosthetic fit and function, as well as the wearer's opinion of appearance and overall satisfaction. This process typically follows a sequence of examining the prosthesis while the patient stands (static analysis), examining the patient's gait (dynamic analysis), and finally examining the prosthesis off the patient (additional static analysis). In many institutions, the physical therapist examines the prosthesis and presents a summary of findings to the clinic team. The team makes the final determination regarding the acceptability of the prosthesis.

No special materials are needed to examine the prosthesis, except for a checklist, a straight (armless) chair, a few sheets of paper, a ruler, lift blocks, and colored chalk. For final evaluation, stairs and a ramp are needed. The checklists referred to in the following sections can be found in Appendices 31.A and 31.B.

At initial evaluation, the team has three options: (1) pass, (2) provisional pass, or (3) fail. Pass indicates that no changes are needed in the prosthesis and the patient can proceed to training. Provisional pass signals that one or more minor problems require correction, none of which would interfere with training. Failure is the team's judgment that the prosthesis has a major fault that should be corrected to the team's satisfaction before commencement of prosthetic training. For example, poor finishing of the prosthetic foot merits a provisional pass, whereas a socket that abrades the amputation limb should be graded as fail. If the therapist intends to provide treatment to a patient who is not managed by a formal clinic team, it is especially critical that one examine the prosthesis before initiating instruction and training to discover any problems that would interfere with the future program. At the final evaluation, two ratings are available: *pass* indicates that no problems exist and the patient uses the prosthesis in a manner commensurate with that individual's physical capacity; *fail* means that major or minor problems remain.

Transtibial Examination

Most items on the checklist in Appendix 31.A are self-explanatory. Each contributes to forming an accurate judgment of the adequacy of the prosthesis.

Static Analysis

The prosthesis is examined while the wearer stands and sits. In addition, the amputation limb and details of the prosthesis are examined. The prosthesis should be compared with the prescription. The individual who authorized the prescription must approve departures from the original specifications.

The new wearer should stand in the parallel bars or other secure environment, attempting to bear equal weight on both feet. The therapist should solicit subjective comments about comfort. Estimates of anteroposterior and mediolateral alignment are aided by slipping a sheet of paper under various parts of the shoe. Ideally, the patient should stand with both heels and soles flat on the floor. Misalignment, indicated by excessive weight-bearing on one portion of the shoe, may be confirmed by subsequent analysis of gait.

Most prostheses are constructed so that when the individual stands, the pelvis is level;[36] if the pelvis tilts, the therapist should place lifts under the foot on the shorter side to restore a level pelvis. If the total lift measures 1/2 in (1 cm) or less, no attention is needed. For greater discrepancy, one should seek causative factors. An amputation limb that sinks too far into the socket will make the prosthetic side appear short, and the wearer will probably complain of discomfort.

Piston action refers to vertical motion of the socket when the patient elevates the pelvis. Slippage can be determined by chalk marking the sock at the posterior margin of the socket, and then having the patient elevate the ipsilateral pelvis. The socket should slip less than 1/4 in (0.5 cm). Looseness, inadequate suspension, or both cause socket slippage. Socket walls should fit snugly, as should the thigh corset if it is part of the prosthesis.

Comfortable sitting is a primary need for all people. The posterior brim should not impinge into the popliteal fossa, and hamstring reliefs should be adequate, especially on the medial side where the semitendinosus and semimembranosus insert relatively distally. Placement of the tabs of the cuff or the joints of the corset also influences sitting comfort.

Dynamic Analysis

Analysis of the gait pattern and performance of other ambulatory activities is an essential part of rehabilitation. For most patients, a major reason for prosthetic fitting is to resume walking. Nevertheless, no prosthesis eradicates entirely the anatomical and physiological changes produced by amputation. When walking, the person who wears a prosthesis compensates for anatomical and prosthetic deficiencies.[66-71] Some are inherent to amputation; others are abnormalities of the body or the prosthesis. Because virtually all people walk with a prosthesis in a manner different from the nondisabled walking pattern, prosthetic gait represents compensation for the patient's altered locomotor apparatus. The term *gait compensation* may be a more accurate descriptor than the more commonly used *gait deviation* inasmuch as the patient with amputation is most unlikely ever to walk exactly like a nondisabled person.

No prosthesis restores sensation, skeletal continuity, muscle integrity, or full body weight. Anatomical deficiencies are aggravated in the presence of pain, contracture, weakness, instability, or incoordination. Similarly, prosthetic components do not replace every function of the missing limb. For example, prosthetic feet do not move through the full excursion of the human counterpart. Inadequacies in the prosthesis compel the wearer to adopt gait compensations. Such problems include a poorly fitted socket, prosthetic misalignment, malfunctioning components, and improper height of the prosthesis. Compounding the problem are incorrect donning of the prosthesis and wearing inappropriate shoes. The physical therapist must determine when gait compensation exists and the potential causes so that remedial action may be taken. Otherwise, the patient is compelled to expend more energy walking and to exhibit a more conspicuously abnormal gait. The new wearer will have had brief experience walking in the prosthesis during the course of prosthetic fabrication. Although a smooth gait is unlikely on the day of the initial examination, gross departure from the usual gait exhibited by others with similar prostheses should be noted and causes sought.

Transtibial analysis focuses on action of the knee on the amputated side during stance phase. Both knees should flex in a controlled manner during their respective early and late stance phases. Excessive flexion of the knee on the amputated side indicates that the socket is aligned too far anterior in relation to the foot or is excessively flexed; this deviation may cause the patient to fall. If the knee flexes too much only during early stance, the cause may be a heel cushion that is too firm for that wearer. Conversely, insufficient knee flexion results from posterior displacement of the socket or inadequate socket tilt. When viewed in the frontal plane, the socket brim should maintain reasonable contact with the leg; excessive lateral thrust of the prosthetic brim suggests that the prosthetic foot has been positioned too far medially. Table 31.1 summarizes the prosthetic and anatomical causes of transtibial gait compensations/deviations.

At the initial evaluation, performance on stairs and inclines may be omitted because the patient has not had training in these activities.

Inspection of the Prosthesis Off the Patient

The posterior wall should be approximately at the same level as the build-up for the patellar *ligament* (tendon) when the patient stands. To check this, the prosthesis is stood upright on a table; one end of a ruler is then placed on the anterior socket bulge and the opposite end on the posterior brim. In a well-constructed prosthesis, the ruler will slant upward toward the rear, indicating that when the individual stands in the prosthesis and compresses

Table 31.1 Transtibial Prosthetic Gait Analysis

Compensation/Deviation	Prosthetic Causes	Anatomical Causes
Early Stance		
1. Excessive knee flexion	High shoe heel Insufficient plantarflexion Stiff heel cushion Socket too far anterior Socket excessively flexed Cuff tabs too posterior	Flexion contracture Weak quadriceps
2. Insufficient knee flexion	Low shoe heel Excessive plantarflexion Soft heel cushion Socket too far posterior Socket insufficiently flexed	Extensor spasticity Weak quadriceps Anterior-distal pain Arthritis
Midstance		
1. Lateral thrust	Excessive foot inset	
2. Medial thrust	Excessive foot outset	
Late Stance		
1. Early knee flexion: also referred to as "drop off"	High shoe heel Insufficient plantarflexion Keel too short Dorsiflexion stop too soft Socket too far anterior Socket excessively flexed Cuff tabs too posterior	Flexion contracture
2. Delayed knee flexion: perception of walking uphill	Low shoe heel Excessive plantarflexion Keel too long Dorsiflexion stop too stiff Socket too far posterior Socket insufficiently flexed	Extensor spasticity

the heel cushion, the posterior wall will be at the proper height.

The amputation limb should be examined for signs of proper loading with respect to the type of prosthesis worn. Any straps or cuff should provide reasonable adjustability. Construction is a guide to future durability, as well as contributing to acceptable appearance of the prosthesis.

Transfemoral Examination

A similar checklist is used to evaluate the transfemoral prosthesis (Appendix 31.B). It is important to recognize that seldom is one item of major significance. The therapist and entire team should look for patterns that might herald future difficulty. For example, misalignment detected in static analysis should be confirmed during gait.

Static Analysis

The patient who has a flesh roll above the socket either did not don the socket properly or has a thigh that is larger than that for which the socket was made. Perineal pressure results from sharpness of the medial brim or insufficiency of the adductor longus relief in a quadrilateral socket.

The knee unit should be stable enough to withstand a blow delivered by the therapist to the posterior aspect of the unit when the patient stands. Stability is influenced by the *alignment* of the knee in relation to the hip and prosthetic ankle. The farther posterior the knee bolt, the more stable the knee will be. Polycentric linkage and mechanical stabilizers also contribute to stability. If the socket is opaque, the only way to judge its snugness is by palpating tissue protruding through the valve hole when the valve is removed.

The checklist is designed to help the clinician determine the fit of the socket, regardless of shape or material. If the prosthesis has a quadrilateral socket, proper location of the adductor longus tendon and ischial tuberosity ensures that the patient has donned the socket correctly. A horizontal posterior brim allows weight to be borne on the gluteal musculature as well as the ischial tuberosity. The ischial containment socket is intended to cover the

ischial tuberosity, yet allows the client to move the hip in all directions comfortably, without socket gapping.

The lateral attachment of the Silesian belt should be superior and posterior to the greater trochanter for best control of prosthetic rotation. Anteriorly, the attachment should be at the level of the ischial tuberosity, or slightly below, to aid in adducting the prosthesis.

The pelvic joint and band should fit the torso snugly for optimum control of the prosthesis and to minimize bulkiness. The joint axis should be superior and anterior to the greater trochanter.

The patient should be able to sit comfortably with the prosthesis. Posterior discomfort may indicate inadequate hamstring relief, or a sharp or thick posterior brim.

Dynamic Analysis

Gait analysis gives the clinic team members the opportunity to determine the adequacy of socket fit and of prosthesis alignment and adjustment. The patient also influences the walking pattern by the timing and force of muscular contraction and the presence or absence of contractures. The goal of walking with a transfemoral prosthesis is a comfortable, safe, efficient gait, rather than duplicating the gait of someone wearing a transtibial prosthesis or one who does not have amputation.[72] Table 31.2 summarizes the prosthetic and anatomical causes of transfemoral gait compensations/deviations.

Compensations/Deviations Best Viewed from Behind

Many individuals with transfemoral amputation abduct the prosthesis to improve frontal plane balance (*abducted gait*). Hip abduction contracture predisposes patients to this deviation, which is seen in stance phase. Inadequate socket adduction, socket looseness, or medial discomfort also causes the fault. *Circumduction* is a displacement exhibited in swing phase if the prosthesis is too long or if the patient is reluctant to allow the knee unit to bend. Socket looseness also may result in circumduction. The patient may shift the trunk excessively. *Lateral trunk bending* toward the prosthetic side during stance phase generally accompanies abducted gait. It should be noted, however, that all individuals with transfemoral amputation have an incomplete abductor mechanism, and tend to compensate by bending toward the prosthetic side, especially when fatigued. Although the anatomical hip and gluteus medius are usually in good condition, lack of skeletal continuity to the ground (imposed by the amputation) compromises the effectiveness of abductor contraction. If the prosthesis is too long, the patient will abduct; if it is too short, the patient will bend the trunk laterally.

Whips refer to medial or lateral rotation of the heel at late stance. If the socket does not fit well, contraction with bulging of the thigh musculature will cause the

Table 31.2 Transfemoral Prosthetic Gait Analysis

Compensation/Deviation	Prosthetic Causes	Anatomical Causes
Lateral Displacements		
1. Abduction: stance	Long prosthesis Abducted hip joint Inadequate lateral wall adduction Sharp or high medial wall	Abduction contracture Weak abductors Lateral/distal pain Adductor redundancy instability
2. Circumduction: swing	Long prosthesis Locked knee unit Loose friction Inadequate suspension Small socket Loose socket Foot plantarflexed	Abduction contracture Poor knee control
Trunk Shifts		
1. Lateral bend: stance	Short prosthesis Inadequate lateral wall adduction Sharp or high medial wall	Abduction contracture Weak abductors Hip pain Instability Short amputation limb
2. Forward flexion: stance	Unstable knee unit Short walker or crutches	Instability
3. Lordosis: stance	Inadequate socket flexion	Hip flexion contracture Weak extensors

Compensation/Deviation	Prosthetic Causes	Anatomical Causes
Rotations		
1. Medial (or lateral) whip: heel off	Faulty socket contour Knee bolt externally (or internally) rotated Foot malrotated Prosthesis donned in malrotation	With sliding friction unit, fast pace
2. Foot rotation at heel contact	Stiff heel cushion Malrotated foot	
Excessive Knee Motion		
1. High heel rise: early swing	Inadequate friction Slack extension aid	
2. Terminal impact: late swing	Inadequate friction Taut extension aid	Forceful hip flexion
Reduced Knee Motion		
1. Vault: swing	See above: circumduction	With sliding friction unit, fast pace
2. Hip hike: swing	See above: circumduction	Weak dorsiflexors Plantarflexor spasticity Pes equinus Weak hip flexors
Uneven Step Length	Uncomfortable socket Insufficient socket flexion	Hip flexion contracture Instability

prosthesis to rotate abruptly as it is being unloaded at the end of stance phase. Although less likely, malrotation of the knee unit or foot-ankle assembly may contribute to whipping. *Rotation of the foot on heel contact* is a much more serious deviation. It indicates inadequate compression of the heel cushion or plantar bumper and can result in a fall.

Compensations/Deviations Best Viewed from the Side

Forward trunk shifting in stance phase is a compensation that some patients use to cope with knee instability. If the walker or crutches are too short, the individual will lean forward. Lumbar *lordosis* results from inadequate socket flexion and is aggravated by a hip flexion contracture.

Improper adjustment of the knee unit gives rise to *uneven heel rise* (excessive knee flexion) and *terminal swing impact* (abrupt knee extension). If both deviations are present, the probable cause is insufficient friction. If the knee exhibits impact without undue heel rise, it is more likely that the extension aid is too tight.

To compensate for reduced knee motion, the vigorous walker may demonstrate *vaulting* by excessively plantarflexing the sound ankle to afford extra room to clear the prosthesis during prosthetic swing phase. A less strenuous compensation for excessive actual or functional prosthesis length is *hip hiking*, when the patient elevates the pelvis on the prosthetic side.

Unequal step length will be evident if the patient has a hip flexion contracture or inadequate balance. A longer step taken with the prosthesis gives the person more time on the sound limb. A flexion contracture or insufficient socket flexion (limiting hip extension range) prevents the sound limb from passing the prosthetic side during swing phase on the sound side (i.e., shorter step length on the sound side).

Inspection of the Prosthesis Off the Patient

Following the static evaluation, the therapist should examine the prosthesis and amputation limb as indicated on the checklist. A resilient back pad (placed externally on the posterior wall) enables the patient to sit quietly without undue trouser or skirt abrasion. The pad is unnecessary with a flexible socket.

Facilitating Prosthetic Acceptance

Amputation generally is regarded as a grievous occurrence, with its visibility a constant reminder of the individual's abnormality. The physical therapist can help the patient and family accept the reality of amputation and the prosthesis by verbal and nonverbal communication. One's calm respect for the patient as a worthy human being, regardless of limb condition, should set a model

for the attitudes of others. Clinic team management accords not only the benefits of better prosthetic provision but also brings the individual in contact with clinicians who convey experience and confidence in dealing with problems that the person may have considered unique.

As soon as possible, the hospitalized patient should be treated in the physical therapy department, rather than at bedside. The bustle of the department should help dispel despondency. Although postoperative mourning is expected, prolonged depression is not constructive. Peer support groups are often very effective in aiding acceptance of the prosthesis and in learning special procedures for accomplishing activities. Observation and eventual participation in specially designed sports programs is another way people learn to cope and gain the most from rehabilitation. The physical therapist, by virtue of close daily contact with the patient, is also in a position to recommend to the clinic those who might profit from psychological counseling or psychiatric services, particularly when pain is an issue. Appendix 31.C provides website-based prosthetic resources for clinicians, families, and patients.

Prosthetic Training

Learning to use a prosthesis effectively involves being able to don it correctly, develop good balance and coordination, walk in a safe and reasonably symmetrical manner, and perform other ambulatory and self-care activities. Anticipated goals and expected outcomes depend on the patient's physical and psychological status, preprosthetic experience, and quality of prosthesis. Using the prosthesis only to assist in transferring from the wheelchair to the toilet may be an appropriate outcome for an elderly person with multiple disabilities, whereas the program for the youngster with traumatic amputation might extend to a full range of sports.

Donning

Correct application of the prosthesis and frequent inspection of the amputation limb are very important, especially for the beginner and those with poor circulation. Patients with partial foot, Syme's, and transtibial amputations can don the prosthesis while seated, after having applied the correct number and sequence of socks or sheath. Then, in most instances, the individual simply inserts the amputation limb into the socket. With SC/SP suspension, one applies the liner to the amputation limb, then inserts the limb and liner into the socket. The initial entry into the socket with corset suspension may be made while sitting; however, final tightening of laces or straps should be done in the standing position to ensure that the limb is lodged suitably in the socket.

Those with transfemoral amputation also can begin the donning process while seated. Total suction wearers may use either a pulling or pushing method. To pull oneself into the socket, the patient applies a light dusting of talcum powder to the thigh to reduce friction. Then one applies a pulling sock, a tubular cotton stockinet approximately 30 in (76 cm) long, a roll of elastic bandage wound around the thigh, or a nylon stocking. Whatever the donning aid, it should be placed high in the groin to pull in proximal tissues. After placing the sock-encased thigh into the socket, one draws the distal end of the aid through the valve hole. Although it is possible to complete the donning process while seated, most people prefer to stand while pulling the sock or other aid out through the valve hole. By leaning forward, the body's weight line will prevent the prosthetic knee from flexing inadvertently. The patient alternately flexes and extends the sound hip and knee while tugging downward on the donning aid until it slips out from the prosthesis. Finally, one inserts the valve. Another approach to donning is to coat the thigh with lubricating lotion, push it into the socket, and then install the valve.

Patients who use partial suction apply a sock, making certain the proximal margin of the sock extends to the inguinal ligament. The patient then introduces the amputation limb into the socket, taking care that the thigh is correctly oriented; pulls the distal end of the sock down through the valve hole enough to ensure that the skin is smooth; tucks the sock back into the socket; and inserts the valve. Finally, one secures the pelvic band or Silesian belt. If suction is not used, donning is similar to the method used with partial suction, except that there is no valve.

Balance and Coordination

Exercises are similar for all patients with LE amputations, although the individual with a transfemoral or hip disarticulation prosthesis may be expected to encounter more difficulty controlling the mechanical knee, as compared to those with two anatomical knees. All must learn to balance on the amputated side.[73-77] A graduated program for increasing prosthetic tolerance minimizes the danger of skin abrasion, particularly if the amputation limb presents skin grafts, poor circulation, or diminished sensation. The patient should alternately exercise and rest, with cardiopulmonary monitoring a routine part of the program, especially for high-risk individuals.

Some clinicians eschew parallel bars because the fearful patient pulls on them, which will be fruitless when progressing to a cane. When bars are used, the therapist should encourage the patient to rest the open hand on the bar for support, rather than using a viselike grip. A plinth or sturdy table offers the dual advantages of providing good support on only one side, ordinarily the contralateral side, and unidirectional control, because the patient can only push, never pull, for balance.

Static erect balance reintroduces the novice to bipedal posture. The patient should strive for level pelvis and shoulders, vertical trunk without excessive lordosis, and equal weight-bearing. The therapist should guard and assist the patient as necessary. When the physical therapist stands near the prosthesis, this encourages the

patient to shift his or her weight onto it. To suggest symmetrical performance, refer to the limbs as "right" and "left," or "sound" and "prosthetic," rather than discouraging the patient with "good" and "bad." The client must learn to use proximal sensory receptors to maintain balance and perceive the position of the prosthesis without looking at the floor. Some patients respond well to increased use of visual feedback (e.g., using a mirror).

Dynamic exercises improve medial–lateral, sagittal, and rotary control. The patient learns that hip flexion causes the knee to bend, and hip extension stabilizes the knee during stance phase. Placing the sound foot ahead of the prosthesis makes the prosthetic knee more stable. Patients should be instructed in weight shifting in both symmetrical and stride positions and in stepping movements. Stepping on a low stool or step platform with the sound foot obliges the patient to shift weight onto the prosthesis and increases stance phase duration on the prosthesis. Having all exercises performed rhythmically with both the right and left LEs fosters symmetrical performance.

Gait Training

Walking is a natural progression from dynamic balance exercises as the patient takes successive steps. Patients tend to place greater load and exert more propulsive force on the intact side; consequently, gait training should emphasize symmetrical performance.[67-73] Inasmuch as hamstrings become the main muscles of propulsion, strengthening exercises are indicated. Some people respond well to proprioceptive neuromuscular facilitation.[74] Rhythmic counting and walking in time with music in 2/4 time also improves gait symmetry and speed. In the physical therapy department, an apparatus that includes a suspension harness (partial body weight support) provides a protected environment for the patient to learn gradual weight-bearing on the prosthesis. A balance apparatus (e.g., Balance Master®) providing electronic feedback with or without emphasis on psychological awareness of bodily position is another training option.

Either a cane or pair of forearm crutches is an appropriate aid for the client who is unable to achieve a safe gait without undue fatigue. Sometimes the cane is used only outdoors to aid in negotiating curbs and other ground irregularities and to signal oncoming traffic. Ordinarily the cane is used on the contralateral side to enhance frontal plane balance. If bilateral assistance is required, a pair of forearm crutches is preferable to two canes. The crutches remain clasped around the forearms when the user opens a door. Axillary crutches tempt the patient to lean on the axillary bars, risking impingement of the radial nerves; they are also inconvenient when climbing stairs. An aluminum walker provides maximum stability, which is particularly useful for patients with generalized weakness. The walker should be adjusted so that the user does not lean too far forward. Patients with transtibial amputation walk faster with a two-wheeled walker as compared with a four-footed walker.[75] Fear of falling can undermine walking and social activity participation. Improving the patient's balance confidence is essential to lessen this concern.[76,77]

Functional Training

The prosthesis wearer who is learning to walk also should gain experience in performing a wide variety of functional mobility skills. Activities such as transferring to various chairs add interest to the program and, for some patients, may be more important than long-distance ambulation.

The training program for vigorous individuals includes stair climbing, negotiating ramps, retrieving objects from the floor, kneeling, sitting on the floor, running, driving a car, and engaging in sports. The fundamental difference between these activities and walking is the way each LE is used. Walking implies symmetrical usage, but the other activities are done asymmetrically, with greater reliance on the strength, agility, and sensory control of the sound limb.

Generally, the patient should have the opportunity to analyze each new situation and arrive at a solution to the problem, rather than depending on directions from the therapist. Most tasks can be accomplished safely in several ways. The learner profits from practice in clinical decision making and observing other prosthesis wearers as well as from professional instruction.

Transfers

Rising from different chairs, the toilet, and car are primary skills even for people who are elderly or debilitated. Most patients enter the physical therapy department in a wheelchair. Initially, the patient can park the chair at the parallel bars or at a plinth. After locking the wheelchair and raising the footrests, the patient should sit forward and transfer weight to the intact leg, then push down on the armrests. The individual will find that placing the sound foot close to the chair enables rising by extending the knee and hip on the sound side. Sitting is accomplished by placing the sound foot close to the chair and lowering oneself by controlled hip and knee flexion on the sound side.

For both standing and sitting, the beginner should have the advantage of a chair with armrests that enables use of the hands to control and assist trunk movement. Later the person should practice sitting in deep upholstered sofas and low chairs, as well as benches, the toilet, and other seats that do not have armrests. Transfer into an automobile should be an integral part of the training activities; otherwise, the patient faces a gloomy future, confined to home or dependent on special transportation systems. To enter the right (passenger) side of an automobile, the prosthetic wearer faces toward the front of the car. The person with a right prosthesis puts the right hand on the door post and the left hand on the

back of the front seat, then swings the left leg into the car, slides onto the car seat, and finally places the prosthesis in the car. The individual with a left prosthesis may find that sitting sideways with both feet out the car door is easiest. One then pivots on the seat while swinging the prosthesis into the car, then puts the intact right foot inside the car.

Climbing Stairs, Ramps, and Curbs

Patients with Syme's and transtibial amputations generally ascend and descend stairs and inclines with steps of equal length in step-over-step progression.[78-80] Those with unilateral transfemoral amputation, in contrast, usually ascend by leading with the sound foot and learn to descend by first placing the prosthesis on the lower step. A few individuals with transfemoral amputation subsequently learn to control prosthetic knee flexion in order to descend step-over-step. Those fitted with the Power Knee® may be able to ascend stairs step-over-step.

Curbs present a slightly different problem, because there is no handrail. The techniques are basically the same, however.

Ramps may be difficult if the prosthetic foot does not have sufficient anteroposterior excursion.[81,82] With steep stairs, ramps, and curbs, the individual may climb diagonally or sidestep with the prosthesis kept on the downhill side. Patients should also learn how to maneuver over obstacles on the walking surface.[83]

Final Evaluation and Follow-up Care

Economic strictures may compel the therapist to conclude the training program after the patient is able to walk and to negotiate basic transfers and stair climbing but before the full range of training activities is completed. Before discharge, the patient and prosthesis should be reexamined to make certain that socket fit, prosthetic appearance, and function are acceptable. The checklist used for initial evaluation can be used. The physical therapist should instruct the patient with regard to the patient's responsibility for reporting skin redness and any loose or missing parts from the prosthesis.

The new prosthesis wearer should return to the training site at regular intervals so that the clinic team may examine socket fit. Most will require major socket revision or replacement during the first year to accommodate amputation limb volume reduction. Follow-up visits are good opportunities to augment training and to encourage the individual to engage in the widest possible range of activities.

Functional Capacities

Functional capacities refer to the individual's ability to walk, transfer from chairs, climb stairs, and perform other ambulatory activities, including recreational endeavors. A primary responsibility of the clinic team is to predict the probable function of the person with a new amputation, to determine whether the individual would benefit from a prosthesis, and what degree of activity is likely. Because many people with LE amputation are elderly with several medical problems, the need for accurate forecasting and ongoing monitoring is especially critical.

Walking with a prosthesis increases energy cost.[84-88] Compared with those people with two sound limbs, the individual with a unilateral transtibial prosthesis requires slightly more oxygen when walking at a comfortable speed;[89,90] the person wearing a transfemoral prosthesis consumes nearly 50% more oxygen than normal,[91] although selection of prosthetic feet and knee units usually modifies the energy demand.[92-95] The prosthesis wearer chooses a comfortable pace, because at a speed that is natural for the individual, the energy cost per minute is similar to that of the person who does not require a prosthesis, although speed is slower. The lower the amputation level, the less the metabolic disadvantage. Among persons with transtibial amputations older than 40, those with long amputation limbs average minimal increase in energy, but persons with shorter limbs work harder. Those with bilateral transtibial amputations expend less energy than those with unilateral transfemoral amputations. Individuals whose amputation was traumatic perform more efficiently than those whose amputation was caused by vascular disease at every amputation level. People who sustained trauma walk faster and use less oxygen than their dysvascular counterparts.

The increased metabolic expenditure results in part from the socket, which surrounds semifluid tissue, giving imperfect anchorage imposing challenges to limb control. The foot-ankle assembly transmits no plantar tactile or proprioceptive sensation, does not move through as large an excursion as the anatomical foot, and does not initiate the dynamic propulsion characteristic of normal gait. The transfemoral prosthesis also incorporates a knee unit that provides no proprioception to the wearer. The problem is aggravated by the fact that a prosthesis is operated by remotely located muscles that contract longer and more forcefully than in normal gait. With transfemoral amputation, for example, the wearer positions the prosthetic foot by hip motion. The resulting alteration of motion is reflected in asymmetry of timing, further disturbing gait smoothness. Individuals with prostheses walk with greater vertical movement, inasmuch as the knee, whether mechanical for the transfemoral prosthesis wearer or anatomical in the transtibial wearer, does not flex as much as the contralateral knee during stance phase.

Use of a hip disarticulation prosthesis demands considerable energy expenditure.[96]

People wearing bilateral prostheses consume even more oxygen and walk more slowly than those with unilateral amputation at a given level.[97]

With the exception of patients on beta-blockers, heart rate response is an important indication of the metabolic cost of prosthetic use for most individuals. Overall, strength, balance ability, etiology of amputation, and level of amputation predict the extent of impairment.[98]

Other measures of functional capacities include utilization of prostheses[99-102] and quality-of-life surveys.[103-116] Return to work[117-118] and ability to drive an automobile[119,120] are other indicators of rehabilitation success.

Sports participation (Fig. 31.36) is an excellent extension of rehabilitation for patients of all ages.[121-134] Older adults may enjoy fishing, golfing, dancing, Tai Chi Chuan, and shuffleboard, and younger people may add basketball, tennis, archery, and track events to their range of activities. Most sports do not require any adaptation to the prosthesis. Horseback riding is a superb activity that fosters trunk control and seated balance. The hiker should pack extra amputation limb socks or a sheath to protect the skin; a well-fitting, comfortable hiking boot is essential. Bowling and participating in shot put are facilitated by emphasizing balance on the intact LE. For sports that involve running, an energy-storing/releasing foot is most suitable. The socket should fit snugly with very secure suspension to minimize abrasion of the amputation limb. Clients with Syme's or transtibial amputations usually run with reasonably symmetrical step lengths, although they will favor the sound limb, which has greater propulsive ability.[7] Those with a knee disarticulation or transfemoral amputation will derive most of the propulsive force from the sound leg and use the prosthesis as a momentary prop. Many marathon competitions have a category for people with disabilities. Jumping, as in basketball, requires the athlete to generate a substantial upward force with the sound leg; landing is more comfortable on the sound leg, particularly for those who wear transfemoral prostheses. Some activities are facilitated by minor modification of the equipment, such as a toe loop on a bicycle pedal or an adapted prosthesis.

Other activities are generally performed without a prosthesis, such as swimming and skiing. The skier will probably use ski poles equipped with small rudders, in a "three-track" manner. Soccer is usually played without a prosthesis, with the player using a pair of crutches. Some individuals enjoy playing tennis and field events in a wheelchair. Equipment and techniques developed for individuals with paraplegia usually can be adapted for people with amputations.

Recreational programs designed for adults with amputations help the participants to return to active lifestyles. The physical therapist should be able to refer patients to convenient recreational clubs and sporting events. The desired outcome is to maximize each person's functional capacity and quality of life.

SUMMARY

This chapter has focused on the prosthetic management of adults with lower-limb amputations. Characteristics and function of the principal lower-limb prostheses and prosthetic components have been discussed. In addition, the responsibilities of the physical therapist in prosthetic management have been emphasized. Successful prosthetic rehabilitation depends on close collaboration among the patient, physical therapist, physician, prosthetist, and other team members. This will provide an environment for information exchange and foster coordinated management. The result will be an optimum match between the patient's physical and psychosocial characteristics and a prosthesis capable of fulfilling its intended purposes.

Questions for Review

1. What are the principal causes of amputation in the elderly? In the young?
2. Describe appropriate prostheses for individuals with the following partial foot amputations: phalangeal, transmetatarsal, and Syme's.
3. Distinguish between the Syme's and the transtibial amputation limbs and prostheses.
4. What prosthetic feet are especially suitable for elderly patients? Why?
5. Name the reliefs and build-ups in the transtibial socket.
6. Contrast the modes of suspension for the transtibial prosthesis. Which suspension is indicated for an individual with a very short amputation limb?
7. Classify knee units according to friction mechanisms.
8. Compare the quadrilateral and the ischial containment transfemoral sockets.
9. Describe the modes of suspension of the transfemoral prosthesis. In which type(s) does the client wear a sock?
10. How is the wearer of a hip disarticulation prosthesis prevented from inadvertently flexing the prosthetic hip and knee?
11. Outline a maintenance program for a transfemoral prosthesis with hydraulic knee unit and endoskeletal shank.
12. What factors should be considered before formulating a prosthetic prescription?
13. How can the physical therapist determine and improve the patient's psychological status?
14. What features of the transtibial prosthesis are considered in static evaluation? In dynamic evaluation?
15. Delineate the training program for a patient with a transfemoral prosthesis.

CASE STUDY

The patient is a 67-year-old man with diabetic arteriosclerosis. He sustained a right transtibial amputation 5 months ago. He was treated in the inpatient physical therapy department for 3 weeks. The wound healed satisfactorily. His physical therapist taught him to transfer independently and ambulate using a temporary prosthesis and a walker. He was discharged with a home program consisting of exercises to promote strength, joint mobility, and endurance. He was also told to keep an elastic shrinker sock on his amputation limb whenever he was not wearing the temporary prosthesis. In addition, the physical therapist instructed the patient in care of the left foot, including thorough foot washing every evening; inspecting all surfaces of the foot, using a mirror; wearing a clean sock and well-fitting shoe each day; and careful nail trimming. He was fitted with a permanent prosthesis 3 months after surgery. The prosthesis consisted of a SACH foot, endoskeletal shank, total contact socket, and cuff suspension. He returned to the rehabilitation department today complaining of difficulty keeping his balance on the irregular terrain on the golf course where he had gone for the first time since his surgery. He also mentioned that his golf score was poorer than it had ever been.

PAST MEDICAL HISTORY

The patient was in fairly good health until 6 months ago, when he went on a long-awaited trip to Europe. On the trip he did much more walking than usual, even though he had to stop every 50 feet because of cramping pain in his legs. His wife noticed that the hallux and second toe on his right foot were discolored. The discolored area became painful. After his return home, he was examined by his primary care physician and was diagnosed with gangrene and adult-onset diabetes. Despite aggressive wound care, the gangrene progressed to involve the entire foot. An amputation was required. His diabetes is now stabilized with diet and medication.

SOCIAL HISTORY

The patient is a retired accountant who lives with his wife. For years, he played golf on vacations. Upon retirement last year, he had looked forward to more frequent golfing.

PHYSICAL THERAPY EXAMINATION FINDINGS

- *Cognitive status*: Alert, oriented, memory intact
- *Vision*: Intact with corrective lens
- *Cardiopulmonary*:
  - Vital signs seated at rest: Blood pressure 140/86, heart rate 84, respiration within normal limits (WNL)
  - Endurance: Fair, tolerance to activity is approximately 30 minutes (with some fluctuation); occasional rest periods required
- *Integumentary*: Incision well healed without adherent scar
- *Neuromuscular*:
  - Sensation: Both upper and lower extremities: sharp/dull, light touch, temperature, and proprioception all WNL bilaterally
  - Reflexes: WNL

Range of Motion

- Goniometric examination of both LEs: WNL

Observational Gait Analysis (General Findings)

- Overall decrease in speed of movement
- Diminished, awkward weight transfer

Hip/Pelvis (Bilateral)

- Decreased pelvic rotation
- Diminished hip flexion

Knee

- Diminished right knee flexion

Foot/Ankle

- Minimal medial–lateral motion of the right prosthetic foot

Gait

The patient is a functional ambulator using a transtibial prosthesis. Gait is slow, with longer steps on the right side; without the cane he leans to the right side. When outdoors he uses a cane in the left hand. He can climb stairs slowly, using the handrail. On uneven surfaces, he widens his walking base and walks slowly.

Strength

Manual Muscle Test (MMT) Grades

		Right	Left
Hip	Flexion	4/5	4/5
	Extension	4/5	4/5
	Abduction	4/5	4/5
	Adduction	4/5	4/5
	Internal rotation	4–/5	4–/5
	External rotation	4–/5	4–/5
Knee	Flexion	4–/5	4/5
	Extension	3+/5	4–/5
Foot/ankle	Dorsiflexion	N/A	4/5
	Plantar flexion	N/A	4/5
	Inversion	N/A	4/5
	Eversion	N/A	4/5
Upper limb	WFL	WFL	WFL

N/A = not applicable owing to amputation; WFL = within functional limits.

Prosthetic Examination

- Socket is loose, as indicated by piston action

Balance

Standing

- Static: Good; able to maintain static position for unlimited period
- Dynamic: Fair +; difficulty maintaining balance on uneven terrain

Sitting

- WFL

Examination of Function

- Patient independent in transfers: bed, chair (FIM level = 7); requires minimal assistance in floor-to-stand transfers.
- Patient is independent in all basic activities of daily living (BADL).
- Patient is independent in approximately 80% of instrumental activities of daily living (IADL) (limitations imposed by fatigue and low ambulatory tolerance).

PATIENT DESIRED OUTCOMES

- Play golf at previous level of proficiency
- Walk without depending on cane when outdoors
- Improve endurance

GUIDING QUESTIONS

1. Formulate a clinical problem list, including impairments, activity limitations, and participation restrictions.
2. Formulate a patient asset list.
3. Establish anticipated short-term goals and expected long-term outcomes, with regard to impact on:
   - Impairments
   - Activity limitations
   - Participation restrictions
   - Risk reduction/prevention
   - Health, wellness, and fitness
   - Patient/client satisfaction
4. Formulate a plan of care, with reference to *Guide to Physical Therapist Practice*.
5. Identify three impairments to address initially to improve this patient's activity limitations and participation restrictions.
6. Describe three treatment interventions focused on functional outcomes that could be used during the first weeks of therapy, indicating how you could progress each intervention.
7. What important safety precautions should be observed during treatment of this patient?
8. Describe strategies that can be used to develop self-management skills and promote self-efficacy in achieving goals and outcomes.

appendix
31.A Transtibial (Below-Knee) Prosthetic Examination

1. Is the prosthesis as prescribed?
2. Can the client don the prosthesis easily?

Standing

3. Is the client comfortable when standing with the heel midlines 6 in (15 cm) apart?
4. Is the anterior–posterior alignment satisfactory?
5. Is the medial–lateral alignment satisfactory?
6. Do the contours and color of the prosthesis match the opposite limb?
7. Is the prosthesis the correct length?
8. Is piston action minimal?
9. Does the socket contact the amputation limb without pinching or gapping?

Suspension

10. Does the suspension component fit the amputation limb properly?
11. Does the cuff, fork strap, or thigh corset have adequate provision for adjustment?

Sitting

12. Can the client sit comfortably with hips and knees flexed 90°?

Walking

13. Is the client's performance in level walking satisfactory?
14. Is the client's performance on stairs and ramps satisfactory?
15. Can the client kneel satisfactorily?
16. Does the suspension function properly?
17. Does the prosthesis operate quietly?
18. Does the client consider the prosthesis satisfactory as to comfort, function, and appearance?

Prosthesis Off the Client

19. Is the skin free of abrasions or other discolorations attributable to this prosthesis?
20. Is the socket interior smooth?
21. Is the posterior wall of the socket of adequate height?
22. Is the construction satisfactory?
23. Do all components function satisfactorily?

Transfemoral (Above-Knee) Prosthetic Examination

appendix 31.B

1. Is the prosthesis as prescribed?
2. Can the client don the prosthesis easily?

Standing

3. Is the client comfortable when standing with the heel midlines 6 in (15 cm) apart?
4. Is any flesh roll above the socket minimal?
5. Is the client free from vertical pressure in the perineum?
6. Do the contours and color of the prosthesis match the opposite limb?
7. Is the prosthesis the correct length?
8. Is the knee stable?
9. When the socket valve is removed, is the distal tissue firm?

Quadrilateral Socket

10. Does the ischial tuberosity rest on the posterior brim?
11. Is the posterior brim approximately parallel to the floor?
12. Is the adductor longus tendon located in the anterior–medial corner?

Ischial Containment Socket

13. Does the posterior–medial corner of the socket cover the ischial tuberosity?
14. Can the client hyperextend the hip on the amputated side comfortably?
15. Can the client flex the hip 90° comfortably, without socket gapping?
16. Can the client abduct the hip on the amputated side comfortably, without socket gapping?

Suspension

17. Does the Silesian bandage control prosthetic rotation and adduction adequately?
18. Does the pelvic band conform to the torso?

Sitting

19. Can the client sit comfortably with hips and knees flexed 90°?
20. Does the socket remain securely on the thigh, without gapping or rotating?
21. Are both thighs approximately the same length and height from the floor?
22. Can the client lean forward to touch the shoes?

Walking

23. Is the client's performance in level walking satisfactory?
24. Is the client's performance on stairs and ramps satisfactory?
25. Does the suspension function properly?
26. Does the prosthesis operate quietly?
27. Does the client consider the prosthesis satisfactory as to comfort, function, and appearance?

Prosthesis Off the Client

28. Is the skin free of abrasions or other discolorations attributable to this prosthesis?
29. Is the socket interior smooth?
30. With the prosthesis fully flexed on a table, can the thigh piece be brought to at least the vertical position?
31. If the socket is totally rigid, is a back pad attached?
32. Is the construction satisfactory?
33. Do all components function satisfactorily?

The Prescriptive Wheelchair

Faith Saftler Savage, PT, ATP

Chapter 32

LEARNING OBJECTIVES

1. Describe the components of the examination process for prescribing a wheelchair.
2. Discuss the relationship between elements of patient history and the wheelchair prescription.
3. Describe the optimal sitting posture for an individual using a seating system.
4. Explain the different methods of seating simulation and the expected outcomes.
5. Describe factors that affect determination of seat and back support features.
6. Discuss the benefits and contraindications of various seating system features.
7. Recognize the components of a problem solving model and describe each component when presented with a clinical case study.

CHAPTER OUTLINE

EXAMINATION *1405*
- History Taking *1405*
- Overview: Tests and Measures *1405*

SEATING PRINCIPLES *1407*
- Principle 1: Stabilize Proximally to Promote Improved Distal Mobility and Function *1407*
- Principle 2: Achieve and Maintain Pelvic Alignment *1407*
- Principle 3: Facilitate Optimal Postural Alignment in all Body Segments, Accommodating for Impairments in Range of Motion *1407*
- Principle 4: Limit Abnormal Movement and Improve Function *1408*
- Principle 5: Provide the Minimum Support Necessary to Achieve Anticipated Goals and Expected Outcomes *1408*
- Principle 6: Provide Comfort *1408*

WHEELCHAIR PRESCRIPTION *1408*

WHEELCHAIR TRAINING STRATEGIES *1432*

ROLE OF THE CERTIFIED REHABILITATION TECHNOLOGY SUPPLIER *1432*

SUMMARY *1433*

Physical and occupational therapists are often called on to prescribe a wheelchair. A properly prescribed wheelchair can be a useful device in reintegrating a person with a disability into the community, whereas a poorly prescribed one can actually exacerbate the problems associated with activity limitations and disability. This chapter presents a systematic approach to determining the appropriate components of a prescriptive wheelchair, beginning with a thorough examination and culminating with a plan of care (POC) that includes the proper seating system and wheeled mobility base. The seating system and mobility base combine to create a prescriptive wheelchair, a seated environment from which the patient can achieve maximum function.

The editors acknowledge the contributions of Adrienne Falk Bergen, PT, ATP, to earlier versions of this work.

Optimal fit of a wheelchair is important to assist the person in improving mobility, posture, and function. Properly fitted wheelchairs assist with preventing problems associated with poor posture, including pressure sores, respiratory difficulties, discomfort, and abandonment of equipment. Cosmetics (appearance), durability, weight, and intended use need to be considered when determining the most appropriate wheelchair system.

Determining the appropriate wheelchair and seating system requires a thorough examination to ensure optimal equipment is obtained. Too often, a basic commercial system is provided, but this is frequently not the best solution. The solution must consider multiple patient-, environmental-, and diagnosis-related factors and requires a comprehensive examination by the professional team. The examination is time consuming and may require several sessions to complete. However, additional time provided "up front" will

decrease errors and future costs associated with the mistakes created by data obtained from a less than optimal examination.

Wheelchairs are not just mobility devices but are also *seating support devices*. If inappropriate seating supports are provided, the end user (i.e., the patient) may be unable to propel a manual wheelchair, operate a power wheelchair, or achieve effective positioning at a table for meals. All relevant aspects of a person's lifestyle should be considered to ensure safety and optimal function.

The entire team contributes to the wheelchair prescription decision making. It is important that all those concerned with the person's present and future function be a part of this team. The team may include the wheelchair user, therapists, family members, caregivers, nurses, physicians, educators, vocational counselors, and a qualified rehabilitation technology supplier. To ensure that the most suitable device is obtained, the team must have a clear idea of who will be using it, what functional level is expected, and where the chair will be used. Team members contribute to the examination reports and letter of medical necessity, which must be prepared to secure funding. Once the chair is supplied, the appropriate team members are responsible for adjusting and fitting the final device, as well as teaching the patient and any caregivers how to use and maintain the unit to ensure optimal long-term performance.

A prescriptive wheelchair is a combination of a postural support system and a mobility base that are joined to create a dynamic seated environment (Fig. 32.1). The *postural support system* is made up of the surfaces that contact the user's body directly. This includes the seat, back, and foot supports, as well as any additional components needed to maintain postural alignment. Maintenance of postural alignment may require such additions as a head support; lateral supports for the trunk, hips, and knees; medial support for the knees; and upper extremity (UE) support surfaces, as well as straps (e.g., anterior chest or pelvis) needed to keep the user interfaced with the support surfaces. The *mobility base* consists of the tubular frame, armrests, foot supports, and wheels. Once the decisions are made about the type of support system needed, the team must then decide what type of mobility base best suits the user's functional level and environmental needs. Clear information will be needed to ensure that the postural support system and the mobility base interface properly. For users who utilize more than one mobility base (e.g., power and manual), the most cost-effective approach is to have one support system interface with all the mobility bases. This is not always practical, and sometimes it is best to have the full-support system on the chair used most frequently, and forgo optimal postural support in the backup system used to facilitate transport for short trips.

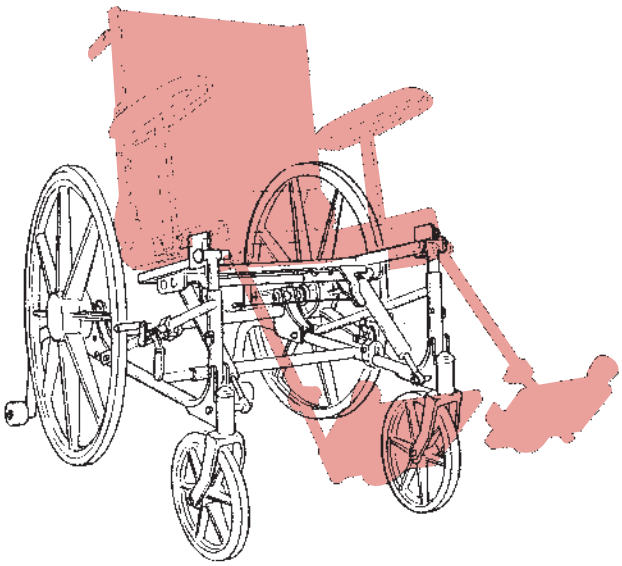

Figure 32.1 A prescriptive wheelchair consists of the postural support system and a mobility base.

Creating a dynamic seating system involves several important steps:

- Gathering background information, including diagnosis, prognosis, functional skills, anticipated goals, and expected outcomes
- Performing a comprehensive examination
- Conducting seating simulations (testing linear and angular dimensions determined from the mat examination in a seating device with the ability to add postural supports to assist in determining optimal seating supports) and equipment trials (testing manual wheelchairs, power wheelchairs, and/or seating supports and cushions before ordering equipment)
- Developing a POC that includes appropriate recommendations and product choices

As noted, the overall desired outcome is to create a dynamic seating system that provides a comfortable base from which the user can attain maximum function. Before the examination, team member expectations should be discussed. A great deal can be learned at this point about what the various team members hope the system will be able to do for the patient. It is extremely important that all issues are identified and openly discussed before the process is begun. Patients, family members, or caregivers may assume that the wheelchair and seating system can achieve unrealistic goals (e.g., normalize posture, provide total pain relief, allow independent transfers). When these unlikely goals are not met, these individuals are often so disappointed that they cannot see the other benefits of the system. Early, open discussion is critical to the decision making process.

EXAMINATION

History Taking

Background information is an essential part of the examination process. During the history taking, one can determine what seating and mobility options have been successful in the past, as well as those that have been unsatisfactory; initial goals and concerns related to the new equipment can also be identified. All areas (patient, environmental, and diagnosis related) that require compatibility or interface with the mobility and seating support system should be discussed. For instance, if someone uses a van for transportation, door opening size and seat setup should be discussed. Moving from one style of chair to another might prevent easily getting through the van door if the individual is sitting taller in the new chair or experience difficulty turning the chair once inside the van owing to increased length of the new wheelchair.

Of considerable importance is knowledge of how positioning of one body part affects another. Impairments of a single joint or body segment can directly affect sitting position and alignment. For example, if there is inadequate hip flexion, what happens to the body when in a seated position? Is there any chance that limited range of motion (ROM) will change over time? Can adjustability be built into the seating system to accommodate changes? Should other positioning programs be instituted in addition to seating to assist with improving ROM?

Information about past and future surgeries should be gathered to have a better understanding of current seating needs as well as to gain insight into future requirements. For example, a person who has undergone a spinal fusion may have a pelvic obliquity that cannot be corrected and requires accommodation in the seating system. A person who has had hip surgery (e.g., femoral osteotomy, total hip replacement) may have a leg length difference and the seat cushion needs to accommodate the difference in leg lengths. A person with hip pain may require a seating design to accommodate ROM limitations that may be the cause of the pain. After completing the mat assessment but before completing the seating assessment, it may be necessary to consult with the physician regarding tone management, pain management, or other surgical intervention that may be necessary. A person with multiple sclerosis (MS) with increased lower extremity tone may have significant knee ROM limitations that need to be addressed before seating in a wheelchair. A baclofen pump may be necessary to control tone and assist with increasing ROM before completing the assessment for the seating system. A person with cerebral palsy (CP) may have significant hip ROM limitations that require surgical intervention to improve sitting posture.

Overview: Tests and Measures

Strength and Endurance

Gross and fine motor skills are examined to determine the amount of support a person needs for seating. Strength, endurance, and their impact on function should be addressed within the context of the person's day. A person might function well for 1 hour in the morning and need minimal support during that time but may need more support in the afternoon owing to poor endurance and fatigue. This may make a difference in the ability to perform functional activities throughout the day.

Sensation and Skin Integrity

Individuals who use a wheelchair for locomotion have an increased chance of developing pressure sores from prolonged sitting. The ability to change position or to request positioning changes (if unable to perform independently) based either on a timed interval or due to discomfort is important in the prevention of pressure sores. Individuals with decreased sensation (e.g., spinal cord injury [SCI]) are unable to perceive discomfort from prolonged positioning. In such situations, positioning changes should occur at timed intervals and be incorporated into the daily schedule.

Location and size of old wounds should be noted to ensure appropriate pressure-relieving strategies are provided. Location of new wounds must be investigated to determine the cause (e.g., faulty bed or wheelchair positioning). The proposed seat cushion and back support should be examined and evaluated to determine their potential for promoting healing of any current pressure sores and preventing development of new pressure sores. Pressure mapping is accomplished using a special piece of material with sensors combined with computer software that shows high- and low-pressure areas when sitting on a specific cushion. This map can be used to assist in determining an appropriate seat cushion and is beneficial as a teaching tool when providing instruction in using a tilt-in-space feature, a recline feature, and any adjustments to the seat cushion. When using the tilt feature and recline feature, the pressure on the map changes and areas of high pressure will diminish, assisting individuals in understanding the need for changing their position. Various cushions can also be tested to assist the examiner and individual in choosing the most appropriate seat cushion based on pressure distribution.[1-3]

Vision and Hearing

Vision affects ability to drive a power wheelchair and to maneuver a manual wheelchair. Visual impairments may be more apparent outdoors rather than indoors. It is important to determine how visual problems affect mobility and to determine if the person can learn compensatory techniques to be independent and safe.

Hearing deficits can also pose safety concerns. If driving outdoors, a person with a hearing impairment may not hear a car horn or someone calling to them to stop. Various headrests may diminish the ability to hear well. Determining optimal equipment to compensate for hearing loss is important for safety and independence.

Health Status

Poor positioning of the pelvis and trunk can increase the risk of developing urinary tract and respiratory infections. Complete bladder emptying is more difficult if a person sits in a posterior pelvic tilt. Other risk factors for urinary tract infections include poor technique during intermittent catheterization or changing of indwelling catheter. If a person sits with a kyphotic or scoliotic spine, breathing is compromised and clearing lungs of secretions is more difficult, which increases the risk for respiratory infections.[4,5]

Nutrition has a direct impact on overall health. Poor nutrition can increase healing time, increase risk of developing pressure sores and infections, and create weight management problems. Impaired swallowing will also affect nutrition. Weight gain and loss either from food intake, gastrointestinal tube placement, or medications should be discussed to make informed decisions about seat width of the wheelchair.

Functional Abilities

Toileting

Bathroom issues should be addressed to determine if the person uses a toilet, urinal, catheter, or protective undergarments. If using the toilet, the ability to transfer from the wheelchair to and from the toilet will be important. The effect of the seat height on transfers and the ability to swing away the footrests to approach the toilet must be considered. If using a urinal, the seat style needs to be discussed to prevent accidental tipping of the urinal. If using a catheter and the person empties the urine collection bag into the toilet, access to the toilet needs to be discussed. If the person frequently experiences urinary accidents, a waterproof cover on the seat cushion may be considered.

Bathing and Washing

Accessing the bathroom sink, bathtub, and shower is more difficult when sitting in a wheelchair. Many bathrooms are small and it can be difficult or impossible to maneuver in this space. Concerns include seat height for transfers, style of footrests for transfers, and access to sink for washing. Bathroom modifications may be needed for safety and improved access (see Chapter 9, Examination of the Environment).

Dressing

Some individuals find it easier to don clothing when in their wheelchair. Footrest and armrest style and durability need to be considered to ensure the system will accommodate the extra weight placed on both these components during dressing activities. Use of tilt-in-space seating or a reclining back system may benefit the person who dresses in the wheelchair.

Eating

The seat and armrest height of the wheelchair may preclude positioning the wheelchair at some tables or desks. The style of table or desk may also interfere with access (e.g., number and arrangement of legs, height of working surface, presence of drawers). If a person needs assistance during mealtime, caregivers need to have ease of access. Positioning of head/neck and trunk alignment is important while eating to ensure a safe environment, optimize swallowing, and minimize choking potential.[6] Power seat elevators can increase access to tables of varying heights.

Communication

Some patients require alternative forms of communication. Consultation with the speech-language pathologist is important to determine the type of communication device being used and the method of mounting the device to the wheelchair. This may include a tray to support the device or a separate mounting system attached to the wheelchair. Switches may be used to operate the device; mounting of switches will need to be determined to ensure optimal access and ease of use.

Transfers

The type of transfer used is another important consideration when prescribing a wheelchair. The patient's transfer performance (e.g., complete independence, supervision, moderate assistance) will affect selection of wheelchair features. Armrest style, footrest style, trunk support style, and seat height can all influence safety, as well as the type and amount of assistance required.

Ambulation

Although a person requires a wheelchair for long-distance travel, he or she still may be able to ambulate short distances. The person needs to be able to stand up from the wheelchair and access the assistive device. The seat height, footrest style, and armrest style are important to ensure safe standing and seating to and from the wheelchair. An assistive device (e.g., cane, crutches, walker) may need to be attached to the wheelchair via a special holder and the optimal method of access determined.

Wheelchair Mobility—Manual and Power

Wheel position is important for independent manual mobility. If the feet are used to propel the chair, seat height is important to ensure that the feet reach the floor and to prevent the person from sliding down in the wheelchair. Hand control position is important for independent power mobility. If unable to use a standard hand control, other drive controls are available; strategic

placement of alternative controls will assist in providing independent power mobility. If the person is dependent and caregivers are moving the wheelchair, the style of push handles and wheel locks is important.

Environmental Issues and Transportation

Many issues affect a person's ability to access his or her environment. Stairs interfere with access, as do narrow doorways. Small elevators will affect a person's ability to move safely in and out of the elevator, as well as access the push buttons to reach various floors. Transportation also affects access.[7] Wheelchairs may need to be folded for car transport. Van transportation can be difficult as well. The doorway opening and tie-down system inside the van can affect safety. Although it is safer to have a wheelchair facing forward, some vans are equipped with tie-down systems for the wheelchair to be oriented sideward. This can make it more difficult for a person to maintain a safe sitting position. Wheelchair frames and wheels are not designed to withstand the forces generated in a crash when a chair is oriented sideward. There is inadequate support to the individual when oriented sideways and there is a greater tendency to fall/tip sideways causing injury. The person may transfer into a regular seat once inside the van; safe storage of the wheelchair is then a consideration. Steep or stone driveways, dirt roads, potholes, and lack of beveled curbs will all adversely affect a person's ability to safely access the community.

Cognitive and Behavioral Issues

Cognitive and behavioral issues can affect the type of equipment provided to a person with disabilities. The person may be extremely rough on equipment and/or may use equipment as a weapon to hurt others. When providing various types of equipment, safety should always be considered first. Large rehabilitation centers often have programs in place to address these types of issues.

SEATING PRINCIPLES

Seating principles provide important general guidelines for patient positioning in a seating device. The overarching intent of the principles is to maximize function by promoting comfort, stability, and optimal interaction with the environment.

Principle 1: Stabilize Proximally to Promote Improved Distal Mobility and Function

This principle is a basic underlying strategy and commonly used by therapists treating individuals with neuromuscular involvement. Stabilizing proximally provides a foundation for distal movement. When eating, stabilizing an elbow on a table and then stabilizing a wrist may promote independence during meals. To improve trunk posture, stabilizing the pelvis is important. In sitting, pelvic stability should be addressed first because it is the foundation for the rest of the body. When assessing how much or where stability is needed, start with the pelvis and move down, then up, and reassess at each level to determine where active control and skill development is needed, as well as the amount of support needed to maintain good posture.

Principle 2: Achieve and Maintain Pelvic Alignment

The pelvis should be positioned in a neutral to slight anterior tilt and optimally be level (not oblique or rotated). This position allows for maintaining the normal lumbar curve, provides weight-bearing on the ischial tuberosities, and promotes active trunk ROM and co-contraction of trunk muscles. Weight-bearing on the ischial tuberosities also promotes symmetry and provides a more stable upright position (rather than sitting on the sacrum or coccyx). Promoting flexion at the hips and extension in the low back can be effective in decreasing abnormal tonal patterns. A level pelvis allows for equal weight-bearing and even pressure distribution and improves alignment in body areas above and below the pelvis. To achieve good pelvic alignment, ROM limitations must be accommodated, as well as all linear dimensions (e.g., thigh and calf length, trunk and hip width). To maintain this alignment, pelvic positioning devices may need to be considered. A pelvic positioning device is a flexible strap or rigid bar that assists in controlling pelvic movement. A flexible strap should lie just below the anterior superior iliac spines (ASISs), be very snug, and be at a 45° to 90° angle to the seat surface. This angle of pull is dependent on how the person moves the pelvis. Key considerations for the pelvic flexible strap positioning device include placement or angle, size, method of cinching, direction of pull, and location of buckle. A rigid device should lie just below the ASISs (also called a sub-ASIS bar) with the bar attached to metal brackets that mount to the seat or frame of the chair. This device prevents pelvic movement and may be beneficial for an individual with excessive pelvic shifting.[8] Another method to maintain pelvic position is to use knee blocks. The knee blocks provide anterior support to the knees and prevent the individual from sliding forward in the wheelchair.

Principle 3: Facilitate Optimal Postural Alignment in all Body Segments, Accommodating for Impairments in Range of Motion

Once the pelvis is stabilized, attention is directed toward alignment of other body segments. Good alignment promotes improved balance, stability, comfort, and function; helps prevent deformity from habitual asymmetrical posturing; and prevents skin breakdown from uneven pressure. To achieve optimal alignment, it must be

determined if improved alignment can be achieved passively on a mat table and then in the seated position. If good alignment can be achieved, it must be determined whether the person can maintain alignment using muscular effort or if external supports are required. Time must be allocated to practice motor skills and movements within the context of improved postural alignment, especially if dramatic alignment changes have ensued. For joints and/or body segments that are not amenable to passive alignment, accommodation is needed (e.g., fixed contractures). For example, accommodation would be needed for a person who presents with long-standing hip ROM limitations from prolonged sitting in a *windswept lower extremity (LE) posture* (one hip in abduction and external rotation and the opposite in adduction and internal rotation). Attempts at aligning the LEs would cause pelvic rotation and trunk rotation. The LEs must be positioned in the windswept posture. Alignment of the pelvis takes priority over alignment of other body segments. Providing optimal pelvic and trunk alignment is most important.

Principle 4: Limit Abnormal Movement and Improve Function

Seating equipment can be designed to inhibit abnormal tone, postures, and movements and to improve health, comfort, and function. Abnormal movements should be discouraged or blocked (controlled) based on anticipated goals and expected outcomes. Observation and analysis of abnormal movements will provide clues to what triggers the response. Determining initiating triggers will inform decisions about seating strategies that may contribute to inhibiting unwanted movement. This requires good problem solving skills. Determining the source of the problem may allow decreased use of support blocks.

Principle 5: Provide the Minimum Support Necessary to Achieve Anticipated Goals and Expected Outcomes

The patient is provided the least restrictive supports required to facilitate the acquisition of new skills and foster independence rather than create unnecessary dependence on equipment. This is especially important to the younger person who is growing and changing, as well as the person who has not had the opportunity to improve function owing to poor positioning and excessive equipment use. Supports can be used intermittently throughout the day to provide learning opportunities (acquisition of new skills) over time. Using a minimum of supports can improve cosmetic appearance and self-esteem. Other equipment may need to be used for specific activities or for opportunities to improve strength and skills.

Principle 6: Provide Comfort

Seating equipment should be comfortable. Discomfort leads to increased abnormal tone and movement, postural asymmetry, and fatigue; decreased endurance, attentiveness, and concentration; and finally disuse of equipment. Critical to the provision of equipment is involvement of the user who should participate in the process and be allowed an opportunity to express likes and dislikes of the system. A poorly fitting system only creates more problems for a person who is already making lifestyle changes to accommodate his or her activity limitations.

WHEELCHAIR PRESCRIPTION

The physical therapy data collection for a prescriptive wheelchair includes determining level of function and posture in existing equipment, performing various measures on a mat table, and performing a seating simulation. If significant changes are being made to a seating system, the simulation will provide the patient an opportunity to "test" and provide feedback about the seating recommendations.

It is important to take time at the beginning of the examination process to explain to the patient and caregivers what will be happening, what information will be gathered, and why the information is important. Everyone should be made to feel that his or her input is necessary and valuable. Time should be allocated during data collection for comments or questions from the patient, caregivers, and other team members. Before each stage of the process, the patient should be asked if it is acceptable to proceed. For example, "I would like to put my hands on your pelvis, is that okay?" It is important to move slowly and speak calmly, because quick movements or loud speech may increase anxiety. For some patients, this may increase muscle tone, interfering with data collection. It is important to explain what is being observed or measured so that patients and caregivers can understand information exchanged among team members, and so they can fully comprehend the team's findings and the subsequent recommendations.

Although time consuming, it is absolutely critical that the physical examination be complete and accurate because changes may be difficult to make later. Accurate recording provides a permanent record of why certain decisions were made. During the ordering or manufacturing process, additional decisions concerning modifications may be needed. If accurate measurements are on file, decisions can often be made without recalling the person to the clinic.

Function and Posture in Existing Equipment

Observing the patient in his or her existing wheelchair provides a great deal of information. The patient should be in the best or most commonly assumed position, with supports and straps in place. Questions should include how the patient and/or caregiver perceive the device is working; has it always worked like this, or has its function decreased over time? If it worked well initially, but does not work well now, is this because of patient change

(weight gain or loss, growth, functional gain or loss) or equipment change (broken or missing parts, decreased reliability)? Information can be gathered during this portion of the examination about patient and caregiver attitudes and technology savvy, as well as their physical use of the equipment. Throughout the initial visit, team members should continuously observe the existing equipment, the patient, the caregivers, and their physical and psychosocial interactions.

The team should gather data about the patient's postural alignment at the head, shoulders, trunk, pelvis, and LEs using both visual observation and palpation. Pelvic alignment is examined by palpation along the pelvis crests and on the ASISs. The position of the pelvis (e.g., rotation, posterior or anterior tilt) should be carefully documented.

With the patient's shirt removed or at least lifted to nipple level, trunk posture can be observed directly. A combination of visual observation and palpation will allow determination of alignment (for example, abdominal wrinkles usually mean a rounded spine). In the presence of abnormal alignment, the therapist should determine (1) if alignment can be corrected using gentle pressure; and (2) what factors may be interfering with good postural alignment.

The patient should transfer onto a mat table. Observation of the specific transfer method used and level of assistance required will avoid creating a new system that interferes with this function.

Mat Table Measures

Supine Position

The supine examination provides an opportunity to learn about the person's strength and range of available movement, as well as how movement of one body part affects tone, comfort, position, control, and performance in other body segments. The goal is to preserve spinal alignment whenever possible, maintaining the natural lumbar curve whenever it can be produced. The person should be examined in a gravity-minimized position (supine [preferred] or side-lying) to determine if ROM limitations exist. This position also allows preliminary linear measurements, including thigh length, calf length, trunk width, and hip width.

The supine examination usually requires more than one examiner. The patient should be positioned supine on a firm surface (a mat table or carpeted floor works well; a bed may not be firm enough). The range of available pelvic and hip movements as they relate to spinal and pelvic alignment should be determined. The purpose is to determine the maximum ROM available before spinal and pelvic alignment is disturbed.

Range of Motion

Hip flexion, knee extension with hips flexed, and ankle dorsiflexion with knees flexed are the most important LE ROM values to obtain.[9,10] A complete ROM examination of both UEs and LEs, head/neck, trunk, and pelvis is needed since limitations in these areas will affect a person's ability to propel the wheelchair, position the head for safe eating, and sit with good upright alignment.

Hip flexion is measured with the person in the supine position (Fig. 32.2). Knees should be flexed to decrease the influence of the hamstring muscles. The pelvis should be in a neutral to slight anterior tilt position. Both hips should be flexed slowly keeping one hand flat under the lumbar/sacral area of the person's spine until posterior movement of the pelvis (out of a slight anterior tilt) is felt. The end of hip flexion ROM for seating is defined as the angle of hip flexion just before the pelvis moves posteriorly.

Goniometric values for hip abduction, adduction, and internal and external rotation should also be obtained. If the pelvis is oblique or rotated, it may be necessary to allow the LEs to assume the windswept position, or be abducted before measuring hip flexion. The goal is to achieve neutral pelvis alignment before measuring and to ensure that the pelvis does not shift into a posterior pelvic tilt, obliquity, or rotated position during the examination.

Knee extension is measured with the person in the supine position with both hips flexed to the optimal angle determined (above) and the knees initially flexed (Fig. 32.3). While maintaining the hip angle and keeping one hand under the lumbar/sacral area of the spine, the knees are extended slowly toward the ceiling until

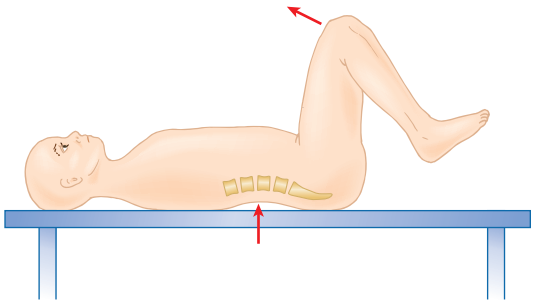

Figure 32.2 The examiner must monitor the lumbar curve as the hips are flexed.

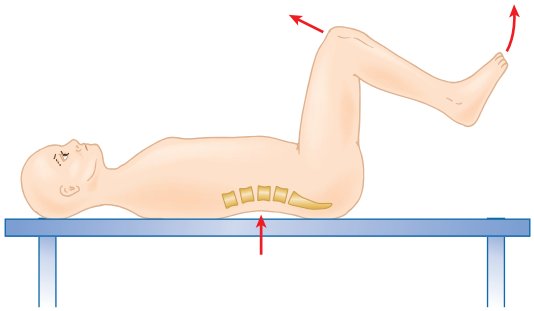

Figure 32.3 The examiner must monitor the lumbar curve and hamstring tightness behind the knees as the knees are extended.

the pelvis begins to move or excessive tightness/tension is felt in the hamstrings. It is especially important to maintain the appropriate hip position while extending the knees since the hamstring muscles are a two-joint muscle and the amount of range achieved is dependent on the position of the hips.[11] When the hips are extended, knee extension range tends to be increased and when the hips are flexed, knee extension range tends to be decreased due to hamstring muscle tightness.

Ankle dorsiflexion ROM is also measured in the supine position. Hips and knees should be positioned in available hip flexion and knee extension alignment (as determined above). The ankle should be maintained in a neutral inversion/eversion position and an attempt made to achieve neutral dorsiflexion/plantarflexion position at the ankle. The gastrocnemius muscle is a two-joint muscle and ROM at the ankle is affected by the position at the knee. If the knee is extended and muscle tightness is present, decreased dorsiflexion is noted. With the knee flexed, increased dorsiflexion is achieved. Although it is important to measure ROM with knee extended (bed positioning, standing, and ambulation), this is an assessment for seating and muscle tightness limitations must be addressed in a simulated position on the mat to better understand posture achieved in sitting.

Range of motion of the spine, head/neck, and UEs should be examined to determine the impact of limitations on posture. If significant scoliosis exists, decisions will need to be made regarding method to support the scoliosis and obtain optimal trunk position because this will affect pelvic position. Contractures in the neck region affect head position. Attempts to align the head with a lateral flexion contracture may cause the trunk to shift to the side. Once the trunk shifts, the pelvis and LE positions will be affected. The UE position becomes critical when determining ability to propel the wheelchair or if specific UE positioning (e.g., support surface) is required to maintain current ROM.

Other measurements needed when the person is supine include thigh length, calf length, and pelvic width. These will be starting point measurements for testing in a seated position.

Thigh length measures are taken in supine on a mat table or other firm surface with the hips and knees in the optimal position determined above. The measure is taken from the mat surface to just before the popliteal fossa (Fig. 32.4). Accuracy is important in measuring thigh length. If the measurement is too long, it will be difficult to get the hips fully back on the seat and properly supported in the wheelchair; this will create problems over time. If the person has a windswept or abducted lower extremity posture, measure on a straight line to the shortest side. If needed, use a clipboard or other firm surface to act like the seat surface for more accurate measuring. Leg (calf) length should be taken when the person is supine on a mat table. The hip, knee, and ankle should be positioned as previously determined. Measure from the popliteal fossa to the bottom of the heel to determine leg length. For increased accuracy, remeasure in the sitting position with appropriate footwear. Preliminary measurement for pelvic width should be taken in the supine position. This is the widest portion of the hips from one greater trochanter to the other. Final measurement needs to be completed in the sitting position owing to soft tissue spread.

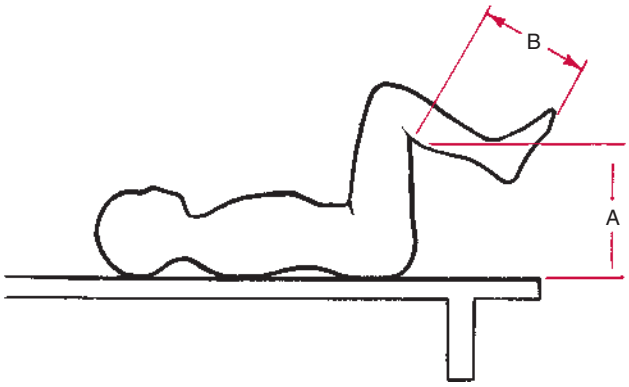

Figure 32.4 **(A)** In the supine position with the hips and knees flexed the examiner can measure the undersurface of the thigh from the popliteal fossa to a firm support surface **(B)**. Note that this position can also be used to measure leg length from the popliteal fossa to the heel.

Seat to Back Support Angle

Measuring hip flexion will assist in determining the trunk to thigh angle and ultimately the seat to back support angle[12,13] (Fig. 32.5). If hip flexion is to 75°, the trunk to thigh angle is 105°. In addition to the trunk to thigh angle, other data needed to determine the final seat to back support angle include the center of mass of head and trunk over the sitting base, body contours, tone, movement patterns, and comfort. The combined information guides determination of the final seat to back support angle. For example, if hip flexion is to 95°, the trunk to thigh angle is 85° (Fig. 32.6A). However, this position may not provide good stability, resulting

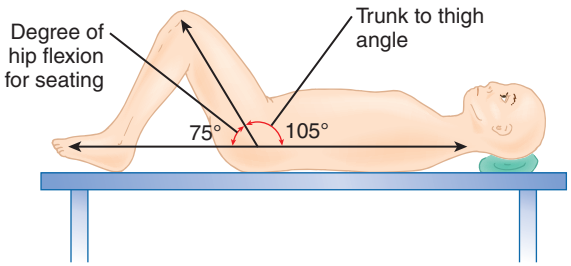

Figure 32.5 The amount of hip flexion determines the trunk to thigh angle. If the degree of hip flexion for seating is 75°, the trunk to thigh angle is 105°.

in trunk flexion and making it more difficult to maintain an upright sitting posture (Fig. 32.6B). In this example, the patient may need a final seat to back support angle of 100° to address center of mass, body contour, and comfort issues (Fig. 32.6C). Many times the trunk to thigh angle will be the seat to back support angle, but tone, movement, and comfort should not be overlooked when finalizing this angle.

Seat to Leg Support Angle

Knee extension ROM assists in determining thigh to leg angle (Fig. 32.7). The final seat to leg support angle is determined by considering the thigh to leg angle, abnormal tone, movement patterns, and comfort[12,13] (Fig. 32.8). Hamstring muscle tightness must be accommodated to prevent the pelvis from shifting into a posterior pelvic tilt. Many people will require a seat to leg support angle of 90° or less to accommodate hamstring tightness or fixed knee flexion contractures to maintain a neutral pelvic tilt position.

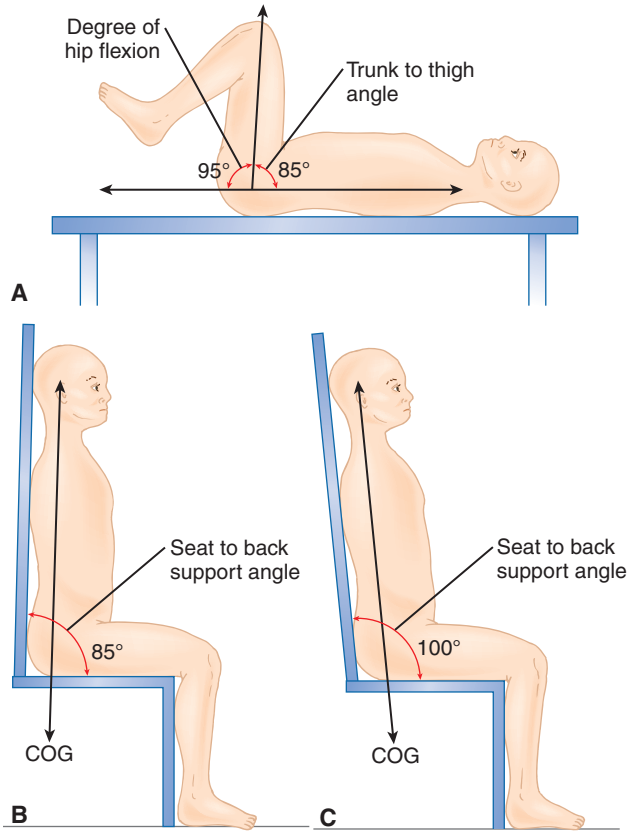

Figure 32.6 **(A)** If the degree of hip flexion for seating is to 95°, the trunk to thigh angle is 85°. **(B)** Seat to back support angle does not always correlate with trunk to thigh angle. In this example, if the seat to back support angle is set at 85°, tolerance to sitting in this position may be poor and cause the person to fall forward or constantly be working to hold himself or herself upright. Body shape, center of mass, and sitting tolerance must be addressed. **(C)** Opening the seat to back support angle to 100° better accommodates body shape and center of mass and tolerance to sitting upright improves.

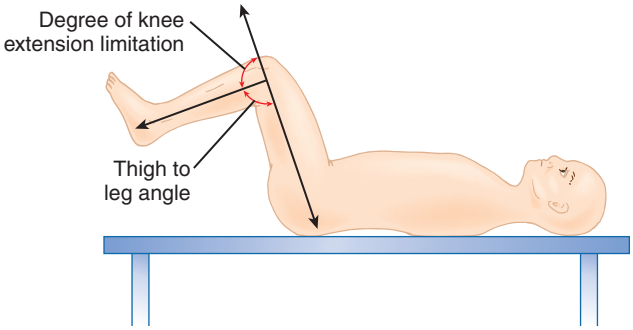

Figure 32.7 Thigh to leg angle is determined during mat examination and is based on the degree of knee extension limitation when the hip is positioned in available ROM.

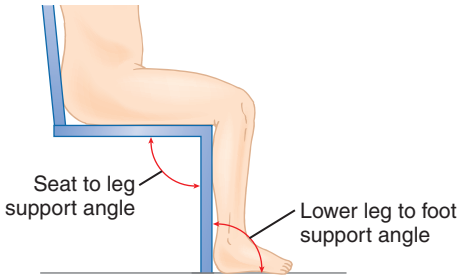

Figure 32.8 Seat to leg support angle and lower leg to foot support angle are final seating angles determined during seating simulation accommodating range of motion, tone, and comfort at the knees and ankles.

Lower Leg Support to Foot Support Angle

Ankle dorsiflexion ROM assists in determining lower leg to foot support angle (Fig. 32.9). The final lower leg to foot support angle is determined by considering ankle ROM and deformities and abnormal tone and movement patterns[12,13] (see Fig 32.8). The use of ankle-foot orthoses (AFOs) will also affect the final lower leg support to foot support angle.

Seated Examination

Seated examination using a simulator allows testing of hypotheses generated during the supine examination and provides an opportunity to determine patient tolerance to the recommended angles and to check if the thigh length is accurate.[14] The ideal simulator chair has an adjustable seat to back support angle, seat to leg support angle, and lower leg to foot support angle and the ability to adjust seat depth, calf length, and trunk length. Other features of an optimal simulator include the ability to add lateral trunk supports, lateral knee supports, medial knee supports, arm supports, head

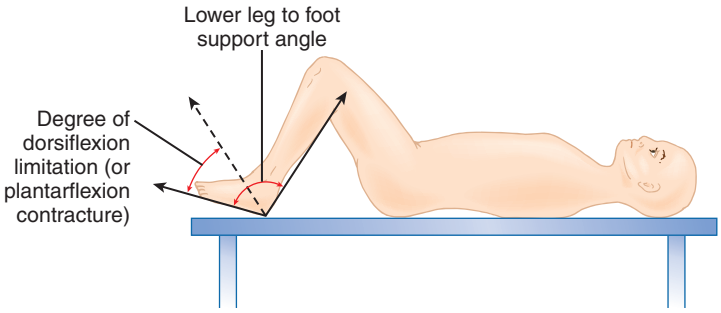

Figure 32.9 Lower leg to foot support angle is determined during mat examination and is based on ankle range of motion.

supports, and other support surfaces to determine optimal positioning. An adjustable chair provides the evaluator with the ability to use the chair for a variety of people to determine optimal sitting posture. The ability to tilt the wheelchair assists in assessing the effect of gravity on the patient.[15] A planar seating simulation chair is available commercially specifically for assisting therapists in determining positioning needs (Fig. 32.10). If unable to obtain this specific chair, a tilt-in-space and recliner wheelchair can be used for testing, but care should be taken to obtain the necessary seat to back support angle, thigh length, and wheelchair width if using this type of system for seating simulation.

Seating simulation provides the opportunity to observe tone and movement, alignment, and function. Supports may be added and subtracted to assist in determining if a person tolerates more or less support. Changing the amount of tilt influences the impact of gravity on a person's ability to sit upright. Finally, asking the person how he or she feels and working together assists in improving posture, comfort, and function.

Some aspects of seating simulation can also be performed while seated on a mat table. The examiner's hands are used to determine amount of support and location of supports. Trunk strength and balance can be assessed while sitting on the mat table, but if the person has significant physical involvement, it is very difficult to accurately determine seating supports needed in this position (Fig. 32.11).

Using a simulation chair in the supported sitting position, all angular dimensions should be finalized, including seat to back, seat to leg, and lower leg to foot support angles. The linear dimensions need to be finalized as well (Fig. 32.12.) The examiner should remeasure the sitting depth from behind the buttocks to the popliteal fossa (Fig. 32.12A). This may differ from the supine measurement, and careful examination should reveal whether the difference is secondary to correctable postural difficulties or simply variable flesh distribution in sitting versus supine. Leg measurement (Fig. 32.12B), from the popliteal fossa to the heel with customary footwear in place, will be needed to determine footrest length on the wheelchair. The sitting knee flexion angle

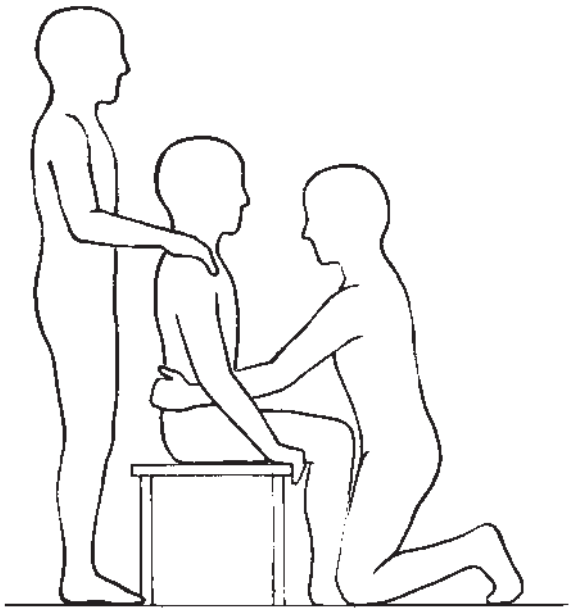

Figure 32.11 The sitting position can be used to determine the amount and location of required support.

should also be documented (Fig. 32.12C). Measurement of back height should be taken from the sitting surface to the posterior superior iliac crests (Fig. 32.12D), lower scapula (Fig. 32.12E), top of the shoulder (Fig. 32.12F), occiput (Fig. 32.12G), and crown of the head (Fig. 32.12H). These measurements will provide a detailed record should decisions regarding wheelchair back height be needed once the examination is completed. Measurement of the *hanging elbow* (Fig. 32.12I) is needed to determine proper armrest height. With the person in a corrected sitting position, the UE is positioned at the side of the body with 90° of elbow flexion and the shoulder in a neutral position. A measurement is taken from the bottom of the elbow or forearm to the sitting surface.

During the seated examination, measurements should be taken of width (Fig. 32.12J) and depth (Fig. 32.12K) of the trunk and width (Fig. 32.12L) of the hips for decisions regarding support accessories and width of the seating system and the mobility base. If the patient is seated asymmetrically, it will be necessary to measure across the widest span of the patient's seated body (e.g., outside hip on the adducted side to outside knee of the abducted leg). A measurement of foot length (Fig. 32.12M) should also be taken. To ensure accurate recommendations it is important to consider orthoses, clothing, and recent weight loss or gain, as well as the patient's potential for growth, when recording these measurements. If it takes more than a few months to secure funding it may be necessary to remeasure the client before placing the order.

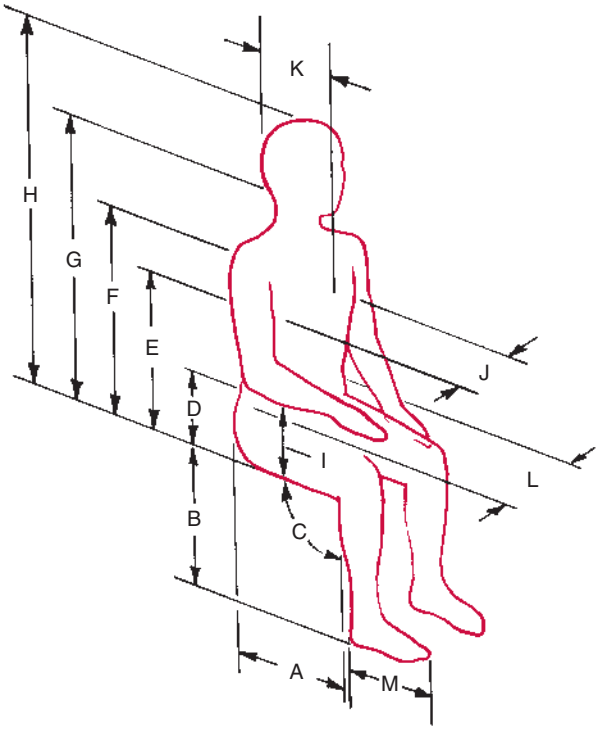

Figure 32.12 The following measurements are added to those taken in the supine position. **(A)** Sitting depth from behind the buttocks to popliteal fossa (right and left side); **(B)** leg measured from popliteal fossa to heel (right and left side); **(C)** knee flexion angle; **(D)** back height from sitting surface to posterior superior iliac crest, **(E)** from sitting surface to lower scapula, **(F)** from sitting surface to top of shoulder, **(G)** from sitting surface to occiput, and **(H)** from sitting surface to crown of head; **(I)** hanging elbow from sitting surface to the elbow or forearm; **(J)** width and **(K)** depth of trunk; **(L)** width of hips; and **(M)** measurement of foot length.

Wheelchair Testing

Once optimal positioning is determined, discussion can then follow regarding functional needs of the wheelchair user that need to be addressed, such as eating, communication, computer access, switch access, manual and/or power mobility, or transfers.

Time should be allocated for testing trial equipment in the clinic setting. This provides an opportunity for the patient to determine personal tolerance to the recommended changes. If possible, testing of trial equipment should be done in the patient's home environment and community to allow the patient to practice using the equipment and ensure that the equipment meets the expected outcomes.

INTERVENTION

The data gathered during the physical examination, seating simulation, and wheelchair testing are now analyzed to determine equipment parameters based on specific client-centered goals. Discussion ensues to determine if the client is functioning at highest potential or if additional support would help to improve function of distal body parts.[16,17] Each piece of equipment provided needs to be justified; for example, justification for lateral knee supports might be the need to maintain neutral alignment of the LEs or the need to prevent excessive active hip abduction. For each component required for postural support, mounting location, method of stabilization, strength, and durability must be finalized. For example, lateral trunk supports might be needed for postural support but will interfere with a sliding board transfer. Swing-away hardware will move the support out of the way, but the specific hardware to use is dependent on the ability of the client or caregiver to access the hardware and shift it out of the way. Testing of these details is important to ensure that maximal independence is achieved with the new equipment.

Problem Solving Model

A problem solving approach can guide selection of needed seating features by using a sequence of (1) identification of equipment-related clinical problems; (2) establishing objectives for equipment intervention; (3) making equipment property recommendations; and (4) identification of equipment specifications.[18,19] Box 32.1 provides an example of this strategy.

Box 32.1 Example of Problem Solving Model Grid

Clinical Problems	Objectives for Equipment Intervention	Equipment Property Recommendations	Product Specifications
Diagnosis of cerebral palsy (CP); fluctuating muscle tone with wide excursion, ataxic tremors on active movement, poor grading of movement, and poor ability to isolate muscle groups	Increase stability through pelvis, trunk, and lower extremities (LEs) to improve upper extremity (UE) function	Molded surfaces that provide maximal contact and control to increase body stability Stabilizing bar for left UE to improve function in right UE	Determine specific molding system Determine final location for stabilizing bar and type of bar to use for maximal durability
Range of motion (ROM) limitations: hip flexion: 0–80°; knee extension with hip flex: 0–100°, ankle dorsiflexion with knee flexed: 0–0° (no motion), able to achieve good pelvic position, mild trunk scoliosis, good UE ROM	Accommodate ROM limitations with seat to back support angle of 100°, seat to lower leg support angle of 80°, and lower leg to foot support angle of 90° to assist in maintaining pelvis in slight anterior tilt, level and not rotated and maintain symmetrical trunk alignment	Adjustable-angle back hardware to accommodate hip ROM limitation Swing-away footrest system with angle-adjustable footplates to accommodate knee and ankle ROM Foot stabilizers to assist with maintaining stability and posture	Adjustable-angle backposts Adjustable-angle footplates Shoe holders with hook-and-loop or D-ring closure for independence
Poor posture in current manual wheelchair, sits in posterior pelvic tilt, spine is kyphotic with mild scoliosis	Achieve and maintain slight anterior pelvic tilt, level and not rotated Accommodate for mild scoliosis and maintain symmetrical trunk alignment Increase trunk elongation	Medial knee support, pelvic positioning strap to stabilize pelvis, molded seat and back system for optimal control, support, and postural correction	Medial knee support separate from molded seat for transfers Push-button pelvic positioning strap 1.5 in (3.8 cm) wide with flat mount (no grommets) Molded seat and back system
Propels manual wheelchair slowly for short distances only with wide excursion of movement and increased energy expenditure	Increase independence in mobility by providing power mobility. Decrease energy expenditure and decrease wide excursion of movement	Power wheelchair system with parameters that can be adjusted for ataxic movement, decreased movement control, speed, and acceleration Power base that provides increased foot/caster clearance	Test various power wheelchairs to determine optimal base for driving and positioning Determine if able to achieve good posture throughout the day with one set position or if needs a tilt-in-space seating system
Requires supervision for transfers in and out of wheelchair	Improve independence in ability to transfer in and out of wheelchair	Accommodate leg length and ROM at knee and ankle Keep seat as low to floor as possible but maintain caster clearance Swing-away footrest system Flat seat surface for ease in getting on and off seat Flip-down medial knee support Adjustable-height armrests	Swing-away footrests with angle-adjustable footplates ensuring access and independence with swing-away feature Flip-down medial knee support ensuring ability to move support out of way independently Adjustable-height armrests

Box 32.1 Example of Problem Solving Model Grid—cont'd

Clinical Problems	Objectives for Equipment Intervention	Equipment Property Recommendations	Product Specifications
Uses keyboard for computer independence	Maintain independence in computer keyboard access	Swing-away joystick mount to ensure access to tables	Swing-away joystick mount ensuring ability to independently move it out of the way.
Uses urinal for independence in bathroom	Maintain independence in bathroom	Flip-down medial knee support	Flip-down medial knee support ensuring independence

It can assist in guiding the thought process and ensuring that all issues are addressed. This allows thoroughness and improves the ability to articulate reasons for choosing specific wheelchair components. The process is patient centered rather than product centered and will assist in obtaining optimal equipment.

Clinical Problems, Objectives, Property Recommendations, and Product Specifications

Clinical Problems

Information needed in this area includes data obtained from history, preliminary examination, supine and seated examinations, and determination of functional abilities to preserve and functional abilities to attain.

Objectives

Goals should be set related to positioning and alignment, motor control, health, function, environmental issues, and social/emotion issues. Goals can be general (e.g., improve skin integrity) but will need to become more specific (e.g., reduce pressure under left ischial tuberosity to prevent pressure sores in this area) to determine equipment properties.

Property Recommendations

Consideration is given to the different surfaces and features of the equipment. *Properties* are the specific details of the final product. The surface shape and flexibility, dimensions, placement, and attachment features should be included in this section. Careful consideration of properties will ensure a final product that promotes optimal independence.

Product Specifications

The list of property recommendations will be reviewed to determine the final product. If no commercial option is available with the needed properties, determination of a method to customize is needed. The supplier should be knowledgeable and be able to assist the therapist in obtaining the most appropriate equipment to address all needs.

The benefit of using this decision making process is to help keep the process client centered rather than product driven. It promotes problem solving and improves accuracy when choosing final product components.

When using this process, the person's diagnosis assists in determining specific properties of final equipment, as well as the priority of the properties. If working with someone with an SCI with previous pressure sore problems on the buttocks, the properties of the seat cushion become important. If working with someone with progressive MS, the ability to modify the equipment over time will be important. When considering the patient's medical diagnosis, it is important to determine if the condition is stable and if not, the type of changes that are expected. If the medical condition is stable but the person is newly injured (e.g., SCI), changes to equipment may be needed over time as the person adjusts to using a wheelchair for primary mobility purposes. If working with someone who is stable and has always done things one way, it is important to provide him or her with other options and determine if poor habits can be changed.

A well-planned seating system may be able to normalize tone, decrease pathological reflex activity, improve postural symmetry, enhance ROM, maintain and/or improve skin condition, increase comfort and sitting tolerance, decrease fatigue, and improve function of the autonomic nervous system. In addition, the base of the seating system can allow for changes in orientation in space (recline and tilt). A properly prescribed mobility base will improve access to the physical environment (both manual and power-activated), whether alone or with a caregiver. It should be effective for accomplishing all home, school, work, and recreational activities and, where necessary, assist the caregiver with patient management.

When setting priorities, it is important that clinical team members do not overload the patient with their professional opinions. Clinical teams may not be fully aware of the barriers facing the individual using a wheelchair in his or her physical environment. Clinicians may observe a patient ambulating in the

clinic and feel that with added practice he or she could ambulate full time. This clinician may consider recommending crutches and a simple manual wheelchair. In the patient's real environment, however, long distances may need to be traversed to independently shop, attend community activities, and function at school or work. Walking to these activities would require extraordinary effort, and propelling a standard manual wheelchair may not offer much additional assistance. A motorized scooter or wheelchair may be more effective as a supplement for environmental mobility.

Postural Support System

The components of the system that will directly affect comfort and maintenance of posture are the seat surface, back surface, pelvic positioner, UE surface, and LE surfaces. These areas should be addressed together as the postural support system. Increased contact between the user and the support surfaces increases comfort and control and decreases pressure over bony prominences.[20-23] The continuum of available support surfaces runs from firm *planar surfaces* (wood, firm foam) (Fig. 32.13), through *deformable surfaces* (knit-covered foam) (Figs. 32.14 and 32.15), and *contoured surfaces* (Fig. 32.16), up to and including *custom-molded surfaces* (Fig. 32.17).

Angular relationships between the surfaces at the hip and knee joints (thigh and back surfaces, thigh and leg surfaces) previously determined during seating simulation must be included in final setup of postural support surfaces. This information will allow the planned intervention to accommodate limitations in ROM, ensure proper alignment of body segments, and minimize pressure distal to the joint. Changes of

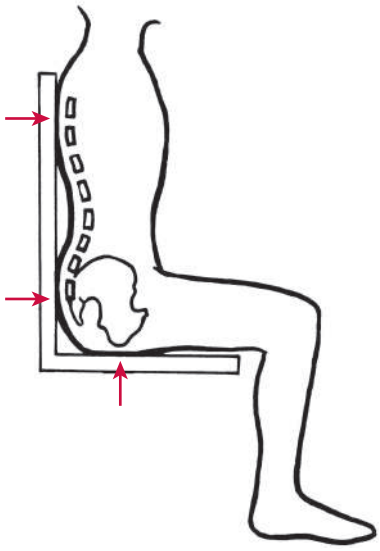

Figure 32.13 Patients seated on planar surfaces may show increased pressure over bony prominences.

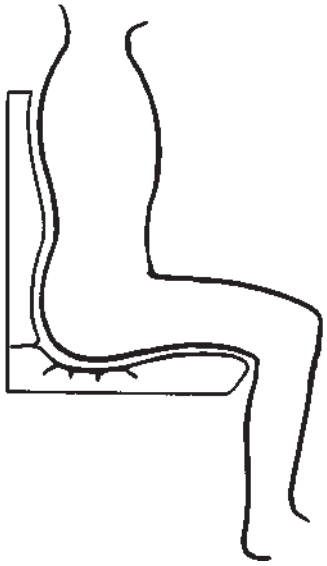

Figure 32.14 Some types of foam will contour as a response to body weight.

Figure 32.15 An option for creating contoured seats is use of varying density (firmness) of foam.

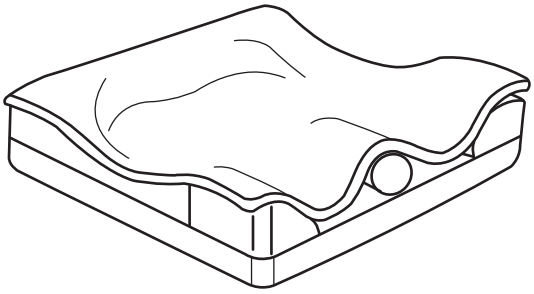

Figure 32.16 Firmer foam shapes can be placed under a more flexible foam to create a contoured cushion.

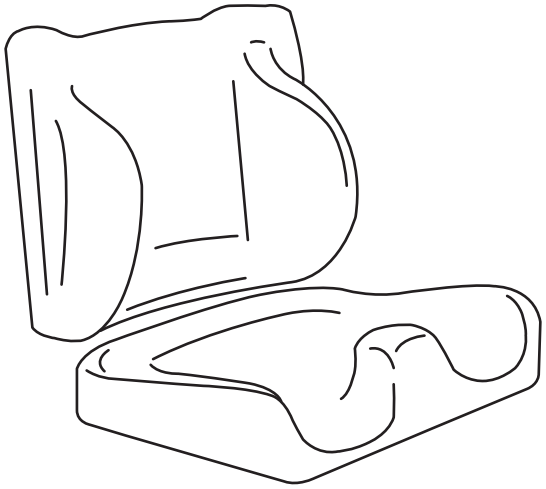

Figure 32.17 Custom-molded cushions match the patient's body contours.

orientation in space (fixed or dynamic) affect the user's comfort level, pressure over skin surfaces, fatigue, and ability to work in gravity-minimized and gravity-influenced positions. Attention to these features will help ensure the success of the seating intervention. Appendix 32.A provides an overview of features of the wheelchair postural support system.

Seat Support

The seat support is the surface under the buttocks and thighs. A firm seat support is critical in creating good LE alignment, good pressure distribution, and improved comfort. Many basic manual wheelchairs come with sling upholstery. Over time, this type of surface creates poor pelvic positioning (Fig. 32.18). The hips tend to slide forward and the thighs tend to shift into hip adduction and internal rotation. Sling upholstery is used to increase the ease of folding the wheelchair. However, if the system is needed for more than transportation, a firm seat support should be added to the wheelchair. A solid seat board can be placed under the cover of a seat cushion to provide the firm base of support or a special seat pan (solid seat of metal or plastic that mounts directly to the seat frame or with attaching hardware to seat frame) can be added to the wheelchair once the upholstery is removed (Fig. 32.19).

Different seat supports have different properties. Foam, air, gel, combination types, and custom-shaped cushions are used to promote improved positioning, improved stability for UE activities, improved pressure relief, and improved comfort.[24] The person should test various seat cushions to determine what system is optimal.

Properties of the seat that need to be considered include the surface shape, firmness, flexibility, dimensions, placement, and attachment features. The most

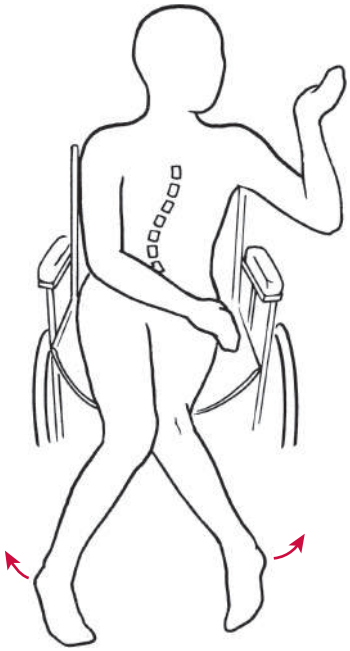

Figure 32.18 Overall poor sitting posture and asymmetries created by a sling seat.

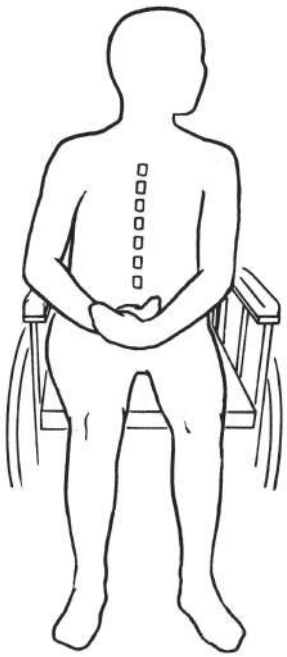

Figure 32.19 A firm sitting surface enhances sitting posture and provides a stable base of support.

critical dimensions include the seat depth and seat width. If the seat depth is too long, it promotes a posterior pelvic tilt and kyphotic spine posture. If the seat width is too wide, it will make propelling the wheelchair more difficult and if too narrow, increase pressure on the hips from the armrests and footrest system.

Box 32.2 provides a list of questions that should be considered when finalizing the seat support.

Box 32.2 Questions to Consider When Finalizing the Seat Support

- Does the seat provide adequate support to promote good sitting posture?
- Will the pressure distribution on the seat prevent pressure sores?
- Is the shape of the seat cushion appropriate for the patient's body contours?
- Does the person need a custom shape to accommodate deformities and maximize support?
- Is pressure relief provided if the person is unable to complete weight shifts independently using UEs or through a tilt or recline option?
- Is the seat depth an appropriate length?
- Is the seat width appropriate for propelling the wheelchair and for comfortable positioning?
- Is the seat surface appropriate for safe transfers into and out of the wheelchair?
- Are special combinations of foam, air, or gel seat cushions needed to maximize comfort and pressure relief?

Box 32.3 Questions to Consider When Finalizing the Back Support

- Is the back support in an appropriate position for upright trunk posture (seat to back support angle, orientation in space)?
- Is the back support an appropriate shape to fit the patient's body contours? (If using a commercially available back support with contour it should be examined to ensure the support will fit the person. At times, the patient's hips may be too wide to fit between the fixed lateral supports of a commercial back.)
- Does the patient require a custom shape to provide full contact and support?
- Does the back support provide adequate control for muscle weakness and trunk asymmetries?
- Is the back comfortable when used in a tilted or reclined position?
- Does the back support allow performance of functional activities (propelling, reaching, transfers)?
- Is pressure distribution/relief adequate for a person with a bony spine, protruding sacrum, or to prevent pressure sores?
- Are special combinations of foam, air, or gel needed to maximize comfort and pressure relief?

Back Support

The back support is the surface behind the trunk. A firm back support is critical to promote good trunk posture and, in conjunction with lateral trunk supports, contributes to maintaining midline posture. Many basic manual wheelchairs have sling upholstery and this promotes poor trunk posture. There is an increased risk of a kyphotic spine and posterior pelvic tilt. The back support height can be varied depending on the needs of the individual. A shorter back may be appropriate for a person propelling the wheelchair with a taller back needed for a person who uses the tilt-in-space feature. A shorter back is more appropriate for a person with good trunk control and the ability to maintain good alignment without using lateral trunk supports. Back height is determined based on the person's trunk control, functional abilities, and comfort.

Different back supports have different properties. Foam, air, gel, combination types, and custom-shaped cushions are used to promote improved positioning, pressure relief, and comfort. The person should test various back cushions to determine what system is optimal.

Properties of the back that need to be considered include the surface shape, firmness and flexibility, dimensions, placement, and attachment features. The most critical dimensions include the back height and back width. Box 32.3 presents questions that should be considered when finalizing the back support.

In addition to the seat and back support, other supports might be necessary to ensure optimal positioning, pressure relief, and comfort, including lateral trunk and hip supports, lateral and medial knee supports, head and foot support, anterior chest and UE support, and pelvic support.[25] When determining the need for the support, consideration should be given to surface shape, firmness and flexibility, dimensions, placement, and type of attachment.

Pelvic Positioner

A belt or more rigid pelvic positioner may be needed to maintain good pelvic position (prevent the hips from sliding) and/or for safety.[26] The direction, angle of pull, and number of anchor points of the belt is important.[27] For example, if one hip tends to pull forward consistently, it may be useful to have the belt tighten by pulling it down toward that hip. The angle of pull to the seating surface should normally be 45° to 60° (Fig. 32.20).[26] Some patients respond well to belts that form a 90° angle with the sitting surface. This pull discourages patients who tend to extend in their wheelchairs as a result of increases in tone. This 90° placement also leaves the pelvis free for anterior tilting, an assist for those patients who can use this mobility for added function (Fig. 32.21). Some patients can benefit from multiple angles of pull. For these clients, a four-point belt might be most appropriate. A four-point belt provides four places to anchor the belt. The top two anchors assist in pulling the pelvis back against the back support

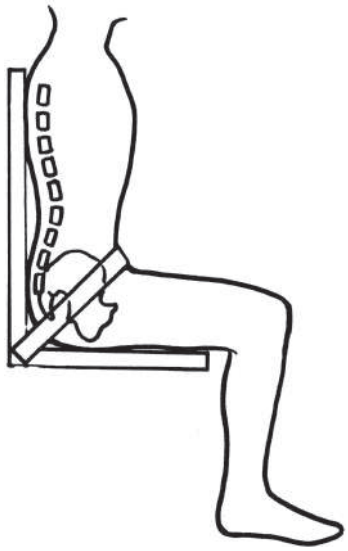

Figure 32.20 The pelvic belt should cross the pelvicfemoral junction at approximately a 45° to 60° angle to the seating surface.

Figure 32.21 A belt placed over the upper thigh (at a 90° angle to the sitting surface) will free the pelvis for natural anterior tilting.

and the bottom two anchors assist in preventing the pelvis from shifting forward and up. Other pelvic positioners are available as discussed in Seating Principle 2: Achieve and Maintain Pelvic Alignment.

Upper Extremity Supports

Wheelchair armrests have many important functions. They provide a support surface for arms as well as a surface for pushing up to standing and a mechanism for ischial pressure relief (sitting pushups). The armrests are also used to support trays for UE support or communication devices. The height, length, and width of the armrests are important measurements to ensure independence and comfort. If the armrests are too high, undue stress can be placed on the shoulders and if too low, slumping to reach the support frequently occurs. If the armrests are too wide, it may interfere with lifting the armrest for transfers or affect the ability to propel the wheelchair. If too narrow, the arms may slip off rendering the armrests ineffective in assisting with trunk posture.

For some individuals, the armrests will be used to mount an *upper extremity support surface (UESS)* such as a tray or trough. These surfaces provide several important functions. They can be used to achieve symmetrical positioning of the UEs, maintain corrected alignment of the glenohumeral joint and scapula, and serve as a work or communication surface. They also can act as an adjunct to the postural control system by supporting the weight of the upper limbs and decreasing pull on the shoulders and trunk.

Lower Extremity Supports

Style and position are important considerations when selecting foot support systems. Placement of the foot support system will directly affect the position of the entire lower body, affecting tone and posture in the trunk, head, and arms. Adequate hip flexion will help keep the pelvis well positioned on the sitting surface. Appropriate foot support height and style are required for maintenance of this position. Foot supports that are too low will result in lower knees, placing the hips in a more open angle and encouraging forward sliding of the pelvis. Foot supports that are too high may unload the thighs, placing increased weight on the ischial tuberosities. Elevating leg rests even in their lowered position may place excessive stretch on tight hamstrings, pulling the pelvis into a posterior tilt (Fig. 32.22). Any limitation of motion imposed by the hamstrings will directly influence the choice of foot positioners. To achieve maximum comfortable hip flexion, it may be necessary to flex the knees more than 90°, requiring special intervention on the foot supports. Decisions regarding straps and foot positioners must be made early, based on available ROM, to ensure caster (front wheel) clearance on the final unit.

Secondary Support Surfaces

Other supports may be needed to improve trunk alignment, LE alignment, and head position. These supports are added to the main support surfaces and include, but are not limited to, lateral trunk supports, medial and lateral knee supports, lateral thigh supports, headrest, and anterior chest supports. When determining the need for these supports, a specific goal should be identified to justify each item.

The Wheeled Mobility Base

The wheeled base forms the mobility structure for the seating system. Mobility bases include manual systems

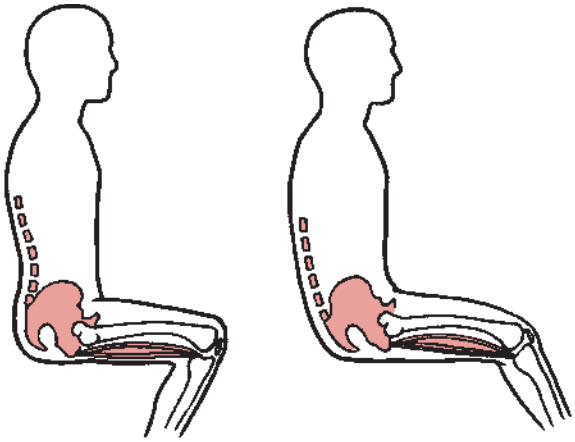

Figure 32.22 Sitting alignment with the hamstrings on slack and the knees flexed (*left*) and positioning assumed with feet resting on elevating foot rests (*right*) causing tension on the hamstring that pulls the pelvis into a posterior tilt.

Figure 32.23 Wheelchairs with large front wheels and small rear casters may be easier for some patients to push, but are more difficult to use outdoors. *Courtesy of Sunrise Medical, Carlsbad, CA 92008.*

and power systems. Manual systems can be set up for independent use where the user is able to propel the wheelchair or dependent use where a caregiver moves the chair.

Manual Mobility Systems

Dependent manual systems include strollers, pushchairs, and some manual wheelchairs. These systems typically have small wheels that are not intended for self-propulsion. They may also be set up for increased ease of folding for transportation.

Four different methods of self-propulsion are available in the independent manual mobility category. Independent manual propulsion using both hands is indicated for those with good UE function and strength and is the most common. This system is usually set up with large rear wheels. However, the large wheels can be positioned in the center of the base (mainly used with children) or in the front of the base (Fig. 32.23). Positioning the wheels in different configurations can improve the ability to reach and propel the wheelchair. This is especially critical when considering the possible implications for long-term function of the shoulder girdle.

Research indicates that patients who use manual wheelchairs, especially if they are not properly fitted to their bodies and functional level, are in danger of UE damage from *repetitive strain injuries* (RSIs). Repetitive strain injuries can result in damage to soft tissue (tendons, ligaments, nerves) or bony structures secondary to frequent repeated motions such as wheelchair push strokes. The damage can include inflammation, compression, and/or tears in the shoulder joint and surrounding structures, resulting in pain and decreased function.[28,29]

Repetitive strain injuries have been identified in the shoulders, wrists, and hands of wheelchair users. Even patients without documented RSI report increased pain in these joints with prolonged wheelchair use.[30,31] Small muscles are required to produce large forces repeatedly to move the chair through space. These same muscles are typically required for a variety of activities of daily living (ADL) tasks, thus increasing the demands placed on the same muscles with the potential of causing trauma. Muscles are used in atypical positions, and become overstretched and overused. Stress on the muscles and joints increases with increased wheelchair weight, increased user weight, and environmental factors. Many symptoms are not felt until the condition is well advanced. Rotator cuff injuries and instability of the glenohumeral joint are common at the shoulder. Since a number of muscles cross the wrist and elbow, problems occurring at the wrist often create pain at the elbow. Medial epicondylitis and carpal tunnel syndrome (CTS) are common. See Box 32.4 Evidence Summary for a summary of studies addressing UE pain associated with wheelchair propulsion.

When prescribing wheelchairs and features for patients who are able to self-propel, consideration must be given to preventing RSI whenever possible. An important prevention strategy is careful positioning of the UE to allow the most efficient stroke during propulsion, reducing the amount of force needed per stroke and reducing the number of strokes required to move the chair. It is also critical to observe wrist alignment and make any needed recommendations to minimize trauma and the chance of impingement leading to CTS.[32-34] Other criteria that should be

Box 32.4 Evidence Summary Studies Addressing Pain Associated with Wheelchair Propulsion

Reference	Purpose	Subjects/Design	Results	Conclusions/Comments
Sie et al[28] (1992)	To document the prevalence of UE pain according to specific UE regions, and the relationship of UE pain to time since injury in Ss with SCI.	Nonrandomized cohort study; questionnaire sent to 239 Ss > 1 year post-SCI; mean age 37.4 years. Ss interviewed for presence of UE pain (shoulders, upper arms, elbows, lower arms, wrists, and hands), screened for CTS.	55% of Ss with tetraplegia (quadriplegia) reported pain in at least one region of UE, 40% in more than one region. 64% of Ss with paraplegia reported UE pain, 32% in more than one region. 59% of all Ss reported some UE pain, 30% reported pain requiring medication, limiting function, or causing pain with ADL. Ss with paraplegia reported less significant pain than those with tetraplegia. 41% of all Ss reported shoulder pain.	Shoulder region was the most common painful area in Ss with tetraplegia, and second most common in Ss with paraplegia. There was a general trend indicating that UE pain increased with time past since injury, up to 20 years. There was a steady increase in frequency of CTS-related complaints with time since injury up to 19 years, in Ss with paraplegia.
Fullerton et al (2003)[a]	To compare the onset and prevalence of shoulder pain in the athletic and nonathletic W/C user populations.	Cohort study; 20-item questionnaire, mailed to a randomized group of 500 individuals through the Virginia SCI Registry, 257 Ss were obtained, 86% had SCI. Patients were considered athletic if (1) trained at least 3 hours/week, (2) involved in at least 3 competitions per year, (3) had a W/C modified for sports. 172 of the Ss were identified as athletes.	48% of all Ss reported shoulder pain, 70% of these Ss sought treatment for pain, and 92% had pain with ADL. 66% of nonathletes reported pain, only 39% of athletes reported pain. Pain and athletic status were not significantly related to onset of shoulder pain. There was no significant difference between Ss with tetraplegia and Ss with paraplegia. Age had a strong effect for both pain and athletic status. Nonathletic Ss were found to be more than twice as susceptible to shoulder pain as athletes independent of age, SCI level, and number of years in W/C.	A limitation of this study is that one question remains unanswered: Do nonathletes have more pain because they are not athletic, or are they not athletic because of shoulder pain? There is a possibility of sampling bias because many of the questionnaires were hand-distributed.

Box 32.4 Evidence Summary Studies Addressing Pain Associated with Wheelchair Propulsion—cont'd

Reference	Purpose	Subjects/Design	Results	Conclusions/Comments
Curtis et al (1999)[b]	To compare the prevalence and intensity of shoulder pain experienced during daily functional activities in W/C users with tetraplegia and paraplegia.	Nonrandomized cohort study; self-report survey; 55 women and 140 men; 92 Ss with tetraplegia (mean age 32.9 years) and 103 Ss with paraplegia (mean age 34.4 years). Ss used manual wheelchair for 3 hours per week and had at least 1 year since onset of SCI. Groups were partitioned according to age, level of daily activity, and years of W/C use.	There was no significant difference between Ss with tetraplegia and with paraplegia in terms of age, years of wheelchair use, and weekly hours of activity. Ss with paraplegia performed more transfers per week and spent more hours per week using W/C (both significant). Less than 15% of all Ss experienced shoulder pain before becoming W/C users, 78% with tetraplegia and 59% with paraplegia had felt shoulder pain since they started using the W/C. There was significantly higher prevalence of previous, bilateral, and current shoulder pain in Ss with tetraplegia than those with paraplegia. Both groups had most severe shoulder pain when pushing the W/C up an incline, pushing for more than 10 minutes, and while sleeping.	This study documents a strong influence of shoulder pain on the performance of functional activities after SCI. Ss with tetraplegia, increased age, and duration of W/C use were associated with avoiding strenuous functional activities.
Veeger et al (2002)[c]	To examine the mechanical load on the glenohumeral joint and on the shoulder muscles during W/C propulsion at everyday intensities.	Nonrandomized cohort study; three experienced male W/C users, ages 22, 27, and 38. Weight 180, 176, and 209 lb (81.5, 80, and 95 kg), respectively. All participated in W/C sports on a weekly basis. Each underwent four, 4-minute W/C exercise tests at two target resistances (10 and 20 N), and target speeds (0.83 and 1.39 m.s[–1]), during which data were collected for construction of a musculoskeletal model of the UE. Anthropometric parameters of the model based on data from two cadaver studies. Individual muscle performance estimates based on this model.	Push time shortened significantly when velocity increased, while recovery time was reduced considerably with an increase power output. The muscle that produced the largest force during the push phase was the subscapularis. Supraspinatus and infraspinatus were also highly active. Pectoralis major produced a moderate internal rotational force. Biceps produced more force than triceps during push phase. During recovery phase, the scapular part of the deltoid produced more force than all other muscles. The supraspinatus was by far the most taxed muscle when force output is considered relative to maximal force.	Peak glenohumeral contact forces varied between 800 and 1400 N. The supraspinatus and infraspinatus may be responsible for an external rotation compensatory moment for the deltoid (excessive internal rotation may cause the greater tubercle to move directly under the acromion, thus increasing probability for impingement). Despite the relatively low contact forces, the peak forces and peak stresses in the rotator cuff muscles (particularly supraspinatus) appear high. These high peak stresses might cause overuse injuries.

Box 32.4 Evidence Summary Studies Addressing Pain Associated with Wheelchair Propulsion—cont'd

Reference	Purpose	Subjects/Design	Results	Conclusions/Comments
			Also highly active were the forearms (pronators and the supinating effect of the biceps).	
Boninger et al (2001)[d]	To investigate MRI and radiographic abnormalities in individuals with paraplegia who were W/C users.	Nonrandomized cohort study; 28 Ss with paraplegia, 19 male and 9 female (mean age 35 yr), with a traumatic SCI at the 4th thoracic level or below, occurring more than 1 year before the start of the study. Ss used manual W/C full-time for mobility. Each subject completed a standardized questionnaire, had a uniform physical examination focusing on the shoulder, and underwent imaging studies (radiographic and MRI). BMI was calculated.	5 Ss displayed osteolysis of the distal clavicle, 11 displayed subacromial spur, and 8 displayed AC DJD. Only nine Ss had radiographs that were read as entirely normal. One subject was found to have a rotator cuff tear. Distal clavicular edema was the most common abnormality found in MRI (20 subjects), 18 Ss displayed AC DJD, CA ligament problems were common as well. Ss with a high BMI had a greater degree of abnormality.	It is hypothesized that shoulder injuries are due to the repetitive loading that occurs during transfers and W/C propulsion. BMI alone was not related to abnormalities, which may suggest that taller subjects who weigh more have musculoskeletal systems that are better able to handle increased stresses.
Samuelsson et al (2004)[e]	To describe the consequences of shoulder pain on activity and participation in Ss with paraplegia who use a W/C, and describe the prevalence and type of shoulder pain.	Nonrandomized cohort study; 56 potential Ss with paraplegia due to SCI (12 women, 44 men, mean age 49 years), more than 1 year before study were screened for participation via questionnaire; 21 (37.5%) of those responding had shoulder pain. 13 of these Ss were used to delineate the type and consequence of shoulder pain. The CMS, WUSPI, KBADLI, and COPM were used to describe the impact of shoulder pain on activity.	The highest pain intensity was found for loading a wheelchair into a car, followed by pushing up inclines outdoors and usual ADL at work and school. 54% of Ss presented with problems related to self-care activities; 23% productivity; 23% leisure activities. The most common problem was transferring in and out of a car (62%) and W/C propulsion (46%).	Sitting posture may be related to shoulder pain in this population. W/C users with SCI tend to adopt a kyphotic posture, which causes an abnormal rotation of the scapula. This could contribute to entrapment of the greater tubercle beneath the acromion. The most defined problems related to shoulder pain were associated with W/C use.

considered in prescribing a self-propelled wheelchair include selecting a chair that

- Has the lightest weight possible
- Has a stable frame for most efficient movement
- Is well manufactured, with high-quality bearings (increased ease of motion for moving parts) for less roll resistance when push forces are applied, and secure nonmoving parts
- Provides optimal wheel size and type consistent with patient size and function
- Provides the best possible combination for ease of propulsion and stability

Many features must be considered when determining the optimal manual wheelchair setup for a person who is able to self-propel. Many bases are available, each with small differences that can increase or decrease the person's functional skills A rigid frame is lighter weight than a folding frame but may be more difficult to transport for some individuals. The ability to adjust the front and rear seat height by changing casters, fork lengths, and rear wheel size can assist a person with balance issues. The ability to change the seat back angle and the frame angle can assist a person with postural issues.

The second method of self-propulsion is using a one-arm drive system. This is appropriate for a person who is only able to functionally use one UE. In this case, there are two rims on the side being used to propel the wheelchair. The outer rim enables the chair to turn in one direction, the inner rim to turn in the other direction, and engaging both rims enables the chair to move forward (Fig. 32.24).

The third method of self-propulsion is using one or both feet. When using this method, care should be taken to ensure that the seat is low enough to the floor so the person continues to have good positioning and does not risk sliding out of the wheelchair.

Figure 32.24 A double handrim on one side allows the user to drive a one-arm drive wheelchair with one hand. *Courtesy of Sunrise Medical, Carlsbad, CA 92008.*

The final method that can be used for self-propulsion is a combination of one arm and one leg. In this case, care must be taken to have the seat low enough to the floor, as well as have the rear wheel an appropriate size and position to use for functional mobility.

Power Mobility Systems

A power mobility system (Fig. 32.25) consists of a base or frame, a seating system, and electronics (batteries, motors, control module, and driver control).

If a person is unable to mobilize a manual wheelchair and is cognitively aware of surroundings, power mobility should be considered.[35-38] It should also be considered for wheelchair riders who are marginal self-propellers in manual wheelchairs. They may be able to move around indoors, and on level surfaces outdoors, but cannot move around in the community environment without unduly stressing muscles and joints, creating postural problems, and/or imposing cardiovascular strain. Long-term overuse injury of muscles and joints and the possibility of skeletal deformity must be discussed with the patient and caregiver as part of the examination process. Patients must face the possibility that injury may create problems significant enough to impede function in critical areas such as transfers and ADL.[28-34,39-43]

An examination of the patient's full environment must be made to determine if power mobility will be helpful and usable (see Chapter 9, Examination of the Environment). Architectural barriers such as steps might preclude the use of power mobility or require that the patient have both a power and manual system for use at different times. In addition, attention should be given to how the chair will be transported, and the level of technology tolerance of both the consumer and caregiver. For patients whose condition is changing, a long-term plan must be established to guide decision making when choosing products. When considering power mobility for individuals who may have cognitive impairments, the rule of thumb is that the driver is aware of safety for himself or herself and others. In most cases, the ability to stop and to judge when to stop is more difficult to teach than driving itself. Awareness, reliable movement, motivation, and good response time are all important factors in wheelchair use.

Control Options

A variety of control options are available for powered mobility, including hand control, head array systems, sip 'n' puff breath control system, single switch systems, and scanning array systems.

Hand Controls

The most efficient method for driving a power wheelchair is with a hand. Joystick controls are used to control the direction and speed of the wheelchair. The final placement of the joystick is important to ensure that the person can reach the control without difficulty and without putting excessive stress on the wrist, elbow, or

A

B

C

Figure 32.25 **(A)** Motorized wheelchairs offer patients with poor coordination, weakness, or paralysis an opportunity to move around in their environment. This chair is also equipped with a power-operated seating system. *Courtesy of Sunrise Medical, Carlsbad, CA 92008.* **(B)** Patient seated in a motorized chair; note that this chair includes a storage space for canes behind seat back. **(C)** Close-up of platform flip-up footrest.

shoulder. Access to on/off switch, mode switch, and/or speed dial must be assessed to ensure independent control and prevent accidental hitting when driving.

Head Array Systems

Some individuals are unable to use their hand to mobilize the wheelchair but have good head control. A head array system can be used for driving. A simple system consists of three switches. The switch behind the head allows the chair to move forward, the one to the left side of the head turns the chair left, and the one to the right side of the head turns the chair to the right. Hitting a combination of the switches allows the user to maneuver the chair with increased ease. A fourth switch can be used for reverse or to toggle the system so the rear pad on the head array becomes reverse. This fourth switch can also be used to change the speeds and operate other wheelchair functions. Good head control is needed to operate this type of system.

Sip 'n' Puff System/Breath Control System

The sip 'n' puff system is used with breath control. A straw is used in the mouth. A hard puff allows the chair to move forward, a hard sip for reverse, a soft puff is right, and a soft sip is left. The air control is from the mouth rather than from the lungs. Systems can be calibrated for easier or harder puffs and sips. The system can be set up in latch mode (forward is locked after a hard puff) so the person is not required to constantly be puffing into the straw to keep the chair moving forward. Once in latch mode, small puffs or sips provide steer correction. A hard sip stops the chair. When using this type of system, it is important to have good lip closure without leakage through the mouth or nose for optimal efficiency. A combination of sip 'n' puff and switches can be used for driving a wheelchair if a person has difficulty differentiating the hard and soft puffs and sips.

Single Switch Systems

A variety of single switches can be set up for driving a power wheelchair. If a person is unable to use a head array or sip 'n' puff system, single switches can be set up at any area with even minimal active movement (e.g., hand, elbow, head, chin, knee, foot, and so forth) to control the wheelchair. A tray can be used with good gross movement of the UE to activate a series of switches with each one assigned a different function. The switches can be different styles, sizes, and colors to differentiate function. Four switch placements are needed to operate a wheelchair using this method.

Scanning Array System

A scanning array is available for a person who only has one switch placement site available. A light scans around a display highlighting different directions. When the light hits the direction of travel, activation of the switch moves the chair in that direction. Once the contact is removed from

the switch, the scanner light continues to move around the display in a preset fashion. Although this type of system can be slow and tedious, the ability to drive independently is extremely rewarding for the motivated person.

Other Systems

Foot, arm, and chin control systems are available for driving a power wheelchair. A variety of switch options are available that include proximity switches, zero touch switches, and infrared switches for driving a power wheelchair. Testing of the recommended equipment is essential to ensure that the person can drive safely and efficiently both indoors and outdoors.

Power Wheelchair Bases

Four types of power wheelchair bases are available for mobility, and each system has its own set of benefits. Every person is different and many people can only drive one type of power base. Testing is needed for both new users and experienced users who may want to change the type of chair they have been driving.

Scooters

This style chair can be three or four wheeled and operates with a hand control lever system (see Chapter 9, Examination of the Environment). The seat options tend to be limited in sizes and supports. Many individuals like scooters for the ability to maneuver in small places, the ability to rotate the seat for transfers, and in some cases, the ability to elevate the seat for improved reach. These can be easier to disassemble for transport but might not have the power or electronic capabilities needed for driving outdoors. Although scooters tend to be less costly, consideration of a person's disability, changing needs, and environmental issues need to discussed before moving forward with purchasing a scooter.

Rear Wheel Drive Bases

A rear wheel drive wheelchair has the fixed drive wheels in the rear of the chair and the casters are in the front. Individuals driving this type of base see exactly where they are going and are able to watch their feet to ensure they do not hit walls, doors, or other items. Until recently, this was the most commonly used wheel drive base. With improved technology, center wheel drive bases are now the most commonly used base system.

Center Wheel Drive Bases

A center wheel drive wheelchair has the fixed drive wheels in the center of the chair and small casters both in front and in the rear of the chair. The chair turns from the center and care must be taken when turning to know what is behind and in front of the chair. Better LE positioning can be attained owing to improved caster clearance.

Front Wheel Drive Bases

A front wheel drive wheelchair has the fixed drive wheels in the front of the chair and the casters are in the rear. When turning the chair, the back end moves first and care must be taken to ensure sufficient posterior clearance. This type of chair allows closer proximity to tables or sinks. Lower extremity positioning is improved with no caster clearance issues.

Seating System Features

Adjustable Tilt-in-Space Seating Systems

Manual and power wheelchairs can have an adjustable tilt-in-space feature. The tilt-in-space feature is a seating system with a fixed seat to back support angle, fixed seat to lower leg support angle, and fixed lower leg to foot support angle that can be adjusted to tilt rearward or upright depending on the needs of the person (Fig. 32.26). In a manual wheelchair, in most cases, a caregiver needs to change the tilt position. In a power wheelchair, the person can independently adjust the seat tilt with switch access. The tilt feature is beneficial for individuals who have fair to poor trunk control and are unable to sit up straight against gravity for the full day. The tilt provides them with a resting and repositioning position. The tilt also assists with positioning a person in the wheelchair after transfers. The tilt feature can assist in improving balance and head positioning, improving skin integrity by assisting with shifting pressure from buttocks to back, and improving comfort.[44,45]

Adjustable Recline System and Elevating Leg Rest System

Both manual and power wheelchairs can have an adjustable backrest system and an adjustable leg rest system. This allows the person to recline in the wheelchair. This can assist with pressure relief and pressure distribution, bowel and bladder care, orthostatic hypertension, comfort, and ROM.[44] Each of these features can be ordered separately. On a manual wheelchair, a caregiver must adjust the recline and leg rest features. On a power wheelchair, the person can use power recline and power elevating leg rests independently with switch access. If manual elevating leg rests are obtained, the person will be dependent for leg positioning. Care must be taken when determining the need for both these features. In most cases, elevating the leg rests does not decrease edema; the legs need to be raised above the heart to achieve this effect. Hamstring muscle tightness needs to be examined to determine if appropriate sitting posture can be maintained with the legs elevated. Too often, extending the knees causes sliding of the pelvis on the seat surface. This increases the potential of pressure sores under the buttocks and promotes poor trunk posture. If increased muscle tone is present in the LEs, knee extension may cause spasms and pull the knee into flexion, often causing the leg to slip off the elevating leg rests and potentially causing injuries. The recline feature also needs to be examined carefully to ensure that the change in back position does not increase the potential for sliding down in the wheelchair.

Figure 32.26 **(A)** Tilt-in-space wheelchairs tilt through space with their angles preset. **(B)** Patient performing pressure-relief maneuver in tilt-in-space chair. **(C)** Close-up of goal-post joystick.

Power Seat Elevator

A power seating system may include a power seat elevator feature. This feature allows the seat to be raised or lowered to accommodate for height differences and improve reach. This can improve access to tables, sinks, cabinets, and so forth. The feature can also increase ease for transfers on and off the toilet and bed. In the raised position, it can also provide improved social interaction. The power wheelchair can be driven using this feature, but the speed of the chair is slowed for safety concerns.

Standers

A stander is a device that allows a person to come to standing who ordinarily would be unable to stand without support. The stander can be a stand-alone device with or without wheels. For a person who would like to stand throughout the day without transferring to a different device, a stander is available in a manual wheelchair and a power wheelchair. In the manual wheelchair, the system is set up to raise and lower the person using his or her own arm strength. The added stander portion increases the weight of the chair but allows changing position throughout the day as needed to stand, stretch, reach, and work. In the power system, a switch is used to activate the stander and the same benefits achieved with a manual system can be achieved in the power system.

Power Assist Wheels

Power assist wheels are attached to a manual wheelchair. This provides the person with an assist on each propulsion.[46-49] It increases the ease of pushing a manual wheelchair both indoors and outdoors. This can assist a person who prefers to use a manual wheelchair rather than shifting to a power wheelchair.

Specific Wheelchair Frame Features

Sling Back and Sling Seat Upholstery

Sling back and seat upholstery are standard items on basic manual wheelchairs. This is convenient when a person needs to fold the wheelchair for car transportation. However, sling upholstery can promote poor sitting posture, posterior pelvic tilt, hyperextended neck, and poor LE positioning. The sling upholstery should only be used when the chair is primarily being used for transportation, if the person will only be using it for short periods of time, if the person is able to reposition himself or herself and is not at risk for developing contractures, and if the system needs to be as light as possible for mobility. Sling back upholstery is a standard item on basic power wheelchairs. Caution should be used when recommending this type of back due to the potential for poor trunk posture, increased kyphosis, and increased hyperextended neck posture. If at all possible, sling upholstery should be avoided due to potential for development of poor posture and increased health problems. Firm back and seat supports can be added to the wheelchair and removed for transportation purposes. Figure 32.27 provides an overview of the foundational components of a prescriptive wheelchair.

Back Angle Adjustment

The back angle adjustment is available on some basic manual and power wheelchairs and most tilt-in-space seating systems. The back posts can be angled and bolted in a specific position. Depending on the wheelchair manufacturer and the wheelchair style, various amounts of back angle are available. Some chairs only have 10° of adjustment while others have 30° of adjustment. This feature is beneficial for a person with limited hip flexion, as well as a person who needs a fixed rearward tilt position who does not want a tilt-in-space seating system.

Seat Frame Angle and Height

The manufacturer of manual wheelchairs sets the seat frame angle and height. Some wheelchairs are available with adjustable axle plates and adjustable forks. This provides the ability to alter the wheel size, caster size, and wheel placement to achieve a specific height and specific frame angle (Fig. 32.28). This can help a person with hamstring tightness by improving clearance for feet or assist a person with difficulty sitting upright to be tilted rearward slightly for improved posture and UE control. This can also assist a person with reaching the floor for propulsion using the feet or improve the ease for performing transfers.

Footrest System

The footrest system is made up of hangers, extensions, and footplates. The hangers mount to the wheelchair, and the extensions provide the appropriate length for the calf and footplate support. The hangers swing out of

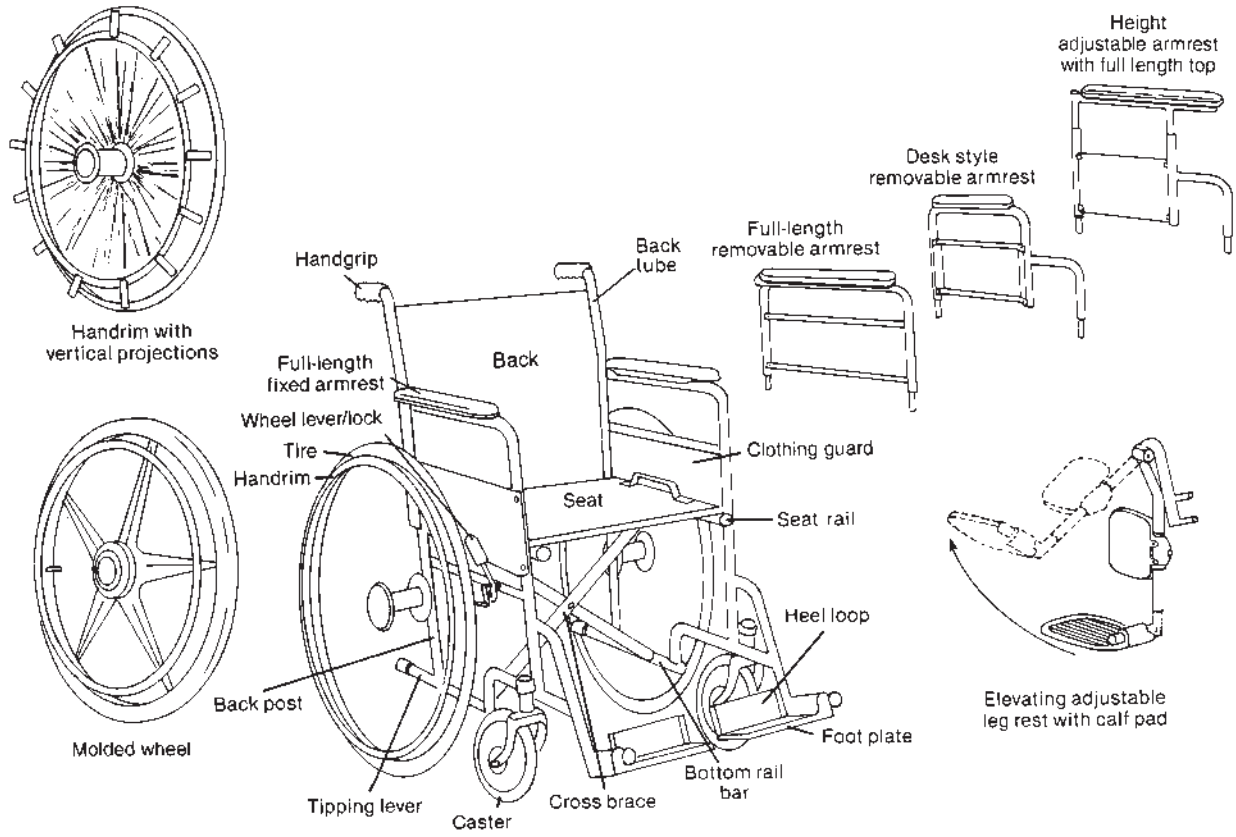

Figure 32.27 Foundation components of a prescriptive wheelchair.

the way for transfers. If transferring independently, practice trials using the release mechanism will ensure patient skill and safety in their operation. The footplates can be fixed or adjustable. The adjustable footplates (footplate can be moved and, depending on placement and angle, affects the foot and knee position) allow optimal positioning of the foot when tightness is present at the knees (seat to lower leg support angle) or foot (lower leg to foot support angle). This provides increased flexibility for positioning, especially if a person has changing needs.

Armrest System

Armrests come in desk length or full-length styles. They can be fixed height or adjustable height. There are a variety of methods to move the armrests out of the way for access to tables and for transfers. The person's functional skills will determine what system is optimal for independence.

Wheel Options

Rear wheel options on a manual wheelchair are important to ensure independent propulsion. If wheels are too large, excess strain can be put on the shoulders. If wheels are too small, they may be difficult to reach and propel. The type of wheel is important depending on the types of terrain the person will be using. Knobby tires may assist in rough terrain. A variety of wheel rims are available. Aluminum rims can be coated, have projections, or be a smaller size depending on method used for pushing.

Caster size options are numerous. A larger caster (8 in) may interfere with foot clearance depending on positioning needs. A smaller caster may provide improved positioning of feet and greater ease turning the wheelchair. Larger casters may improve ease of traveling over potholes or grates.

Options on a power wheelchair are more limited depending on the style of the wheelchair, but the tires tend to be wider for better traction. More options are available for casters on a rear wheel drive wheelchair and some prefer a larger front caster for improved driving on uneven terrain.

Seat Width and Depth

Manual and power wheelchairs come in a variety of widths and depths. If providing a person with a manual wheelchair, it is important to make sure the chair is not too wide or too narrow since this will affect the ability to propel the wheelchair (Figs. 32.29 and 32.30). Testing of the various chair widths is important to ensure that the shoulders are protected from excessive strain. The seat depth is important to ensure that optimal positioning can be achieved with seating supports.

Power wheelchairs and tilt-in-space seating systems may be available with adjustable seat widths and depths. This feature allows fine-tuning adjustments and attaining optimal sitting posture over time. Often, a range is provided for the adjustable seat width. Care should be taken to choose the most optimal range. For instance, if a width of 20 in (50.8 cm) is needed, a frame may be selected that can be adjusted from 16 to 20 in (40.6 to 50.8 cm) or 20 to 24 in (50.8 to 60.9 cm). If the patient is unlikely to gain weight, the smaller size should be chosen; if the potential for weight gain is evident, the larger size should

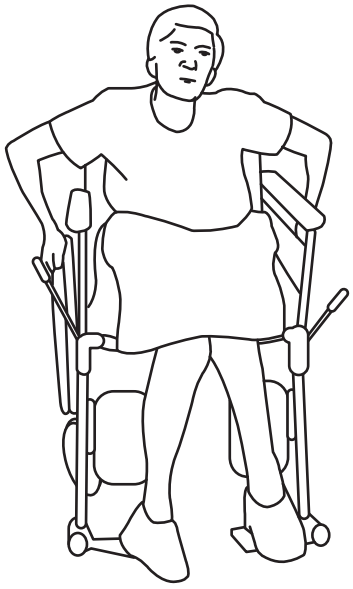

Figure 32.29 A wheelchair that is too wide will make wheel access and propulsion more difficult for the patient.

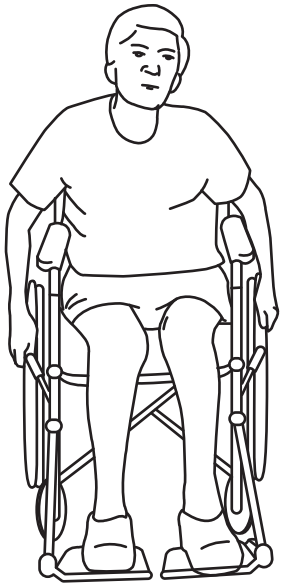

Figure 32.30 A narrower wheelchair allows easier wheel access and propulsion.

Figure 32.31 This court chair is shown being used for tennis play. It can also be used for basketball. The back is very low to allow free trunk and arm movement. The wheels are radically cambered for stability. *Courtesy of Sunrise Medical, Carlsbad, CA 92008.*

be chosen. The newer power wheelchairs tend to have more seat depth adjustability, but again, care should be taken with the base length of the chair to make sure it will not be too long for maneuvering safely indoors.

SPORTS AND RECREATION

Many users are active in recreational and competitive sports, some of which are done from the wheelchair. These patients may need more than one wheelchair: a *street* or *everyday* chair, and a finely tuned *competition chair* or *recreational chair* (Figs. 32.31 to 32.37). For some sports such as archery, discus, shot put, and precision javelin, a more stable chair is an advantage. A wide wheel camber (angle of the wheel, top of the wheel is closer to the user and the bottom of the wheel is further away to provide a more stable system) (Fig. 32.31) can achieve this even on a lightweight frame. For basketball, tennis, and dancing, the chair's responsiveness is critical. Competition chairs are usually of rigid construction, and made of very strong lightweight materials. Wheel and caster placement, tires, axles, and bearings can make a radical difference in chair performance when matched with the user's body weight and configuration. Users who participate in more than one activity may want a chair with a great deal of adjustability to allow parameter changes for various activities or multiple chairs, if possible.

Individuals who use their wheelchairs on off-road, challenging trails will require knobby tires (see Fig. 32.28), because the tread of normal wheelchair tires will tend to get stuck in softer ground. Those who compete in road racing will need competition chairs that have taken many of their design features from racing bicycles: narrow, hard tires; frames made of lightweight alloys, titanium, or carbon; low seats for minimum air resistance; and small

push rims for higher gearing. Racers usually sit in a tucked position, with approximately 120° of hip flexion, knees flexed, and legs strapped together to present a very sleek line and minimal wind resistance as the unit (wheelchair and user) moves quickly along the track. For tennis and dance, the chair is trimmed down to its sleekest configuration with all accessories, even wheel locks, removed. Wheel hubs and spoke configurations are designed to hold a tennis ball during competition. The backs are as low as possible to leave the user's upper body free for movement (see Fig. 32.31).

WHEELCHAIR TRAINING STRATEGIES

Many individuals using a wheelchair for the first time will require a training period. During this time the individual will learn how to propel the chair in all directions (i.e., using both arms, one or two arms in combination with one or two legs, or one arm using a dual-wheel drive system). He or she must also learn how to operate the wheel locks, foot supports, and armrests, and to use the mechanisms safely without tipping forward or sideways out of the chair seat. He or she will learn how to transfer in and out of the chair with the least possible assistance. Some users will always require maximal assistance for transfer activities, but others will be able to achieve functional independence. Chair features such as removable or swing-away arm and foot supports and lowered seat heights may be important for independence. For patients who perform standing transfers (independent or assisted), special attention should be given to the user's ability to get out of or back into the chair, because the seat height may prove problematic. Most chairs with a cushion allow a user to slide forward and come to standing. Many patients may benefit from adjustable height armrests. In addition to adjusting for arm support needs, these armrests can be raised during sit-to-stand transfers.

Although sidewalk cutouts are now mandated in many areas, patients who are capable of independent community mobility benefit from learning to do *wheelies* to negotiate existing curbs. The chair is balanced on the rear wheels while the front casters are elevated and then propelled forward to mount the curb.

Patients who drive need to practice transfers from the wheelchair to the car seat. The wheelchair is then pulled into the vehicle either behind the seat, or across the person's body into the passenger seat. Alternatively, the individual may transfer into the front passenger seat and then pull the wheelchair into the vehicle. The method selected is very dependent on the chair's folded size and weight, the user's upper body skill and strength, and the internal configuration of the car. Active patients also need to practice controlled falls out of the wheelchair and floor-to-wheelchair transfers that can be utilized in the event of falls.

Power chair training is slightly different, and usually concentrates primarily on driving skill and safety. The initial challenge is to locate a reliable access control site and method (e.g., hand control with a joystick, head control with individual switches). Training then involves working with the user on consistent responses (especially to "stop" commands, or the recognized need to stop based on the user's awareness) and accurate maneuverability. Although switch activation can be judged using a computer program, actual road time is necessary for training and ensuring that the driver knows how to respond to a variety of situations, distractions, and obstacles.

It is also important for wheelchair users to learn how to ask for help and how to direct helpers who might be touching them or the wheelchair. Some rehabilitation facilities have large fleets of sample chairs that can be used with patients for examination and training. If this option is not available, a qualified supplier or manufacturer's representative in the area should be contacted.

ROLE OF THE CERTIFIED REHABILITATION TECHNOLOGY SUPPLIER

Traditional home care and/or durable medical equipment companies are qualified to accept basic prescriptive wheelchair information (basic manual wheelchairs only) over the phone. They keep standard-sized items in stock, and can get them to the user quickly, often within 24 hours. More specialized equipment usually requires input to the team from an Assistive Technology Professional (ATP) who has passed the Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) national certification examination or a Certified Rehabilitation Technology Supplier (CRTS) who is a member of the National Registry of Rehabilitation Technology Suppliers (NRRTS) and is also an ATP. He or she is a specialist in the field of complex rehabilitation technology service delivery and can work with the team to design a system that fits the patient's unique needs. Once the team's goals are explained to the supplier, he or she will be able to provide a list of available products that match the user's needs. It is critical that the team hear about all of the options, not just the products available from one manufacturer. The CRTS or ATP will be able to explain the pros and cons, as well as the prices of various products and options, to everyone involved. It may be advisable for the user to actually try several products before a decision is made. The supplier can work with the team to arrange this opportunity.

Once a system has been selected, the clinical team's recommendations (including physical, psychosocial, and cognitive factors if applicable) are compiled into a letter of medical necessity. The letter of medical necessity (with physician and clinic team member signatures), a physician's prescription, and price estimate are then forwarded to the third-party payer(s). The justification package should explain the medical need for each feature requested, along with the anticipated goal the feature will accomplish, and expected outcome from the intervention. Providing measurable functional outcomes is essential to help the payer make an informed decision.

The CRTS or ATP should keep all of the team members apprised as the process moves along from submission through approval, ordering, and receipt of the chair and its components. Once the system is complete, the supplier must deliver it as instructed by the prescriber (to the clinic, school, or home of the user). At delivery, those involved with formulating the prescription should have an opportunity to inspect the system and be sure that it meets the specifications, as well as to observe and

assist as the supplier makes final adjustments. The process may require more than one or two visits for complex systems that require interim fittings.

On final delivery, the CRTS or ATP explains to the user and/or caregivers how to use the chair, including use of all safety features (straps, wheel locks, anti-tipping devices), assembly and disassembly for folding, and normal maintenance (including battery maintenance on power wheelchairs and scooters). Once the chair is delivered, the user and/or caregivers should carefully read any manuals provided and mail in all warranty and registration materials. The user and/or caregivers are responsible for all normal cleaning and maintenance. The supplier and the company he or she works for should be located close enough to the user to provide emergency repairs as needed. Warranty repairs are the responsibility of the supplier who provided the chair (most warranties cover the cost of labor for 12 months following purchase and then labor costs become the responsibility of the owner).

SUMMARY

A systematic approach to prescribing a wheelchair has been presented. The individual components of both the postural support and the wheeled mobility base have been described. The primary outcome in developing any prescriptive wheelchair is maximum function and independence. It must be the result of a thorough evaluation using a patient-centered problem solving approach, with attention to the specific factors discussed in this chapter. Input from the user and all team members during the decision making phase is critical. This process will result in an optimally designed chair capable of achieving its intended purpose. Using a patient-centered approach with open communication among team members, rehabilitation technology supplier, and manufacturer will ensure that each prescriptive wheelchair will meet the needs of the individual.

Questions for Review

1. Explain what information or data are gathered during each of the following portions of the examination process:
   a. Background information
   b. Examination of function using existing equipment
   c. Examination in the supine position
   d. Examination in the seated position
2. Discuss the importance of using seating principles when performing seating assessments.
3. Explain the difference between range of motion for a seating assessment and range of motion for a standard physical therapy examination.
4. When determining seat to back support angle, what parameters are used to finalize this angle?
5. What techniques should be used when measuring seat depth?
6. Why should recommended equipment be tested by the intended user? What specific issues need to be tested?
7. When would you recommend a wheelchair with sling seat and back upholstery?
8. When would you recommend the following types of cushions?
   a. Firm seat cushion
   b. Contoured seat cushion
   c. Air seat cushion
   d. Custom-molded seat cushion
9. Why is a pelvic positioner important and what methods can be used to make it more effective?
10. Describe the following wheelchair components; compare and contrast their functional benefits:
    a. Detachable swing-away footrests versus elevating leg rests
    b. Fixed-height armrests versus adjustable-height armrests
    c. Single-axle placement versus multiple-axle placement
    d. Proportional drive versus micro-switch driving

11. Identify four methods of self-propulsion in manual mobility and the benefits of each method.
12. Explain the benefits and contraindications of power mobility.
13. Identify four methods for driving a power wheelchair and discuss the clinical presentation of the patient who will benefit from each system.
14. Describe the various power wheelchair bases available and the benefits of each system.
15. Discuss the pros and cons of a tilt-in-space system versus a recline system with elevating leg rests.

CASE STUDY

Patient is a 56-year-old male with a diagnosis of multiple sclerosis. He currently uses a scooter for mobility and complains of seat discomfort and difficulty getting under tables. He resides in a long-term care facility.

Patient sits in a posterior pelvic tilt with a kyphotic spine in his scooter. He tends to lean to the left side. His hips and knees are in increased flexion due to the seat height being too low. Patient stabilizes himself in the scooter by maintaining his hands on the scooter handles at all times.

Patient is able to drive the scooter safely and independently. He is able to perform his ADL while using the scooter.

Patient has minimal range of motion limitations that affect his seating when assessed in the supine position. Hip flexion is 0 to 80° bilaterally. He lacks 90° of knee extension when hip is flexed to 80° bilaterally. Ankle dorsiflexion is neutral bilaterally when knee is flexed to 90°. Pelvic movement is flexible. Trunk posture is good but patient has the tendency to lean his shoulders to the left side with a shift of his trunk to the right side. Increased tone noted in both lower extremities. Patient has a stage II pressure sore on his right ischial tuberosity.

Patient was positioned in a seating simulation chair. Improved posture noted in trunk and pelvis in comparison to position in scooter. He preferred to be tilted rearward slightly and noted that this position assisted with his balance. The change in posture was significant and he will need a trial with this posture to ensure ability to perform ADL and improve his comfort with postural alignment changes.

Goals for patient include the following:

- Improve sitting posture and comfort
- Improve skin integrity
- Improve access to sink and tables for functional activities
- Improve independence in mobility in facility and out in community

GUIDING QUESTIONS

1. What type of power wheelchair would you have this patient test?
2. What type of electronics should be considered?
3. Based on range of motion limitations, what are the concerns for a seating system?
4. What type of seat cushion would you recommend?
5. What type of back cushion would you recommend?
6. Fill out a problem solving grid and address issues of posture, skin integrity, health/medical issues, functional tasks and abilities, environmental issues, caregiver needs, social and emotional issues, and mobility issues. Use the following four column headings in developing the grid: Problems and Potential Problems, Objectives, Properties, and Product.

Features of the Wheelchair Postural Support System

appendix 32.A

	Characteristics	Postural Control Provided (at Impairment Level)	Functional Assistance Provided (at the Activity Limitation/ Disability Level)	Advantages	Disadvantages
Seat Supports					
Solid insert	Padded insert board; reinforcement board inside cushion cover; contoured or flat insert board between cushion and wheelchair upholstery. Can be used with any cushion, custom made or premade, for comfort or pressure relief. Velcro® interface to upholstery. Spans seat rails or mounts to upholstery between seat rails. Works best with cushions that have zip-off cover to allow use of wide strips of Velcro® interfacing to hold cushion securely. Addition of extra Velcro® sewn to upholstery and underside or cover will hold better during sliding transfers.	Creates stable, level base of support. Decreases tendency toward adduction and internal rotation of LEs, posterior pelvic tilt, and slipping forward in the seat.	Good base on which to promote trunk extension and upper body stability. Enhances distal function (head and UEs).	Low cost. Adds minimal weight to frame. Removes easily for chair folding. Wheelchair can still be used if solid insert is lost or forgotten.	Increases seat height. Can shift on seat and produce asymmetrical sitting surface.

Continued

	Characteristics	Postural Control Provided (at Impairment Level)	Functional Assistance Provided (at the Activity Limitation/ Disability Level)	Advantages	Disadvantages
Solid hook-on seat	Seat upholstery is removed and solid seat is installed using hardware to hook to seat rails. Hardware can be fixed level with seat rails or dropped lower than seat rails. Angle and height adjustable; allows changing position of seat surface on frame of new or existing frame.	Improves pelvic position. Creates stable, level base of support. Decreases tendency toward adduction and internal rotation of LEs, posterior pelvic tilt, and slipping forward on the seat. Encourages level pelvis, neutral pelvic tilt, symmetrical spinal alignment. Raising anterior portion of seat can help keep patient back on wheelchair seat. Raising posterior aspect of seat can facilitate trunk co-contraction.	Good base on which to promote trunk extension and upper body stability. Enhances distal function (head and UEs). With forward slope, allows increased ROM in UE for reach and wheel approach.	Can change slope of seat without tilt-in-space chair. Wheelchair cannot be used if seat support is missing; ensures use at all times. Dropped style can reduce effect of thick seat cushion on seat height. Does not shift during transfers. Seat angles can be changed to accommodate limited ROM.	More difficult to remove for folding than Velcro® interface. Adds weight to frame.
Seat Cushions					
Comfort cushion (planar/ contoured)	Usually planar, but may have slight generic contour. Varying degrees of firmness available for different comfort levels. Can be made of layered foam to mix firmness for postural control and to accommodate limited ROM (e.g., greater flexion in one hip as compared to the other can be accommodated by different firmnesses, or by actually cutting the foam into different shapes).	Increases comfort; facilitates level pelvis; promotes a neutral pelvic position. Provides surface to create stable base of support.	Appropriate for patients with minimal seating needs. Does not interfere with sliding transfers.	Inexpensive. Lightweight. Patient can sit anywhere on cushion without discomfort. Totally flat cushions with one firmness throughout can be rotated to decrease spot wear.	No pressure relief. Minimal support. Minimal postural control.

	Characteristics	Postural Control Provided (at Impairment Level)	Functional Assistance Provided (at the Activity Limitation/ Disability Level)	Advantages	Disadvantages
Pressure-relieving foam (contoured, custom contoured)	Based on principle that increased surface contact results in improved pressure distribution/relief. Custom made or premade contour depends on need to accommodate individual postural asymmetries. Varying degrees of firmness available. Can be made of layered foam to mix firmness for postural control and to accommodate limited ROM. Generic shapes work best with symmetrical individuals.	Shaped to control postural alignment. Increases comfort; facilitates level pelvis; promotes a neutral pelvic position. Provides surface to create stable base of support. Custom-made contour more effective when accommodating asymmetries.	Appropriate for patients with moderate to significant seating needs. Assists with controlling posture and/or accommodating pelvic asymmetries to allow level shoulders and more erect head position. Increases sitting time; decreases problems with pressure over bony prominences; improves postural stability allowing increased upper body function.	Increased surface contact, creating improved pressure distribution. Accommodates moderate to severe postural asymmetry. Easier for caregivers to position and reposition the patient. Low maintenance.	More expensive. May interfere with sliding transfers. Patient may feel "locked in" because movement on cushion surface is restricted.
Pressure-relieving fluid or fluid/foam combination	Based on the principle that increased surface contact results in improved pressure distribution/relief; generic contour or planar surface with fluid-filled sack. Bony prominences are "immersed" in the fluid, increasing surface contact. Some types have positioning components to accommodate for postural asymmetries and provide improved postural control. Combination units allow the foam base to be cut to accommodate limited ROM. Generic contoured shapes work best with symmetrical individuals.	Provides surface to create stable base of support. Some have add-on pieces to control postural alignment. Increases comfort; facilitates level pelvis; promotes a neutral pelvic position. Increases sitting tolerance for patients who sit with oblique pelvis. Provides appropriate support for pelvis to promote level shoulders and erect head.	Appropriate for patients with moderate to significant seating needs. Assists with controlling posture and/or accommodating pelvic asymmetries to allow level shoulders and more erect head position. Results in increased sitting time; decreased problems with pressure over bony prominences; improved postural stability; and increased upper body function. Gel medium usually increases stability at the pelvis; the pelvis sinks in and is "held" by the foam base, essentially broadening the base of support area.	Increases surface area, contact creates improved pressure distribution. Accommodates moderate to severe postural asymmetry. Increases stability at the pelvis. Easier for caregivers to position and reposition patient.	More expensive. Some maintenance required. Heavier than foam or air. Patient may feel "locked in" because movement on cushion surface is restricted.

Continued

	Characteristics	Postural Control Provided (at Impairment Level)	Functional Assistance Provided (at the Activity Limitation/ Disability Level)	Advantages	Disadvantages
	Firm underbase provides stable support for proper seating alignment.				
Pressure-relieving air	Appears planar, but responds to patient weight. Patient is "immersed" in the cushion based on regulation of the amount of air. Based on principle that increased surface contact results in improved pressure distribution/relief; bony prominences are "floating."	Does not provide a very stable base of support; some users find it too unstable. Individuals with decreased trunk stability tend to keep arms closer to the body for stability, decreasing UE reach distance. Some air cushions are segmented to allow more air into selected segments to improve postural control (it should be noted that segmented cushions are less pressure relieving because the air cannot flow from one segment of the cushion to another). Additional postural accommodation can be provided by placing foam pieces under the cushion.	Indicated for patients with moderate to significant pressure-relieving needs. Results in increased sitting time; decreased problems with pressure over bony prominences.	Very lightweight. Accommodates moderate to severe postural asymmetry. Increases surface contact for improved pressure distribution.	More expensive. Base provided may be too unstable for some users; unstable base may make transfers difficult. Air pressure must be monitored carefully. Continuous maintenance required.
Back Supports					
Pita back	Solid board (padded or unpadded) that slips into a pocket in the back upholstery. Provides mild to moderate level of support.	Assists patients who need a reminder to sit with trunk extension. Assists with maintaining a	Provides enough support to encourage trunk extension.	Lightweight. Slips in and out easily for folding.	Only provides slight degree of support. Wheelchair can be used without this back support.

	Characteristics	Postural Control Provided (at Impairment Level)	Functional Assistance Provided (at the Activity Limitation/ Disability Level)	Advantages	Disadvantages
	Useful for patients who need a slight reminder to sit upright.	neutral pelvis and an upright sitting posture.			It can be lost or left behind when the chair is folded.
Solid back insert	Maintains pelvic alignment when correctly interfaced with seat surface (based on ROM examination to determine available hip flexion). If attached to the upholstery by Velcro®, or hung between the back canes, it provides moderate support and will not decrease seat surface depth on the chair. If hung or belted in front of the back canes, will decrease seat surface depth. Will assume the angle of the back canes unless braced across the top. Special foaming can be used to accommodate back contour or provide some postural control.	Maintains pelvic alignment when interfaced with seat surface. Enhances upright sitting, trunk and head alignment. Provides some lateral control if shaped foaming is used.	Enhances trunk control to allow improved distal function.	Removes easily for folding. Assists with postural control. Adds minimal weight to chair.	May not be stable in chair. Wheelchair can be used without this back support. It can be lost or left behind when the chair is folded.
Solid hook-on back	Very stable back support that can be aligned and angled as needed to create appropriate seat/back angle; accommodates for limited ROM. Can hold planar, contoured, or molded back, or air flotation cushion for pressure relief. Can be manufactured or custom made.	Enhances upright sitting; accommodates for limited ROM; accommodates for any degree of deformity; provides support as needed. Maintains client in position deemed appropriate based on examination findings.	Provides support to enhance movement control of the UE and the head. Increases surface area, contact provides improved comfort and pressure relief. Maintains trunk alignment to enhance pelvic positioning.	Solid support structure. Resists extensor thrusting. Accepts planar, contoured, or molded surfaces. Wheelchair cannot be used without this back support in place. Allows attachment of additional supports such as headrests, which work best	Increases weight of wheelchair. Requires manipulation of hardware to remove and fold wheelchair.

Continued

	Characteristics	Postural Control Provided (at Impairment Level)	Functional Assistance Provided (at the Activity Limitation/ Disability Level)	Advantages	Disadvantages
	Allows for provision of maximum support when needed. Mounts using permanent or removable hardware; with use of permanent hardware, can actually strengthen frame.			when back structure is solid and stable.	
Specialized Support Components					
Head/neck supports	Provides support for patients with fair, poor, or absent head control. Mounting hardware can be fixed, removable, and/or flip back; hardware can be adjusted in one, two, or multiple planes.	Posterior, lateral, and anterior head or neck controllers available. Promotes maintenance of a neutral cervical spine and head position. Eliminates lateral flexion and rotation, which, when not controlled, can disturb trunk and pelvic alignment.	Supports the head to assist with respiration, visual interaction with environment, feeding, and swallowing. Improves safety during transport on level surfaces and when patient is transported seated in wheelchair placed in a motor vehicle.	Provides support and improves alignment. Improves safety during transport.	May interfere with head movement. May trigger extensor thrust. May cause skin problems in areas of high pressure.
Lateral trunk supports	Indicated in the presence of weak or spastic trunk muscles. Can be straight or contoured for more control. Mounting hardware can be fixed or swing-away for transfers.	Improves trunk stability and alignment (within available range); improves pelvic alignment. Controls lateral trunk flexion.	Improves trunk control; facilitates UE movement and distal control. Improves respiration, feeding, and swallowing.	Improves stability and alignment. Improves head alignment and control. Enhances safety during movement through space.	May interfere with trunk movement. Increases weight of the system. May interfere with attempts to self-propel with UE.
Anterior chest support	Assists with maintenance of upright trunk posture and control of shoulder position. Can be minimally supportive or maximally supportive depending on configuration of features (e.g., straps, padded straps, butterfly, and bib).	Supports trunk along anterior surface of trunk and shoulders, eliminates forward lean. May influence and discourage shoulder protraction.	Trunk support may improve respiration, eating, and swallowing. Stabilizes trunk to allow improved UE function and head control. Shoulder control promotes better head posture.	Supports trunk in upright position. Stabilizes trunk to free arms and head for movement. Improves head position for respiration, eating, swallowing, and visual interaction with environment.	Restricts trunk movement. Overuse limits patient's opportunity to improve trunk control.

	Characteristics	Postural Control Provided (at Impairment Level)	Functional Assistance Provided (at the Activity Limitation/ Disability Level)	Advantages	Disadvantages
Lateral hip guides	Improves pelvic alignment on seat. Assists with maintaining pelvic position on contoured seat.	Improves weight distribution on pelvis. Improves pelvic positioning; enhances alignment of upper and lower body segments; contributes to alignment of entire body. Assists with maintenance of pelvic alignment, which reduces asymmetries in trunk and LEs.	Allows patient to achieve or tolerate better alignment. Increases sitting time.	Improves and maintains alignment. Improves symmetrical weight-bearing through pelvis.	May interfere with transfers if not removable. Patient may feel "locked in" on seat. Increases weight of the system.
Lateral knee guides	May be built into the cushion contours, or fabricated from separate pieces of padded wood or plastic attached to the seat or armrest of the wheelchair; should extend to the end of the knee if maximal control is required.	Helps to maintain LE alignment; reduces excessive abduction and external rotation (e.g., patients who tend to fall into abduction, push into abduction, or whose legs do not come into neutral). Improves neutral alignment of LEs; assists with maintenance of pelvic position. Maintains LE alignment in combination with anterior knee block.	Improves pelvic position. Promotes improved trunk position and UE function. Maintains neutral alignment of LEs. Reduces forward sliding of pelvis on seat.	Maintains LE alignment. Assists with maintenance of pelvic position on seat.	If high enough to provide control, may interfere with transfers unless removable. Adds weight to the seating system.

Continued

	Characteristics	Postural Control Provided (at Impairment Level)	Functional Assistance Provided (at the Activity Limitation/ Disability Level)	Advantages	Disadvantages
Medial knee block	May be built into the cushion contours, or be a separate or removable flip-down block. For maximal control, the medial knee block should be positioned at the distal portion of the limb, between the condyles. The support should never be used to stabilize the pelvis on the seat by pressing into the groin; it also should not be used to stop the user from sliding off the front of the seat.	Prevents LEs from moving into adduction. If wide enough, may decrease spasticity. Maintains LE alignment. When used with windblown position,[a] medial knee block can prevent pelvis from continuing to rotate forward. Use of wider blocks will keep the greater trochanter properly seated in the hip joint.	Helps to maintain a broad, stable base of support; this base improves alignment of the upper body.	Maintains LE alignment. Reduces extensor tone. May help to elongate adductors. Provides broad base of support.	May interfere with transfers. Increases weight of seat.
Anterior knee block	Increases pelvic stability; most effective way to maintain proper pelvic position on the seat. *Note*: If hips are subluxed, dislocated, or not properly formed, approval from an orthopedist should be obtained.	Maintains pelvic alignment; maintains pelvis in neutral; prevents pelvis form moving forward on seat surface. Assists with maintenance of LE alignment when used with medial and lateral knee controls.	Helps to maintain a broad, stable base of support with neutral pelvic alignment; this base will promote improved alignment and functional use of upper body. When used in conjunction with forward-sloped seat, may facilitate trunk co-contraction, extension, and improved UE ROM.	Maintains LE alignment. Reduces extensor tone. Provides broad base of support. Increases stability.	May impose too much pressure at the hips and over the patellas. Patient may feel restricted.

[a]Windblown position: Both LEs oriented to one side with one LE adducted and the other abducted.
LE = lower extremity; ROM = range of motion; UE = upper extremity.

A

Acalculia Inability to perform simple arithmetic operations; inability to calculate.

Acceleration The rate of change of velocity with respect to time.

Accelerometer Device used to measure the vertical, anterior-posterior, and medial-lateral accelerations of the body.

Accessibility The degree to which an environment affords use of its resources with respect to an individual's level of function.

Accessible design Structural plan of buildings or dwellings that meet prescribed standards for accessibility.

Accessory (joint play) motions Motions between adjacent joint surfaces that occur when a bone moves through a range of motion. These motions are not under voluntary control and include glides (slides), distractions, compressions, rolls, and spins.

Acting out Instead of expressing feelings verbally, the patient uses actions to release stress.

Active range of motion (AROM) *See* **Range of motion**.

Activities of daily living (ADL) Daily living skills necessary for an individual to manage his or her life.

Basic ADL (BADL) include skills such as oral hygiene, showering or bathing, dressing, feeding, toilet hygiene, and personal device care (e.g., a splint).

Instrumental ADL (IADL) include housekeeping, preparing meals, shopping, telephoning, and managing finances, as well as work and leisure activities, functional communication and socialization, community mobility, and health maintenance. Often included in IADL are sexual expression, medication routine, and emergency response.

Activity (WHO/ICF) The execution of a task or action by an individual.

Activity limitations (WHO/ICF) The difficulties an individual may have in executing activities.

Acute coronary syndrome (ACS) (ischemic heart disease, coronary artery disease) A spectrum of entities that suddenly impairs blood flow through the coronary arteries, ranging from the least involved condition on the spectrum (unstable angina) to acute myocardial infarction and sudden cardiac death.

Acute pain *See* **Pain**.

Acute stress disorder (ASD) Diagnostic subset of "stress disorders" that generally indicate a sudden onset of relatively short duration. According to DSM-IV-TR criteria, symptoms must range in duration between 2 days and 4 weeks.

Adaptability The ability to adapt and refine a learned skill to changing task and environmental demands.

Adaptation Alteration of a skill or the environment to compensate for dysfunction.

Adaptive equipment Devices or equipment designed and fabricated to improve performance in activities of daily living.

Agility The ability to perform coordinated movements combined with upright standing balance.

Agoraphobia Fear of going outdoors or leaving one's home.

Agraphia Disorder of writing not due to motor difficulties in letter formation.

Akathisia Motor restlessness and intolerance of inactivity.

Akinesia Complete or partial loss of voluntary muscle movement.

Algometer Instrument used to measure sensitivity to pain.

Alignment Position of one component relative to another; refers to both angular and linear positions.

Allodynia An ordinarily painless stimulus, once perceived, is experienced as being painful.

Alternating attention The capacity to move between tasks and respond appropriately to the demands of each task.

Altruism Acting for the benefit of others regardless of the consequences for oneself.

Amyotrophic lateral sclerosis (ALS) A degenerative disease of the nervous system of unknown cause, affecting both upper and lower motor neurons; commonly known as Lou Gehrig's disease.

Analgesia Absence of pain in response to stimulus that would normally be painful.

Anarthria Lack of speech resulting from pathology, particularly in the brainstem, causing severe impairment of the motor–speech system. *See also* **Dysarthria**.

Aneurysm Localized arterial wall weakness with abnormal dilation of a blood vessel owing to a congenital defect.

Anger Strong feeling of hostility or displeasure brought on by a psychological interpretation of having been denied, offended, or wronged followed by the wish for retaliation.

Angina Oppressive pain or pressure in the chest caused by inadequate blood flow and oxygenation of the heart muscle.

Angiogenesis Formation of new blood vessels.

Angular acceleration Rate of change of the angular velocity of a body with respect to time.

Angular velocity Rate of body segment rotation around an axis.

Ankle-brachial index (ABI) Test designed to assess the vascular system; lower extremity blood pressure is divided by upper extremity blood pressure and a ratio or index is calculated. Segmental pressures can also be examined to determine different pressures and levels of vascular flow.

Ankylosis Joint fusion that may be the result of destruction of articular cartilage and subchondral bone, infection, or by surgery.

Anorexia Loss of appetite or aversion to food; emotional disorder marked by obsessive efforts to lose weight.

Anosmia Loss of the sense of smell.

Anosognosia Perceptual impairment including denial, neglect, and lack of awareness of the presence or severity of one's disability.

Anterior cord syndrome A spinal cord injury (SCI) resulting in loss of motor function (corticospinal tract damage) and loss of the sense of pain and temperature (spinothalamic tract damage) below the level of the lesion. Proprioception, light touch, and vibratory sense are generally preserved.

Antibody A substance produced by B lymphocytes in response to a unique antigen.

Antigen Any substance capable of eliciting an immune response or of binding with an antibody.

Anxiety Emotional state consisting of uneasy feelings of anticipation or dread of real or imagined danger; associated with an autonomic response.

Aphasia Communication disorder caused by brain damage and characterized by an impairment of language comprehension, formulation, and use; excludes disorders associated with primary sensory deficits, general mental deterioration, or psychiatric disorders. Partial impairment often is referred to as dysphasia.

Broca's aphasia (expressive or motor aphasia) A type of nonfluent aphasia; characterized by awkward articulation, restricted vocabulary, and restriction of simple grammatical forms with relative preservation of auditory comprehension. Associated with lesions involving the third frontal convolution of the left hemisphere (Broca's area).

Fluent aphasia Characterized by impaired auditory comprehension and fluent speech that is of normal rate and melody.

Global aphasia Severe aphasia with marked dysfunction across all language modalities; severely limited residual use of all communication modes for oral–aural interactions; global is not a type of aphasia but a designation of severity.

Nonfluent aphasia Characterized by limited vocabulary, slow, hesitant speech, some awkward articulation, and restricted use of grammar in the presence of relatively preserved auditory comprehension.

Primary progressive aphasia (PPA) A slowly progressive isolated aphasia not due to stroke, trauma, tumor, or infection, which does not fit neatly into existing aphasia classification schemes. It can exist in the absence or relative absence of generalized intellectual and behavioral disturbances or cognitive impairment generally associated with dementia.

Wernicke's aphasia (sensory aphasia or receptive aphasia) The most common type of fluent aphasia; characterized by impaired ability to understand spoken or written words. Associated with lesions to the Wernicke's area of temporal lobe of dominant hemisphere.

Apnea Absence of respiration, usually temporary in duration.

Apprehension test Test in which a patient's joint is placed in a vulnerable position for subluxation or dislocation; test is positive if the patient becomes apprehensive.

Apraxia An impairment of voluntary learned movement that is characterized by an inability to perform purposeful movements not accounted for by inadequate strength, loss of coordination, impaired sensation, attention deficits, or lack of comprehension.

Ideational apraxia An inability to perform a purposeful motor act, either automatically or on command; the patient no longer understands the overall concept of the task.

Ideomotor apraxia The inability to perform a motor act on command and to imitate gestures, even though the patient understands the concept of the task and is able to carry out habitual tasks automatically.

Apraxia of speech (verbal or speech apraxia) Impairment of volitional articulatory movement secondary to cortical dominant hemisphere lesion; manifested in imprecise and awkward articulation and distortion of phoneme production without commensurate pathology of the motor–speech system.

Arousal Alertness; the state of being prepared to act.

Arrhythmia A disturbance in the electrical activity of the heart that results in impaired electrical impulse formation or conduction.

Arteriole Smallest subunit of the arterial system.

Arteriosclerosis A thickening or hardening and loss of elasticity of arterial walls.

Arteriosclerosis obliterans Arteriosclerosis in which the lumen of the artery is completely occluded.

Arteriovenous malformation (AVM) An abnormality in embryonic development leading to a skein of tangled arteries and veins (usually without an intervening capillary bed); rupture produces hemorrhage.

Arthralgia Pain in one or more joints.

Arthrodesis Surgical immobilization of a joint that allows the bones to fuse.

Arthrokinematics Motion of adjacent joint surfaces that occurs when a bone moves through a range of motion.

Arthroplasty Joint surgery in which the joint components are replaced with artificial components (common examples are the hip and knee).

Associated reactions Automatic responses of the limbs that occur as a result of action occurring in some other part of the body, either by voluntary or reflex stimulation. In hemiplegia, associated reactions are stereotyped and abnormal.

Associative stage Middle of three stages of motor learning (proposed by Fitts) in which establishment of a motor pattern is achieved through continued practice.

Asthenia Generalized muscle weakness, especially in muscular or cerebellar disease.

Asynergia Loss of ability to associate muscles together synergistically for complex movements.

Ataxia Uncoordinated movement that manifests when voluntary movements are attempted; may influence gait, posture, and patterns of movements.

Atherosclerosis A form of arteriosclerosis marked by cholesterol-lipid-calcium deposits in the walls of arteries that may restrict blood flow.

Athetosis Condition in which slow, involuntary, writhing, twisting, "worm-like" movements occur.

Attention Capacity of the brain to process information from the environment or from long-term memory.

Auditory agnosia Inability to recognize nonspeech sounds or to discriminate between sounds.

Auscultation Listening for sounds within the body, especially from the chest, neck, or abdomen.

Auscultatory gap During blood pressure determination, a period of silence during auscultation; may occur in the presence of hypertension or aortic stenosis.

Autolytic débridement Use of the body's endogenous enzymes to digest devitalized tissue and promote formation of granulation tissue.

Autonomic dysreflexia (hyperreflexia) A pathological autonomic reflex seen in patients with spinal cord injuries; typically occurs in lesions above T6 (above sympathetic splanchnic outflow). It is precipitated by a noxious stimulus below the level of the lesion and produces an acute onset of autonomic activity; considered an emergency situation characterized by hypertension, bradycardia, headache, and sweating.

Autonomous stage The final of three stages of motor learning (proposed by Fitts) characterized by motor performance that, after considerable practice, is largely automatic.

Axonotmesis Nerve injury that damages the axon but leaves the neural tube intact; produces Wallerian degeneration distal to a lesion.

B

Baker's Cyst (popliteal cyst) A benign swelling of the semimembranous bursa found behind the knee joint.

Balance (postural stability) The ability to control the center of mass (COM) within the boundaries of the base of support (BOS); a state of equilibrium.

Barognosis Ability to recognize weight.

Basic activities of daily living (BADL) *See* **Activities of daily living**.

Benign paroxysmal positional vertigo (BPPV) Vertigo and nystagmus as a result of otoconia in the semicircular canals, displaced from the utricle.

Beveled Cut in a slanting manner from horizontal to vertical.

Bio-burden Quantity of bacteria in a wound; the quantitative biopsy is the gold standard for determining bio-burden.

Biomedical model Conceptual model of health and illness that is based on biological factors.

Biopsychosocial model A model of illness that uses a combined approach of incorporating biological/physiological, psychological, and social realms.

Blanch To lose color.

Blanch test (blanching test) A test of the integrity of the circulation performed by applying and then quickly releasing pressure, such as pressure to a fingernail or toenail; the blanched nail normally regains a pink appearance within 2 seconds or less. Failure to do so suggests impaired blood flow to the extremity.

Blast injury When an explosive device detonates it produces a transient shock wave, which can cause traumatic brain injury (TBI).

Blood pressure Amount of pressure within the arteries throughout the cardiac cycle; a product of CO_2 and peripheral vascular resistance.

Diastolic pressure The pressure of the blood during relaxation (diastole) and filling of the ventricles; in health normally about 60 to 79 mm Hg.

Systolic pressure The pressure of the blood during contraction (systole) of the ventricles; in health normally about 100 to 119 mm Hg.

Body functions (WHO/ICF) The physiological functions of body systems, including psychological functions.

Body image A visual and mental image of one's body that includes feelings about one's body, especially in relation to health and disease.

Body mass index (BMI) An index used to control for both height and weight; determined by dividing body weight by standing height.

Body scheme A postural model of one's body, including the relationship of the body parts to each other and the relationship of the body to the environment.

Body structures (WHO/ICF) The anatomical parts of the body, such as organs, limbs, and their components.

Bootstrap technique In statistics, a technique used to establish the boundaries (prediction regions) about the mean curve for healthy control subjects; establishes the limits of normal variability for a given variable.

Bouchard's node A bony enlargement of the proximal interphalangeal (PIP) joint of a finger; commonly associated with osteoarthritis.

Boutonniere deformity Finger position marked by extension of the metacarpophalangeal (MCP) and distal interphalangeal (DIP) joints and flexion of the proximal interphalangeal (PIP) joint; caused by rupture of the extensor tendon of the involved finger. Commonly associated with rheumatoid arthritis.

Bradycardia Slow heartbeat marked by a pulse rate below 60 beats per minute in adults.

Bradykinesia Extreme slowness and difficulty maintaining movement.

Bradyphrenia Slowness of thought and information processing; seen in some forms of dementia and Parkinson's disease.

Bradypnea Abnormally slow respiratory rate consisting of 10 or fewer breaths per minute.

Brainstem herniation Secondary brain damage and neurological deterioration owing to significant edema and elevated intracranial pressures, resulting in contralateral and caudal shifts of brain structures.

Break test Method of applying resistance during manual muscle testing or handheld dynamometry in which the patient holds a joint position usually at end range; patient is instructed not to let the examiner "break" the hold.

Broca's aphasia *See* **Aphasia**.

Brown-Sequard syndrome A spinal cord injury resulting from hemisection of the cord. On the ipsilateral (same) side as the lesion, damage to the lateral corticospinal tract results in paralysis; damage to the dorsal column results in loss of proprioception, light touch, and vibratory sense. On the side contralateral (opposite) to the lesion, damage to the spinothalamic tracts results in loss of sense of pain and temperature.

Bruit An adventitious sound heard in a blood vessel during auscultation that is caused by turbulent flow of blood.

Bunion Lateral deviation of the great toe; hallux valgus.

C

Cachexia State of ill health with an appearance of malnutrition and wasting that is associated with many chronic diseases.

Cadence Number of steps per unit of time.

Calculation ability Competence in foundational mathematical abilities such as addition, subtraction, multiplication, and division.

Caloric test A procedure use to assess vestibular function in patients who complain of dizziness, standing balance disturbances, or unexplained sensorineural hearing loss. With the patient supine, each ear canal is irrigated with warm (44°C [111.2°F]) water for 30 seconds, followed by irrigation with cooler (30°C [86°F]) water. Warm water elicits rotatory nystagmus to the side being irrigated; cooler water produces nystagmus to the opposite side.

Canalithiasis Fragments of otoconia floating freely in the endolymph of the semicircular canal; associated with positional vertigo.

Capacity (WHO-ICF) An individual's ability to execute a task or an action; the highest probable level of functioning in a given domain at a given moment.

Capacity qualifiers An indication of the extent of activity limitation; used to describe an individual's highest probable level of functioning (ability to do the task or action).

Capsular pattern A characteristic pattern of restricted passive osteokinematic motion, usually involving more than one motion at a joint that indicates intra-articular joint inflammation or capsular fibrosis.

Cardiac index (CI) Cardiac output (CO) in relation to the body surface area (BSA), expressed in meters such that CI = CO/BSA.

Cardiac output (CO) The amount of blood discharged from the ventricles per minute, expressed in L/min; the product of heart rate (HR) and stroke volume (SV).

Cardiogenic shock Inadequate cardiac output (CO) and insufficient arterial blood pressure (BP) to perfuse the major organs owing to severe left ventricle (LV) failure.

Cardiomyopathy Any disease that affects the heart muscle, diminishing cardiac performance.

Cardiovascular disease (CVD) Any disease of the heart or blood vessels, including atherosclerosis, cardiomyopathy, coronary artery disease, peripheral vascular disease, and others.

Carpal tunnel syndrome Compression of the median nerve in the carpal tunnel, which results in weakness, pain, and changes in sensation in the hand and fingers.

Causalgia *See* **Complex regional pain syndrome**.

Cauterization Closing of tissue with a caustic chemical agent.

Center of mass (COM) The midpoint of body mass in erect standing posture; the COM is located at the level of the second sacral segment.

Center of pressure (COP) The point of application of the ground reaction force (in a symmetrical bilateral stance, it is located between the feet).

Central cord syndrome A spinal cord injury (SCI) resulting in more severe neurological involvement of the upper extremities (cervical tracts are more centrally located) than of the lower extremities (lumbar and sacral tracts are located more peripherally). Varying degrees of sensory impairment occur but tend to be less severe than motor deficits.

Central pain Pain initiated or caused by a primary lesion or dysfunction in the central nervous system.

Central post-stroke (thalamic) pain Central pain that occurs after infarction involving the spinothalamic system, ventral posterolateral thalamus, or subcortical parietal lobe; pain is described as constant and burning with intermittent sharp pains; exacerbated by noxious stimuli.

Central vestibular lesion A lesion in the vestibular nuclei or pathways carrying vestibular afferent input to the parieto-insular lobe of the cortex.

Cerebral edema An accumulation of excess fluids within the brain that begins within minutes of the insult (brain injury); significant edema can elevate intracranial pressures, leading to intracranial hypertension and brainstem herniation.

Cerebral embolus Bits of matter (blood clot, plaque, and, less commonly, air and fat) formed elsewhere are released into the bloodstream and travel to the cerebral arteries, where they lodge in a vessel, producing occlusion and infarction.

Cerebral hemorrhage (nontraumatic spontaneous hemorrhage) Typically occurs in small blood vessels weakened by atherosclerosis, producing an aneurysm.

Cerebral infarction Ischemia and necrosis of an area of the brain following a reduction of blood flow that falls below the critical level necessary for cell survival.

Cerebral shock Transient hypotonia and motor loss following injury to the brain.

Cerebral thrombosis The formation or development of a blood clot within the cerebral arteries or their branches; also includes extracranial vessels (carotid or vertebral arteries).

Cerebrovascular accident (CVA) *See* **Stroke**.

Cervical vertigo Term used to describe symptoms of dizziness, imbalance, and lightheadedness believed to arise from a cervical pathology.

Charcot joint A progressive, degenerative arthropathy of single or multiple joints caused by underlying neuropathy.

Cheyne-Stokes respiration Breathing pattern characterized by a period of apnea lasting 10 to 60 seconds, followed by gradually increasing depth and frequency of respirations (hyperventilation); occurs with depression of the cerebral hemispheres (e.g., coma), in basal ganglia disease, and occasionally in congestive heart failure.

Chorea A movement disorder characterized by involuntary, rapid, irregular, jerky movements; seen in Huntington's disease (also called choreiform movements).

Choreoathetosis Movement disorder with features of both chorea and athetosis; seen in some forms of cerebral palsy.

Chronic pain *See* **Pain**.

Chronic pain syndrome *See* **Pain**.

Chronic venous insufficiency Venous insufficiency that persists over a long period of time.

Circadian rhythm Biological process that occurs on a regular and predictable 24-hour cycle (e.g., variations in vital sign values).

Circle of Willis Normal anatomical union of the anterior, middle, and posterior cerebral arteries (branches of the carotid and vertebrobasilar arteries) forming an anastomosis at the base of the brain.

Claw toe Contraction of the proximal interphalangeal and distal interphalangeal joints of a toe, usually not the big toe; caused by tightened ligaments and tendons that produce severe pressure and pain.

Clinical reasoning The multidimensional process that involves a wide range of cognitive skills used to process information, reach decisions, and determine actions.

Closed-loop control system A motor control system that employs feedback and a reference for correctness to compute error and initiate subsequent corrections.

Closed skills Skills performed in a stable, predictable (closed) environment.

Closed wound care technique Wound-care approach that involves covering a wound from the outside environment with an appropriate dressing.

Clubbing Bulbous swelling of the distal fingers accompanied by a loss of the normal angle between the nail bed and the skin; associated with diagnoses imposing long-standing hypoxia and cyanosis such as congenital heart defects and pulmonary disorders; may also occur in the toes.

Cluster analysis A statistical technique for classifying patterns (e.g., gait), locomotion by placing subjects in

homogeneous groups, or clusters, based on specified input parameters.

Cognition The act or process of knowing, including awareness, reasoning, judgment, intuition, and memory.

Cognitive-behavioral therapy (Cognitive therapy) A psychosocial intervention that helps decrease anxiety by promoting a change in attitudes, values, or beliefs; helps to change negative maladaptive thoughts and beliefs into positive, more adaptive ones.

Cognitive deficits Below average functioning in memory, judgment, construction, attention, sequencing, planning, recognition, or sorting.

Cognitive distortions Misperceptions of thoughts, ideas, or beliefs, or exaggerations.

Cognitive restructuring The cognitive-behavioral therapy technique of reshaping a person's thoughts/beliefs.

Cognitive stage The first of three stages of motor learning (proposed by Fitts), in which the learner develops an overall understanding of the skill (cognitive map); heavily based on cognitive and visual processes.

Cogwheel rigidity *See* **Rigidity**.

Coma A state of unconsciousness from which one cannot be aroused; the patient is unresponsive to stimulation. The patient's eyes are closed, there are no sleep/wake cycles, and the patient is ventilator dependent.

Community integration Introducing or reintroducing a person into a community.

Compensated heart failure Heart failure in which the patient's congestive symptoms can be relieved by medical intervention.

Compensation (1) Making up for a defect, such as hypertrophy of cardiac muscle to offset an impairment in circulatory function; (2) accomplishment of a movement pattern or task in a way that is different than the method used before the injury.

Compensatory intervention (training) *See* **Intervention**.

Complete blood count (CBC) Analysis of blood that includes separate counts for red and white blood cells.

Complete decongestive therapy (CDT) A specialized treatment used primarily for lymphedema consisting of manual lymphatic drainage, lymphedema bandaging, skin care, compression garments, and exercise used to open collateral lymphatics, remove excess fluid from an affected limb, and provide support to the impaired integumentary system until elastic qualities return.

Complete spinal cord injury (ASIA A) No sensory or motor function in the lowest sacral segments (S4 and S5).

Complex regional pain syndrome (CRPS) A complex disorder or group of syndromes that include reflex sympathetic dystrophy (RSD) (type 1) and causalgia (type 2); symptoms include intense burning pain and related sensory abnormalities, abnormal blood flow and sweating, abnormal motor function, and trophic skin changes.

Compression The approximation of joint surfaces.

Compression therapy The use of external compression to provide therapeutic levels of support for the venous and/or lymphatic systems. May be provided with one or a combination of the following: over-the-counter or custom compression garments, bandaging, multiple-layer applications of foam and bandaging, intermittent compression pump.

Computer-aided design/computer-aided manufacture (CAD-CAM) Technique for prosthetic socket construction that involves electronic mapping of the amputated limb, relating the limb shape to socket designs, and automatic carving of a positive model over which plastic is molded to create the socket.

Conduction aphasia A rare form of aphasia, characterized by intact auditory comprehension, fluent speech production, and inability to repeat what is heard.

Congestive heart failure (CHF) Heart failure accompanied by signs and symptoms of edema (i.e., pulmonary and/or peripheral congestion).

Consciousness A state of awareness; implies orientation to person, place, and time.

Contextual factors (WHO/ICF) Represent the entire background of an individual's life and living situation and include the following:

Environmental factors Components of the physical, social, and attitudinal environment in which people live and conduct their lives, including social attitudes, architectural characteristics, and legal and social structures.

Personal factors Characteristics of an individual's life, including gender, age, coping styles, social background, education, profession, past and current experience, overall behavior pattern, character, and other factors that influence how disability is experienced by an individual.

Conversion disorder A psychological disorder expressed by symptoms or deficits in sensory or motor systems that mimic a neurological or general medical disease.

Coordination The ability to execute smooth, accurate, and controlled motor responses.

Coping skills Strategies used to adapt to and manage life's demands and roles, stress, illness, disability, or other life changes.

Coronary artery bypass graft (CABG) Surgical approach that uses a donor vessel to bypass a coronary artery lesion (narrowed lumen) and establish an alternate improved blood supply.

Coronary artery disease (CAD) Also called coronary heart disease (CHD), the pathological process of atherosclerosis specifically affecting the coronary arteries.

Cortical blindness A total failure to appreciate incoming visual sensory information owing to a lesion in the cortex, rather than injury to the eyes.

Crackles (rales) An abnormal auscultatory finding within the lungs characterized by rattling or bubbling sounds that occur because of secretions in the air passages of the respiratory tract; the sound often is compared with that of rustling a cellophane bag.

C-reactive protein (CRP) A protein produced by the liver and found in the blood; used as a measure of disease activity (immune response).

Creative arts therapists Masters'-level therapists who use an artistic modality such as art, drama, music, or dance to sustain or increase patients' functional capacities and psychosocial well-being. They are referred to as art therapists, drama therapists, music therapists, and dance therapists.

Crepitus Crackling or grating feeling or sound under the skin and in the joints; usually indicates damage or wearing of cartilage.

Cultural restraints Taboos within a particular society such as incest or manifesting anger.

Cupulolithiasis Fragments of otoconia attached to the cupula of the semicircular canals; associated with positional vertigo.

Cyanosis Bluish-gray discoloration of the skin and mucous membranes caused by an excess of deoxygenated hemoglobin in the blood; associated with decreased cardiac output, exposure to cold (vasoconstriction), or arterial or venous obstruction.

Central cyanosis Diffuse skin color changes in "central" aspects of the body (e.g., trunk, head), as well as color changes in mucous membranes; indicates marked arterial desaturation and occurs when oxygen saturation is less than 80%. Associated with diseases of the cardiovascular/pulmonary system.

Peripheral cyanosis Color changes in the nail beds and lips owing to decreased cardiac output, exposure to cold (vasoconstriction), or arterial or venous obstruction; frequently transient and is often relieved by warming the area.

Cycle time (stride time) The amount of time required to complete a gait cycle; measured in seconds.

Cyst An abnormal sac with a membranous lining that contains gas, fluid, or a semisolid material.

Cystic fibrosis A potentially fatal autosomal recessive disease that manifests itself in multiple body systems, including the lungs, the pancreas, the urogenital system, the skeleton, and the skin. Causes chronic obstructive pulmonary disease (COPD), frequent lung infections, deficient pancreatic enzymes, osteoporosis, and an abnormally high electrolyte concentration in the sweat.

D

Dakin's solution A diluted sodium hypochlorite solution used to treat skin and tissue infections. The active ingredient is chlorine bleach.

Débridement The removal of foreign material and necrotic or damaged tissue from a wound.

Decerebrate rigidity Sustained contraction and posturing of the trunk and limbs in a position of full extension; seen in the unconscious patient with severe brain injury and a lesion in the brainstem between the superior colliculi and vestibular nucleus.

Decorticate rigidity Sustained contraction and posturing of the trunk and lower limbs in extension, and the upper limbs in flexion, fists clenched; seen in the unconscious patient with severe brain injury and a lesion at the level of the diencephalon (above the superior colliculus).

Deep brain stimulation (DBS) The implantation of electrodes into the brain where they block nerve signals that cause symptoms; pacemaker is implanted within the chest; used in the treatment of Parkinson's disease.

Deep partial-thickness burn Burn injury that extends down into the deep reticular layer of the dermis.

Deep vein thrombosis (DVT) Formation of a blood clot in the deep venous system; occurring most frequently in the lower extremities; clinical manifestations include warmth, pain, and swelling in the affected extremity.

Defense mechanism A psychological means of coping with conflict or anxiety; examples include denial, sublimation, repression, rationalization, conversion, and dissociation.

Degenerative joint disease (DJD) *See* **Osteoarthritis**.

Delirium (acute confusional state) A clouding of consciousness with dulling of cognitive processes and general impairment of alertness; patients may demonstrate confusion, agitation, disorientation, and illusions or hallucinations.

Dementia A broad base of cognitive deficits caused by a progressive organic mental disorder; characterized by confusion, disorientation, memory loss, personality disintegration, and deterioration of intellectual capacity and function.

Demyelination Disruption of the myelin sheath that slows neural transmission and causes nerves to fatigue rapidly; seen in multiple sclerosis.

Denial Refusal to acknowledge the truth or reality of a situation; a defense mechanism used to alleviate the anxiety and pain associated with functional limitation or disability; removes realities from conscious awareness.

Depression A mental state characterized by feelings of despair, hopelessness, and loss of interest or pleasure in living.

Major depression A depressive episode that lasts two or more weeks and affects occupational and social functioning.

Dermatome A band or region of skin supplied by a single sensory nerve.

Desquamation Peeling of the outer layers of the epidermis.

Detoxification unit A 5- to 7-day inpatient unit that treats people who are withdrawing from drugs/alcohol.

Devaluation The patient is overly critical of others and of himself or herself and may insult therapists and other personnel.

Diagnosis (physical therapy) The identification of the impact of a condition on function at the level of the system (especially the movement system) and at the level of the whole person.

Diaphoresis Profuse sweating.

Diaphragmatic breathing Deep inhalations that utilize the lower portion of the lungs and the diaphragm muscle.

Diastole Period of cardiac muscle relaxation, alternating in the cardiac cycle with systole or contraction; cardiac muscle fibers lengthen and the chambers fill with blood.

Diastolic pressure *See* **Blood pressure**.

Diffuse axonal injury (DAI) The predominant mechanism of injury in most individuals with severe to moderate traumatic brain injury (TBI). The mechanism of DAI is microscopic; the acceleration/deceleration forces cause disruption of neurofilaments within the axon leading to axonal degeneration.

Diplopia Double vision; two images are seen that are displaced either horizontally or vertically.

Disability (WHO/ICF) Encompasses dysfunction at one or more of the following levels: impairment, activity limitation, and participation restriction.

Disablement An interaction/complex relationship between a health condition and contextual factors (i.e., environmental and personal factors).

Discourse Conversation; generally refers to written or spoken communication.

Disease A pathological condition of the body or abnormal entity with a characteristic group of signs and symptoms affecting the body; with known or unknown etiology.

Disease-modifying antirheumatic drugs (DMARDs) A classification of antirheumatic agents that can alter the course of disease, as opposed to simply treating symptoms such as inflammation and pain.

Distraction The linear separation of joint surfaces.

Distress A term denoting a negative perception or response to a stressor whereby the stressor becomes immobilizing (overwhelming), initiating a sympathetic physiological stress response on the individual. Also see *stress reaction, eustress.*

Divided attention The capacity to respond simultaneously to two or more tasks or stimuli when all stimuli are relevant.

Dix-Hallpike test *See* **Hallpike-Dix maneuver**.

Dizziness Sensation of lightheadedness, whirling, or feeling a tendency to fall.

Donor site Site from which a skin graft is taken.

Double support time The amount of time spent in the gait cycle when both lower extremities are in contact with the supporting surface; measured in seconds.

Dual-diagnosis programs Long-term treatment interventions designed for people suffering from co-occurring substance abuse and mental illness; focus is on helping individuals become sober, remain abstinent, and manage psychiatric symptoms; typically provided at specialized treatment centers.

Dynamic postural control The ability to maintain postural stability and orientation while superimposing movement (e.g., weight shifting, reaching, stepping).

Dysarthria A category of motor speech disorders caused by impairment in parts of the central or peripheral nervous system that mediate speech production. Respiration, articulation, phonation, resonance, and/or prosody may be affected; volitional and automatic actions (e.g., chewing and swallowing) and movement of the jaw and tongue may also be deviant. It excludes apraxia of speech and functional or central language disorders.

Dysautonomia Dysfunction of the autonomic nervous system, with a wide range of autonomic irregularities; a clinical feature of parkinsonism, Shy-Drager syndrome, and others.

Dyscalculia Impaired ability to perform simple arithmetic operations; difficulty in accomplishing calculations.

Dysdiadochokinesia Impaired ability to perform rapid alternating movements.

Dysequilibrium Impaired balance; sensation that one is off balance.

Dysesthesia An unpleasant abnormal sensation, such as a sense of burning, cutting, numbness, prickling, stinging, or tingling of the skin.

Dyskinesia Impaired ability to execute voluntary movement; characterized by uncontrolled or involuntary movements.

Dysmetria Impaired ability to judge the distance or range of a movement.

Dysphagia Inability to swallow or difficulty swallowing.

Dyspnea Air hunger resulting in difficult or labored breathing; sometimes accompanied by pain. Normally accompanies vigorous exercise.

Dyspraxia A disturbance in the programming, control, and execution of volitional movements.

Dyssynergia (movement decomposition) Impaired coordination of muscular contractions and movement.

Dysthymic disorder Chronic depression and dysphoric mood, resulting in poor appetite or overeating, insomnia or hypersomnia, low energy, low self-esteem, and poor concentration.

Dystonia A movement disorder characterized by disordered tone and involuntary movements involving large portions of the body, typically twisting or writhing motions.

E

Ecological approach A health promotion approach that considers the important influence of the social and physical environments on an individual's behaviors.

Ejection fraction (EF) The relationship between stroke volume (SV) and left ventricular end diastolic volume (LVEDV) such that EF = SV ÷ LVEDV. This value represents the ratio of the volume of blood ejected by the left ventricle (LV) per contraction relative to the volume of blood received by the LV following diastole. Normal EF is approximately 55%–75% (67% ± 8%) and is widely used clinically as an index of contractility.

Electrical burn Injury sustained from the passage of electrical current through the tissues of the body.

Electromyography (EMG) Recording of motor unit activity to evaluate the scope of a neuromuscular disorder by assessing muscle potentials during various stages of contraction and at rest.

Elephantiasis Most severe stage of lymphedema. It results from long-standing, untreated lymphedema.

Enablement A process by which physical or mental capacities are restored or developed by addressing the interaction between the person and the environment.

End-feel The normal tissue resistance experienced by the therapist when excessive pressure is applied at the end of a range of motion or accessory motion.

End-of-dose deterioration (wearing-off state) A worsening of symptoms during the expected timeframe of medication effectiveness; seen with long-term use of L-dopa therapy in patients with Parkinson's disease.

Endogenous Originating or produced within the organism.

Endolymph Fluid within the semicircular canals that contains a high concentration of potassium, with a lower concentration of sodium. It moves freely within each canal in response to the direction of the angular head rotation.

Environmental accessibility Absence or removal of physical barriers from the entrance of and within a building or dwelling to allow use by individuals with disabilities.

Environmental barrier Physical impediments that prevent individuals from functioning optimally in their surroundings, including safety hazards, access problems, and home or workplace design difficulties (e.g., revolving doors, stairways, narrow doorways).

Environmental control unit (ECU) An electrical interface that allows the user to control a variety of electrical appliances and devices; operation is accomplished by use of a central control panel.

Environmental factors (WHO/ICF) The physical, social, and attitudinal environment in which people live and conduct their lives, including social attitudes, architectural characteristics, and legal and social structures.

Enzymatic débridement Removal of necrotic tissue by use of topical ointments, impregnated with enzymes, placed directly in the wound.

Eosinophils A type of white blood cell, usually only accounting for about 5% of all white blood cells.

Episcleritis Irritation and inflammation of the episclera, a thin layer of tissue covering the white part (sclera) of the eye.

Epithelial healing The process of regeneration of the epidermis through epidermal cell migration, proliferation, and differentiation.

Epitope A molecular region on an antigen's surface capable of eliciting an immune response and of combining with the specific antibody produced by such a response.

Erythema Redness of the skin due to capillary dilation. In light-skinned individuals this will appear pink to bright red. In dark-skinned individuals, there is a deepening of normal color or a purple coloration.

Erythrocyte sedimentation rate (ESR) A measure of the rate of sedimentation of red blood cells (RBCs) in an anticoagulated whole blood sample over a specified period of time; an indicator of inflammatory and necrotic processes.

Eschar The dead, necrotic tissue cast off from the surface of the skin, especially after a burn wound; material is often crusty or scabbed.

Escharotomy Midlateral incision of the burned eschar used to relieve pressure in an extremity or on the trunk.

Euphoria An exaggerated feeling of well-being, a sense of optimism incongruent with the patient's incapacitating disability.

Eupnea Normal respiration.

Eustress A term denoting a positive perception or response to a stressor whereby the stressor is seen as, or becomes, enervating or motivating, rather than overwhelming or negative.

Evidence-based clinical practice guidelines (EBCPGs) Systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances.

Evidence-based practice (EBP) The integration of best research evidence with clinical expertise and the patient's unique values and circumstances.

Exacerbation (relapse) An acute worsening or flare-up of neurological signs and symptoms lasting more than 24 hours but generally of longer duration; seen in multiple sclerosis.

Executive functions (higher-order cognitive functions) Those cognitive abilities that enable a person to engage in purposeful behaviors; includes volition, planning, purposeful action, recognizing errors, problem solving, and thinking abstractly.

Exercise A subcategory of physical activity; consists of planned, structured activity intended to improve or maintain one or more components of physical fitness.

Exercise tolerance test (ETT) (stress test or graded exercise test) An examination of the ability of the cardiovascular system to accommodate increasing metabolic demand with increasing exercise intensities; monitored using electrocardiographic, hemodynamic, and symptomatic responses. Myocardial ischemia, electrical instability, and other exertional intolerance abnormalities are determined.

Exostoses A spur or bony outgrowth from a bone.

Expected outcomes The intended results of patient/client management; the predicted changes in impairments, activity limitations, and participation restrictions along with health, risk reduction and prevention, wellness and fitness, and optimization of patient/client satisfaction expected as a result of implementing the plan of care. Outcomes define the patient's expected level at the conclusion of the episode of care and should be measurable and time limited.

Expiratory reserve volume (ERV) The amount of air that can be exhaled after a tidal exhalation.

Externalized hostility Putting blame on external situations or people instead of taking responsibility for one's undesirable predicaments.

Exteroceptors Sensory receptors that provide information from the external environment.

Extra-articular Occurring outside a joint.

Exudate Fluid, cells, and other materials released from cells or blood vessels through small pores or breaks in cell membranes; usually has a high content of serum proteins, cells, or solid debris (perspiration, pus, serum).

F

Fasciculations Spontaneous potentials seen on EMG with irritation or degeneration of the anterior horn cell, chronic peripheral nerve lesions, nerve root compression, and muscle spasms or cramps.

Fatigue The inability to contract muscle repeatedly over time.

Feedback Response-produced sensory information received during or after movement; used to monitor movement output for corrective actions; may be intrinsic or augmented.

Feedforward control The sending of signals in advance of movement to ready a part of the system for incoming sensory feedback or for a future motor command; allows for anticipatory adjustments in postural activity.

Festinating gait Walking characterized by a progressive increase in speed with a shortening of stride; common in Parkinson's disease.

Fibrillation potentials Small, spontaneous, biphasic EMG spikes, classically indicative of lower motor neuron disorders or myopathies, occurring with a muscle at rest.

Fibrin A whitish-yellow protein formed by the action of thrombin on fibrinogen.

Fibroblasts Cells or corpuscles from which connective tissue is developed; produces collagen, elastin, and reticular protein fibers.

Fibrosis A condition marked by proliferation of fibrous connective tissue; spreads over or replaces normal smooth muscle or other normal organ tissue.

Finger agnosia The inability to identify the fingers on one's own hands or on the hands of the examiner, including difficulty in naming the fingers on command, identifying which finger was touched, and mimicking finger movements.

Fistula An abnormal tube-like passage from a normal cavity or tube to a free surface or to another cavity.

Flail joint An unstable, weakened joint.

Flat affect Displaying little or no emotion.

Fluent aphasia *See* **Aphasia**.

Focused attention *See* **Selective attention**.

Foot angle Angle of foot placement with respect to the line of progression; measured in degrees.

Force plates Load transducers capable of measuring ground reaction forces and the center of pressure.

Form discrimination The ability to perceive or to attend to subtle differences in form and shape.

Free-floating anxiety A psychodynamic construct denoting generalized feelings of anxiety whereby the individual is unable to state or locate the source, cause, or reason for such feelings.

Freezing A sudden episode of immobility or block in movement, seen in Parkinson's disease.

Full-thickness burn Burn involving the entire thickness of the epidermal and dermal skin.

Full-thickness skin graft Graft containing epidermis and full dermal thickness.

Function (APTA/*Guide to Physical Therapist Practice*) Those activities identified by an individual as essential to support physical, social, and psychological well-being and to create a personal sense of meaningful living.

Functional capacities The ability to perform in the following performance components: cognitive, social interactions, frustration tolerance, concentration, ambulation, stress management, time management,

activities of daily living, and life roles (work, education, household maintenance, and parenting).

Functional limitation (APTA/*Guide to Physical Therapist Practice*) The restriction of the ability to perform at the level of the whole person, a physical action, task, or activity in an efficient, typically expected, or competent manner.

Functional maintenance program A rehabilitation program designed to manage the effects of progressive disease; includes strategies to prevent or slow decline of function, and promote regular exercise, good health, and self-management skills.

Functional mobility skills (FMS) Those activity skills that involve movement of the body, including transfers, walking, and lifting or carrying objects.

Functional residual capacity (FRC) The combination of residual volume and expiratory reserve volume.

Functional training The education and training of patients in basic and instrumental activities of daily living (ADL) that are intended to improve the ability to perform physical actions, tasks, or activities in an efficient, typically expected, or competent manner.

Function-induced recovery (use-dependent cortical reorganization) The ability of the nervous system to modify itself in response to changes in activity and the environment; neural reorganization occurs as a result of increased use of involved body segments in behaviorally relevant tasks (e.g., forced use).

Fund of knowledge Mental status screening test that utilizes questions related to the patient's learning history and life experiences.

G

Gangrene Tissue death or necrosis; usually due to impaired or absent blood supply. May be localized or involve an entire extremity or organ.

Gaze A state of looking in one direction; directional gaze is determined by control of different combinations of contractions by the extraocular muscles.

Gaze instability A disturbance of eye conjugate movement in which gaze is deviated or unstable. Patients with gaze instability have difficulty maintaining visual focus during head motion.

General adaptation syndrome (GAS) An organism's immediate reaction to an extreme catastrophe; a defensive adaptation response aimed at dealing with real or perceived emergency situations.

Generalized anxiety disorder Excessive worry, apprehension, and concern persisting for at least 6 months; may be accompanied by irritability, fatigue, and disturbed sleep patterns.

Genu valgum A deformity in which the lower extremities curve inward with knees close together; knock-knees.

Genu varum A deformity in which the lower extremities curve outward with knees wide apart; bow legs.

Glide (slide) The linear (translatory) motion of one surface sliding over another surface; the same point on one surface comes into contact with new points on the other surface.

Gliosis Proliferation of neuroglial tissue within the central nervous system that results in glial scars (plaques); seen in MS.

Global aphasia *See* **Aphasia**.

Goals (anticipated) The intended results of patient/client management; the changes in impairments, activity limitations, and participation restrictions along with health promotion, risk reduction and prevention, wellness and fitness, and optimization of patient/client satisfaction that are expected as a result of implementing the plan of care. Goals define the interim steps that are necessary to achieve expected outcomes and should be measurable and time limited.

Gold standard Accepted, accurate measure of a particular phenomenon that can serve as the normative standard for other measures.

Granulation tissue A matrix of collagen, hyaluronic acid, and fibronectin in a newly formed vascular network.

Graphesthesia (traced figure identification) Recognition of numbers, letters, or symbols traced on the skin with vision occluded.

Grief A psychological state of distress or sadness associated with a significant loss.

Ground (floor) reaction force (GRF) Vertical, anterior-posterior, and medial-lateral forces created as a result of foot contact with the supporting surface; forces are equal in magnitude and opposite in direction to the force applied by the foot to the ground.

Guided movement Involves physically or verbally assisting the learner through the task or activity to be learned; behaviors are limited or controlled to prevent errors.

H

Habituation training Training using repeated movements to reduce symptoms associated with the provocative motion.

Hallpike-Dix maneuver Positional test used to reproduce symptoms of vertigo and nystagmus and diagnose benign positional vertigo.

Hallucination Sensing things that are not tangibly real and believing that they are. When visually hallucinating, people see things that are not really there. During auditory hallucinations, people hear voices and believe that others are talking to them. Tactile hallucinations are sensations of the skin that are not real, such as feeling bugs crawling on one's skin.

Hallux valgus An abnormal deviation of the big toe away from the midline of the body or toward the other toes of the foot.

Hammer toe A deformed claw-shaped toe characterized by hyperextension of the metatarsophalangeal and distal interphalangeal joints and flexion of the proximal interphalangeal joint.

Handheld dynamometer A portable testing device placed between the patient's body part and the therapist's hand that measures mechanical force.

Hassles Scale An instrument measuring the irritating and frustrating demands of everyday transactions experienced by an individual.

Head-shaking–induced nystagmus (HSN) Test used to discern asymmetry of peripheral vestibular input to the central vestibular neurons.

Head tilt Term used to indicate a static lateral flexion of the neck; may indicate utricular dysfunction.

Health A state of complete physical, mental, and social well-being and not merely the absence of diseases and infirmity.

Health condition (WHO/ICF) An umbrella term for disease, disorder, injury, or trauma; may include other circumstances, such as aging, stress, congenital anomaly, or genetic predisposition. It may also include information about pathogeneses and/or etiology.

Health education One component of health promotion, and is any combination of learning experiences designed to encourage, assist, and support individuals to voluntarily engage in health-supporting behaviors.

Health promotion Any planned combination of educational, regulatory, social, and political interventions designed to support the health of individuals or communities.

Heart failure The inability of the heart to circulate blood effectively to meet the body's metabolic needs; caused by impaired ventricle functioning of the heart, as well as dysfunction of other organs, including lungs, kidneys, and liver.

Left-sided heart failure (LHF) Occurs with failure of the left ventricle (LV) to maintain left ventricular output; leads to a backup of fluid into the left atrium (LA) and lungs, producing hallmark pulmonary signs of shortness of breath (SOB) and cough.

Right-sided heart failure (RHF) Occurs with failure of the right ventricle (RV) to maintain right ventricular output; leads to a backup of fluid into the right atrium (RA) and venous vasculature, producing hallmark peripheral signs of jugular venous distention and peripheral edema.

Heart sounds The auscultatory sounds of the cardiac cycle, identified as S1 (lub), which occurs at closure of the mitral (and tricuspid) valve and marks the beginning of systole, and S2 (dub), which occurs at aortic (and pulmonic) valve closure and marks the end of systole.

Heberden's node A bony enlargement of the end joint of a finger (DIP) commonly present with osteoarthritis.

Help-rejecting Patient approach to dealing with the stress of having covert hostile feelings toward caregivers by frequently asking for help and then rejecting every suggestion.

Hemarthrosis A bloody effusion within a joint.

Hemianopia (hemianopsia) Inability to see in one half of the visual field.

Hemiballismus Sudden, jerky, forceful, flailing motions of one side of the body.

Hemiparesis Weakness on one side of the body.

Hemiplegia Paralysis on one side of the body.

Hemispace One half of the spatial field around the body.

Hemorrhagic stroke *See* **Stroke**.

Hemosiderin staining A brownish discoloration of the skin due to a pigment released from hemoglobin following red blood cell lysis.

Hemostasis An arrest of bleeding.

Heterotopic ossification Abnormal bone growth in muscle or other connective tissue; can restrict range of motion and lead to impaired function; also known as ectopic bone formation.

Holistic A treatment approach that values the multifaceted dimensions of a patient's life, including social roles, culture, religion, gender, age, community, ethnicity, personality, social support, and anything else that has influenced or now influences the patient.

Holmes-Rahe Social Readjustment Rating Scale One of the better-known and widely used assessment instruments that quantifies the effects of life changes on stress and health.

Honeycombing A radiological term used to describe the presence of many small, thick-walled, air-filled cysts that result from interstitial pulmonary fibrosis and tissue remodeling.

Hyperalgesia An excessive sensitivity to pain.

Hyperarousal Excessive responsiveness to sensory stimulation; found in traumatic brain injury, post-traumatic stress disorder, alcohol withdrawal, and other conditions.

Hypercapnea Increased levels of carbon dioxide in the blood; caused by inadequate ventilation or large imbalance between ventilation and perfusion of the blood.

Hyperesthesia Increased sensitivity to stimulation, excluding the special senses. Hyperesthesia includes both allodynia and hyperalgesia, but the more specific terms should be used wherever they are applicable.

Hyperinflation An abnormal increase in the amount of air within the thorax at the end of a tidal exhalation.

Hyperkeratosis A local overabundant thickening of skin.

Hyperkinesia (hyperkinesis) A general term used to describe abnormally increased muscle activity or movement; restlessness.

Hypermetria Excessive distance or range of a movement; an overestimation of the required motion needed to reach a target object.

Hypermobility Excessive joint motion.

Hyperpathia A painful syndrome characterized by an abnormally painful reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold.

Hyperreactivity Increased or excessive activity of any cell, organ, tissue, or organism.

Hyperreflexia Increased reflex responses.

Hypertension Higher than normal blood pressure; systolic blood pressure (SBP) is consistently greater than 140 mm Hg and/or diastolic blood pressure (DBP) is equal to or greater than 90 mm Hg.

Hypertonia Abnormally increased muscle tone.

Hypertrophic scar Scar overgrowth that stays within the boundaries of a wound and is characteristically described as red, raised, and firm.

Hyperventilation Abnormally fast rate and depth of respiration.

Hypocapnia An abnormally low level of carbon dioxide in the blood; associated with hyperventilation.

Hypokinesia A state of diminished ability to move; an overall decrease in motor reaction to stimulus, difficulty initiating movement, and a decrease in the total number and amplitude of movements.

Hypokinetic dysarthria Difficult and defective speech characterized by decreased voice volume, monotone/monopitch speech, imprecise or distorted articulation, and uncontrolled speech rate; common in Parkinson's disease.

Hypometria Shortened distance or range of a movement; an underestimation of the required motion needed to reach a target object.

Hypomimia A reduction in movements and expressiveness of the face.

Hypomobility Restricted joint motion.

Hypotension An abnormally low blood pressure not adequate for normal perfusion and oxygenation of the tissues.

Orthostatic hypotension A sudden drop in blood pressure with movement to an upright position after getting up from a bed or chair.

Hypothermia Core body temperature is below 35°C (95°F).

Hypotonia Muscle tone is reduced below normal resting levels.

Hypoventilation Decrease in the rate and depth of respiration.

Hypovolemia Abnormally low volume of circulating blood in the body.

Hypovolemic shock Shock caused by substantial fluid loss from intravascular space (e.g., loss of blood or electrolyte solution).

Hypoxemia Decreased oxygen concentration in arterial blood; measured by arterial oxygen partial pressures values.

Hypoxia Oxygen deficiency in body tissues.

I

Iatrogenic Any injury or illness that occurs as a result of medical or surgical treatment.

Ideational apraxia *See* **Apraxia**.

Ideomotor apraxia *See* **Apraxia**.

Illness Encompasses the personal behaviors that emerge when the reality of having a disease is internalized and experienced by an individual.

Imagery Visualizing a scene or mentally rehearsing a script for a specific purpose such as relaxation.

Immediate postoperative prosthesis (IPOP) Following lower limb amputation, immediately fitting the residual limb with a prosthetic socket-shaped dressing in surgery.

Immediate recall Retention of information that has been stored for several seconds.

Immune response Response to an antigen that occurs when lymphocytes identify an antigenic molecule as foreign and produce antibodies and lymphocytes capable of reacting with it and rendering it harmless.

Impairment (WHO/ICF) A problem in body function or structure, such as a significant deviation or loss.

Inclinometer A device that uses gravity's effect on pointers or fluid levels to measure joint position and motion.

Incomplete injury (SCI) A spinal cord injury having motor and/or sensory function below the neurological level including sensory and/or motor function at S4 and S5.

Indurated Hardened, as in an area of hardened tissue.

Inhalation injury Injury to the lungs due to breathing hot and/or toxic gases; associated with burns in a closed space.

Inhibitory cutoff The velocity at which inhibition (hyperpolarization) of the vestibular afferents in the contra-rotational labyrinth becomes zero.

Initial contact (gait) The moment in time when the outstretched limb first contacts the ground to initiate

stance and a new gait cycle; period of double-limb support.

Initial swing (gait) The first one third of swing; begins when the foot lifts from the ground.

Inspiratory capacity (IC) Tidal volume plus inspiratory reserve volume; the amount of air that can be inhaled from the end of a tidal exhalation.

Inspiratory reserve volume (IRV) The amount of air that can be inspired after a tidal inspiration.

Instrumental activities of daily living (IADL) *See* **Activities of daily living**.

Intention tremor (action tremor) *See* **Tremor**.

Intermittent claudication Severe pain in the lower extremity that occurs with activity but subsides with rest; the result of inadequate arterial blood supply to the exercising muscles.

Internalized anger Anger turned inward instead of expressed outwardly toward a situation or person.

International Classification of Functioning, Disability, and Health (ICF) A meaningful description of the components of health and its relationship to a person with a health condition; from the World Health Organization (WHO).

Interoceptive exposure exercises A desensitization tool often used for post-traumatic stress disorder to help patients cope with uncomfortable physiological sensations.

Interval measure Utilizes a classification scheme in which values are separated by equal intervals, but has no true zero.

Intervention (APTA/*Guide to Physical Therapist Practice*) The purposeful interaction of the physical therapist with the patient/client and, when appropriate, other individuals involved in the care of the patient/client, using various physical therapy procedures and techniques to produce changes in the condition.

Compensatory intervention Treatment directed toward improving the patient's status in terms of impairments, activity limitations, participation restrictions, and recovery of function; directed toward performing the movement pattern or task in a way that is different than the method used prior to the injury. Includes use of adaptive equipment and technology to accomplish the task.

Restorative intervention Treatment directed toward remediating or improving the patient's status in terms of impairments, activity limitations, participation restrictions, and recovery of function; directed toward performing the movement pattern or task in the same manner as was performed premorbidly.

Intracerebral hemorrhage (IH) Rupture of a cerebral blood vessel with subsequent bleeding into the brain.

Intracranial pressure (ICP) Measure of pressure inside the cranium; normal ICP is 5 to 10 mm Hg.

Intrusive recollections The experiencing of dreams and nightmares about disturbing events of the past; often experienced with post-traumatic stress disorder.

Ipsilateral pushing (contraversive pushing, Pusher syndrome) An unusual motor behavior following stroke characterized by active pushing with the stronger extremities toward the hemiparetic side, leading to a lateral postural imbalance and a tendency to fall toward the hemiparetic side.

Ischemia A temporary deficiency in oxygenated blood supply to an organ or tissue.

Ischemic cascade (secondary injury) Brain cell injury and death that progresses rapidly within the core infarction area and over time within the ischemic penumbra (the transitional area surrounding the ischemic core).

Ischemic stroke *See* **Stroke**.

Isokinetic dynamometer A testing and exercise device that controls the velocity of a limb's movement, keeping it at a constant rate while offering accommodating resistance throughout the range of motion.

J

Joint mobilization Passive therapeutic techniques applied specifically to joint structures that utilize arthrokinematic motions to increase or maintain joint play and range of motion or to treat pain.

Joint play (accessory) motions Motions that occur between joint surfaces that accompany osteokinematic motions but are not under voluntary control; includes glides (slides), distractions, compressions, rolls, and spins. Joint play can also refer to the distensibility of the joint capsule and ligaments that allow joint motion to occur.

K

Kinematic analysis A description of the type, amount, and direction of motion; does not include the forces producing the motion.

Kinesthesia The ability to perceive the extent (range) and direction of movement; awareness of movement.

Kinetic analysis The study of the forces that cause motion.

Knowledge of performance (KP) Augmented feedback about the nature or quality of the movement pattern produced; information about movement kinematics.

Knowledge of results (KR) Augmented feedback about the nature of the end result of movement produced in relation to the goal; information about movement outcome.

L

Lacunar infarction *See* **Stroke**.

Lag phenomenon Describes a substantial difference in passive versus active range of motion secondary to tendon damage or muscle weakness.

Lateropulsion Tendency to fall to one side.

Lead pipe rigidity *See* **Rigidity**.

Lead-up tasks Component tasks or activities used to prepare learners for more important and complex functional tasks.

Left-sided heart failure *See* **Heart failure**.

Lexicon The vocabulary of a language, an individual speaker, or group of speakers, or a subject.

Lhermitte's sign A sign of posterior column damage in the spinal cord; flexion of the neck produces an electric shock–like sensation running down the spine and into the lower extremities.

Life roles Areas of responsibility in a person's life, such as father, worker, student, community member, or athlete.

Ligamentous instability test (ligament stress test) A test in which a patient's joint is maneuvered passively to determine the integrity of ligaments and other joint structures.

Lightheadedness Sense of feeling as if about to faint.

Limits of stability (LOS) The maximum distance an individual is able or willing to lean in any direction without loss of balance or changing the base of support (BOS); the midpoint of limits of stability is centered alignment (center of mass [COM] alignment).

Linear velocity The rate at which a body moves in a straight line.

Linear work Force multiplied by distance.

Lipodermatosclerosis The progressive replacement of skin, subcutaneous connective, and adipose tissues by fibrous tissue (sclerosis). This can occur as a result of calf pump failure in chronic venous insufficiency, and as a result of long-standing inflammation or edema in lymphedema.

Loading response (gait) The phase during which body weight is rapidly accepted onto the outstretched limb; the shock associated with loading the limb is absorbed while stability is maintained; period of double limb support.

Locked-in syndrome (LIS) Tetraplegia (complete paralysis) and lower bulbar palsy (anarthria) with preserved consciousness following stroke involving bilateral infarction of the ventral pons.

Locus of control A belief about one's ability to control life conditions and events.

Long-term memory Recall of early experiences and information acquired over a period of years from the distant past.

Lower motor neuron A peripheral motor neuron that originates in the ventral horns of the gray matter of the spinal cord and terminates in skeletal muscles.

Lower motor neuron syndrome Lesions affecting the anterior horn cell or peripheral nerve produce decreased or absent tone, hyporeflexia, weakness or paralysis, muscle fasciculations and fibrillations with denervation, and neurogenic atrophy.

Lymphedema An abnormal accumulation of tissue fluid in the interstitial spaces produced by impairment of normal uptake of tissue fluid by the lymphatic vessels or the excessive production of tissue fluid caused by venous obstruction that increases capillary blood pressure; can be primary (congenital) or secondary (following surgical removal of lymph channels).

Primary lymphedema Lymphedema caused by a condition that is congenital or hereditary with abnormal lymph node or lymph vessel formation.

Secondary lymphedema Lymphedema caused by injury to one or more components of the lymphatic system; some portion of the lymphatic system has been blocked, dissected, fibrosed, or otherwise damaged or altered.

Lymphorrhea Flow of lymph from ruptured lymph vessels to the surface of the skin.

Lymphscintigraphy A test performed using dye and a specialized camera and computer to visualize a variety of lymphatic system functions.

M

Maceration The process of softening a solid (skin) by saturating it with fluid or drainage.

Make test (active resistance test) A method of applying resistance during manual muscle testing in which the patient moves through an arc of motion against the therapist's resistance. In handheld dynamometry, the term also has been used to indicate a patient's performance of a maximal isometric contraction against the therapist's resistance.

Maladaptive thought patterns Repetitive thoughts that inhibit a productive, happy life.

Malignant pain *See* **Pain**.

Malinger To feign illness or symptoms often to support claims made in a lawsuit.

Mallet finger Flexion of the distal phalanx of a finger caused by avulsion of the extensor tendon; also called drop finger or baseball finger.

Manual muscle testing (MMT) A formal examination and grading system that uses arc of motion, gravity, and manually applied resistance to quantify muscle strength on an ordinal scale.

Maximal oxygen uptake (VO_{2max}) The product of maximal cardiac output (L blood·min^{-1}) and arteriovenous oxygen difference (mL O_2 per L blood).

Memory Mental process that allows retention and recall of past experiences, perceptions, knowledge, or thoughts.

Ménière's disease Recurrent group of symptoms including episodic vertigo, tinnitus, sensation of fullness in the ear, and hearing loss.

Mesh graft Process whereby the donor skin is placed through a device that increases the surface area of the graft.

Metabolic equivalents (METs) A rating of energy expenditure for a given activity based on oxygen consumption; one MET represents the basic systemic oxygen requirement at rest, roughly 3.5 mL O_2/kg/min.

Metatarsalgia A cramping burning pain below and between the metatarsal bones.

Micrographia An abnormally small handwriting that is difficult to read; commonly seen in Parkinson's disease.

Micturition Voiding of urine; urination.

Mid stance (gait) The phase during which body weight progresses over a single stable limb.

Mid swing (gait) The phase that occurs during the middle third of swing as the thigh advances forward and the tibia achieves a vertical position.

Milroy's disease The autosomal dominant, congenital form of lymphedema resulting in the aplasia or hypoplasia of lymph vessels.

Minimal clinical important difference (MCID) The smallest difference in a measured variable that signifies an important rather than trivial difference in the patient's condition.

Minimal detectable change (MDC) The smallest amount of change in a measurement which exceeds the measurement error of the instrument.

Minimally conscious state Condition of low arousal in patients with severe traumatic brain injury. There is some, but minimal evidence of self-awareness or environmental awareness. Cognitively mediated behaviors occur inconsistently and are reproducible or sustained such that they can be differentiated from reflexive behaviors.

Moment torque A force that produces rotation; force multiplied by the perpendicular distance from the axis of rotation.

Motivation The internal state that tends to affect or stimulate behavior and direct an individual toward a goal.

Motor ability (capability, aptitude) A relatively stable characteristic or trait that is genetically determined or developed during growth and maturation; largely unmodifiable by practice.

Motor control An area of study dealing with the understanding of the neural, physical, and behavioral aspects of biological (human) movement.

Motor development The evolution of changes in motor behavior occurring as a result of growth, maturation, and experience across the life span.

Motor learning A set of internal processes associated with practice or experience leading to relatively permanent changes in motor skill capability.

Motor level In spinal cord injury, the most caudal segment of the spinal cord with normal motor function bilaterally.

Motor neuron disease A heterogeneous spectrum of inherited or acquired clinical disorders of the upper motor neurons, lower motor neurons, or both.

Motor plan An idea or plan for purposeful movement made up of component motor programs; a complex motor program.

Motor planning Movement preparation including the when, where, and how to initiate movement.

Motor (procedural) memory The memory for movement or motor information.

Motor program An abstract representation that, when initiated, results in the production of a coordinated movement sequence.

Motor unit action potential (MUAP) Depolarization of the motor nerve produces electrical activity that is recorded and displayed graphically as the MUAP; characterized by its amplitude, duration, and shape.

Multidisciplinary team conference A meeting of professionals with different fields of expertise (e.g., medicine, social work, nursing, occupational and physical therapy, speech-language pathology) used to discuss the progress and future plans of patients.

Multi-infarct dementia Deteriorative mental state characterized by reduction in intellectual faculties; the result of multiple small strokes.

Multiple sclerosis (MS) A chronic disease of the central nervous system characterized by inflammation, selective demyelination, and gliosis of neurons of the brain and spinal cord. This results in disruptions in nerve impulse conduction causing symptoms of weakness, loss of coordination, numbness, and disturbances of visual, bowel, bladder, and sexual functions.

Murmur An abnormal sound when listening to the heart or neighboring large blood vessels.

Muscle endurance The ability to sustain forces repeatedly or to generate forces over a period of time.

Muscle performance The capacity of a muscle or group of muscles to generate forces.

Muscle power Work produced per unit of time or the product of strength and speed.

Muscle strength The force exerted by a muscle to overcome resistance in one maximal effort.

Muscle tension State of partial muscle contraction that is characterized by persistent, involuntary contraction of muscle fibers or of a muscle or muscles; can be increased with pain and excessive irritability.

Muscle tone The velocity-dependent resistance to stretch exhibited by muscles.

Musculoskeletal injury Injury to muscular or skeletal system that affects movement.

Acute stage First 48 to 72 hours following the onset of injury; usually characterized by tissue inflammation associated with hyperemia.

Chronic stage Time span beyond 3 to 6 months following the onset of a condition; characterized by the body's attempt at tissue repair.

Subacute stage The time period between the acute and chronic stages of a condition; considered to begin by 72 hours after injury and continuing for as long as 3 to 6 months.

Mutism Inability or unwillingness to speak.

Myocardial infarction (MI) Death of myocardial cells as a result of coronary artery occlusion.

Myocardial oxygen demand (MVO) The amount of oxygen required for the metabolic needs of the myocardium; clinically calculated as the product of heart rate (HR) and systolic blood pressure (SBP), known as the rate pressure product (RPP).

Myodesis Suturing muscle to bone.

Myopathy Primary disease of muscle; may be congenital or acquired.

Myoplasty Plastic surgery of muscles.

Myositis Inflammation of muscle tissue; often produces pain, stiffness, and weakness.

Myxoid Containing or resembling mucus.

N

Necrosis The death of cells, tissues, or organs.

Nerve conduction velocity (NCV) test Involves direct stimulation of motor or sensory nerves to determine the velocity of conduction of an impulse; used to identify blockage or disruption of nerve integrity.

Neurapraxia A temporary impairment in nerve conduction typically caused by local compression or blockage of a peripheral nerve, such as in carpal tunnel syndrome.

Neurological level In spinal cord injury, the most caudal level of the spinal cord with normal motor and sensory function on both the left and right sides of the body.

Neuroma A benign neoplasm composed largely of neurons and nerve fibers usually arising from nerve tissue; associated with radiating pain along the peripheral nerve.

Neuropathy Any disease of nerves; characterized by inflammation or degeneration.

Polyneuropathy Affects multiple nerves and typically results in sensory changes, distal weakness, and hyporeflexia (e.g., diabetic polyneuropathy).

Neuroplasticity The ability of the nervous system to adapt to trauma or disease; the ability of nerve cells to alter their structure and function in response to internal and external factors.

Neurotmesis Nerve injury with complete loss of function of the nerve and disruption of the neural tube.

Neutrophils A common type of white blood cell, making up about 50% to 75% of all white blood cells; these cells increase in response to infection.

Nocebo (nocebo effect) The opposite of a placebo or the placebo effect. A nocebo is an inert treatment or event that increases symptoms because the patient believes it will increase symptoms. The expectation of pain can result in both increased pain from painful stimuli and allodynia, pain from a normally nonpainful stimulus.

Nociceptive pain *See* **Pain**.

Nominal measure Utilizes a classification scheme based on categories without order or rank, the simplest of which are dichotomous response sets such as "present/absent" and "yes/no"; may also have more than two categories.

Noncapsular pattern A restriction of passive osteokinematic motion; not consistent with proportioned restriction of a capsular pattern; indicates a cause other than intra-articular inflammation or capsular fibrosis.

Nonfluent aphasia *See* **Aphasia**.

Numbing or psychic numbing (emotional anesthesia) Feelings of being detached or estranged from others, a loss of ability or interest in previously enjoyable activities, or the lack of any emotions or feelings.

Nutritionist A professional trained to educate and provide patients with appropriate diets based on their individual needs, and to educate them on the benefits of good nutrition.

Nystagmus Involuntary rhythmic or cyclical movements of the eyes in any direction. If due to vestibular asymmetry, it has clearly defined fast and slow components beating in opposite directions.

Pendular nystagmus Nystagmus characterized by movement that is approximately equal in both directions.

Positional nystagmus Nystagmus induced by change in head position.

Spontaneous nystagmus Nystagmus that is present when the head is still. Often due to acute vestibular pathology and generally resolves within 7 days.

O

Obligatory synergies Strongly linked muscles that act together in an abnormal and stereotyped movement pattern; isolated joint movements outside an obligatory synergy are not possible.

Occupational therapist A professional who helps patients maximize functional capacities and performance using a holistic approach and a variety of modalities including group, family, role related activities, individual therapy sessions, and activity analyses and training.

Ocular pursuit The ability of the eyes to follow a moving object.

Ocular tilt reaction (OTR) Triad of ocular signs including skew deviation, ocular torsion, and head tilt.

Ocular torsion The superior poles of the eyes rotate in a clockwise or counterclockwise direction.

On–off phenomenon Abrupt and often unpredictable fluctuations in motor performance and response; common in Parkinson's disease with progression and long-term use of L-dopa therapy.

Open-loop control system A motor control system that employs a control system with preprogrammed instructions (motor program) to a set of effectors; run off virtually without the influence of peripheral feedback or error detection processes.

Open skills Skills that are performed in a changing, unpredictable environment.

Open (wound care) technique Absence of dressings; often used after skin grafting to the face.

Opera-glass hand A deformity of the hand seen in chronic absorptive arthritis; the fingers and wrists are shortened with bone absorption and skin hangs in folds over the joints creating an appearance that the phalanges are retracted telescopically into one another.

Ordinal measure Utilizes a classification scheme that rates observations in terms of the relationship between items (e.g., less than, equal to, or greater than).

Orientation The ability to comprehend and to adjust oneself within an unfamiliar environment with respect to awareness of time, person, and place.

Orthopnea Labored breathing that occurs when lying flat and improves by moving to sitting or standing.

Orthostatic hypotension *See* **Hypotension**.

Oscillopsia A subjective perception that stationary objects in the visual environment are swinging or in motion.

Osteoarthritis (OA) (degenerative joint disease [DJD]) Disease of the cartilage characterized by degenerative and/or hypertrophic changes in the bone and cartilage in one or more joints eventually leading to joint destruction, pain, swelling, and stiffness.

Osteokinematics Gross, angular motions of bones around a joint axis, such as flexion, extension, abduction, adduction, or rotation.

Osteomyelitis Inflammation of the bone marrow and adjacent bone, caused by a pathogenic organism.

Osteophyte A pathological bony outgrowth usually from the joint margin.

Osteoporosis A condition characterized by decrease in bone mass with decreased density and enlargement of bone spaces producing porous and brittle bones.

Osteotomy Surgical excision of a bone usually performed to correct a deformity.

Otolith organs Vestibular organs that detect linear acceleration.

Ototoxicity Toxicity of cranial nerve VIII or the vestibular system; caused by certain antibiotics (aminoglycosides [gentamycin, streptomycin]).

P

Pack-years (smoking) The number of packs of cigarettes smoked per day times the number of years of smoking.

Pain An unpleasant sensory and emotional experience associated with actual or potential tissue damage, (or described in terms of such damage) or psychological origin.

Acute pain Pain that is associated with tissue damage or the threat of such damage that typically resolves once the tissue heals or the threat resolves.

Chronic pain Pain that persists past the healing phase following an injury; impairment is greater than anticipated based on the physical findings or injury and occurs in the absence or observed tissue injury or damage.

Chronic pain syndrome Pain that exists when individuals have developed extensive pain behaviors such as preoccupation with pain, passive approach to health care, significant life disruption, feelings of isolation, doctor shopping, or are demanding or angry.

Malignant pain Pain associated with cancer.

Nociceptive pain Pain that arises from actual or threatened damage to non-neural tissue and is due to the activation of pain receptors, nociceptors.

Psychogenic pain An older term for pain believed to be caused by psychological influences when organic were absent or not severe enough to explain complaint.

Recurrent pain Repeated episodes of acute pain.

Referred pain Spontaneous pain outside the area of injury or source of pain.

Pain neuromatrix A complex network of synaptic links within the central nervous system, initially determined by genetics but modified by psychological and sensory inputs both before and during the pain experience.

Palliative care A care approach for individuals with life-threatening illnesses that focuses on improving quality of life for patients and their families through the management of pain and other physical, psychosocial, and spiritual problems.

Pallor Paleness or absence of color in the skin.

Panic attack Sudden onset of intense apprehension, fear, or discomfort; may include feelings of imminent danger or impending doom.

Panic disorder A disorder in which individuals suffer from recurrent panic attacks.

Pannus Inflammatory granulation tissue seen in rheumatoid arthritis that spreads from the synovial membrane and invades the joint eventually leading to joint ankylosis.

Papilloma Epithelial tumor of skin consisting of hypertrophied papillae covered by a layer of epithelium. Warts and polyps are examples of papillomas.

Papules Red elevated areas on the skin.

Paraplegia Complete paralysis of all or part of the trunk and both lower extremities.

Paresthesia An abnormal sensation, whether spontaneous or evoked.

Paroxysmal nocturnal dyspnea (PND) Labored or difficult breathing (shortness of breath [SOB]) that awakens a person suddenly from sleep.

Partial-thickness burn Burn involving the epidermis and part of the dermis. Subcategories are superficial partial-thickness and deep partial-thickness burns, depending on the amount of dermis involved.

Participation (WHO/ICF) Involvement in a life situation.

Participation restrictions (WHO/ICF) Problems an individual may experience in involvement in life situations.

Passive range of motion (PROM) *See* **Range of motion**.

Pastoral counselors People with a particular religious affiliation trained to counsel others in need; many hospitals are staffed with pastoral counselors available 24 hours a day.

Patellar-tendon-bearing (PTB) Refers to the total-contact transtibial socket that places moderate load on the patellar tendon.

Pendular nystagmus *See* **Nystagmus**.

Perception The process of selection, integration, and interpretation of stimuli from one's own body and the surrounding environment.

Percussion (respiratory technique) A procedure utilized with pulmonary postural drainage to loosen secretions from the bronchial walls; the therapist uses slightly cupped hands to percuss the chest wall.

Percutaneous transluminal coronary angioplasty (PTCA) A procedure in which a catheter is placed within the coronary arteries at the site of a lesion; a balloon is inflated and stent positioned to compress plaque against the arterial wall, thereby increasing the luminal area. The balloon is deflated and removed and the stent remains to hold the lumen open.

Performance The ability to produce a movement; a manner of functioning dependent on an understanding of the nature of the task and practice.

Performance-based test Examination of a particular skill based on observation during the performance of an activity.

Performance curve Used to plot performance trials and determine the average of a subject or group of subjects across a number of practice trials.

Performance qualifiers Indicate the extent of participation restriction (difficulty) in performing tasks or actions in an individual's current real-life environment.

Perfusion The flow of blood to an organ's tissue.

Perilymphatic fistula (PLF) A rupture of the oval or round windows, causing an opening between the middle and inner ear.

Peripheral arterial disease (PAD) Atherosclerotic disease affecting the aortoiliac, axillary, carotid, or femoral arteries; contributes to claudication, ischemic rest pain, amputation, stroke, and other conditions.

Peripheral cyanosis *See* **Cyanosis**.

Peripheral neuropathy Pathological condition of the peripheral nerves; characterized by muscle weakness, paresthesias, impaired reflexes, and autonomic symptoms.

Peripheral vascular disease (PVD) Any condition of the blood vessels that causes partial or complete obstruction of flow of blood to or from the arteries or veins outside the chest.

Peripheral vestibular lesion A lesion of the peripheral vestibular organ or cranial nerve VIII.

Perseveration (perseverate) Abnormal compulsive and inappropriate repetition of words or behaviors; observed in patients with diseases of the frontal lobes of the brain or schizophrenia.

Persistent vegetative state A continuing and unremitting clinical condition of complete unawareness of the environment accompanied by sleep–wake cycles with either complete or partial preservation of hypothalamic and brainstem autonomic functions. The patient may have reflexive movement and the eyes may be open, but there is no awareness of the surroundings or situation. Cognitive and communication function is absent.

Personal factors (WHO/ICF) The particular background of an individual's life, including gender, age, coping styles, social background, education, profession, past and current experience, overall behavior pattern, character, and other factors that influence how disability is experienced by an individual.

Pes equinus A foot deformity in which the heel is elevated and the foot is maintained in plantarflexion.

Pes planus A foot deformity in which the longitudinal arch is flattened; flat foot.

Pes valgus (talipes valgus) A foot deformity in which the heel and foot are turned outward.

Pes varus (talipes varus) A foot deformity in which the heel and foot are turned inward.

Phantom limb pain Any of a series of painful sensations experienced in the limb or part of a limb that has been amputated.

Phantom limb sensation The feeling that a limb or part of a limb is still there after it has been amputated; normal response following amputation that subsides over time.

Phobia An unrelenting, irrational, intense fear of a specific object or situation; associated with a persistent desire to avoid the feared (phobic) stimulus; may interfere with social functioning.

Phoneme The smallest phonetic unit in a language that is capable of conveying a distinction in meaning, as the "m" of mat and the "b" of bat in English.

Phonology The study of how sounds are organized and used in natural languages.

Physical activity Any body movement produced by skeletal muscle contraction that increases energy expenditure above resting level.

Physical function (APTA/*Guide to Physical Therapist Practice*) Fundamental component of health status describing the state of those sensory and motor skills necessary for usual daily activities, including work and recreation.

Piston action (pistoning) Vertical motion of the prosthetic socket on the amputated limb; evident during gait as an up-and-down movement of the prosthesis. Pistoning is caused by looseness of the socket or inadequate suspension, or both.

Pitting edema Peripheral edema particularly evident in gravity-dependent lower extremities by the presence of indentations in the skin when pressure is applied.

Placebo (placebo effect) A placebo is an inert treatment, such as a sugar pill or fake treatment, that is beneficial because the patient believes it will be beneficial.

Plan of care (POC) (APTA/*Guide to Physical Therapist Practice*) An outline of anticipated patient management including anticipated goals and expected outcomes; the predicted level of optimal improvement; specific interventions to be used and proposed duration and frequency of interventions; and anticipated discharge plans.

Polyarthritis Arthritis involving two or more joints.

Polycythemia A greater than usual amount of circulating red blood cells.

Polyethylene Thermoplastic material used for flexible prosthetic sockets; the plastic becomes malleable when heated, permitting its contour to be changed.

Polyneuropathy *See* **Neuropathy**.

Polyphasic potentials Motor unit potentials with more than three phases, typically seen with active contraction in myopathies or with reinnervation.

Positional nystagmus *See* **Nystagmus**.

Position in space impairment The inability to perceive and interpret spatial concepts such as up, down, under, over, in, out, in front of, and behind.

Positive sharp waves Spontaneous, biphasic EMG spike with a sharp initial positive deflection (below baseline) followed by a slow negative phase; typically indicative of motor neuron disorders, denervation, or myopathies.

Post-traumatic amnesia (PTA) Loss of memory for events immediately following a trauma/brain injury.

Post-traumatic stress disorder (PTSD) An anxiety disorder resulting from exposure to a traumatic event or ongoing chronic abuse.

Postural control The ability to control the body's position in space for stability and orientation.

Postural drainage (respiratory technique) Positioning a patient such that the bronchus is perpendicular to the ground and the mucociliary transport of secretions is facilitated.

Postural orientation The control of relative positions of body parts by skeletal muscles with respect to each other and gravity; the ability to maintain normal alignment relationships between the various body segments and between the body and environment.

Postural stress syndrome Postural abnormalities and stress secondary to lack of movement, muscle rigidity, faulty posture, and ligamentous strain.

Postural tremor (static tremor) *See* **Tremor**.

Pragmatic language Refers to the component of communication that goes beyond language in terms of isolated word meaning and grammar; a system of rules that governs the appropriate use of language for the communicative context, especially in interpersonal situations.

Premorbid Occurring before a patient became ill or injured.

Pressure Calculated as the force per unit area; generally expressed as N/cm^2 or kPa.

Pressure ulcer (pressure or bed sore) Damage to the skin or underlying structures as a result of tissue

compression and inadequate perfusion; typically occurs on skin areas over bony prominences in patients who are bed or chair bound.

Pre-swing (gait) The phase during which body weight is rapidly unloaded from the reference limb to the contralateral limb that has just made contact with the ground; period of double-limb support.

Prevention (APTA/*Guide to Physical Therapist Practice*) Activities that are directed toward (1) achieving and restoring optimal functional capacity; (2) minimizing impairments, activity limitations, and participation restrictions; (3) maintaining health; and (4) creating appropriate environmental adaptations to enhance independent function.

Primary prevention Prevention of disease in a susceptible or potentially susceptible population through specific measures.

Secondary prevention Efforts to decrease the duration of illness, severity of diseases, and sequelae through early diagnosis and prompt intervention.

Tertiary prevention Efforts to limit the degree of disability and promote rehabilitation and restoration of function in patients/clients with chronic and irreversible diseases.

Primary excision Surgical removal of eschar.

Primary lymphedema *See* **Lymphedema**.

Primary prevention *See* **Prevention**.

Primary progressive aphasia (PPA) *See* **Aphasia**.

Prognosis The predicted optimal level of improvement in function and amount of time needed to reach that level.

Proprioception The awareness of position sense and posture.

Proprioceptors Sensory receptors that respond to pressure, position, or stretch; found in muscles, tendons, ligaments, joints, and fascia.

Prosodic features The rhythmic and intonational elements of speech that are relatively independent of the quality of speech sounds; they are organized into autonomous systems, of which the most important are rate, stress, and intonation.

Prosopagnosia An inability to recognize faces or other visual stimuli as being familiar and distinct from one another.

Protective sensation The level of intact sensation needed to allow an individual to sense trauma to the body part in order to protect the traumatized area.

Protrusio acetabuli An uncommon defect of the acetabulum whereby the acetabulum is too deep and may extend into the pelvis.

Pseudobulbar affect (PBA) (emotional dysregulation syndrome) Unstable or changeable emotional state characterized by sudden and unpredictable episodes of crying, laughing, or other emotional displays inconsistent with mood and context.

Pseudoexacerbation Refers to the temporary worsening of symptoms that typically comes and goes quickly, usually within 24 hours; for example, excess heat in patients with multiple sclerosis.

Pseudolaxity Apparent laxity of a ligament due to joint space narrowing.

Pseudomonas aeruginosa A gram-negative bacteria noted for its resistance to antibiotics.

Psychiatric nurse Nurses who work with clients with psychiatric disorders with specific knowledge and expertise in this area.

Psychiatrist A physician who has completed 4 years of residency (1 year in internal medicine and 3 years in psychiatry) who provides psychiatric treatment using psychotropic medications and/or individual therapy.

Psychoeducation Instruction provided to patients with mental health conditions and/or their family members or caregivers.

Psychogenic pain *See* **Pain**.

Psychological function Ability to use mental and affective resources effectively relative to the requirements of a particular situation.

Psychological needs Emotional requirements that differ among individuals but may include love, attention, peace of mind, nurturance, feeling safe, and social support.

Psychologist A professional with a doctoral degree in psychology trained in research, personality theories, psychopathology, cognition, assessment of psychiatric patients, group therapy, cognitive-behavioral therapy, and other interventions.

Psychomotor retardation Slow movements that result from depression.

Psychosocial adaptation (to a disability or chronic illness) An ongoing, dynamic, evolving process through which a patient strives to attain an optimal state of function within his or her environment.

Psychosomatic Feeling ill without evident physical cause.

Pulmonary edema Pulmonary congestion; may be due to an increase in capillary hydrostatic pressure (e.g., left ventricular dysfunction), decreased plasma oncotic pressure, lymphatic insufficiency, altered alveolar-capillary membrane permeability, or other less common causes.

Pulse pressure The difference between the diastolic and systolic blood pressures.

Purposeful activities Activities used in rehabilitation for the purpose of attaining goals (goal-directed) and that patients find meaningful.

Pursed-lip breathing (respiratory technique) Breathing through puckered or pursed lips; slows breathing rate and extends exhalation time to make room for the next inhalation; exhalation is actively pushed through a narrowed mouth (or pursed lips).

Pus Viscous fluid mixture of debris, fluid, dead and dying cells, and necrotic tissue components that have accumulated at an injury site.

Pusher syndrome *See* **Ipsilateral pushing**.

Push–pull mechanism Term useful to describe how the brain discerns a direction of rotation by comparing excitatory and inhibitory input from each vestibular system.

Pyrexia Increased body temperature; fever.

Pyrogens Fever-producing substances.

Q

Quality of life (QOL) The sense of total well-being that encompasses both physical and psychosocial aspects of an individual's life.

R

Radiometer A temperature-measuring device designed to measure infrared radiation.

Ramp grade Degree of inclination or slope of a ramp; 1:12, or 1 in of threshold height for every 12 in of ramp length.

Range of motion (ROM) The arc through which movement occurs at a joint or series of joints.

Passive range of motion (PROM) The amount of joint motion available when a joint is moved through the range without assistance from the patient.

Active range of motion (AROM) Amount of joint motion available with unassisted voluntary joint motion.

Rapport The relationship, usually positive, between two people (e.g., between patient and professional staff member).

Rating of Perceived Exertion (Borg RPE Scale) A subjective scale that allows an individual to estimate effort and exertion, breathlessness, and fatigue during physical work; the original 15-grade interval scale with grades ranging from 6 (no exertion at all) to 20 (maximum exertion) was developed by Gunnar Borg.

Rating of shortness of breath (Dyspnea Scale) A subjective assessment of shortness of breath as it relates to exercise intensity.

Ratio measure A classification scheme in which values are separated by equal intervals and have a true zero.

Raynaud's disease A primary vasospastic disease of small arteries and arterioles; there is an exaggerated vasomotor response initiated by exposure to cold or emotion disturbance. Etiology is unknown.

Raynaud's phenomenon Intermittent attacks of pallor or cyanosis of the small arteries and arterioles of the fingers as a result of inadequate arterial blood flow.

Rebound phenomenon When resistance to an isometric contraction is removed suddenly the body segment forcibly moves a short distance in the direction in which effort was focused before "rebounding" in the opposite direction. Absence of this check reflex is associated with cerebellar disease.

Recovery Regaining health, living skills, and well-being after an illness or injury.

Recovery of function The reacquisition of movement skills lost through injury; the motor task is performed in the same manner as it was before the injury.

Recurrent pain *See* **Pain**.

Referred pain *See* **Pain**.

Regression A turning back or return to a former state; a return of symptoms.

Rehabilitation counselors Professionals who help people with disabilities to maximize their level of function and employability.

Relaxation response The sense of calm and well-being attained by using stress management techniques.

Reliability Degree to which an instrument measures a phenomenon dependably, time after time, with accuracy and predictably and without variation. Types of reliability include *intratester* and *intertester*.

Remission The lessening in severity (partial) or an abatement of symptoms (complete).

Removable rigid dressing A rigid postamputation dressing that can be removed as desired.

Residual limb The part of the extremity that remains after amputation.

Residual volume (RV) The volume of air remaining within the lungs when expiratory reserve volume (ERV) has been exhaled.

Resistance (psychological) A patient's reluctance to follow a rehabilitation plan or to discuss certain feelings because of a conscious or unconscious fear.

Resistance exercise Exercise in which a muscle contraction is opposed by an outside force, to increase strength or endurance.

Respiration The exchange of gas within the body. *External respiration* is the exchange of gas between the alveoli and the pulmonary capillaries. *Internal respiration* is the exchange of gas between the capillary and the tissue.

Resting tremor *See* **Tremor**.

Restorative intervention *See* **Intervention**.

Restrictive lung disease A group of pulmonary disorders characterized by difficulty in expanding the lungs and a reduction in total lung volume.

Rete pegs Ridge-like undulations between the contact layers of the epidermis and the dermis.

Retention Refers to the ability of the learner to demonstrate a skill over time and after a period of no practice (retention interval).

Retention interval An interval of no practice between the end of original learning and the retention test.

Retention test A performance test administered after a retention interval for the purposes of assessing learning.

Reticular A delicate network of cells or fibers of connective tissue.

Retinal slip Occurs when visual images fall off the fovea of the retina. Also, a technique used to induce adaptation.

Retractions The moving inward of the soft tissue of the intercostal, subcostal, or subclavicular region during inspiration; a marker of respiratory distress.

Rheumatoid arthritis (RA) A chronic autoimmune disease affecting the synovium characterized especially by pain, stiffness, inflammation, swelling, and sometimes destruction of joints and includes systemic features such as malaise, fever, and organ involvement.

Rheumatoid factors (RFs) Autoantibodies that are present in the blood of many people with rheumatoid arthritis (immunoglobulins) and, when present, suggest greater likelihood of severe disease.

Right–left discrimination disorder The inability to identify the right and left sides of one's own body or that of the examiner.

Right-sided heart failure *See* **Heart failure**.

Rigidity An increase in muscle tone causing resistance to passive motion; stiffness, immovability.

Cogwheel rigidity Jerky, ratchet-like resistance to passive movement as muscles alternately tense and relax; occurs when tremor coexists with rigidity.

Leadpipe rigidity A sustained resistance to passive movement with no fluctuations.

Role A specified cluster of behaviors and expectations attached to each distinct, identified relationship to another person or persons (e.g., parent, teacher, health care provider).

Role performance The ability to carry out responsibilities involved in a particular role (*see* **Role**).

Roll An angular motion between two joint surfaces, similar to the bottom of a rocking chair rolling over the floor. New points on one surface come into contact with new points on the other surface.

Roll-gliding The combination of a roll and glide. As a roll occurs between two joint surfaces, one surface slides on the other.

Romberg's sign Inability to maintain standing balance when eyes are closed and the feet are close together; sign is positive if the patient sways and falls when the eyes are closed. Seen in sensory ataxia.

Sharpened Romberg Inability to maintain standing balance when the eyes are closed and the feet are in a heel-toe (tandem) position.

Rotational work Torque multiplied by the arc of movement.

Rubor Redness of the skin caused by inflammation.

Rule of Nines Estimation used to determine the amount of total body surface area that has been burned. It divides the body into segments that are approximately 9% of the total (adults).

S

Saccade Fast, involuntary eye movements.

Salutogenic Health-causing.

Scanning speech A speech pattern that is slow and may be slurred or hesitant with prolonged syllables and inappropriate pauses; the melodic quality of speech is altered.

Schema A rule, concept, or relationship formed on the basis of experience; the basis of schema theory of motor control.

Schizophrenia A chronic major mental illness involving hallucinations, delusions, avolition (lack of desire), flat affect, and/or alogia (restrictions in the productivity and fluency of speech and thoughts) that result in a progressive decrease in overall functioning.

Scleritis An inflammatory disease associated with rheumatoid arthritis that affects the white outer coating of the eye.

Scleroderma A chronic disease of unknown etiology that causes a sclerosis or hardening of the skin and other internal organs.

Sclerotome Deep somatic tissue such as subchondral bone, periosteum, joint capsule, ligament, muscle, tendon, and fascia corresponding to spinal segments providing their sensory innervation.

Secondary lymphedema *See* **Lymphedema**.

Secondary prevention *See* **Prevention**.

Selective (focused) attention The capacity to attend to a task despite competing environmental visual or auditory stimuli.

Self-mutilation The act of causing physical harm to oneself (e.g., cutting one's own skin, pulling out hair, head banging, biting oneself, burning oneself, and causing infections that may result in amputations). Psychiatrically involved patients may engage in these activities to feel real if they are feeling numb, to externalize internal pain, to relieve intense anxiety, or to get attention.

Self-report A data collection approach where the patient is asked questions directly either by the therapist or a trained interviewer (interviewer report) or through the use of a self-administered reporting instrument.

Semantics The study of meaning that is used by humans to express themselves through language.

Semicircular canals (SCCs) Angular accelerometers of the vestibular system.

Sensation The awareness of conditions inside or outside the body resulting from stimulation of the body's sensory receptors and transmission of the nerve impulse along an afferent fiber to the brain.

Sensitivity The proportion of times that a test correctly identifies an abnormality or condition when that abnormality or condition is actually present.

Sensory conflict theory Predominant explanation for motion sickness; describes sensory inputs of proprioception, vestibular, and visual information not matching stored neural patterns.

Sensory integration The ability of the brain to process and organize disparate information from the different senses and develop meaningful perceptions to guide adaptive responses (cognitive or motor).

Sensory level (SCI) In spinal cord injury, the most caudal segment of the spinal cord with normal sensory function bilaterally.

Shaking (respiratory technique) A bouncing maneuver, created by the therapist's hands, is applied to the rib cage throughout the expiratory phase of breathing to assist the mucociliary transport system; promotes release of secretions.

Sharp débridement (wound care) Use of sterile scissors and forceps to remove eschar.

Sheet graft Autograft that is applied in a single sheet without alteration; may be split-thickness or full-thickness in depth.

Shock (physiological) A clinical syndrome marked by inadequate perfusion and oxygenation of cells, tissues, and organs; usually the result of marginal or markedly lower blood pressure.

Shock (psychological) Response to an unexpected trauma with characteristics of disbelief, disassociation, and inability to focus on reality. Shock is one of the first stages of adaptation and may last for hours, days, or weeks, depending on the individual.

Short-term memory (recent memory) The ability to remember current day-to-day events, learn new information, and retrieve information after an interval of minutes, hours, or days.

Sialorrhea Production of excessive saliva with drooling.

Sigh (respiration) A deep inspiration followed by a prolonged, audible expiration; occasional sighs are normal and function to expand alveoli; frequent sighs are abnormal and may be indicative of emotional stress.

Simultanagnosia The inability to perceive a visual stimulus as a whole; also known as Balint's syndrome.

Situational exposure exercises The cognitive-behavioral therapy technique of desensitization where the patient is slowly exposed to anxiety-producing activities that were previously avoided. This technique is often used in the treatment of anxiety disorders such as post-traumatic stress disorder and phobias.

Skew deviation One eye is superiorly displaced in comparison with the other eye.

Skin substitutes Tissues engineered in a laboratory that are used to restore the essential functions of the skin, provide a barrier to the environment, and control evaporative water loss; used in burn care.

Slough Dead or necrotic tissue separated from living tissue or an ulceration.

Smooth pursuit Volitional eye movement used to follow a moving target; most effective for target velocities less than 60°/sec.

Social function Ability to interact successfully with others in the performance of social roles and obligations; includes social interactions, roles, and networks.

Social support The availability of other persons in the environment who can offer emotional support, financial or material help, a listening ear, guidance, or encouragement.

Social workers Professionals who help patients obtain necessary resources in their communities, such as social security, disability, or unemployment benefits; may also offer individual or family therapy.

Somatoagnosia Impairment in body scheme; a lack of awareness of the body structure and the relationship of body parts of oneself or of others.

Spasticity A motor disorder characterized by velocity-dependent increased muscle tone, exaggerated tendon jerks, and clonus; the result of an upper motor neuron lesion.

Spatial relations disorder A constellation of deficits that have in common a difficulty in perceiving the relationship between objects in space, or the relationship between the self and two or more objects; included are disorders of figure–ground discrimination, form discrimination, spatial relations, position in space perception, and topographical orientation.

Specificity The proportion of times that a test correctly identifies the abnormality as being absent when it truly is absent.

Spin The rotation of a surface around a stationary axis; the same point on the moving surface creates an arc of a circle as the surface moves.

Spinal shock (SCI) Transient period of areflexia and flaccid paralysis immediately following spinal cord injury. There is an absence of reflex activity, impairment of autonomic regulation resulting in hypotension, and loss of control of sweating and piloerection; typically resolves in 2 to 6 weeks after trauma.

Splinter skill A trained or learned skill that is acquired in a manner inconsistent with, or incapable of being integrated with, skills the individual already possesses; not easily generalized to other environments or to variations of the same task.

Split-thickness skin graft Graft containing epidermis and part of the dermis.

Spontaneous nystagmus *See* **Nystagmus**.

Spontaneous recovery Recovery resulting from repair processes occurring within the central nervous system immediately after the insult.

Stability or static postural control Refers to the ability to maintain a posture with orientation of the center of mass over the base of support and the body held steady (e.g., holding in sitting, kneeling, or standing).

Standard precautions Guidelines recommended by the Centers for Disease Control and Prevention (CDC) for reducing the risk of transmission of blood-borne and other pathogens in hospitals. These precautions synthesize the major features of universal precautions designed to reduce the risk of transmission of blood-borne pathogens (e.g., hand washing and wearing personal protective equipment) and body substance isolation measures designed to reduce the risk of pathogens from moist body substances and apply them to all patients receiving care in hospitals regardless of their diagnosis or presumed infection status. Standard precautions apply to (1) blood; (2) all body fluids, secretions, and excretions except sweat, regardless of whether or not they contain blood; (3) broken skin; and (4) mucous membranes.

Staphylococcus aureus A microorganism commonly found on the skin, nasal cavities, and oral cavities. A methicillin-resistant strain is called MRSA and a vancomycin-resistant strain is called VRSA. Life-threatening infections have been connected to both strains.

Stemmer's sign The inability to pick up a fold of skin at the base of the second toe. A positive sign means evidence of lymphedema, but the absence of a positive sign does not mean lymphedema is not present.

Step length (gait) The linear distance between two successive points of contact of the right and left lower extremities; measured in centimeters or meters.

Step time (gait) The amount of time that elapses between consecutive right and left foot contacts (heel strikes); usually measured in seconds.

Step width (gait) Width of the walking base (base of support), measured as the linear distance (in the frontal plane) between one foot and the opposite foot; measured in centimeters or meters.

Stereognosis The ability to recognize the shape of objects by touch.

Stereotactic surgery Surgical lesioning of the brain.

Stertor A snoring sound due to secretions in the trachea and large bronchi (adj. *stertorous*).

Stress reaction The observable consequences of the stressor; accompanied by sympathetic signs and symptoms such as palpitations, cold sweat, faint feelings, dilated pupils, pallor, fear, and a host of other complaints.

Stretching The application of manual or mechanical force to elongate (lengthen) structures that have adaptively shortened and are hypomobile.

Stride length (gait) The linear distance between two successive points of contact of the same foot; generally measured in centimeters or meters.

Stride time (gait) The amount of time that elapses during one stride; usually measured in seconds.

Stridor A harsh, high-pitched crowing sound that occurs with upper airway obstructions caused by narrowing of the glottis or trachea (e.g., tracheal stenosis, presence of a foreign object).

Stroke (cerebrovascular accident [CVA]) Acute onset of neurological dysfunction due to an abnormality in cerebral circulation with signs and symptoms that correspond to involvement of focal areas of the brain.

Hemorrhagic stroke Abnormal bleeding into the extravascular areas of the brain; usually results from rupture of an aneurysm, extremely high blood pressure, brain trauma, or brain tumors.

Ischemic stroke The result of a thrombus, embolism, or conditions that produce low systemic perfusion pressures and loss of cerebral circulation resulting in anoxia and infarction.

Lacunar stroke Blood flow is blocked in very small arterial vessels deep within the cerebral white matter with involvement of the internal capsule; characterized by contralateral pure motor or sensory deficits without visual field, cognitive, or speech deficits.

Thrombotic stroke (atherothrombotic brain infarction [ABI]) Formation of a blood clot or thrombus within the cerebral arteries or their branches or the internal carotid or vertebral arteries, causing an occlusion and cerebral infarction; large vessel thrombosis is the most common and is associated with long-standing atherosclerosis.

Stroke volume (SV) The volume of blood ejected from the left ventricle with each myocardial contraction, expressed in mL/min.

Subarachnoid hemorrhage Rupture and bleeding of a cerebral vessel into the subarachnoid space; may occur spontaneously, the result of an aneurysm or arteriovenous malformation, or secondary to trauma.

Subdural hematoma Extravascular blood mass located beneath the dura mater of the brain.

Subluxation Partial dislocation of bones in a joint.

Subordinate part An element of movement without which the task cannot proceed safely or efficiently.

Substance abuse professionals Individuals specifically trained to work with people with substance abuse/dependence problems. Many substance abuse counselors are in recovery themselves, thus adding to their experience and ability to help others with the same problems, and many are Certified Alcohol and Substance Abuse Counselors (CASACs).

Suffering The affective component of pain that includes both emotional (e.g., anxiety and anger) and cognitive (e.g., thoughts of helplessness) components; may be due to a combination of unpleasantness and catastrophizing (making a "catastrophe" out of minor issues).

Summary (additive) measure Approach to grading a specific series of skills by awarding points for each task or activity; totals the score as a percentage of 100 or as a fraction.

Sustained attention (vigilance) The ability to maintain attention to relevant information; sustained attention implies the ability to maintain consistent performance during a continuous activity.

Swan neck deformity A deformed position of the finger, in which there is flexion of the metacarpophalangeal (MCP) and distal interphalangeal (DIP) joints with hyperextension of the proximal interphalangeal (PIP) joint; results from contracture of intrinsic muscles with dorsal subluxation of lateral extensor tendons.

Swing time (gait) The amount of time during the gait cycle that one foot is off the ground; measured in seconds.

Swollen joint count A component of the clinical assessment used to determine disease activity in rheumatoid arthritis. The swollen joint count is a sum of the number of joints deemed inflamed by the examiner.

Syme's amputation Amputation at the supramalleolar level, in which all foot bones are removed and the calcaneal fat pad is attached distally to cushion the end of the limb.

Synergy (normal) Functionally linked muscles that are constrained by the CNS to act cooperatively to produce an intended motor action; used to simplify control, reduce or constrain the degrees of freedom, and initiate coordinated patterns of movement.

Synovectomy Surgical removal of a synovial membrane.

Synovitis Inflammation of a synovial membrane.

Synovium A thin membrane in synovial joints that lines the joint capsule and secretes synovial fluid.

Systems theory A theory of motor control that describes a process by which various brain and spinal centers work cooperatively to accommodate the demands of intended movements; control of movement is viewed as variable.

Systole Period during which the ventricles of the heart are contracting; the contraction phase of the cardiac cycle.

Systolic pressure *See* **Blood pressure**.

T

Tachycardia An abnormally rapid (high) pulse rate; greater than 100 beats per minute in adults.

Tachypnea An abnormally fast respiratory rate; greater than 24 breaths per minute.

Task analysis The breakdown of an activity or task into its component parts and a delineation of the specific motoric, perceptual, and cognitive abilities that are necessary to perform each component.

Team approach A widely used approach to inpatient rehabilitation in which a group of professionals provide multidisciplinary interventions. Participants are usually a physiatrist (a physician specializing in rehabilitation), physical therapist, occupational therapist, social worker, speech-language pathologist, and nurse.

Tender joint count A component of the clinical assessment used to determine disease activity in rheumatoid arthritis. Tender joint count is determined by patients' pain response to pressure exerted on joints by the clinician.

Tenodesis Attaching tendon to bone.

Tensile strength The maximum amount of stress that a material can be subjected to before it breaks or tears.

Terminal stance (gait) The phase during which body weight completes progression over a single stable limb; the reference limb's heel lifts from the ground and a trailing limb posture is achieved.

Terminal swing (gait) The phase that occurs during the final third of swing as the knee extends in preparation for initial contact and start of the next gait cycle.

Tertiary prevention *See* **Prevention**.

Tetraplegia (quadriplegia) Complete paralysis of all four extremities and trunk, including the respiratory muscles.

Thermistor A temperature-measuring device designed to gauge the contact temperature of the skin.

Thoracic excursion Thoracic movement, from full exhalation to full inspiration, measured using a tape measure around the base of the thorax; normal thoracic movement is approximately 2 to 3 inches.

Thought blocking A symptom, usually of schizophrenia, in which the mind goes blank. An episode can last for a few seconds or be a chronic condition.

Thromboangiitis obliterans Inflammation of the intimal layer of a blood vessel, with clot formation, also referred to as Buerger's disease.

Thrombosis The formation or presence of a blood clot within the vascular system.

Thrombotic stroke (atherothrombotic brain infarction [ABI]) *See* **Stroke**.

Thrombus A blood clot that adheres to the wall of a blood vessel or organ.

Tidal volume (TV) The amount of air inspired and expired during normal resting ventilation.

Tinnitus Phantom noise (ringing, roaring, buzzing) detected in one or both ears.

Topographical disorientation Difficulty understanding and remembering the relationship of one place to another.

Torque Force multiplied by perpendicular distance from the axis of rotation; a force that produces rotation.

Total lung capacity The total amount of air that can be held within the thorax (IRV + TV + ERV + RV).

Transfemoral Above-knee.

Transfer of learning Refers to the gain (or loss) in the capability of task performance as a result of practice or experience on some other task.

Transient ischemic attack (TIA) Temporary interruption of blood supply to the brain; symptoms of neurological deficit may last for only a few minutes or hours but do not last longer than 24 hours. After the attack no evidence of residual brain damage or neurological damage remains.

Transitional mobility Refers to skills that allow movement from one posture to another (e.g., supine-to-sit, sit-to-stand).

Transtibial Below-knee.

Tremor Rhythmic, involuntary movements resulting from alternate contraction and relaxation of opposing muscles.

Essential tremor A benign tremor, usually of the head, chin, hands, and occasionally the voice; not associated with other neurological complications.

Intention (action) tremor Tremor is exhibited or intensified when attempting coordinated voluntary movements; seen in cerebellar disease.

Postural tremor Tremor involves the head and trunk and seen when muscles are used to maintain an upright posture against gravity.

Resting tremor Tremor is present at rest and diminished or suppressed by voluntary movement and disappears with sleep; seen in Parkinson's disease.

Senile tremor A benign essential tremor found in individuals older than 60; marked by rapid, alternating movements of the upper extremities that occur during purposeful movements.

Trigger finger Catching, snapping, or locking of the involved finger flexor tendon when it becomes momentarily stuck in the tendon sheath.

Tunneling Tissue destruction that occurs in the form of a tunnel in the fascial layers along the fascial planes between the muscles under the skin.

Turning points Important experiences and realizations that enable people to find new direction, purpose, or meaning in life.

Two-point discrimination Ability to distinguish two blunt points applied to the skin simultaneously.

U

Ulceration An area of epithelial sloughing associated with damage to underlying tissue and a suppurative or nonhealing lesion on a surface such as skin, cornea, or mucous membrane.

Ulnar drift Ulnar drift (also known as ulnar deviation) is a condition where there is a shift in the direction of the fingers or wrist toward the ulna, usually due, in fingers, to inflammation of the MP joints with displacement and corresponding rupture of tendons.

Undermining When débridement removes skin and subcutaneous tissue damage, the results may leave a shape like a cave, or a hole with a lip around the edge that is referred to as undermining.

Unilateral neglect The inability to register and to integrate visual stimuli and perceptions from one side of the environment (usually the left), not attributable to sensory-based problems. As a result, the patient ignores stimuli occurring in that side of personal space.

Universal design A structural plan for buildings and dwellings that meet the requirements of all people, including those with activity limitations and disability; takes into consideration the needs of a wide range of individuals, as well as the changing needs of human beings across the life span.

Upper motor neurons (UMNs) Neurons within the central nervous system that give rise to the descending motor pathways.

V

Validity The degree to which an instrument or tool measures what it is designed to measure; different types of validity include construct, content, criterion-based, concurrent, and predictive validity.

Valsalva maneuver An attempt to exhale forcibly with the glottis, nose, and mouth closed, causing increased intrathoracic pressure, slowed pulse, decreased return of blood to the heart, and increased venous pressure.

Varicose veins Enlarged, dilated superficial veins. The condition can occur anywhere in the body but is most common in the lower extremities and in the esophagus.

Venous reflux The backflow of blood through a vein that has valvular incompetence.

Ventilation The act of moving air in and out of the lungs.

Venules The smallest subunits of the venous system.

Vertebrobasilar insufficiency (VBI) Ischemia in the area of junction for the vertebral and basilar arteries.

Vertical disorientation A distorted perception of the upright (vertical) position.

Vertigo The sensation of moving around in space or of having objects move about the person; sense of spinning.

Vesicular breath sounds The normal intensity of a breath sound heard during auscultation of the lungs.

Vestibular Schwanomma (acoustic neuroma) A benign tumor from the Schwann cells of the vestibulocochlear cranial nerve.

Vestibulo-ocular reflex (VOR) Reflex responsible for generating compensatory eye movements during head rotation. Enables clear vision while the head is in motion.

Vestibulo-ocular reflex gain Ratio of eye velocity to head velocity.

Vestibulo-ocular reflex phase The phase of the VOR that represents the timing relationship between head motion and eye motion. Ideally, eye position should arrive at a point in time that is equal with the oppositely directed head position.

Vestibulospinal reflex (VSR) Reflex responsible for generating compensatory body movements in order to maintain head and postural stability, thereby preventing falls.

Vibration Mechanical oscillation of an object (e.g., tuning fork used for sensory testing).

Visual fixation The ability to maintain focus on an object as it is brought closer to and farther away from the eyes.

Visual object agnosia The inability to recognize familiar objects despite normal function of the eyes and optic tracts.

Visual or linear analogue scale A measurement scale in which a horizontal or vertical straight line is labeled with descriptive or numeric terms to anchor the extremes of the scale; the individual is asked to bisect the line at a point representing the self-reported position on the scale.

Visual proprioception Detection by the visual system of the relative orientation of body parts and orientation of the body in space; provides a basis for movement control.

Vital capacity (VC) The greatest volume of air that can be exhaled from a full inspiration, or the greatest volume of air that can be inhaled from a full exhalation.

Vocational counselor A professional who assists individuals with disabilities to find and maintain employment.

W

Walking velocity The rate of linear forward motion (displacement) of the body per unit of time in a given direction; measured in meters per minute (or centimeters per second). Walking velocity = distance/time.

Wellness The sense that one is living in a manner that permits growth and balance in the physical, emotional, spiritual, intellectual, social, and psychological domains of human experience.

Wernicke's aphasia *See* **Aphasia**.

Wheeze A musical adventitious sound heard during lung auscultation when expired air is forced through a narrowed airway.

Withdrawal Symptoms that accompany cessation of alcohol, amphetamines, sedatives, opioids, cocaine, hypnotics, or anxiolytics that have been abused over a period of time. Withdrawal symptoms differ with the substance abused and are usually the opposite of the symptoms of intoxication, but may also include perspiration, agitation, and physical pain.

X–Z

Xenograft (or heterograft) Skin used as a temporary wound cover, which is harvested from another species of animal, usually a pig.

Zone of coagulation In a burn wound, central area of necrotic tissue.

Zone of hyperemia In a burn wound, an area with increased circulation.

Zone of partial preservation (SCI) In a complete spinal cord injury, an area of partial preservation (sparing) of motor and/or sensory function in segments caudal to the neurological level.

Zone of stasis In a burn wound, an area where circulation is diminished and compromised.

Z-plasty Procedure used to surgically lengthen a burn scar or contracture to allow for greater range of motion.

functional capacity evaluation for, 364–365, 365*(f)*
internal accessibility, 367, 368*(f)*
job analysis for, 361–362, 364, 364*(t),* 387–391
on-site visit for, 366–367
interventions for, 366–367
computer, 367, 368*(f)*
external accessibility, 365–367
funding for, 370
legislation for, 370–371
parking space, 366
work hardening, 365–366, 366*(f)*
workstation, 367, 368*(f)*
workstation chair, 367, 367*(f)*
spinal cord injury, barriers in, 913
World Health Organization's ICF. *See* International Classification of Impairments, Disability, and Handicaps
Wound(s). *See also* Wound healing
acetic acid solutions for, 610
alginate dressings for, 617, 617*(f)*
analgesics for, 611
antibacterials for, 610–611
antiseptics for, 610
autolytic debridement of, 609
autolytic débridement of, 581
biosurgical debridement of, 609, 609*(f)*
characteristics of, 581–582, 583
chemical debridement of, 609
chronic, 583–584, 585*(f)*
cleansing of, 602–604, 604*(f)*
closure of, 582–583
cold laser therapy for, 614, 614*(f)*
creams for, 611
culture of, 582
debridement of, 604–605, 604*(f),* 605*(b)*–608*(b),* 608–609, 608*(f)*
dehiscence of, 582, 582*(f)*
diatherapy for, 612–613
documentation for, 637–638
dressings for, 581, 614–618, 615*(f),* 616*(f),* 617*(f),* 641, 642–644
electrical stimulation for, 612, 612*(f)*
enzymatic debridement of, 609
flexible film dressings for, 618
foam dressings for, 616, 616*(f)*
gauze/fiber dressings for, 615, 615*(f)*
growth factors for, 611
healing of. *See* Wound healing
hyaluronic acid derivative dressing for, 618
hydroactive dressings for, 617, 617*(f)*
hydrocolloid dressings for, 616–617, 617*(f)*
hydrogel dressings for, 616, 616*(f)*
hydrogen peroxide solution for, 610
hyperbaric oxygen therapy for, 613–614
hypochlorite solutions for, 610
impregnated gauze for, 615
infection of, 584
laser debridement of, 605
maggot debridement of, 609, 609*(f)*
mechanical modalities for, 611–614
negative pressure therapy for, 614, 614*(f)*
nonforceful irrigation of, 604, 604*(f)*

nonselective debridement of, 604, 604*(f)*, 605, 605*(b)*–608*(b)*
nonthermal diathermy for, 612–613
ointments for, 611
povidone-iodine for, 610
pulsatile lavage with suction for, 603–604, 604*(f)*, 605
pulsed radiofrequency therapy for, 612–613, 612*(f)*
scars and, 625–626, 625*(f)*
sharp debridement of, 608–609, 608*(f)*
skin substitutes for, 617–618
spray cleansing of, 604, 604*(f)*
surgical debridement of, 605
thermal diathermy for, 612–613
topical agents for, 610–611
transparent film dressings for, 615–616, 616*(f)*
ultrasound for, 611–612, 612*(f)*
ultraviolet radiation for, 613
web sites on, 641
wet-to-dry dressings for, 605, 605*(b)*–608*(b)*
whirlpool cleansing of, 602–603
Wound healing, 579–585
abnormal, 583–584, 585*(f)*
angiogenesis in, 579
assessment form for, 637–638
in burns, 1099–1100
extrinsic factors in, 585
iatrogenic effects on, 585
infection in, 584
inflammation phase of, 579–580
intrinsic factors in, 584–585
maturation phase of, 580
moisture in, 580–581
nutrition in, 581
oxygen in, 580
by primary intention, 582
proliferation phase of, 580
scar and, 583, 625–626, 625*(f)*
by secondary intention, 582–583
by tertiary intention, 583
web sites on, 641
